Autoantibodies from systemic autoimmune disease patients' sera were instrumental in defining the function of the U1 and other U snRNPs carrying Sm antigenic determinants. In 1979, Lerner and Steitz first reported that the U series of small nuclear RNAs was immunoprecipitated by human sera containing anti-nRNP or anti-Sm activity [33]. This led to characterization of the small RNA species and the discovery that the U1, U2, and other Sm antigen-containing ribonucleoproteins are critical for splicing precursor heterogeneous nuclear RNAs into messenger RNA [41]. The importance of these particles in RNA splicing is underscored by the observation that splicing is inhibited *in vitro* in the presence of anti-nRNP or Sm autoantibodies [42]. During splicing, a series of U snRNP particles assembles into an even larger structure termed a spliceosome, which recognizes intron–exon junctions, cleaves intervening sequences, and rejoins the mature mRNA [41]. U1 small RNA recognizes a precursor RNA and base pairs with the 5′ splice site leading to cleavage and leaving an invariant guanosine residue at the 5′ end of the intron, which subsequently forms a lariat-like structure. Lariat formation requires binding of the U2 snRNP to the branch point [41]. After cleavage at the 3′ end of the intron, the U5 and U4/U6 snRNPs bind near the 3′ splice site, forming a spliceosome, and the exons are religated to produce mature mRNA. Spliceosomes are responsible for the fine speckled immunofluorescence pattern associated with anti-nRNP or anti-Sm autoantibody activity (Fig. 1A).

Understanding the structure of the U1 snRNP particle (Fig. 3) greatly simplifies understanding the immunoprecipitation patterns exhibited by sera from patients (Fig. 4). Sera containing either anti-Sm or anti-nRNP antibodies immunoprecipitate the U1 small RNA molecule, as shown by analysis of the ^{32}P-labeled RNAs attached to the immunoprecipitates (Fig. 4A). Sera containing anti-Sm immunoprecipitate the U2, U4, U5, and U6 small RNAs, but sera having only anti-nRNP activity do not. This is explained by the fact that the Sm core particle is a component of each of the snRNP particles, whereas the U1-70K, U1-A, and U1-C proteins recognized by anti-nRNP antibodies (Fig. 3) are unique to the U1 snRNP. Analysis of the proteins immunoprecipitated by anti-Sm versus anti-nRNP antibodies reveals a similar set of polypeptides (Fig. 2B and Fig. 4B, A–G) because the Sm core particle is associated with the anti-nRNP reactive proteins U1-A, and U1-C in the abundant U1 snRNP (the U1-70K protein is not visualized by standard protein immunoprecipitation techniques because it is methionine deficient and therefore labels inefficiently). The different fine specificities

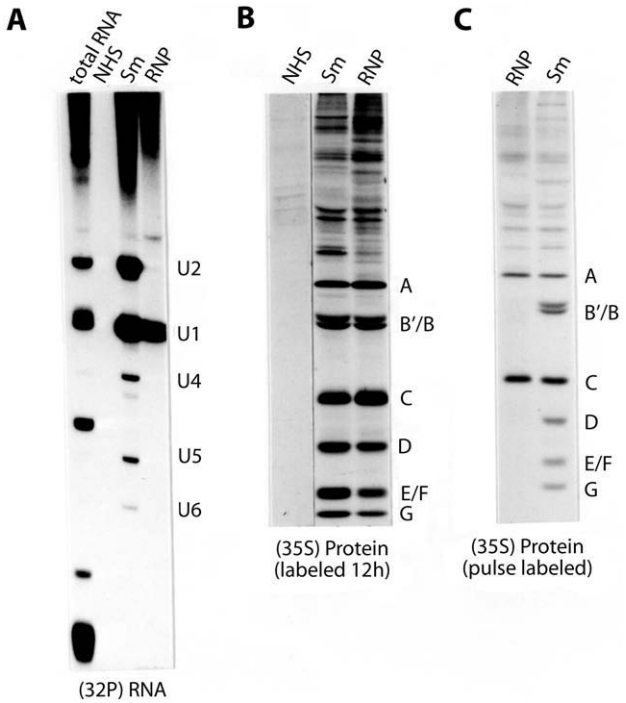

FIGURE 4 ***Immunoprecipitation of the U1 snRNP particle.*** (**A**) K562 (human erythroleukemia) cells were labeled with [^{32}P]orthophosphate, and an extract was immunoprecipitated with anti-Sm or anti-nRNP serum or with normal human serum (NHS). Immunoprecipitates were subjected to phenol extraction, and the radiolabeled RNA was analyzed by gel electrophoresis followed by autoradiography. Positions of U2, U1, U4, U5, and U6 small RNAs are indicated. From Satoh *et al*. [42a], with permission. (**B**) The same sera were used to immunoprecipitate extracts from cells labeled for 12 h with [^{35}S]methionine. Note that both anti-Sm and anti-nRNP immunoprecipitates exhibit the same pattern (bands A–G). (**C**) Sera were used to immunoprecipitate the extract from cells pulse labeled for 6 min with [^{35}S]methionine. This allows the autoantibodies to recognize newly synthesized components of the U1 snRNP before they are assembled completely. Note the difference between the pattern exhibited by anti-nRNP serum (bands A and C) vs anti-Sm serum (which also contains anti-nRNP antibodies, and immunoprecipitates bands A and C as well as B′/B, D, E/F, and G).

of anti-nRNP and anti-Sm are obvious when immunoprecipitation is carried out after dissociating the U1 snRNP into its individual components [43, 44] or before complete assembly of the particle (e.g., by pulse labeling) (Fig. 4C). In this case, anti-nRNP sera immunoprecipitate the U1-A and U1-C proteins, but not the components of the Sm core particle (B′/B, D, E, F, G). Anti-Sm sera nearly always contain anti-nRNP activity as well [36, 45] and thus immunoprecipitate all of the proteins under these conditions (Fig. 4C).

IMMUNE RESPONSE TO MACROMOLECULAR COMPLEXES

Autoantigen structure has implications for autoantibody specificity. Autoantibodies characteristic of SLE and other systemic autoimmune diseases occur as groups of interrelated specificities. Mattioli and Reichlin [36] first reported the strong association of anti-Sm antibodies with anti-nRNP. "Linked sets" of autoantibodies have been described in other systems as well [46]. Anti-Ro (SS-A) and La (SS-B) antibodies are associated with one another [47] and with antibodies to the Y5 small RNA molecule [48], with which both antigens associate [49]. Likewise, autoantibodies to DNA and histones (chromatin) are associated with one another [50, 51]. Thus, macromolecular complexes appear to be seen by the immune system as units.

Autoantibodies to Components of the U1 snRNP: A Prototype-Linked Set

Anti-Sm autoantibodies are strongly associated with anti-nRNP [36, 45]. In most cases, levels of anti-nRNP in human autoimmune sera greatly exceed the levels of anti-Sm [45]. Interestingly, MRL mice make primarily anti-Sm [43]. Analysis of the fine specificities of antibodies reactive with components of the U1 snRNP indicates that many sera contain autoantibodies to multiple polypeptides. In one study [52], only 1 of 29 sera containing anti-nRNP or Sm antibodies recognized a single protein component of the U1 snRNP, and the majority recognized three or more (Table 5).

Another class of autoantibodies recognizes antigenic sites found only on the native antigen: conformational epitopes dependent on the tertiary structure of individual proteins, such as U1-C [43] or epitopes related to the quaternary structure of the U1 snRNP. The latter include an epitope or epitopes formed by the association of the E, F, and G Sm polypeptides [53] and autoantibodies that stabilize the protein–protein interactions between the U1-C protein and the Sm core particle or between U1-A and the Sm core particle [44].

In addition to autoantibodies to the protein constituents of the U1 snRNP, the U1 small RNA can be recognized by autoantibodies [54, 55]. Autoantibodies to U1 RNA are detected in about 40% of anti-nRNP/Sm-positive sera [56, 57]. Interestingly, these antibodies are uniquely reactive with the stem of stem-loop II and in the loop of stem-loop IV of U1 RNA (Fig. 3) [55, 57]. With the exception of autoantibodies to the 5′ trimethylguanosine cap shared by U1-U5 small RNAs [58], autoantibodies specific for U2, U4, U5, or U6 small RNAs have not been reported. Autoanti-

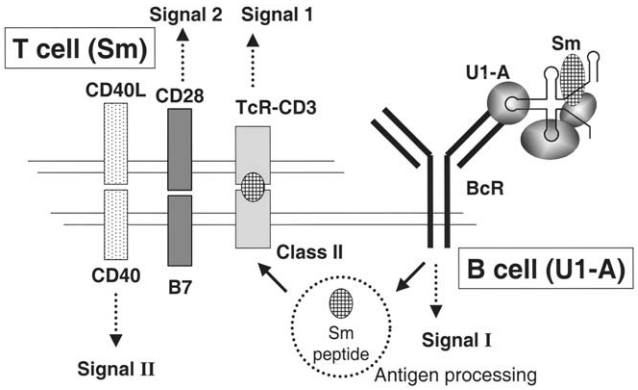

FIGURE 5 ***Pathogenesis of T- and B-cell responses to the U1 snRNP antigen.*** The mechanism of intermolecular–intrastructural help in the production of antibodies against the U1 snRNP is illustrated. An autoreactive B cell carrying surface immunoglobulin receptors for the U1-A protein takes up the U1 snRNP (signal I). The complex is degraded by endosomal proteases resulting in the presentation of a peptide derived from the Sm core particle to an activated autoreactive T cell in the context of MHC class II. The T cell expresses CD40 ligand (CD40L), which engages CD40 on the surface of the B cell, providing a costimulatory signal (signal II). T-cell activation also requires two signals: one delivered by engagement of the T-cell receptor (TcR)–CD3 complex and the other by the engagement of B7 on the activated B cell by the costimulatory molecule CD28. In this way, a T cell expressing a receptor for an Sm peptide can stimulate autoantibody production by B cells specific for other proteins, such as U1-A.

bodies to U1 RNA are linked strongly to the production of anti-nRNP antibodies and are absent in sera containing anti-Sm, but not nRNP, antibodies [56].

Intermolecular–Intrastructural Help

Immune responses to multicomponent autoantigens are in many respects analogous to responses against viral particles. In the latter case, T cells specific for one component of the virion provide help to B cells producing antibodies against other components (Fig. 5), a phenomenon termed "intermolecular–intrastructural help" [59]. This has been examined closely in humoral immune responses to influenza, hepatitis B, and vesicular stomatitis virus (VSV) [60–62]. In the case of influenza, T cells specific for the nucleoprotein help B cells specific for the hemagglutinin [60]. In the special case of a complex consisting of both foreign and self-antigens, T cells specific for nonself components may drive the production of autoantibodies to the self-components [62, 63]. For example, transgenic mice expressing the membrane-associated glycoprotein of vesicular stomatitis virus (VSV-G) do not produce autoantibodies to the "self" antigen VSV-G when immunized with that protein. However, autoantibodies are induced readily when transgenic mice are infected with wild-type VSV [62]. Activated B cells specific for self VSV-G process intact VSV particles and present nonself VSV peptides to T_H cells resulting in autoantibody production.

Intermolecular–intrastructural help may also play a role in the development of autoimmune responses to the U1 snRNP. Mice immunized with human U1-A (Fig. 3) plus affinity-purified mouse U1 snRNPs develop autoreactive T cells specific for mouse U1-A and autoantibodies to the self U1-A, U1-70K, and B′/B proteins, as well as U2-B″, which shares an antigenic determinant with U1-A [64]. Immunization with ribonuclease-treated snRNPs leads to the development of anti-U1-A and U2-B″ antibodies, but not anti-U1-70K or anti-B′/B, suggesting that the spreading of autoimmunity to other components requires intact U1 snRNPs.

Intermolecular–intrastructural help may also promote the progression of autoimmunity against Ro60 (SS-A) and La (SS-B). Autoantibodies to these proteins, which transiently associate with one another in the cell [49], frequently coexist in SLE patients' sera. Mice immunized with recombinant murine La (SS-A) develop anti-La autoantibodies, suggesting that immunological ignorance may govern nonresponsiveness to La [65]. Interestingly, these mice also develop anti-Ro (SS-A) antibodies. Conversely, immunization with Ro causes the production of anti-La as well as anti-Ro antibodies. A similar phenomenon occurs in rabbits immunized with Sm-B peptides [66]. The simplest explanation is that T cells specific for the immunizing antigen can provide help to B cells carrying receptors for other components of the Ro-La complex or U1 snRNP (Fig. 5). The same mechanism is likely to be involved in autoim-

mune responses to chromatin [51]. In mice with spontaneous lupus, αβ and γδ T-cell receptor-bearing T cells specific for nucleosomal peptides have been implicated in the production of anti-DNA antibodies [51, 67, 68]. T_H clones promote the production *in vitro* of anti-dsDNA and ssDNA, as well as histone autoantibodies [51], consistent with the model. The antigenic peptides appear to be generated only when intact nucleosomes are taken up by antigen-presenting cells (APC), suggesting that the interaction of DNA with the histones is a critical determinant of antigen processing [51].

B cells may be critical APC that promote the spread of autoimmunity to other components of a macromolecular complex. Although much less efficient at nonspecific phagocytosis of antigens than "professional" antigen-presenting cells, such as macrophages or dendritic cells, B cells bearing specific surface immunoglobulin receptors focus antigen on their surface, allowing them to take up the antigen recognized by their surface receptors 1000 to 10,000 more efficiently than macrophages [69]. The expression of MHC class II permits B cells to display peptide–MHC class II complexes that activate T-cell responses. B cells can be highly efficient antigen-presenting cells that can deliver a potent T-cell stimulatory signal if the costimulatory molecules B7-1 or B7-2 on their surface engage CD28 on the surface of the T cell (Fig. 5). However, they also can deliver a potent tolerogenic signal in the absence of B7 expression [70]. Unlike macrophages or dendritic cells, which express B7 constitutively, expression is inducible on B cells. The potential for activated autoreactive B cells to promote the diversification of autoimmunity is supported by studies of cytochrome c [71, 72]. Mice immunized with foreign cytochrome c in adjuvant produce a population of antibodies cross-reactive with self-cytochrome c. Adoptive transfer of foreign cytochrome c-primed B cells to naive mice causes T cells of the recipients to respond to murine cytochrome c, suggesting that the activated autoreactive B cells can prime autoreactive T cells. Similarly, the activation of B cells specific for the U1-A component of U1 snRNPs can prime autoreactive T cells, leading to diversification of the immune response to U1 snRNPs [73].

ROLE OF T-CELL DEFECTS IN AUTOANTIBODY PRODUCTION

T-Cell-Dependent vs -Independent Autoantibody Production

Like antibody production in general, autoantibody production can be T cell dependent or independent. The importance of T-cell help has been examined in both human SLE and animal models. Evidence for T-cell-dependent autoantibody production includes the predominance of IgG2a antinuclear antibodies in MRL mice [74], the lower levels of autoantibodies in MRL/*lpr* or NZB/W mice treated with anti-CD4 antibodies or CTLA4Ig [75–77], and the necessity for cognate T–B-cell interactions in autoantibody production [78]. The strongest evidence that autoantibodies are generated through a process of autoantigen-driven B-cell activation is the large number of somatic mutations in anti-DNA and anti-Sm autoantibody V regions [79, 80]. Many of the anti-DNA antibodies from MRL/*lpr* mice are members of the same expanded clones [79]. Moreover, the high frequency of replacement versus silent mutations and their nonrandom distribution argues that anti-DNA antibodies are selected on the basis of their receptor specificity. Thus, the analysis of autoantibody V regions strongly suggests that T cells are involved.

Autoreactive T cells that proliferate and/or secrete cytokines in response to lupus antigens, such as histones, have been identified in mouse models of lupus and have a helper phenotype. Autoreactive T cells also have been identified in human lupus, including T cells responsive to histones or nucleosomes [67], U1 snRNP antigens [81, 82], and the ribosomal P antigen [83]. As in the mouse, autoreactive T-cell clones bearing αβ as well as γδ T-cell receptors have been isolated. Although most of the autoantibodies characteristic of lupus (see earlier discussion) are T cell dependent, low-affinity, polyreactive anti-ssDNA autoantibodies produced by the B1 subset bear germline Ig variable region sequences and may be less dependent on T-cell help.

Self-tolerance in T Cells

The immune system has evolved to avoid reactivity with self through clonal deletion of autoreactive cells and peripheral inactivation (anergy). Self-antigens may also be sequestered or otherwise prevented from encountering the immune system [84], resulting in a state of immune ignorance. These control mechanisms appear to apply to B as well as T cells. The major mechanism for removing autoreactive T cells with high-affinity antigen receptors is clonal deletion in the thymus [85, 86]. In contrast, immunological tolerance to antigens not expressed in the thymus is maintained by peripheral T-cell inactivation [87, 88].

Ligation of the T-cell antigen receptor (Fig. 5, signal 1) is insufficient, by itself, to activate naïve T cells to proliferate or differentiate. Activation requires a costimulatory signal (signal 2) delivered by antigen-presenting cells [87, 89, 90]. In the absence of a costimulatory signal, T-cell receptor occupancy by antigen results in unresponsiveness (anergy) or apoptotic cell death. The best-characterized costimulatory molecules are B7-1 (CD80) and B7-2 (CD86), which are expressed on the surface of

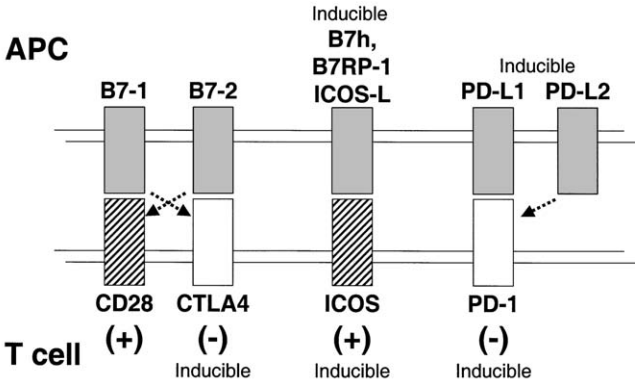

FIGURE 6 ***Diversity of T-cell costimulatory molecules.*** Receptor pairs involved in costimulating T-cell activation are illustrated. The B7-1 and B7-2 proteins (CD80 and CD86, respectively), which are expressed constitutively by professional antigen-presenting cells (APC), can costimulate T-cell activation through interactions with CD28 or can downmodulate activation by interacting with CTLA4. The B7h (B7RP-1, ICOS-L) protein is expressed inducibly by APCs and delivers a positive costimulatory signal to T cells expressing ICOS (also inducible). Two additional molecules expressed inducibly by APC, PD-L1 and PDL-2, can downregulate T-cell activation by interacting with the inducible T-cell surface marker PD-1. Thus, costimulatory molecules expressed by the APC can either positively (cross-hatched) or negatively (unshaded) regulate T-cell activation by interacting with proteins expressed either constitutively (CD28) or inducibly (CTLA4, ICOS, PD-1) by the T cell.

macrophages, dendritic cells, activated B cells, and other antigen-presenting cells [89, 91, 92]. Delivery of signal 2 along with signal 1 to a naïve T cell alters gene expression, increasing expression of the IL-2 receptor α chain, IL-2, and CD40 ligand (CD154) [90]. In naïve T cells, the constitutively expressed CD28 molecule is the only receptor for B7-1 and B7-2, but after cross-linking of CD28 by B7, expression of the higher affinity receptor CTLA-4 (CD152) is induced (Fig. 6). CTLA-4 is a negative regulator containing an immunoreceptor tyrosine-based inhibitory motif (ITIM) that serves to inhibit T-cell activation when ligated along with the T-cell receptor [93, 94]. When B7 engages CTLA-4, the tyrosine phosphatase SHP-2 is recruited, resulting in the downregulation of T-cell receptor signaling. Due to its 20-fold higher affinity for B7, CTLA-4 engagement inhibits the production of IL-2, thus limiting the proliferation of activated T cells. It also plays a critical role in the induction of peripheral tolerance (anergy) [94]. Moreover, CTLA-4 is expressed on a subset of human regulatory T cells expressing CD4 and CD25, which has been implicated in the regulation of autoimmunity [95, 96].

More recently, additional CD28-like proteins have been identified (Fig. 6), including an inducible costimulator (ICOS) and PD-1. ICOS binds to a ligand expressed in an inducible manner by dendritic cells, monocytes B cells, and nonprofessional APC, which has been designated B7h or B7RP-1 (ICOS-L) [97, 98]. B7h (B7RP-1) differs from B7-1 and B7-2 in its inducible expression by nonprofessional antigen-presenting cells, such as fibroblasts, in response to tumor necrosis factor (TNF)-α or LPS. Expression of B7h (B7RP-1) may help augment T-cell activation in inflamed nonlymphoid tissues. A similar situation exists in the case of a counterreceptor PD-L1 for the CD28-like inhibitory molecule PD-1. PD-1 binds to two inducible ligands (PD-L1 and PD-L2) expressed by interferon (IFN)-γ-activated monocytes and dendritic cells [99, 100]. Interestingly, PD-L1 is also expressed in certain nonlymphoid parenchymal tissues, such as the heart and lung. PD-1 is a negative regulator of T-cell activation and, like CTLA-4, contains an ITIM [101]. It is expressed only at low levels in resting lymphocytes, but is strongly induced following activation, suggesting that its negative regulatory effect is manifested at a late stage of activation to restrict progression of the response rather than at the early activation stage [101]. Other B7-like molecules have been described as well, but their function is less well defined [102]. It is apparent that T-cell activation is tightly regulated. In view of the importance of costimulatory signals in determining tolerance vs activation, defects in these complex regulatory pathways have the potential to promote autoimmunity.

T-Cell Costimulation in Autoimmunity

The regulation of costimulatory activity can influence susceptibility to autoimmune diseases (Table 6). Treatment of murine lupus with CTLA-4-Ig, which blocks B7-1 and B7-2, results in decreased anti-DNA antibody production and decreases proteinuria [76]. Conversely, ectopic expression of B7-1 in the presence of inflammation (TNF-α) in the pancreas can induce type I diabetes in mice [103], and ectopic expression of B7-1 on T cells may contribute to the lupus-like manifestations of *lpr* and *gld* mice [104]. CD28-deficient mice exhibit abnormalities in the production the T-cell-dependent isotypes IgG1 and IgG2b, but not IgG2a [105]. Interestingly, they remain susceptible to autoimmune disease and still can produce IgG2a autoantibodies, although disease severity in an autoimmune myocarditis model was reduced [106]. However, polyclonal B-cell activation and anti-DNA antibodies in the graft-versus-host disease model of lupus are both CD28 dependent [107]. These data suggest that there are redundant costimulatory pathways and that other costimulatory molecules, such as ICOS, may compensate for the absence of CD28. ICOS-deficient mice have defective T-cell activation but unex-

TABLE 6 Defective Regulation of T-Cell Activation: Effects on Autoimmunity

[a] Not available.

pectedly are more susceptible to experimental autoimmune myelitis (EAE) [108, 109], suggesting that ICOS has a protective effect. Clearly, ICOS plays a major role in CD40-mediated class switching and is expressed in germinal centers [110]. CD40-CD40L interaction is critical for class switching, T-cell-dependent antibody responses, and the formation of germinal centers, the main site of T–B collaboration [111–113]. ICOS deficiency profoundly affects antibody responses to T-cell-dependent antigens, such as keyhole limpet hemocyanin (KLH), but has no effect on responses to T-cell-independent antigens [109]. In contrast to its enhancement of T-cell autoimmunity, ICOS deficiency should inhibit T-cell-dependent autoantibody production. This issue remains to be examined, however.

As illustrated by the induction of CTLA-4 expression subsequent to T-cell activation by TcR and CD28 ligation [90, 93], the balance between costimulatory (CD28 and ICOS) and inhibitory (CTLA-4 and PD-1) signals changes after the initiation of an immune response and may be a key regulator of T-cell-dependent immune responses. The relative levels of B7 (costimulatory) vs PL-L1 (inhibitory) may determine the extent of T-cell activation and therefore the threshold between tolerance and autoimmunity [99]. PD-1-deficient mice develop endocapillary proliferative glomerulonephritis resembling lupus nephritis, arthritis with pannus, and dilated cardiomyopathy [101]. Some mice produce IgG1 autoantibodies against a 33-kDa myocardial protein (T. Honjo, 7th International Workshop on Autoantibodies and Autoimmunity, Awajishima, Japan, 2001). As in MRL mice, the disease process is accelerated by the *lpr* mutation, but the effects of PD-1 deficiency on autoantibody formation are atypical for SLE. Anti-dsDNA antibodies and rheumatoid factor are not detected [101]. There is selective glomerular deposition of IgG3 instead of the IgG2a predominance seen in MRL and NZB/W lupus, a selective increase in serum IgG3, and augmented IgG3 antibodies against the T-cell-independent antigen TNP-Ficoll [114]. Because most murine IgG3 antibodies are cryoglobulins [115, 116], the autoimmune syndrome may more closely resemble mixed essential cryoglobulinemia than lupus.

Role of T-Cell Subsets in Autoantibody Formation

$CD4^+$ effector T cells are somewhat arbitrarily classified according to the cytokines they produce. T_H1 cells produce IFN-γ and interleukin (IL)-2, whereas T_H2 cells produce IL-4, IL-5, IL-10, and IL-13, and T_H3 cells produce transforming growth factor β (TGF-β) [117–119]. Although the T_H1-T_H2-T_H3 paradigm is more clear-cut in mice than in humans, it remains a useful concept in the human system. T_H1 and T_H2 cytokines may stimulate the production of different subsets of autoantibodies, and the differential activation of T_H1 vs T_H2 cells could influence autoantibody production. The role of T_H1 and T_H2 cytokines in autoantibody formation is discussed further later.

B7-1, B7-2, and ISOS-L (B7h, B7RP-1) differ in their ability to costimulate different helper T-cell subsets and in the kinetics of their induction [89, 92]. Moreover, T_H1 and T_H2 cells differ in their requirements for costimulation and, consequently, also in their susceptibility to the induction of peripheral tolerance [120, 121]. T_H2 responses are dependent initially on high doses of antigen and on CD28 costimulation, but their maintenance is less dependent on costimulation [122]. In contrast, T_H1 responses are initially less dependent on CD28 costimulation, but more dependent on a continued provision of costimulatory signals than T_H2 responses. T_H2 responses are also relatively more dependent on ICOS costimulation, and ICOS-deficient mice produce only low levels of IL-4 and IL-13 [108].

ROLE OF B-CELL DEFECTS IN AUTOANTIBODY PRODUCTION

The two major subsets of B cells, B-1 and B-2, are defined by their surface phenotypes and anatomical distribution [123]. The B-1 subset is enriched in the peritoneal and pleural cavities and has an IgM^{high}, IgD^{low}, $B220^{high}$, $CD23^{neg}$ phenotype. B-1a cells express moderate levels of CD5, whereas B1-b cells are $CD5^{neg}$. In contrast, the B-2 (conventional) subset is IgM^{low}, IgD^{high}, $B220^{high}$, $CD23^{high}$, $CD5^{neg}$. Most studies suggest that B-1 cells produce polyreactive antibodies, exhibit only limited somatic mutation, develop independently of T cells, and are prone to make low-affinity autoantibodies [123]. In contrast, B-2 cells produce high-affinity, somatically mutated antibodies that are generated in the presence of antigen-specific T cells. B-1 and B-2 subsets express different V_H gene repertoires, suggesting that surface immunoglobulin specificity influences the signals received by B cells during development, helping to determine whether they become B-1 or B-2 cells [124].

The protein tyrosine phosphatase SHP-1 regulates cell numbers in the B-1 compartment [125]. Deficiency of SHP-1 or proteins interacting with it (CD22 and Lyn) results in an enlarged pool of peritoneal B-1 cells and the presence of B-1 cells in the spleen and lymph nodes. SHP-1 is also recruited when surface IgG and FcγRIIb are cross-linked [126], but the effect of FcγRIIb deficiency on the B1 compartment is not known. B-1a cells express CD5, another protein that interacts with SHP-1. $CD5^{null}$ mice do not have increased numbers of B-1 cells, possibly reflecting a compensatory effect of CD22 [125]. Conversely, a deficiency of CD19, a positive regulator of B-2 cell development, decreases the number of peritoneal B-1a cells [127].

B-Cell Activation

Although B-cell responses to repetitive, multivalent antigens, such as pneumococcal polysaccharide, can be T cell independent, the activation of B cells recognizing low valency antigens generally requires two signals: one delivered by the antigen receptor (Fig. 5, signal I) and a costimulatory signal delivered when CD40 on the B cell engages CD40L on an activated T cell (signal II). The B-cell antigen receptor consists of membrane immunoglobulin and the associated molecules Igα (CD79α) and Igβ (CD79β) (Fig. 5). Antigen cross-linking activates the Src-like kinases Lyn, Fyn, and Blk and the tyrosine kinase Syk [125, 128]. CD22 and FcγRIIb negatively regulate antigen receptor signaling via SHP-1 (Fig. 7). Conversely, the CD19-CD21-CD81 (TAPA-1) complex positively regulates signaling and enhances antibody responses to T-cell-dependent antigens. Thus, the strength signal I is exquisitely regulated. Signal II is regulated primarily at the level of the antigen-specific T cell, which expresses CD40L only upon activation [129, 130]. B-cell, like T-cell, activation must be regulated closely in order to avoid autoimmunity.

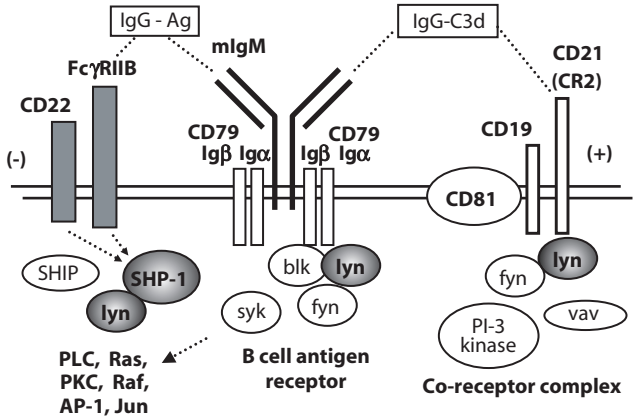

FIGURE 7 ***Regulation of B-cell activation.*** The B-cell antigen receptor (center) consists of membrane IgM (mIgM) and CD79 (Igα and Igβ chains). Signal transduction through the BCR is mediated, in part, by the kinases Lyn, Blk, Fyn, and Syk. BCR signaling is modulated positively by CD19, CD21 (CR2), and CD45, which signal through Lyn, Fyn, and other proteins. BCR signaling is modulated negatively by the inhibitory receptors CD22, pir-b, and FcγRIIb, which signal through SHP-1, Lyn, and other proteins. Deficiency of the negative regulators CD22, FcγRIIb, SHP-1 and Lyn (shaded) results in an autoimmune phenotype.

Self-tolerance in B Cells

Autoreactive B cells, like T cells, are censored by a variety of mechanisms that depend on the presence or absence of T-cell help, the form of the antigen, and the type of B cell. There are differences in the susceptibility of mature vs immature B cells as well as between B cells responding to T-cell-independent antigens (B-1 subset) vs T-cell-dependent antigens (B-2 subset). Deletion (apoptosis), anergy, and immunological ignorance all play a role in determining whether B cells become activated or are tolerized [131]. Peripheral ignorance to lupus autoantigens such as Sm may be maintained by the differentiation of autoreactive B cells into B-1 cells, which have a higher activation threshold than conventional B cells [132]. Abnormal activation-induced cell death, e.g., due to a defect in the apoptosis gene Fas, can promote the activation of B cells that are ignored rather than actively anergized, leading to autoantibody production [133].

[a] Strain dependent.

In the case of active tolerance to multivalent antigens or membrane-bound proteins, such as MHC class I molecules, immature B cells expressing transgenes encoding the rearranged genes for both chains of an autoantibody specific for the antigen never develop and undergo apoptosis [131]. The same is true of B cells expressing receptors with high affinity for double-stranded DNA, which in nonautoimmune-prone mice are deleted in the bone marrow at the pre-B to immature B transitional stage [134, 135]. Like central deletion of T cells, central deletion of autoreactive B cells also appears relatively normal in autoimmune strains such as MRL [136, 137].

In contrast to anti-dsDNA antibodies, anti-ssDNA antibodies are not centrally deleted in nonautoimmune mice. However, upon exiting the bone marrow milieu, they are rendered anergic [134]. Peripheral B-cell tolerance appears abnormal in lupus mice. In contrast to nonautoimmune strains, MRL/*lpr* mice transgenic for an anti-DNA heavy chain (3H9) produce serum IgM anti-ssDNA antibodies, suggesting that peripheral B-cell tolerance is abnormal [138].

B-cell nonresponsiveness to many self-antigens that are present at low levels, probably including some nuclear antigens, appears to be controlled mainly by a lack of T-cell help [131, 139, 140]. In addition, Fas deficiency leads to an abnormal accumulation of $CD4^+$ T cells in the B-cell follicles. Developmental arrest and follicular exclusion of anti-dsDNA B cells are abnormally regulated in MRL/*lpr* mice [141], suggesting that follicular exclusion is an important tolerization mechanism for certain types of autoreactive B cells. As there are multiple mechanisms of B-cell tolerance, the use of broad terms such as "deletion" or "anergy" may be insufficient to describe the multiple checkpoints involved [131].

Abnormal B-Cell Activation Promotes Autoimmunity

As discussed earlier, CD22 and FcγRIIb negatively regulate B-cell antigen receptor signaling via SHP-1 (Fig. 7). Interestingly, mice with defective CD22, Lyn, or SHP-1 have a similar phenotype: increased numbers of B-1 cells and autoantibody production [125]. CD22-deficient mice develop increased numbers of B-1 cells (but not as dramatic as SHP-1-deficient mice) along with high titers of anti-DNA antibodies (Table 7), but it has not been shown conclusively whether they are directed against ssDNA or dsDNA [142]. These and other autoantibodies (e.g., IgG2a anticardiolipin, antimyeloperoxidase) were reported to have high affinities, but unlike Lyn- or SHP-1-deficient animals, CD22-deficient mice do not develop autoimmune disease.

In contrast to CD22-/- mice, Lyn-deficient mice (Table 7) develop splenomegaly, autoantibodies, and renal disease along with increased numbers of B-1b cells and high levels of serum IgM [143]. However, IgG levels are normal, and immune responses to both T-cell-dependent and -independent antigens are abnormal with poorly formed germinal centers [143]. Fas-mediated apoptosis is impaired in Lyn -/- mice and may act synergistically with the increased level of B-cell activation in Lyn -/- mice to promote autoimmunity [144]. The autoimmune disease in Lyn -/- mice remains incompletely characterized: although glomerular immune complexes are present, it is not known if proteinuria ensues, nor is it known whether these mice produce high-affinity autoantibodies typical of SLE, such as IgG anti-dsDNA or anti-Sm.

SHP-1 inhibits B cells from accumulating in the B-1a compartment [125], and not surprisingly, SHP-1-deficient (motheaten viable) mice have a massive expansion of $CD5^+$ B cells and selective IgM hypergammaglobulinemia. In addition to autoantibodies and glomerular immune complex deposition, motheaten mice have a variety of hematological disorders, including the accumulation of macrophages and granulocytes in the lungs, resulting in their demise at ~9 weeks of age [145, 146]. The autoimmune syndrome differs significantly from SLE (Table 7). Although anti-DNA antibodies reactive on solid-phase assays are produced, they do not give a nuclear staining pattern on immunofluorescence [145]. Their cytoplasmic staining pattern suggests that they differ in key respects from the typical anti-dsDNA antibodies of SLE.

Deficiency of FcγRII also leads to autoimmune disease (glomerulonephritis and vasculitis) and the

production of antichromatin and anti-DNA autoantibodies in B6 mice, but not in BALB/c [147]. However, other lupus autoantibodies, such as anti-Sm, are not produced, and it is not known whether true anti-dsDNA autoantibodies are produced. These mice develop prominent proteinuria and kidney disease in a strain-specific manner, closely mimicking SLE.

Strength of the B-cell costimulatory signal (signal II, Fig. 5) also contributes to autoimmunity. CD40L expression is abnormally regulated in both human and murine lupus [148, 149]. Although CD40L transgenic mice do not develop spontaneous autoimmunity [150], CD40–CD40L interactions are important for generating high-affinity autoantibodies. Neutralizing antibodies to CD40L have been used either by themselves or in combination with CTLA-4Ig to treat murine lupus, resulting in the amelioration of renal disease and decreased autoantibody production [151–153]. These antibodies may have a beneficial effect when administered subsequent to the onset of autoimmunity, suggesting that CD40–CD40L interactions are required to maintain autoantibody production. Unfortunately, trials in human autoimmune disease have been stopped due to thrombotic complications [154].

ROLE OF ANTIGEN-PRESENTING CELLS

T and B lymphocytes are the primary mediators of adaptive immunity and consequently are critical players in the formation of autoantibodies. It is important to recognize, however, that the activation of antigen-specific T and B lymphocytes is tightly controlled by antigen-presenting cells and innate immunity.

Innate Immunity

The innate immune system consists of various types of APC, natural killer (NK) cells, complement, and interferons α and β [155, 156]. Dendritic cells (DC) in particular are a key link between innate and adaptive immunity through their ability to initiate and modulate immune responses [155, 157]. Antigens from apoptotic cells are picked up by peripheral DC and transported to the lymph nodes [155, 158, 159]. The presentation of self-antigens to T cells by immature DC is an important mechanism of tolerance induction [160, 161]. In contrast, when DC are confronted with a "dangerous" foreign antigen, which may be associated with self-antigens in an infected cell, they undergo cytokine-mediated maturation leading to the expression of increased surface CD86 (B7-2), MHC class II, and MLR-stimulating activity, with concomitant downregulation of phagocytic capacity [155]. In the presence of IFN-γ, DC mature to a T_H1-polarizing phenotype characterized by high IL-12 production (DC1 effector cells), whereas DC matured in the presence of PGE_2 (DC2 effector cells) are deficient in IL-12 production and have a T_H2 polarizing phenotype [162–164]. Mature DC exert powerful T-cell stimulatory effects, but because of the prior inactivation of self-reactive T cells by immature DC, they generally do not stimulate autoimmunity. $CD11c^+$ myeloid DC and, to a lesser degree, $CD4^+$ DC are reduced greatly in the peripheral blood of SLE patients [165]. Although this may be a consequence of the defective development of DC precursors or more rapid turnover, an alternative explanation is that they are sequestered at sites of inflammation.

Innate Immunity and Autoantibody Formation

The induction of lupus by pristane and other hydrocarbons may be an instance in which disordered innate immunity leads to autoimmunity. Intraperitoneal injection of pristane in nonautoimmune mice induces anti-Sm, anti-nRNP, anti-dsDNA, anti-ribosomal P, and other autoantibodies characteristic of SLE, as well as immune complex-mediated glomerulonephritis and arthritis [19, 20]. Peritoneal macrophages phagocytose the oil and produce exuberant amounts of IL-6, IL-12, and TNF-α. The production of autoantibodies is dependent on these proinflammatory cytokines as well as on intact Fas-Fas ligand signaling, as *lpr* or *gld* strains are resistant [166–168]. Pristane exposure enhances APC survival and results in the acquisition of DC-specific surface markers (M. Satoh, unpublished data). The activation of APC by pristane may be analogous to the stimulation of innate immunity by microbial substances that bind "pattern receptors" [169].

Central Role of IFN-α in Linking Innate and Adaptive Immunity

Three subsets of DC precursors can be identified in peripheral blood: $CD14^+$ monocytes, $CD14c^-$ precursor DC, and $CD11c^+$ precursor DC [156]. The $CD11c^-$ subset, also called "plasmacytoid monocytes" or "plasmacytoid T cells," is identical to a rare cell type that produces large amounts of interferons α and β. These cells, known as interferon-producing cells, have a plasma cell-like morphology with an unusual surface phenotype ($CD4^+$, $CD31^+$, $CD36^+$, $CD68^+$, $CD62L^+$, $CXCR3^+$, and $CD11c^-$, $CD3^-$, $CD19^-$, $CD14^-$, $CD16^-$) and are the major IFN-α-producing cells [170–172]. They migrate to inflamed lymph nodes at high endothelial venules and produce large amounts of IFN-α on

exposure to inactivated herpes simplex virus, influenza virus, or following CD40 ligation [171]. IFN-α promotes survival of antigen-activated T cells [173] and can promote autoantibody formation.

IFN-α is used to treat hepatitis C infection, malignant carcinoid syndrome, and chronic myelogenous leukemia. Therapeutic use has been associated with autoimmune phenomena, including sarcoidosis [174], autoimmune thyroiditis, and autoimmune hepatitis [175]. The induction of antinuclear antibodies and anti-dsDNA antibodies, as well as overt lupus, has been reported as well [176–178]. Moreover, the serum level of IFN-α correlates with anti-dsDNA antibody levels and disease activity in SLE [179–181].

In addition to its effects on T-cell development and autoantibody formation, IFN-α promotes the differentiation of monocytes into DC-like cells [182]. These cells can capture antigens from dying cells and present them to $CD4^+$ T cells [182]. Enhanced expression of superantigens encoded by human endogenous retroviruses (HERVs) with stimulation of T cells expressing particular Vβ chains is another effect of IFN-α that could promote autoimmune disease [183].

Autoimmunity with Abnormal Clearance of Apoptotic Cells

Abnormal clearance of apoptotic material, normally a noninflammatory process mediated by several phagocyte receptors [184–186], may promote autoantibody production (Table 8). A classic example is the acceleration of autoantibody production by Fas or Fas ligand mutations [187]. The mechanisms remain incompletely understood: the prolonged survival of autoreactive lymphocytes, which normally are removed by Fas-mediated apoptosis, could play a role. Alternatively, the inability to remove cells by this pathway could lead to disposal by more inflammatory pathways, such as necrosis. It is interesting that defects in the clearance of apoptotic cells can also promote autoimmunity.

The development of antinuclear antibodies and nephritis (Table 8) by mice deficient in the serum amyloid P component (SAP) [188] is consistent with the idea that abnormal clearance of apoptotic cells promotes autoantibody formation. SAP coats apoptotic cells and blebs containing chromatin fragments and other autoantigens and helps solubilize native chromatin by displacing H1 histone, promoting its clearance by phagocytes. Likewise, C1q-deficient mice clear apoptotic cells abnormally and develop autoantibodies and lupus-like disease [189]. However, an autoimmune-prone background seems to be necessary along with C1q deficiency. The notion that delayed clearance of apoptotic material promotes autoantibody formation is further supported by the development of lupus-like disease and autoantibodies by mice deficient in Mer, a member of the Axl/Mer/Tyro3 receptor tyrosine kinase family [190]. Mer-deficient macrophages show a selective defect in the phagocytosis of apoptotic cells.

[a] Not available.

CYTOKINE DEPENDENCE OF AUTOANTIBODY FORMATION

The importance of APCs in generating autoantibodies is underscored by the critical role of the cytokines they produce. Tumor necrosis factor-α is of particular relevance, although IL-1, IL-6, IL-12, and possibly IL-10 also promote autoantibody formation.

TNF-α and Related Molecules

The induction of antinuclear and anti-dsDNA antibodies and the occasional development of overt SLE are important side effects of TNF-α blockade [176, 191]. In rheumatoid arthritis patients, the incidence of antinuclear antibodies increased from 29 to 53% in infliximab-treated patients and anti-dsDNA antibodies were detected in 14% [192]. However, only rare patients (1 of 156 in this study) developed clinical manifestations of SLE. Thus, TNF-α may be protective against lupus-like disease, as also suggested by mouse studies. TNF-α appears to have a physiological role in suppressing the emergence of autoreactive lymphocytes in the NZB/W model, and deficiency enhances the production of anti-dsDNA antibodies [193, 194]. Low TNF-α responsiveness is characteristic of macrophages from the NZW parent [193], and more recent studies have suggested that a polymorphism of the 3′-untranslated region of the NZW TNF gene may reduce translational efficiency [195]. Similar TNF dependency has been noted in the MRL model [196]. However, other reports suggest that an increased production of TNF-α [197] or an increased signal transduction via TNFRII (p75 TNF receptor) [198] are associated with SLE, although not with autoantibody formation.

BLyS (BAFF, zTNF4, TALL-1, THANK) is a member of the TNF ligand family that binds to a receptor (TACI) expressed on B cells [199, 200]. It is a potent B-cell coactivator, and transgenic mice expressing high levels of BLyS develop polyclonal hypergammaglobulinemia and expansion of B-1a cells. NZB/W and MRL mice have high levels of circulating soluble BLyS, as do lupus patients [199, 201]. The effects of BLyS on IgM levels and on polyclonal hypergammaglobulinemia are more profound than is the enhancement of IgG autoantibodies, suggesting that it may not be a key regulator of autoantibody formation in SLE. Indeed, studies of TACI mutant mice suggest that TACI, through its interactions with BLyS and APRIL, may be more important as a costimulator of T-cell-independent (TI-2) antibody responses against polysaccharides such as pneumococcal polysaccharide [202].

Other Cytokines Produced by APC

IL-10, which is produced by APC and certain T cells (see later), affects polyclonal hypergammaglobulinemia and enhances autoantibody production in mice [203, 204]. IL-6 enhances autoantibody formation in both humans and mice. In pristane-induced lupus, IL-6 is required for the production of anti-DNA and antichromatin autoantibodies, but not for anti-Sm, RNP, or Su [167]. IL-6 accelerates nephritis both in pristane-induced lupus and in spontaneous models [167, 205]. In humans, the overproduction of IL-6 in patients with cardiac myxomas [206] and Castleman's disease [207] is associated with antinuclear and other autoantibodies.

IL-1β also may enhance polyclonal IgG production in mice, but the effect on the production of anti-DNA antibodies is small [208, 209]. There may be a greater effect on nephritis [210]. In addition, IL-1RA-deficient mice develop a chronic inflammatory condition associated with severe arthritis resembling rheumatoid arthritis along with anti-dsDNA autoantibodies [211]. Finally, IL-12 and IL-18 are APC-derived cytokines that induce IFN-γ production and accelerate lupus-like disease and autoantibody production in murine lupus [212, 213]. These cytokines promote the differentiation of helper T-cell subsets that have substantial effects on autoantibody formation.

Cytokines Produced by T Cells

Both T_H1 (IFN-γ) and T_H2 (IL-4, IL-5, and IL-10) cytokines have been implicated in murine lupus. T_H2 cytokines may promote autoantibody production in some situations [204, 214], including the lupus-like disease in mice with chronic graft-versus-host disease [215]. In NZB/W mice, IL-4, IL-5, and IL-6 are involved in anti-DNA antibody production and renal disease [216], and treatment with anti-IL-10 antibodies decreases anti-DNA antibody production, delays the onset of nephritis, and prolongs survival [204]. However, although IL-4 transgenic B6 mice develop spontaneous immune complex nephritis [217], IL-4 transgenic NZW/C57Bl/6Yaa mice are protected [218]. At present, it appears that in most spontaneous and inducible models of lupus in mice, IFN-γ plays a much more important role than IL-4 and IL-10.

Indirect evidence that IFN-γ plays a role in autoantibody formation comes from the observation that anti-Sm and chromatin autoantibodies in MRL/*lpr* mice are predominantly IgG2a, an IFN-γ-dependent isotype [219]. More direct evidence comes from the observation that the expression of IFN-γ in the skin of transgenic mice leads to the production of anti-DNA and -Sm autoantibodies [220]. In pristane-induced lupus the production of anti-DNA and antichromatin autoantibodies and the development of renal disease are abrogated in IFN-γ-deficient mice, and the frequency of anti-nRNP, anti-Sm, and anti-Su autoantibody production is decreased greatly [168]. In contrast, IL-4 deficiency has little effect [168]. Anti-DNA levels are also very low in IFN-γ-deficient MRL/*lpr* [221–223] and NZB/W mice [224], suggesting that the IFN-γ dependence of this specificity is not limited to inducible lupus. Consistent with these observations, neutralizing monoclonal antibodies against IFN-γ or soluble IFN-γ receptors ameliorate lupus in mice [225, 226], whereas IFN-γ treatment accelerates disease progression [225, 227].

The evidence implicating IFN-γ in humans is less compelling. The predominance of IgG1 and IgG3 autoantibodies in SLE [228] is consistent with a role, because these isotypes, like IgG2a in the mouse, are IFN-γ dependent [229]. Also, a polymorphism of the IFN-γ receptor appears to be associated with susceptibility to SLE [230]. The increased urinary excretion of neopterin, a marker of IFN-γ-activated macrophages in active vs inactive lupus is consistent with the possibility that IFN-γ is involved [231, 232]. Moreover, lupus patients exhibit higher levels of serum IL-18 than healthy controls [213]. However, in contrast to mice, it has been suggested that both disease activity and hypergammaglobulinemia correlate directly with IL-10 production and inversely with IFN-γ [203, 233, 234]. Deficient production of IL-12 has also been reported [234]. However, these studies of serum cytokine levels [235] and *in vitro* production of cytokines by peripheral blood mononuclear cells (PBMC) [234, 236] are inconclusive. Isolation of PBMC on Ficoll gradients causes artifactual IL-10 production [237], and the production of cytokines in peripheral blood may not reflect cytokine production in involved tissues, such as the

skin, joints, or kidney. Case reports suggest that treatment of rheumatoid arthritis patients with IFN-γ can induce or exacerbate lupus-like clinical disease as well as the production of antinuclear, anti-dsDNA, and anti-Sm autoantibody production [176, 238–240]. Further studies are needed to determine whether IFN-γ dependence distinguishes murine from human lupus. In view of the demonstration that IL-10 signaling can be uncoupled at the level of transcriptional activation, it is possible that the high levels of IL-10 are accompanied by ineffectual signal transduction [236].

THE BASIS OF ANTIGEN SELECTIVITY

A major gap in our understanding of the pathogenesis of autoimmune responses is how antigen specificity is conferred. It is difficult to explain the exquisite selectivity of the autoantibody response in SLE for a relatively small number of mostly intracellular (nuclear and sometimes cytoplasmic) self-antigens by a global defect in tolerance or the interactions between T and B cells or between APC and T cells. An understanding of antigen selectivity is key to understanding lupus and other autoimmune diseases. Of the thousands of intracellular proteins, why are only a few prominent as autoantigens in lupus? Current thinking focuses on several possibilities: (1) abnormal processing generates autoantigens, (2) autoantigens are selected because they are sequestered into apoptotic blebs, (3) immune responses against foreign antigens can lead to the production of B or T cells cross-reactive with self-antigens, and (4) autoantigens may be encoded by a subset of genes carrying mutational hotspots that lead to the appearance of somatically mutated, and consequently antigenic, self-proteins.

Altered Antigen Processing

The expressed T-cell repertoire responsive to an exogenous antigen is focused onto a limited number of major T-cell-inducing determinants rather than being directed broadly against all portions of the antigen [241]. MHC-linked genes control this through a determinant selection mechanism in which immunodominant peptides bind to MHC molecules that can present the peptide, but not to MHC molecules that do not present the peptide [241, 242]. Another factor influencing T-cell repertoire expression is the existence of hindering structures on naturally processed fragments that differentially affect presentation by different MHC molecules [241, 243]. The effects of these hindering structures can be overcome by "artificial processing" of an antigen, e.g., by cyanogen bromide cleavage. Hindering structures that affect presentation by MHC molecules can include structural constraints imposed by the tertiary structure of a protein [244] and intermolecular contacts between subunits of an oligomeric antigen [245, 246]. For example, recognition of the human chorionic gonadotropin (hCG) α/β dimer by α-specific T-cell hybridomas is reduced dramatically compared to free hCG-α or heat-dissociated dimers, suggesting that the quaternary structure of hCG affects the presentation of antigenic determinants of the monomers by interfering with proteolytic degradation into peptides capable of binding MHC molecules [246].

The amount of a determinant bound to a MHC molecule with high affinity is a major factor influencing T-cell responsiveness [247]. A major determinant is dominant because it is processed efficiently and binds efficiently to MHC. If this determinant is presented to a T cell in the presence of a costimulatory signal, T-cell activation results. Conversely, if costimulation is absent and/or it is presented by immature DC, the same peptide may be an efficient tolerogen [248]. In the case of minor determinants, the level of a peptide may be insufficient to trigger T-cell activation efficiently, and induction of a tolerogenic signal may be equally inefficient. Thus, tolerance is restricted primarily to the major T-cell-inducing determinants [249, 250]. Although T-cell responses to minor determinants are not stimulated under normal circumstances, they might be induced by cross-reactive microbial antigens or by altered self. Once a response to a minor determinant is initiated, it can be perpetuated by self-antigen because the conditions for memory T-cell responses are less stringent than those required for activating naïve T cells [249].

"Cryptic" self-peptides not normally seen by the immune system at sufficient levels to induce tolerance may be presented in several circumstances: (1) when a foreign antigen binds to self [251], (2) when the tertiary structure is altered by the binding of a hapten [252], and (3) when the protein structure is altered by somatic mutation (Fig. 8). This "altered self" model may have important implications for the pathogenesis of autoimmunity.

Induction of Autoimmunity by Complexes of Self and Nonself Proteins

One mechanism of generating altered self is through the binding of a foreign antigen to a self-protein (Fig. 8). Interaction of the p53 tumor suppressor protein with the SV40 large T antigen (SVT) is an example. SVT transforms cells by binding and inactivating p53 [253], increasing the half-life and cellular levels of p53 markedly [254, 255]. Rodents with SV40-induced

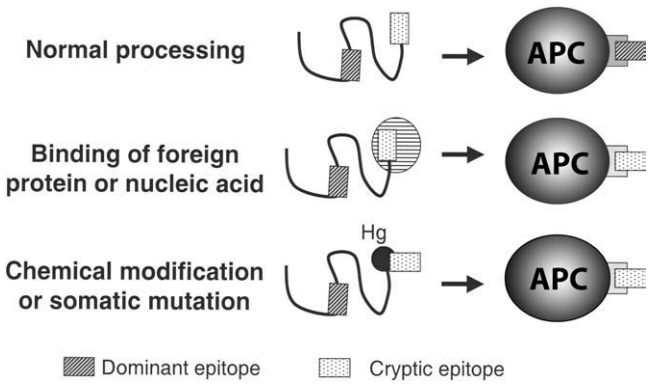

FIGURE 8 ***Generation of cryptic self-cell epitopes.*** The normal processing pathway for a self-protein with major (cross-hatched) and minor (stippled) epitopes by an antigen-processing cell (APC) is shown (top). Only the major epitope is presented at sufficient levels to trigger immune tolerance. (Middle) The binding of a foreign antigen to the self protects the minor epitope from degradation, leading to presentation of the minor epitope. Because tolerance to this peptide has not been established by processing of self, an immune response can be initiated. (Bottom) The antigen has been modified by chemical reaction of mercury with a cysteine residue, altering the conformation or the protein and increasing presentation of the minor epitope. This again leads to the development of immunity. A somatic mutation (not shown) could enhance presentation of the minor epitope similarly.

tumors develop autoantibodies against p53 [256, 257]. Moreover, immunization of mice with low doses of murine p53 does not induce an immune response to the self-antigen, whereas immunization with the same dose of p53 in the form of a complex with SVT results in the production of high levels of autoantibodies to p53 [251]. Once primed with the complex, immunization with murine p53 alone can boost the immune response, possibly because of the lower activation threshold of primed T cells (Fig. 8).

Many other viral infections can precipitate autoimmunity. Epstein–Barr virus infection has been associated with antinuclear antibodies [258], BK virus with antihistone antibodies [63], coxsackievirus infection with autoimmune myocarditis [259], avian leukosis virus with thyroiditis [260], and reovirus infection with polyendocrinopathy [261], to name only a few examples. In reovirus infection, autoimmunity targets only those tissues where the virus actually multiplies [261]. Thus, at least in this example of virally induced autoimmunity, close proximity of the virus and specific autoantigens is a critical factor in the induction of autoantibodies.

Induction of Autoantibodies by Haptens

Chemical alteration of self-proteins is another mechanism for generating altered self (Fig. 8). Mercuric chloride elicits a H-2^s-restricted immune response to the nucleolar antigen fibrillarin [252, 262, 263]. In humans, these autoantibodies are specific for scleroderma [264]. The Hg(II) ion is highly reactive with sulfhydryl groups and more weakly with hydroxyl, carbonyl, and phosphoryl groups [265]. Binding of Hg(II) to cysteines may form metal–protein complexes so stable that they alter conformation and unfolding of proteins inside endosomes, leading to an enhanced presentation of minor cryptic epitopes (Fig. 8).

Apoptosis

A third mechanism for generating altered self is the abnormal degradation of self-proteins (Fig. 8). A number of lupus autoantigens are present in apoptotic blebs and are degraded by caspases and other proteolytic enzymes, such as granzyme B, which may generate immunogenic peptides [266]. These cleavages could define certain proteins as autoantigens [267]. Although apoptosis is a normal cellular process, abnormalities of the usual apoptotic degradation pathways could generate cryptic self-peptides. For instance, the scleroderma-specific autoantigens topoisomerase I (Scl-70), RNA polymerase II, and human upstream binding factor (hUBF, NOR-90) are uniquely fragmented by reactive oxygen species in a metal (iron or copper)-dependent manner, raising the possibility that metal-catalyzed oxidation reactions might target a subset of antigens for autoimmunity [268].

Somatic Mutation of Autoantigens

Mutations arise spontaneously within the coding regions of genes and may be translated into abnormal proteins. A mutation limited to a single cell is unlikely to trigger an immune response due to the low level of altered protein. However, somatic mutations in proliferating cells can induce autoimmunity, probably by altering protein conformation, generating cryptic self-peptides that induce T-cell immunity followed by autoantibody formation [269, 270]. The high frequency of autoantibodies against somatically mutated oncoproteins such as c-myb [271], c-myc [272], and HER-2/neu [273] illustrates this principle. Similarly, autoantibodies are produced against the chronic myeloid leukemia-specific *bcr-abl* joining region formed by the reciprocal translocation between chromosomes 22 and 9 [274]. Autoantibodies to p53 occur at a frequency of ~15% in breast cancer and other tumors associated with p53

FIGURE 9 ***Molecular mimicry.*** Amino acid sequence homology between U1-70K and Moloney murine leukemia virus (MuLV) $p30^{gag}$ proteins is illustrated. Two amino acid sequences from the U1 snRNP 70K protein are aligned with a sequence from MuLV $p30^{gag}$. Homologous sequences are shaded. Immunological cross-reactivity of the homologous sequences can also be shown. Data from Query and Keene [25].

mutations [275–277]. Autoantibodies are present only in sera from patients with missense mutations compatible with the expression of detectable levels of cellular p53 [277, 278]. Moreover, autoantibodies are found only in sera of those patients whose mutant p53 forms a complex with heat shock protein 70 (hsp70), which prolongs the half-life of p53 [277]. No anti-p53 antibodies are found in sera from patients with stop, splice/stop, splice, or frameshift mutations. The autoantibodies recognize wild-type p53, suggesting that they are not specific for the mutant antigens [276, 278].

Molecular Mimicry

Immunological cross-reactivity of one antigen with another, termed "molecular mimicry" [279], may also play a role in autoimmunity. Cross-reactivity of a viral antigen with self can lead to autoantibody production. Cross-reactions between herpes simplex virus and intermediate filaments [280], the Epstein–Barr virus EBNA protein and several cellular proteins [281], and a retroviral $p30^{gag}$ protein and the U1 snRNP 70K protein [25] have been reported. Immunization of mice with the murine leukemia virus $p30^{gag}$ protein induces autoantibodies to a portion of the U1-70K protein exhibiting sequence similarity with the viral protein (Fig. 9), suggesting that retroviral infection can induce autoimmunity to U1-70K.

Autoantibody production may begin as a response to a single cross-reactive epitope, and receptor-mediated uptake of autoantigen by autoreactive B cells could diversify the autoantibody response by generating autoreactive T cells [25]. For example, immunization of mice with foreign cytochrome c induces a population of activated B cells bearing receptors that recognize self-cytochrome c [71, 72]. Adoptive transfer of B cells from these mice to naive recipients can prime autoreactive, cytochrome c-specific T cells. Thus, although molecular mimicry may be limited initially to a single cross-reactive epitope, autoantigen-specific B cells can diversify the response by acting as APC.

Molecular mimicry can also involve groups of self-antigens that share epitopes. For example, all Sm proteins share two regions of sequence homology, Sm motifs 1 and 2 [282]. Consequently, cross-reactive antibodies are prominent in the immune response to U1 snRNPs [66, 283]. Monoclonal antibody Y12, derived from an MRL mouse, recognizes an epitope shared by the highly homologous Sm-B and B′ proteins, as well as a conformational epitope of Sm-D [284] and a conformation-dependent epitope formed by the complex of Sm-E, F, and G [53]. Cross-reactivity of human anti-Sm antibodies with B′/B and D has been reported as well. Other human autoantibodies recognize two epitopes of U1-A cross-reactive with B′/B and C or with U2-B″ [283]. Certain cross-reactive epitopes may not be exposed in the native U1 snRNP particle. Thus, while the majority of anti-nRNP sera exhibit binding to the partially denatured Sm B′ and B proteins on Western blots, they do not recognize the B′/B proteins when incorporated into intact snRNPs. Cross-reactions can also arise due to reactivity of an autoantibody with a common posttranslational modification, such as poly(ADP) ribose [285].

FUTURE DIRECTIONS

Great strides have been made in understanding the pathogenesis of autoantibody production as pathways of lymphocyte activation have become better defined. Studies of genetically altered mice have led to the discovery that many defects are capable of promoting autoimmunity. Progress has also been made in understanding the role of the environment in autoimmunity. However, the basis for antigen selectivity remains poorly understood. Future research will need to focus on the latter question more closely. Also, it will be important to examine which of the genetic defects associated with lupus-like manifestations are relevant to human SLE, as underscored by studies of the Fas^{lpr} mutation. In mice, *lpr* was once regarded as a "lupus gene" because it greatly accelerates lupus-like disease in MRL mice and induces antinuclear antibodies on a B6 background. Human Fas mutations (Canale–Smith syndrome) promote the development of lymphadenopathy, as in mice, but the autoimmune manifestations are not characteristic of SLE [286, 287]. These individuals most frequently develop hematological autoimmunity, including autoimmune thrombocytopenic purpura and autoimmune hemolytic anemia [287]. However, lupus is unusual, both in Fas-deficient patients and in patients with defects of other compo-

nents of this pathway, such as Fas ligand and caspase 10 [288, 289]. Other murine lupus susceptibility genes identified by gene-mapping approaches will need to be scrutinized similarly for their relevance to the human disease. It may be useful to rigorously define pathological manifestations and serological abnormalities that uniquely define the lupus syndrome. Clearly, not all antinuclear antibodies can be equated with the lupus syndrome. Low-affinity anti-DNA or anti-Sm antibodies can be detected in a variety of conditions other than SLE, and their production in mutant mice should not be taken as evidence that the abnormal gene product(s) confers lupus susceptibility. It will be equally important to define more thoroughly the characteristic pathological lesions of lupus. Glomerular immune complex deposition, by itself, is probably not sufficiently specific for the lupus syndrome to be of much value in establishing whether a mutant mouse has lupus. Further complicating the ability to relate the information gained in mouse models to the human situation is the likelihood that SLE is not a single disease. If a loose definition of lupus is applied, mouse data indicate that there are numerous forms of the disease, each with a different clinical syndrome. A stricter definition might make it possible to define lupus as a disease caused by defects in a limited number of immunological pathways. With the rapid pace of discovery in mouse models, it may be timely to reappraise how we define SLE (serologically and pathologically) and to apply similar criteria to mice.

THE CLINICAL PRESENTATION OF SYSTEMIC LUPUS ERYTHEMATOSUS

Robert G. Lahita

INTRODUCTION

Systemic lupus erythematosus (SLE) is an autoimmune disease that affects many organ systems, is more prevalent in females, has no known etiology, and has a distinct association with several immune response genes.

Some of the systems commonly involved include the muscle and joints, brain and peripheral nervous system, lungs, heart, kidneys, skin, serous membranes, and components of the blood. While other systems can be affected, they are affected with lesser frequency. This disease is complex and often affects one organ system to the exclusion of others. Moreover, the clinical manifestations are protean, overlap with other illnesses, and are often subtle. The pathogenetic factors causing lupus remain enigmatic but are likely related and modified by multiple systems, not just the immune system. This explains the convergence of seemingly unrelated abnormalities and the distinctive nature of the specific pathology from patient to patient in this very interesting illness.

The predilection of this disease for females after puberty cannot be adequately explained; however, suspected pathogenetic factors, such as sex steroid hormones or gonadotrophins such as prolactin, may play a role in the severity of the disease and the different clinical presentations. Environmental factors such as drugs, diet, and toxins have also been implicated in the pathogenesis of SLE.

Although there is an association with a constitutive gene on chromosome I in some families, lupus is largely associated with specific immune response genes in the MHC class II or class III regions. Certain genetic MHC II alleles such as HLA-DR2 and DR-3 are also found more commonly with certain autoantibody groups. Patients with inherited complement (MHC class III) deficiencies also develop a form of lupus with specific clinical characteristics (Chapter 5).

Although there are a few nonimmunologic laboratory characteristics of SLE, these are not specific. Immunological tests, which are specific to most autoimmune diseases such as lupus, include the presence of specific cytotoxic lymphocytes and a variety of autoantibodies, including a persistently positive antinuclear antibody (ANA). The following sections present overviews of data presented in other parts of the book.

GENERAL SYMPTOMS

One major problem in the patient with lupus is the nature of the general symptoms associated with the disease. The most problematic include fatigue, weight loss, and fever [1, 2]. These symptoms are often the initial complaint and are attributed to causes other than lupus, forming the basis for misdiagnosis. Fatigue is well recognized and is the most common and often the most debilitating symptom of SLE, as it is commonly overlooked, cannot be quantified except perhaps by exercise tolerance testing, and is often the only symptom to remain after therapy of an acute flare [2, 3]. Patients liken the fatigue of SLE to a chronic influenza. A

curious pattern of fatigue is described in SLE when compared to patients with other connective tissue diseases [4]. In SLE, fatigue decreased in the morning and increased in the evening in contrast to other conditions such as scleroderma where the opposite is true. Weight loss is common in patients with lupus and worsened when there is malabsorption due to overlapping illness such as CREST syndrome or MCTD. Although anorexia is common in severely debilitated patients with associated organ disease such as renal failure, it is not an isolated finding in SLE. The fever of lupus is usually low grade and rarely exceeds 102°F. A temperature greater than 102°F should warrant a search for infection [2]. Patients who are taking immunosuppressive drugs and have fever must be handled differently from the untreated patient, as high fevers may be masked or lowered by such agents and infections in immunosuppressed patients are more likely.

CRITERIA FOR LUPUS

The diagnosis of SLE should be made principally on clinical grounds with the support of laboratory tests [5]. While diagnostic criteria have been proposed for the classification of SLE [5], they are not universally applied in practice. Eleven criteria have been designated by the American College of Rheumatology (ACR) (Table 1) [6] for classification. The presence of 4 or more criteria is mandatory for the appropriate classification of SLE. When used, these have been of value in clinical practice and are 96% sensitive and specific [5]. In some studies of patients with cutaneous lupus, ACR criteria showed a sensitivity of 88%, a specificity of 79%, a positive predictive value of 56%, and a negative predictive value of 96% [7]. Despite this fact, the diagnosis of SLE is given routinely to patients in practice who fail to meet any criteria [8]. Patients who fail to meet 4 of the 11 criteria may have a lupus-like syndrome or a related autoimmune disease. These revised criteria have been reviewed and applied to a number of cohorts [9]. The criteria have also been criticized from a number of groups because of their failure to apply to every lupus-like condition [10]. In 2001, Wilson *et al.* published the criteria for antiphospholipid syndrome. These criteria, which may need revision over time, are very helpful to this important variant of SLE [11].

GENERAL CONSIDERATIONS REGARDING LUPUS

The initial diagnosis of lupus depends on the manner of clinical presentation. Table 2 [12, 13]. In addition, these are often ignored. As a result, one study shows the mean length of time from onset of symptoms to diagnosis to be 5 years, a lapse that could seriously affect prognosis. However, lupus is not always apparent at the initial visit of the patient and continued follow-up with interval histories, clinical examinations, and serological evaluations may be necessary in order to finalize the diagnosis. It is not uncommon for patients to present with isolated arthralgias, Raynaud's phenomenon, hypercoagulable states, fever of unknown origin, or respiratory symptoms such as dyspnea and pleural effusions. In short, the protean clinical manifestations of this illness can make the diagnosis difficult. Patients are often misdiagnosed with rheumatoid arthritis [14], fever of unknown origin [15], fibromyalgia [16], or asked to seek psychiatric help for a functional disorder [17]. Laboratory data in the form of an isolated false-positive syphilis test, a low platelet count, elevated PTT, or leukopenia may suggest many other diseases that are often considered before SLE. SLE is really a clinical diagnosis that relies heavily on a careful history and physical examination because autoantibodies are so frequently associated with nondisease; they alone are supportive but not diagnostic. A history of drug ingestion is particularly important, as reversible drug-induced lupus is responsible for some 10% of cases [18] and is often seen in older patients, particularly males. Lupus can be related to other illnesses that can occur in the patient's family [19]. These include rheumatoid arthritis, multiple sclerosis, idiopathic thrombocytopenic purpura (ITP), rheumatic fever, overlap syndromes such as Sjogren's, scleroderma, and the inflammatory diseases of muscle. There are HLA-D associations to these diseases as well. Fibromyalgia is an extremely important condition that often occurs with SLE. A positive ANA and muscle pain must be differentiated from SLE-induced arthropathy and myopathy [20]. Because of its importance to lupus, a separate chapter (Chapter 25) is included in this version of the book [21].

Many lupus patients are also known to have increased allergy by some early reports [22] to a variety of agents, especially sulfur. Sulfur-containing drugs should be avoided where possible in patients with SLE.

The frequencies of some common clinical presentations are given in Table 3. Simple laboratory tests can be helpful adjuncts in the diagnosis of SLE but should not be used by themselves as the sole criterion. Common laboratory assays can aid the physician in establishing the diagnosis. Most useful are the white blood cell (WBC) count which often shows leukopenia and lymphopenia [12, 23]. Anemia of chronic disease or, in rare instances, autoimmune hemolytic anemia can be differentiated by the examination of red cell indices, a reticulocyte count, a peripheral smear, and a positive

TABLE 1 Revised Criteria for the Diagnosis of Systemic Lupus Erythematosus[a]

Criterion	Definition
1. Malar rash	Fixed erythema, flat or raised, over the malar eminence, tending to spare the nasolabial folds
2. Discoid rash	Erythematous raised patches with adherent keratotic scaling and follicular plugging; atrophic scarring may occur in older lesions
3. Photosensitivity	Skin rash as a result of unusual reaction to sunlight, by patient history or physician observation
4. Oral ulcers	Oral or nasopharyngeal ulceration, usually painless, observed by a physician
5. Arthritis	Nonerosive arthritis involving two or more peripheral joints, characterized by tenderness, swelling, or effusion
6. Serositis	a. Pleuritis: convincing history of pleuritic pain or rub heard by physician or evidence of pleural effusion b. Pericarditis: documented by ECG or rub or evidence of pericardial effusion
7. Renal disorder	a. Persistent proteinuria greater than 0.5 g per day or greater than 3 + if quantitation not performed b. Cellular casts: may be red cell, hemoglobin, granular, tubular, or mixed
8. Neurologic disorder	a. Seizures: in the absence of offending drugs or known metabolic derangement; e.g., uremia, ketoacidosis, or electrolyte imbalance b. Psychosis: in the absence of offending drugs or known metabolic derangement; e.g., uremia, ketoacidosis, or electrolyte imbalance
9. Hematologic disorder	a. Hemolytic anemia: with reticulocytosis b. Leukopenia: less than 4000/mm^3 total on two or more occasions c. Lymphopenia: less than 1500/mm^3 on two or more occasions d. Thrombocytopenia: less than 100,000/mm^3 in the absence of offending drugs
10. Immunologic disorder[b]	a. Anti-DNA: antibody to native DNA in abnormal titer b. Anti-SM: presence of antibody to SM nuclear antigen c. Positive finding of antiphospholipid antibodies based on (1) an abnormal serum level of IgG or IgM anticardiolipin antibodies, (2) a positive test result for lupus anticoagulant using a standard method, or (3) a false-positive serologic test for syphilis known to be positive for at least 6 months and confirmed by *Treponema pallidum* immobilization or fluorescent treponemal antibody absorption test
11. ANA	An abnormal titer of ANA by immunofluorescence or an equivalent assay at any point in time and in the absence of drugs known to be associated with "drug-induced" lupus syndrome

[a] This classification is based on 11 criteria. For the purpose of identifying patients in clinical studies, a person must have SLE if any 4 or more of the 11 criteria are present, serially or simultaneously, during any interval of observation.
[b] The modifications to criterion number 11 were made in 1996.

Coombs test. Thrombocytopenia coupled with elevated coagulation tests such as the PTT might suggest the presence of antiphospholipid antibodies and the lupus anticoagulant. A false-positive syphilis test along with an abnormal PTT can also suggest phospholipid antibodies. An abnormal urinalysis with the appearance of WBCs, red blood cells, granular casts, and proteinuria can also be helpful and raise a suspicion of lupus nephritis. While blood urea nitrogen (BUN) and creatinine levels are not usually elevated at the outset of the disease, they can be useful rarely as baseline values in a patient who progresses to azotemia. A chest X-ray and electrocardiogram should be obtained initially to rule out pulmonary pathology, to explain an enlarged cardiac silhouette, and differentiate EKG signs of pericarditis, enlarged cardiac chambers, or signs of ischemia.

More complex immunologic laboratory tests may both solidify the diagnosis when suspected clinically or contribute to the erroneous diagnosis of SLE in the absence of clinical signs (Table 4). The widespread availability of such testing, the lack of standardization, and inappropriate application of such tests contribute to this confusion. The most useful tests for SLE are the fluorescent antinuclear antibody test, antinative DNA assay, and total hemolytic complement (CH50). All of these tests are subject to wide variation, the ANA because of substrate variability, the anti-DNA because of single-stranded DNA contamination and cross-reactivity with phospholipid, and finally the CH50 because of the temperature lability of complement [24].

Many rheumatologists believe that ANA-negative lupus exists [25], but this is probably an artifact of

substrate. Occasionally, other reactive antibodies, such as anti-Ro, anti-La, and other ribonucleoprotein antibodies, might be found in the absence of an ANA. Conversely, ANAs can be found in a wide variety of nonlupus individuals, such as the elderly, pregnant females, those ingesting certain medications, and in the setting of certain viral syndromes [26]. Antibodies to native DNA [27] and antibodies to Sm antigen, a nuclear glycoprotein, are also quite specific for SLE [28]. Relevant autoantibodies and their associations are given in Table 5 [12, 23].

MUSCULOSKELETAL SYSTEM

One of the most common presenting symptoms of lupus is arthritis. This is usually a nonerosive, nondeforming, and symmetric arthropathy. Multiple joints are involved, and 80–95% of patients with SLE have tender, swollen, and effusive joints. The joints are the most frequently involved organs in SLE. Most frequently involved joints are the proximal interphalangeal, metacarpal phalangeal, knees, and wrists. The deforming arthritis of Jaccoud can occur in the lupus patient. In such patients, swan neck deformity and/or profound ulnar deviation can usually be reduced and is rarely with erosive changes. The most frequent musculoskeletal X-ray changes are soft tissue swelling, acral sclerosis, and periarticular demineralization. Rare erosions of bone can occur and are another form of overlap syndrome [29]. Joints such as the temporomandibular and the sacroiliac may also be involved (the latter particularly in males) in the SLE patient [30]. Involvement of these joints suggests other diseases such as RA [30], mixed connective tissue disease (MCTD), or ankylosing spondylitis. Overlap syndromes such as MCTD resemble RA or scleroderma more than SLE, and erosions are more likely to be found on X-ray. Rheumatoid nodules can occur in SLE with the presence of a high rheumatoid factor [12] but this is rare. These exceptional joint changes contribute to the confusion in making a diagnosis of SLE, particularly in the elderly patient where SLE is distinctly uncommon [31].

Aseptic necrosis, a particular cause of joint pain in SLE patients, should be a part of every differential diagnosis. It is a feature found in patients who are ingesting corticosteroids and those with phospholipid antibodies [32]. Arthritis and use of cytotoxic agents are independent risk factors for the development of osteonecrosis. Avascular necrosis (AVN) is commonly found in the hips, carpal bones of the wrist, and heads of the humeri.

[f] Not available.

Less commonly, the shafts of the long bones can be affected. Anywhere from 5 to 10% of patients with SLE can have AVN [33]; these findings are not always associated with steroid use. In many cases, AVN can be asymptomatic and detected by routine X-ray evaluation [34]. In decreasing order of sensitivity, magnetic resonance imaging (MRI), bone scan [Tc99], and radiograph are useful in detecting AVN. MRI is often positive when all other diagnostic modalities are negative.

Septic arthritis must also be considered as a cause of SLE joint pain [35], particularly when there is swelling and warmth of a joint coupled with peripheral leukocytosis. An aspiration of the swollen SLE joint with subsequent culture is mandatory and can be lifesaving.

Overt myositis can present in 3–5% of SLE patients [35], but clinical features can be found in as many as 50% of patients. Although the creative phosphokinase (CPK) is rarely elevated, the electromyogram (EMG) can be very abnormal. Biopsy of the muscle is rarely required for a definitive diagnosis, but if the CPK is exceptionally high or there is diagnostic confusion, one may wish to consider alternative diagnoses. The lymphocytic, monocytic, and plasma cell infiltration found in primary immune myopathies can be observed in varying degrees with SLE patients. A vacuolar myopathy is rare but may be found in untreated patients [36]. Muscle disease in SLE can also be secondary to corticosteroid therapy [37], and a form of muscle disease indistinguishable from polymyositis can be found in patients ingesting antimalarials [35].

CLINICAL INVOLVEMENT OF THE RENAL SYSTEM

Clinical evidence of kidney involvement is found in one-half to two-thirds of patients with SLE [12, 13, 35, 38]. Renal biopsy evidence of immune complex deposi-

TABLE 5 Some Common Autoantibodies in SLE and Drug-Induced Lupus

Condition	Autoantibody	% positive	Comment
SLE	Anti-dsDNA	30–70	Associated with nephritis, marker for SLE
	Anti-Sm	20–40	Marker for SLE
	Anti-RNP	40–60	Also seen in MCTD and PSS
	Anti-Ro/SS-A	10–15	Associated with sicca syndrome, also seen in Sjögren's syndrome
	Anti-PCNA	5–10	
	Anti-Ku	30–40	Also seen in overlap syndromes
	Antilarnin B	5–10	Also seen in autoimmune liver disease
	Antiribosomal P	5–10	Associated with psychosis
	Antihistone	30	Seen in many disorders
	Anti-ssDNA		Seen in many disorders
Drug-induced lupus	Antihistone	95–100	Seen in many disorders
	Anti-ssDNA		Seen in many disorders

TABLE 6 World Health Organization Classification of Lupus Nephritis[a]

Class	Pattern	Site of immune complex deposition
I	Normal	None
II	Mesangial	Mesangial only
III	Focal and segmental proliferative	Mesangial, subendothelial, ± subepithelial
IV	Diffuse proliferative	Mesangial, subendothelial, ± subepithelial
V	Membranous	Mesangial, subepithelial

[a] Adapted from Appel *et al.* [38], with permission.

tion is found in the kidneys of all patients with SLE [39, 40], regardless of urine sediment. Table 6 [12, 23] shows the various forms of glomerular disease as determined by the World Health Organization (WHO). Both diffuse proliferative glomerulonephritis and progressive forms of focal proliferative nephritis have poorer prognoses than membranous and mesangial forms of the disease [41, 42]. A major clinical point is that each renal lesion has activity. The greater the activity, the more important the need to treat the patient aggressively with large-dose steroids or cytotoxic agents. Those patients with inactive lesions (i.e., membranous nephropathy, sclerotic glomeruli, fibrous crescents, tubular atrophy, or interstitial fibrosis) do not require aggressive therapy. Because this pathology can best be observed with a renal biopsy, these are the principal reasons to obtain such a biopsy. Renal biopsies from SLE patients must always include two components: light microscopy and immunofluorescence. Serial renal biopsy has prognostic value and is recommended for the regulation of therapy [43, 44]. A biopsy without immunofluorescence analysis is not a good manner with which to gauge lupus renal activity. If it is feasible, electron microscopy should also be done.

A renal biopsy done under fluoroscopy or by CT guidance is best for the patient with SLE. An adequate number of glomeruli should be obtained for verifiable diagnosis. Hypothetical problems encountered with the renal biopsy include (1) that the biopsy is static or reflective of one point in time; (2) that the efficacy of the activity/chronicity index is questionable in designing treatment, and (3) no single glomerular lesion can reflect the entire renal picture.

The most serious complications of renal biopsies include pericapsular hemorrhage or clot obstruction in those patients with lupus procoagulants.

In those patients with WBC, erythrocyte, hyaline, or granular casts a BUN and creatinine are helpful in order to assess renal function. For most patients, renal function early in the course of the disease is normal despite abnormal urine sediment. If the activity of the disease progresses unchecked, these parameters can change rapidly. When proteinuria is found qualitatively, it is helpful to obtain a 24-h urine protein and a creatinine clearance to quantify the amounts. Urine protein is a useful measure of renal lupus activity. An incremental change of 500 mg of protein excretion is significant to renal pathology just as a decrement can herald clinical improvement.

There can be many other reasons for decreased renal function in SLE. These include concomitant infections, use of aspirin, NSAIDs, or ACE inhibitors, all of which might induce a decrease of renal circulation, as well as obstruction, or thrombosis of the renal vein. Sonograms, contrast studies, or renal scans can be helpful in the evaluation of renal function when causes other than lupus nephropathy are suspected. Platt *et al.* [45] suggest that ultrasound might be of utility in the prediction of worsened renal disease.

Less common forms of renal involvement in SLE include interstitial nephritis, which is thought to be mediated by immune complexes [46]. This form of renal disease may not present as renal failure but rather as a disorder of acidification and potassium transport or regulation [47]. Studies of renal pathology indicate that thrombosis of the glomerulus [48] and intraglomerular thrombi [49] are alternate causes of proteinuria and renal failure in SLE.

Renal transplantation in lupus is as successful as that in the non-SLE population. However, renal disease can occur again in the transplanted kidneys [50]. For unknown reasons the alleviation of overall disease activity of lupus erythematosus after dialysis for chronic renal disease has been reported.

CLINICAL INVOLVEMENT OF THE CENTRAL NERVOUS SYSTEM

Both cognitive dysfunction and neuropsychiatric lupus are reviewed extensively in Chapters 26, 27, and 28.

Neuropsychiatric manifestations can be found in as high as 66% of patients with SLE [51–54]. The pathophysiology of this clinical manifestation is not widely understood; however, thrombosis and vasculitis are not responsible for the large number of neuropsychiatric manifestations observed. It is likely that another component, nonimmunologic in nature, might be involved [55]. Central nervous system (CNS) manifestations include seizures, psychiatric illness, and disorders of the cranial nerves [56]. The frequency of organic CNS manifestations in SLE has been reported as between 35 and

75% [57]. The peripheral nervous system is involved in as high as 18% of patients [58].

Seizures are found in 15–20% of SLE patients [59]. These can be the result of the disease process, such as lupus vasculitis or acute thrombosis, steroid therapy and its attendant hypertension, or a concomitant metabolic problem such as uremia [56]. Grand-mal tonic–clonic seizures are the most common, although other seizures, such as Jacksonian, psychomotor, and absence attacks, have all been reported [58]. On occasion, patients with SLE can present with status epilepticus. Treatment of seizures in SLE requires anticonvulsants. Corticosteroid therapy itself, particularly pulse therapy, has been associated with the onset of status epilepticus and should be used with caution [60].

Lupus can cause profound psychiatric disturbances in 50–67% of patients [56, 58]. Overt psychosis can occur in 12% of cases as well as a variety of organic brain syndromes [61]. Severe depression is common to lupus patients and is thought to be a disease manifestation rather than reactive depression that results from chronic disease. Sleep disturbances are common in lupus and need not be related to depression. Steroid psychosis is common in lupus patients on high-dose steroids for long periods [62]. Antiribosomal P protein antibodies are positive in over 60% of patients with SLE-related psychosis [63] and can help distinguish these patients from those with steroid psychosis [62].

Ten percent of patients can have cranial nerve abnormalities that can be the presenting symptom in an even smaller number [56]. Although spinal cord involvement in SLE is rare, three types of cord involvement are seen: transverse myelitis [64], demyelination [65], and spinal cord occlusion because of thrombosis [66]. The latter three spinal manifestations are all commonly associated with antiphospholipid antibodies [67].

In the first 5 years of the disease, the incidence of cerebrovascular accident (CVA) is high (6.6% occurring in the first year alone) [68]. Patients with antiphospholipid antibodies have an increased risk of stroke.

Even though movement disorders are not common in lupus, chorea is common in children with SLE and has been described in adults and children with phospholipid antibody [69–71]. It is virtually indistinguishable from Sydenham's chorea. Parkinsonism and cerebellar ataxia are rare [56, 72]. Rarer forms of CNS involvement include pseudo-tumor cerebri, hypothalamic dysfunction (especially due to thalamic infarcts), aseptic meningitis (particularly related to NSAID use), myasthenia, Eaton–Lambert syndrome, and a TTP-like syndrome. The presence of microadenomata in the pituitary gland of some patients with hyperprolactinemia represents a separate condition found in an SLE-like syndrome caused by hyperprolactinemia.

Peripheral nervous system disease is found in 3–18% of patients and is largely a sensory only or combined sensory-motor neuropathy [73]. A Guillain–Barre syndrome, mononeuropathy, or mononeuritis multiplex has also been reported [74].

The laboratory diagnosis of central nervous system disease in SLE is difficult [75]. Spinal fluid pleocytosis and/or high spinal fluid protein levels are the only helpful indicators that CNS disease is present [76]. MRI and position electrom tomography scanning show the most promise for diagnosing disease of the brain. Use of the newer modalities, such as Tc-99-HMAAQ brain SPECT, may have better utility in the diagnosis of CNS SLE [77]. Infarctions and demyelinating lesions of the brain are best found with these modalities [78]. CT scans are good for detecting focal lesions but are often unreliable. Antibodies to ribosomal P protein and antineuronal antibodies, as well as the finding of cytotoxic lymphocytes against myelin in blood, may eventually prove useful, but now are not very specific for cerebritis [63].

CLINICAL PRESENTATION OF CARDIOVASCULAR LUPUS

Cardiac involvement is very common in SLE, as 30–50% of all patients suffer from some form of heart disease [12, 79]. Pericarditis is the most common form of involvement and occurs in some 19–48% [80] of patients. Pleural–pericardial pain can occur at any time. Although pericardial tamponade can be the initial presentation, this is quite rare and most patients present with pain and small effusions. Most pericarditis in SLE can be managed with NSAIDS and/or low doses of corticosteroids. Echocardiography is the best diagnostic test for this manifestation. The differential diagnosis of pericardial effusion in SLE should include tuberculosis or bacterial peritonitis if the patient is immunosuppressed, and in instances when pericardiocentesis is necessary, the appropriate cultures should be sent. Myocarditis is rare in SLE, involving only 5–10% of patients and usually presents with fever, conduction abnormalities, elevated CPK, skeletal myositis, and serositis [81]. In the SLE patient with hypertensive cardiomyopathy, the differential diagnosis can be difficult and may require extensive investigation until a final diagnosis is made. Myocardial infarctions [82] and conduction abnormalities can be secondary to the myocardiopathy. A myocardial biopsy would give a definitive answer, but as with most invasive procedures carries a high morbidity in the SLE patient.

Systolic cardiac murmurs are heard in up to 70% of SLE patients [83]. These may be related to anemia, fever, or hypoxemia and are found with Libman–Sacks endocarditis, a component more frequent with antiphospholipid antibodies [84]. The mitral and aortic valves are involved most commonly [85]. Pulmonary hypertension is quite common in patients with phospholipid antibodies [86], and a pulmonic murmur or a loud second heart sound in the presence of an elevated PTT are clues to this diagnosis, which should be confirmed by echocardiography or catheterization. Interventional pulmonary artery pharmacological dilatation may be required in choosing a proper therapy. Ultimately, those patients who have profound cardiac failure or unrelenting pulmonary hypertension may benefit only from heart and lung transplantation. The most common cardiac murmur in the SLE patient is likely to be the mitral valve prolapse, which may have relationship to antiphospholipid antibodies. Disturbed autonomic function is common in SLE [87] and may be a reason for many of the cardiac symptoms such as tachycardia. Diastolic impairment may also be common in patients that do not have active disease [88].

Vasculitis is common in SLE and may be reflected in the presence of splinter hemorrhages, digital infarcts, or ecthymic skin lesions [89] (Table 7). Involvement of small- and medium-sized arteries may mimic polyarteritis nodosa and produce localized signs. This variant can be life-threatening. Examples include vasculitis of the coronary or mesenteric vessels.

SLE in the human results in a higher incidence of myocardial infarction because of accelerated atherosclerosis, coronary vasculitis, or coronary emboli [90–92].

TABLE 7 Vasculitic Involvement in SLE

Manifestation	Vessels involved and site
Leukocytoclastic angiitis (urticaria, palpable purpura)	Postcapillary venules, upper dermis
Atrophie blanche, livedo vasculitis	Small vessels, middle and lower dermis
Subcutaneous nodules	Medium-sized arteries, panniculus, and lower dermis
Livedo reticularis	Medium-sized arteries, panniculus, and lower dermis
Coronary arteritis	Coronary arteries
Mononeuritis multiplex	Vasa nervorum
Cerebral infarcts	Primarily small vessels
Mesenteric arteritis	Small and medium-sized arteries
Retinopathy	Arterioles, venules

Raynaud's phenomenon in SLE is not as common as in related diseases and is present in 20% of patients [12] and is often associated with pulmonary hypertension. It may itself be a sign of overlap syndrome [93]. Digital vasoconstriction can produce digital ulcers, gangrene, and autoamputation. This phenomenon is often treated with vasodilators, calcium channel blockade, or, in severe cases, laser sympathectomy.

The most common cause of death in SLE is early onset cardiovascular disease. Hyperlipidemia is often implicated as one of the reasons for early ASCVD [94]. Aranow and Ginzler [95] reviewed this topic in detail. Risk factors for accelerated ASCVD are under intense study [96].

PULMONARY DISEASE AND LUPUS

The lungs are commonly affected in lupus patients [97]. Over 50% of SLE patients have some form of pleural disease in their lifetime. Pleural effusions, which are mostly exudative (>3 g protein), are less common than the pain and findings associated with simple pleuritis. The pain of pleuritis can be quite severe and must be distinguished from pulmonary embolus, infectious, or other forms of pneumonia.

While many abnormalities of lung function can exist in SLE, the most common pulmonary abnormality in lupus is reduced carbon monoxide diffusion capacity (DLCO). Evidence of severe restrictive or obstructive disease in SLE is unusual, although this can be the major manifestation in some variant forms of the disease [98].

Less commonly, parenchymal lung involvement occurs suddenly and presents as acute pneumonitis, dyspnea, and pleuritic pain. Subsequent to such a presentation, the patient might continue with extensive pulmonary problems [99]. For example, interstitial pneumonitis and chronic fibrosis can be the result of such a syndrome [100]. Generally, such parenchymal disease can be treated with high-dose corticosteroids, and a good response in pulmonary function is achieved as the desired result. Pulmonary capillaritis is also part of parenchymal disease [101]. Hemoptysis and overt pulmonary hemorrhage are emergencies in SLE patients and can be the result of numerous reversible processes, such as pneumonitis or pulmonary embolus. There is also an association of alveolar hemorrhage with renal microangiopathy [102]. Shrinking lung found on X-rays in some lupus patients is the result of diaphragmatic weakness [103] or paralysis and is thought by many experts to be a sign typical for SLE lung.

Pulmonary hypertension, even in patients with minimal lupus activity, can be severe and progressive [104, 105].

HEMATOLOGY OF SLE

The cellular elements of the blood and the coagulation pathway can be affected in the SLE patient. The latter is largely the result of the antiphospholipid syndrome and is covered elsewhere.

Sixty to 80% of lupus patients have anemia of chronic disease. Other kinds of anemia, such as autoimmune hemolytic anemia, are rare and are found in less than 10% of patients; however, a positive Coombs test can be found in 20–60% of patients [15, 106] and confuse the picture.

Leucopenia can be found in over 50% of patients with SLE and is associated with either granulocytopenia or lymphopenia [107]. Antibodies can be directed to either of these cellular elements at any point in their maturation pathways. When directed against stem cells, they are a cause of aplastic anemia. Most low cell counts in SLE can be reversed with immunosuppressive therapy. Leucopenia, often a good general sign of disease exacerbation, can also occur in response to cytotoxic lupus therapy and must be differentiated from that effect.

Thrombocytopenia, found in 30–50% of SLE patients [106], is related either to antiplatelet antibodies [107] or to phospholipid antibodies. Either can cause profound thrombocytopenia (<50,000). The latter usually responds to corticosteroid, immunosuppressive therapy, or intravenous γ-globulin. Platelet transfusions are contraindicated in most SLE patients except on rare occasion because of the possibility that the patients will be exposed to new antigens. Anticlotting factor antibodies have been found in SLE and are often associated with bleeding. Antibodies are directed most commonly to factors II, VIII, IX, XI, or XII. Acquired von Willebrand syndrome is also seen. Lupus anticoagulants are found commonly in patients with SLE and are associated with mild to profoundly elevated partial thromboplastin times. This abnormality is usually associated with coagulation and not with bleeding [108]. Associations have been observed, and the triad of the lupus anticoagulant, recurrent abortions, and the presence of false-positive tests for syphilis is often found in patients. Patients with lupus can be hypercoagulable for a variety of reasons other than procoagulant antibodies and these include hereditary deficiencies of factors C and S or antithrombin III. One acquired reason is the loss of antithrombin III in the urine of patients with nephrotic syndrome.

Laparoscopy is the best way to remove the spleen i n most cases of refractive thrombocytopenia. Open laparotomy is not advisable in any except the most complicated cases.

CLINICAL PRESENTATION OF LUPUS OF THE SKIN

Ninety percent of lupus patients have some involvement of the skin. Only 40% of patients experience sensitivity to ultraviolet (UV) light and these are mostly Caucasians [15, 41]. Black patients are less sensitive to UV light [109]. The actual percentage prevalence is 57% Caucasian vs 11% Black. The lupus band test, considered by many to be the definitive test for lupus, measures immunoglobulin and complement deposition at the dermal epidermal junction in nonlesional skin of greater than 60% of patients [110]. However, false positives are encountered in rosacea, rheumatoid arthritis, MCTD, renal diseases, and many other disorders. Its true value is probably the differentiation of discoid lupus from SLE. In the former disease, only lesional skin stains positive, whereas in SLE, both lesional and nonlesional skin stain with immunoglobulin at the dermal–epidermal junction.

Acute cutaneous lupus (30–50%) and subacute cutaneous lupus (10–15%) comprise the vast majority of patients with dermal disease. The butterfly malar rash found in 40% of patients is part of acute cutaneous lupus. This rash is acute in onset and usually heals without scarring. Widespread morbilliform eruptions or bullous lesions can be confused with drug eruptions or erythema multiforme. The bullous lesions usually respond to Dapsone therapy.

Subacute cutaneous lupus (SCLE) is an annular, widespread, nonscarring or papulosquamous/psoriasiform lesion that is worsened by sun exposure. This form of lupus is associated with HLA-DR3, anti-Ro antibody, and high titers of ANA. SCLE has also been associated with complement component deficiencies of C2 [111], C1q, and C1s.

Chronic forms of lupus skin disease include several forms of discoid lupus and *lupus profundus*. These discoid lesions are usually localized to the head, scalp, and external ear, but involvement that is more widespread is possible. Unlike those of subacute cutaneous lupus, these lesions can occur in nonsun-exposed areas. Discoid lesions can be chronic and not associated with the other manifestations of SLE. Patients with isolated discoid lupus have a 2–10% chance of developing systemic disease, whereas 10–20% of SLE patients have discoid lesions. Discoid LE is more common in African-Americans.

Lupus panniculitis or *lupus profundus* is an unusual form of chronic cutaneous lupus that is manifested by indurated subcutaneous nodules on the extremities. It is rare, occurs in 2% of patients, and responds to Dapsone therapy.

Alopecia occurs in all patients with SLE at some time in their disease presentation and can be the result of therapy. It is usually reversible alopecia. Livido reticularis, another skin lesion, is not restricted to lupus but also to the antiphospholipid syndrome.

GASTROINTESTINAL TRACT AND LIVER DISEASE IN SLE

The most common manifestation of gastrointestinal lupus is the occurrence of painless ulcers in the nose and mouth of patients. Almost 100% of patients develop these ulcers at some time during the course of their disease. These occurrences often indicate a flare of disease in known patients [112].

Esophageal ulcerations and dysphagia are rarely found [113]. Thirty percent of patients [114] have nausea and vomiting.

Abdominal pain in SLE can result from a variety of causes [115, 116]. These include pancreatitis [114], ischemic bowel, perforation, or mesenteric vasculitis [117, 118]. Each of these can suggest a surgical abdomen and mandate a laparotomy. The tumor marker CA125 can be elevated in cases of SLE-induced gastrointestinal ischemia [119]. Serositis and, in some cases, vasculitis may simulate a surgical abdomen, but these may not require exploratory surgery. A prudent trial of steroids before laparotomy may obviate invasive abdominal surgery [120, 121]. Abdominal surgery is associated with an extremely high mortality rate in the active SLE patient.

Lupus peritonitis is the result of small vessel involvement in the bowel serosa or retro peritoneum or the result of actual perforation of the bowel. Rebound tenderness, fever, nausea, vomiting, and diarrhea can be found [122]. Bacterial peritonitis is quite common in patients with nephrotic syndrome [123]. Paracentesis is of diagnostic help in such instances.

Parenchymal liver disease as a result of lupus is uncommon and more likely represents chronic active hepatitis or cirrhosis [63]. Lupoid hepatitis is a separate entity and is not part of SLE [124]. Liver function studies may be very abnormal in patients with lupus. These abnormalities are usually secondary to drug therapy [63], aspirin ingestion [125], and rarely with thrombosis secondary to phospholipid syndrome.

THE EYE AND SLE

The eye is not commonly involved in SLE [126]. Only 10% or less of patients have episcleritis or conjunctivitis. In a prospective study, retinopathy was detected in 7% of SLE patients [127]. This retinopathy consists of microangiopathic lesions with cotton wool spots and hemorrhages that can be a significant problem in someone with a bleeding diathesis or one who is anticoagulated. Optic neuritis, papilledema, and retinal vein occlusion are also major problems [128]. Lupus retinopathy is common in patients with active SLE (88%) and in those with lupus cerebritis (73%). Patients can also have uveitis, cytoid bodies, and angle-closure glaucoma.

MISCELLANEOUS ORGAN INVOLVEMENT

Less common in the patient with SLE is sicca syndrome. Patients who are older are particularly affected. Patients with lupus can have asymptomatic parotid gland enlargement with abnormal labial biopsies that suggest Sjogren syndrome [129, 130]. Many of these patients have a positive anti-Ro antibody and a Sjogren syndrome overlap. Patients with lupus may have vocal cord paralysis or present with hoarseness because of vasculitis of the recurrent laryngeal nerve.

Lupus may be a cause of sensori neural learning loss. The mechanism of ear damage is not known [131, 132].

NEONATAL LUPUS SYNDROMES

Jill P. Buyon

INTRODUCTION

In 1901, congenital heart block (CHB) was first reported by Morquio [1] and in 1945 was diagnosed antepartum by Plant and Steven [2]. CHB can occur in association with structural heart disease, such as atrioventricular septal defects, left atrial isomerism, and abnormalities of the great arteries [3], with tumors, such as mesotheliomas [4], or as an isolated defect. In 1928 Aylward [5] reported the occurrence of CHB in two children whose mother "suffered from Mikulicz's disease." This curious clinical observation was further solidified by the 1970s with reports of CHB, absent major structural abnormalities, in children whose mothers had autoimmune diseases [6–8] and by the finding that the maternal sera contained antibodies to SSA/Ro ribonucleoproteins [9–12]. It was subsequently noted that many mothers also had antibodies to SSB/La [13–17] (Table 1). Other abnormalities affecting the skin, liver, and blood elements were reported to be associated with anti-SSA/Ro-SSB/La antibodies in the maternal and fetal circulation and are now grouped under the heading of neonatal lupus syndromes (NLS) [18–21]. Neonatal lupus was so termed because the cutaneous lesions of the neonate resembled those seen in system lupus erythematosus (SLE) [20, 21].

NLS, albeit encountered infrequently by those caring for pregnant patients with SLE, presents a unique clinical challenge to the team of rheumatologist, perinatologist, neonatologist, pediatric cardiologist, and dermatologist. For the immunologist, the study of these syndromes may yield important insights into the pathogenesis of autoimmune-mediated tissue damage, whereas the embryologist may uncover relevant milestones in fetal antigen expression. The biology of human viviparity involves a wide variety of fetal–maternal relationships, several of which may facilitate the occurrence of passively acquired autoimmunity [22]. Tissue injury in the fetus is presumed to be dependent on the transplacental passage of maternal IgG autoantibodies from the mother who has an autoimmune process but who may be clinically asymptomatic (Fig. 1). Disease in the offspring parallels the presence of maternal antibodies in the fetal and neonatal circulation and disappears, except for CHB, with the clearance of the maternal antibodies by the sixth to eighth month of postnatal life. The transient hematologic abnormalities and skin disease of the neonate reflect the effect of passively acquired autoantibodies on those organ systems that have the capacity of continual regeneration. In contrast, these regenerative processes apparently do not occur in cardiac tissue; complete block is irreversible to date. Curiously, the transient manifestations of this passively acquired autoimmune syndrome closely mimic the disease manifestations observed in adolescents or adults with systemic lupus erythematosus, whereas while heart block is rarely, if ever, present in these same patients.

The study of NLS exemplifies not only translational research, which inherently draws upon clinical observations and explores them in the laboratory, but "integrational" research, which attempts to fit critical clinical and basic observations together, even those seemingly at odds. When this chapter was initially written in 1991 and further updated in 1998, many questions based on important clinical observations were raised and are

TABLE 1 Studies Demonstrating the Frequencies of Antibodies to SSA/Ro[a] and SSB/La[a] in Women Having Offspring with and without CHB

	CHB present		CHB absent[b]	
Study	**SSA/Ro**	**SSB/La**	**SSA/Ro**	**SSB/La**
Taylor *et al*. [15]	34/35	29/35	8/29	8/29
Buyon *et al*. [16, 17]	34/34	28/34	53/145	19/145

Ramsey-Goldman *et al*. [12]	6/7	NS	41/148	NS
Totals[c]	91/93 (98%)	74/86 (89%)	107/336 (32%)	27/188 (14%)

[a] Antibodies were evaluated by double immunodiffusion, counterimmunoelectrophoresis, ELISA, or immunoblot.
[b] In each study the control group consisted of mothers who were diagnosed as having SLE, SS, or an undifferentiated connective tissue disease with a positive ANA.
[c] Presence of anti-SSA/Ro in CHB versus non-CHB: odds ratio = 78, $P < 0.001$, sensitivity = 0.98, specificity = 0.68, predictive value = 0.46. Presence of anti-SSB/La in CHB versus non-CHB: odds ratio = 35, $P < 0.001$, sensitivity = 0.86, specificity = 0.86, predictive value = 0.73.

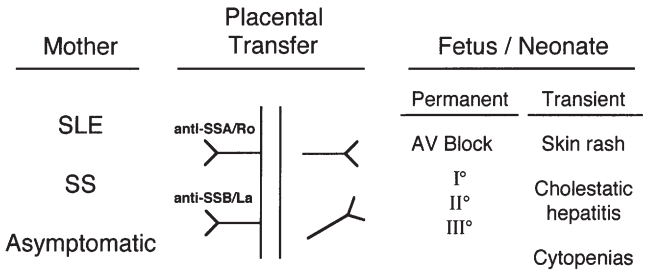

FIGURE 1 Placental transfer of maternal autoantibodies into the fetal circulation may mediate the development of NLS. Hypothetical model.

again reiterated as follows: What accounts for the spectrum of neonatal disease, i.e., why do some offspring remain totally healthy despite circulating maternal autoantibodies whereas others have transient rashes and still others die *in utero* from acute myocarditis? Why is complete heart block irreversible and why is there specificity for the conducting system? Is this an acquired disease that occurs in a previously healthy fetus? Why is the maternal heart unaffected? What is the mechanism of tissue injury? What is the autoantigen–antibody system and how does it relate to the SSA/Ro-SSB/La polypeptides, which are intracytoplasmic cellular components unlikely to be present on the cell surface? Is there a genetic basis for these syndromes? What is the fine specificity of the maternal autoantibody response that is most diagnostically predictive and how can this knowledge guide the approach to therapy? Finally, can we safely tell patients "No antibodies to SSA/Ro or SSB/La, no affected offspring?" Happily, NLS continues to draw tremendous interest and the author is again challenged to address and update these questions by reviewing the results of exciting research recently generated both from the bedside and from the bench.

PASSIVELY ACQUIRED HEART BLOCK: AN IRREVERSIBLE MANIFESTATION OF NEONATAL LUPUS SYNDROMES

Cardiac Histopathology

Histopathologic studies constitute a major basis for formulating hypotheses regarding the pathogenesis of CHB. It appears logical to assume that the time of death relative to initial immune attack may influence the pathologic findings. Evidence of a cellular infiltrate might be present if death occurs close to the time a bradyarrhythmia is first detected, but calcifications may be the sole pathologic finding if death has occurred months later. An inflammatory component is supported by the finding of a mononuclear cell infiltration in the myocardium of a fetus dying *in utero* at 18 weeks of gestation [23] and the demonstration of patchy lymphoid aggregates throughout the myocardium of an infant delivered at 30 weeks and dying in the immediate postnatal period [24]. Moreover, immunofluorescent studies have shown deposition of IgG, complement (including $C1_q$, C4, C3d, C6, and C9), and fibrin [24, 25]. The first cardiac lesion may be a global pancarditis with inflammation of the pericardium, myocardium, and endocardium resulting in subsequent fibrosis of the conducting system clinically manifest as permanent heart block. Litsey and colleagues [25] identified IgG deposits in the epicardial, myocardial, and endocardial tissue of the right atrium on postmortem analysis of a neonate with CHB. Although published literature on serial

echocardiograms in mothers at high risk of a pregnancy complicated by CHB is limited to nonexistent, it has been the general experience that the first clinically apparent abnormality in cardiac function is not myocarditis (i.e., effusions, ventricular dysfunction) but bradycardia. This implies that early inflammation is not clinically detectable and/or that atrioventricular (AV) nodal injury occurs independent of an inflammatory pancarditis.

Specific vulnerability of the conducting system is unexplained [26]. Ho *et al*. [26] described the histopathology of seven hearts with CHB and associated maternal antibodies to the SSA/Ro polypeptide. In all of these hearts there was atrial-axis discontinuity, the AV node was replaced by varying degrees of fibrosis or fatty tissue [26]. The distribution of the distal conducting system was normal.

In five cases of CHB compiled by Carter *et al*. [4] there was disruption of the AV conduction system by a process of uncertain cause. In all five instances the presence of microscopic crystalline structures was associated with the conduction system and with fibrous structures of the heart. These deposits have been designated as products of connective tissue degeneration resulting from an intrauterine inflammatory process. Hogg [27] has reported hematoxylin bodies in the AV node. Further support for an inflammatory process is demonstrated by the findings of calcification along ventricular portions of the conducting system and area of the sinoatrial (SA) node [25, 28]. The origin of diffuse fibroelastosis, which has also been reported in some of these affected babies, is considered to result from dilatation of the cardiac chambers secondary to the compensatory increased stroke volume present in CHB [4]. However, Nield and colleagues [29] have reported 13 CHB patients with endocardial fibroelastosis (EFE), 6 diagnosed *in utero* and 7 in the postnatal period, despite ventricular pacing of all but one infant. EFE is associated with significant mortality and morbidity: 9 (70%) of these 13 patients died and 2 (15%) required heart transplants.

Given the importance of histologic data to infer pathogenic mechanisms, medical records of all families enrolled in the National Research Registry for Neonatal Lupus (established in September 1994) were reviewed to determine the incidence and timing of death, with emphasis on the pathologic findings in the affected fetal hearts [30]. Complete autopsy reports were available in 11 cases. The mean time from detection of CHB to autopsy was 11 weeks. Although in 3 cases there were various lesions of the tricuspid valve, the pathologic descriptions were more suggestive of an imposed injury than a true developmental defect. These included nodularity, dysplasia, hypoplasia and fusion of valve leaflets, and fibrosis. The pulmonary valve was abnormal in 2, 1 was described as stenotic dysplastic, and the other nodular and dysplastic. Aortic valve insufficiency and stenosis and hypoplasia of the mitral valve leaflet were observed in 1. Endocardial fibroelastosis of the right and left ventricles (RV, LV), with or without calcification, was present in 7. Chronic changes in the myocardium were documented in 10 and included biventricular hypertrophy and increased RV and LV walls, thickened but hypoplastic RV, and hyperchromatic nuclei of the myocytes. Abnormalities of the AV node or vicinity were noted in 8 with involution, fibrosis, fatty infiltration, or calcification. However, in 2 the AV node *per se* appeared normal: in one there was calcification in adjacent tissue and in another there was an atrophic His bundle with replacement by dense focally calcified fibrous tissue and scarring of the left and right bundle branches. Although previously unappreciated, autopsies obtained from the research registry revealed a high incidence of valvular abnormalities. While there were sufficient changes in the AV node to account for CHB in most cases, clinical conduction abnormalities may have been secondary to a functional exit block in a normal-appearing node. SA nodal disease expands the spectrum of conduction dysfunction (a fascinating point further addressed later).

These studies leave little doubt that the signature lesion of autoantibody-associated CHB is fibrosis, which can clearly extend beyond the conduction system. As discussed in the update of pathogenesis, the cascade leading to fibrosis is a major focus of investigation. Of interest, slides have been obtained from the heart of an infant diagnosed with CHB *in utero* and dying shortly after birth [31]. The ventricular tissue contained numerous areas of fibrosis and microcalcification in which a predominant infiltrate of transdifferentiated fibroblasts, myofibroblasts, could be readily observed. Macrophages could also be appreciated in areas of scar tissue. In contrast, there were no myofibroblasts or macrophages in the ventricular tissue from an otherwise healthy 24-week abortus. It is especially noteworthy that the fibrosis was not bland but involved an infiltrate of activated myofibroblasts even out to 3 months after the initial insult.

Congenital Heart Block Occurs in an Anatomically Developed Heart and Coincides with Placental Transport

The presence of maternal immunoglobulins in the fetal circulation is directly related to the normal physiology of antibody traffic across the placenta [32]. Maternal antibodies interact with Fc receptors on the trophoblastic cell surface in a specific transport process.

Each Fc receptor has a different ligand specificity and affinity for the IgG subclasses but all receptors bind IgG1 and IgG3 with greater affinity than IgG2 or IgG4 [33]. IgG1, IgG2, and IgG3 are transported relatively early with detectable levels noted at 6–11 weeks of gestation. In contrast, IgG4 is present in the fetal circulation after 19 weeks [34]. The resultant fetal concentrations of total IgG are marginally detectable in the first trimester (<100 mg/dl) and remain low until after 17 weeks, at which time they increase steadily, reaching 400 mg/dl by 24 weeks and 800 mg/dl by 32 weeks as placental transfer becomes more efficient [35]. IgM and IgA antibodies do not cross the placenta.

Perhaps CHB occurs in offspring of mothers whose antibodies are of IgG1 and IgG3 subclasses, while those whose antibodies are predominantly IgG2 and IgG4 are protected. However, no significant differences in subclass distribution have been observed between mothers with anti-SSA/Ro and/or -SSB/La antibodies who had pregnancies complicated by CHB or those who had normal pregnancies [36]. For both groups of mothers, IgG1 antibodies were increased significantly over the other three subclasses in the anti-52-kDa and 60-kDa SSA/Ro responses. IgG1 and IgG3 were the major subclasses represented in the 48-kDa SSB/La responses. All subclasses, including IgG2 and IgG4, were observed in a third to half of the maternal serum with anti-52-kDa and 48-kDa responses. In contrast, anti-60-kDa antibodies were, with rare exception, confined to IgG1. Accordingly, the IgG subclasses of anti-48-kDa SSB/La and 52-kDa or 60-kDa SSA/Ro antibodies do not account for the susceptibility of one fetus versus another for the development of CHB.

The stage of cardiac ontogeny that coincides with the initiation of transplacental passage of maternal autoantibodies into the fetal circulation may influence the extent of tissue injury and permanent dysfunction. The human heart attains most of its adult characteristics by the sixth to eighth week of gestation [37]. Parasympathetic innervation of the heart occurs very early in fetal development, whereas sympathetic innervation develops much later and is completed some months after birth. The SA node can be recognized in the first trimester and by 10 weeks of fetal age attains its own artery. Landmarks of the three internodal pathways from SA to AV nodes appear in the second month of gestation, although the septal course of these pathways does not become fully developed until the closing of the foramen ovale cordis, which occurs shortly after birth. The AV node arises separately from the bundle of His and is joined to it at 8 weeks. The human His bundle undergoes extensive postnatal remodeling to achieve its adult form. Clearly the fetal conduction system has reached functional maturity before maternal antibodies gain access to the fetal circulation.

To support a pathogenic role of maternal autoantibodies in the development of CHB, the onset of bradycardia would be predicted to coincide with heightened placental transport and occur in a previously normal heart. As expected if the hypothesis is correct, Deng *et al*. [38] reported the absence of immunoglobulin deposition in cardiac tissue from 10-week fetuses of two mothers with anti-SSA/Ro antibodies. There is likely to be a "window of vulnerability" when maternal antibodies gain access to the fetal circulation and recognize an antigen, which may be unique to the developing heart that is absent or otherwise inaccessible in the maternal heart.

As seen in Fig. 2, a review of data obtained from the research registry revealed that in 71 (82%) of 87 fetuses, bradycardia was identified before 30 weeks of pregnancy [39]. Detection was clustered most frequently between 20 and 24 weeks. Fourteen (16%) cases were first identified in the third trimester, 5 of which were noted at the time of delivery. The median time of *in utero* detection was 23 weeks. Of the 85 fetuses diagnosed with CHB during pregnancy, 15 were born between 1970 and 1987, 8 of whom were diagnosed before 30 weeks of gestation. Seventy pregnancies occurred between 1988 and 1997, in which 63 were diagnosed with CHB prior to 30 weeks ($P < 0.003$, earlier detection of CHB in pregnancies after 1988 compared to pregnancies before 1988).

Classification of Heart Block

Some confusion still exists regarding the assignment of "congenital" heart block. Webster defines congenital as that "existing at or dating from birth." Data from Hübscher *et al*. [40] strongly suggest that postnatally "acquired" heart block (even without structural abnormalities) is not associated with maternal antibodies to SSA/Ro or SSB/La and is probably best categorized as a separate entity.

Again, the issue of "complete" versus "incomplete" heart block warrants clarification. At the time of writing the initial chapter on NLS, heart block was defined operationally as third degree or congenital *complete* heart block (CCHB), although it was hypothesized that heart block might progress through various stages. Of 187 children in the research registry with CHB associated with anti-Ro/La antibodies in the mother, 9 had a prolonged PR interval on an electrocardiogram (EKG) at birth, 4 of whom progressed to more advanced AV block [41]. A child whose younger sibling had third-degree block was diagnosed with first-degree block at age 10 years at the time of surgery for a broken wrist.

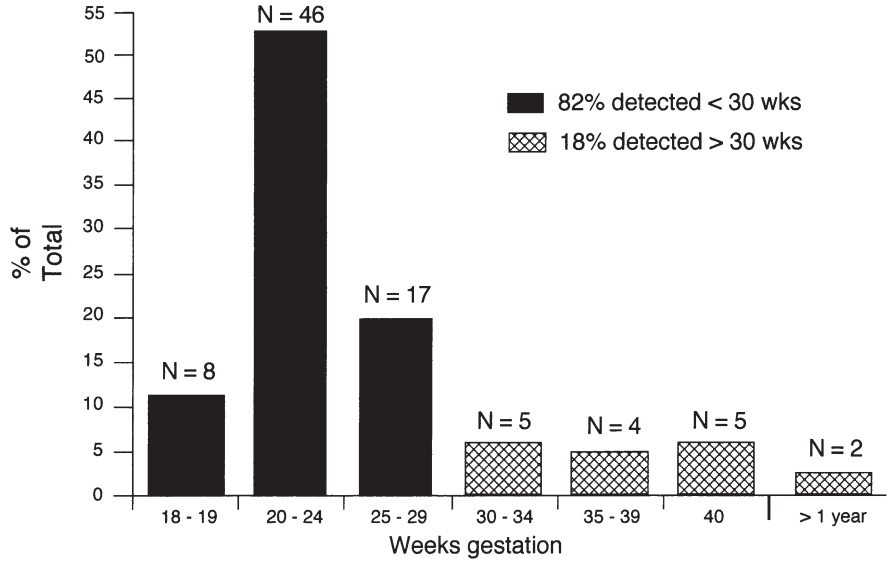

FIGURE 2 Time of detection of CHB. In one child, third-degree block was diagnosed at age 2 years, 7 months; in the other, first-degree block was diagnosed at age 10 years.

Two children diagnosed *in utero* with second-degree block were treated with dexamethasone and reversed to normal sinus rhythm by birth, but ultimately progressed to third-degree block. Four children had second-degree block at birth: of these, two progressed to third-degree block. Accordingly, the general abbreviation "CCHB" is not precise and CHB (*congenital* heart block) has been adopted. The implications of this spectrum of conduction abnormalities from the perspectives of pathobiology and treatment are discussed in subsequent sections.

When CHB is associated with major structural abnormalities, such as transposition of the great vessels, maternal autoantibodies are generally not present. This defect of cardiogenesis occurs prior to the 10th week of gestation and results in the disruption of the development of the AV conducting system. Such cases should be considered as a distinct classification of CHB secondary to abnormal cardiac embryogenesis and not likely the result of passively acquired autoimmunity. Examination of a heart from a child with this type of CHB, whose maternal serum did not contain autoantibodies, revealed nodoventricular discontinuity, with the AV node well formed and normally situated [26]. Similarly, mass lesions developing in the conducting system, such as mesotheliomas of the AV node, would constitute another distinct type of CHB.

THE TRANSIENT SKIN RASH

In striking contrast to the typical late second trimester onset of CHB, skin lesions generally become manifest several weeks into postnatal life. Less commonly the rash is present at birth. Ultraviolet exposure may be an initiating factor and can exacerbate an existing rash [42]. Thornton *et al*. [43] reported that telangiectasia may be a presenting feature and can occur in sun-protected sites independent of "lupus dermatitis." Cutaneous activity, inclusive of erythema and the continued appearance of new lesions, is generally present for several weeks with resolution by 6 to 8 months of age coincident with the clearance of maternal autoantibodies from the baby's circulation. However, hypopigmentation may persist into the second year of life. Lee [42] observed two children with persistent telangiectasias and one child with a small but persistent patch of hyperpigmentation; 11 other children, including several with extensive skin disease, have had complete resolution of the rash.

The rash frequently involves the face and scalp with a characteristic predilection for the upper eyelids (Fig. 3) [44]. In some instances the rash is present in other locations and can cover virtually the entire body. A review of the corporeal distribution of 57 infants (20 males, 37 females) diagnosed with cutaneous NLE (absent heart disease) enrolled in the research registry has been recently reported [45]. All had facial involvement (periorbital region most common) followed by the scalp, trunk, extremities, neck, intertriginous areas, and rarely the palms and soles. In most cases the infant's rash was temporally related to UV exposure; mean age of detection was 6 weeks and duration was 22 weeks. The lesions were described as superficial inflammatory plaques resembling subacute cutaneous lupus erythematosus of the adult [46]. They are typically annular or elliptical with erythema and scaling. Hypopigmentation was frequent and may be a prominent feature. The more characteristic lesions of adult discoid lupus, such as

FIGURE 3 Typical skin rash with predilection for the periorbital area. This rash resolved completely without scarring. Photograph courtesy of Dr. Susan Manzi, reproduced from Buyon [44], with permission.

follicular plugging, dermal atrophy, and scarring, were generally not observed in the neonatal skin rash. The lesional histology supports the clinical descriptions of subacute cutaneous lupus with basal cell damage in the epidermis and a superficial mononuclear cell infiltrate in the upper dermis [47, 48]. As observed in subacute cutaneous lupus, immunofluorescence is positive with the finding of a particulate pattern of IgG in the epidermis [42].

LESS COMMONLY ENCOUNTERED MANIFESTATIONS OF NLS

The clinical spectrum of NLS includes hepatic involvement, a manifestation that could well be underestimated as routine neonatal evaluation does not include a liver profile. Permanent sequelae can occur in the liver, but unlike the heart may be clinically insignificant [18, 44–47, 49–52]. Laxer *et al*. [18] have described three living infants and one perinatal death with NLS associated with significant hepatic involvement. The living infants presented with neonatal cholestasis as a major component of their clinical picture. Pathologic changes included giant cell transformation, ductal obstruction, and extramedullary hematopoiesis. The authors speculated that an inflammatory hepatitis proceeding to hepatic fibrosis may ensue, analogous to the mechanism hypothesized to occur in cardiac tissue. Rosh *et al*. [49] reported an infant born with CHB in whom severe neonatal cholestasis developed, requiring surgical exploration to exclude extrahepatic biliary atresia. The clinical picture included an elevation of the serum glutamic-pyruvic transaminase, glutamic oxaloacetic transaminase, alkaline phosphatase, and γ-GTP. A percutaneous liver biopsy revealed mild fibrosis, bile ductular proliferation, and a mixed inflammatory infiltrate in the portal tracts. Lee *et al*. [50] described three infants with hepatic dysfunction; all had laboratory and histologic evidence of significant cholestasis. One occurred in the setting of intractable congestive heart failure. At autopsy immunofluorescence revealed widespread deposits of IgG. A second infant had thrombocytopenia and hepatosplenomegaly at birth followed at 3 weeks of age by a cutaneous eruption characteristic of NLS. Liver biopsy revealed hepatocellular cholestasis, lobular disarray, and mild pseudoacinar formation. A third neonate developed a typical rash at 2 weeks and transaminitis with jaundice by 8 weeks. Liver biopsy revealed canalicular and hepatocellular cholestasis. Lee *et al*. [51] investigated the incidence of hepatobiliary manifestations among 219 NLS patients in the research registry. Nineteen (9%) had probable or possible hepatobiliary disease, appearing as the sole manifestation of NLS in 3 cases and in association with cardiac or cutaneous manifestations in 16 cases. Six (including one reported previously by Schoenlebe *et al*. [52]) of the 19 infants died, either during gestation or within the first few weeks of life. Three clinical variants were observed: (1) severe liver failure present during gestation or in the neonatal period, often with the phenotype of neonatal iron storage disease; (2) conjugated hyperbilirubinemia with mild or no elevations of aminotransferases occurring in the first few weeks of life; and (3) mild elevations of aminotransferases occurring at approximately 2 to 3 months of life. The prognosis for the children in the last two categories was excellent.

These reports and others [53] suggest that the diagnosis of NLS-related liver disease should be considered in situations in which liver enzymes and bilirubin levels are most consistent with cholestasis in the absence of a major structural abnormality of the biliary tree. Reassuringly, in babies that survive cardiac manifestations, the general observation is that hepatic disease resolves.

While the nervous system has not been regarded as an organ characteristically affected in NLS, clinical detection may be a limiting factor. There have been several reports of neurologic sequelae in NLS. Specifically, aseptic meningitis occurred in an infant with CHB

and circulating maternal anti-SSA/Ro and anti-SSB/La antibodies [54]. There has been one case report of NLS and transient hypocalcemia with seizures [55]. Wong and colleagues [56] observed sonographic evidence of infantile lenticulostriate vasculopathy (LSV) in a case of NLS. The authors suggested that sonographic LSV is a nonspecific marker of a previous insult to the developing brain, the clinical significance of which is uncertain. Bourke and Burns [57] described an infant with thrombocytopenia and a generalized annular rash with scattered telangiectases at birth in the setting of antibodies to SSA/Ro and SSB/La. At the age of 1 year the child was found to have an abnormal gait and examination revealed mild spastic diplegia of the lower limbs. The authors appropriately pointed out that the central nervous system abnormalities might have been due to an intracerebral hemorrhage in the neonatal period. This curious observation of late-onset lower limb spasticity has been reported in one other infant with antibodies to SSA/Ro and butterfly rash at birth [58]. In sum, the mechanism of these neurologic sequelae is entirely elusive and awaits further observation in other neonates born to mothers with anti-SSA/Ro-SSB/La antibodies.

Hematologic abnormalities have been described as a manifestation of NLS. Thrombocytopenia has been observed together with other manifestations of NLS [19]. Some of these infants have a petechial or purpuric eruption as the initial feature. Thrombocytopenia was present in 10% of the neonates referred to Lee [42]. Gastrointestinal bleeding occurred in one of these infants. In contrast to the cardiac manifestations, which do not parallel disease in the mother, and the cutaneous manifestations, which occasionally occur in the mother but often not in synchrony with her affected offspring, the hematologic manifestations may more closely parallel maternal disease. However, Watson *et al*. [19] described thrombocytopenia in offspring of anti-SSA/Ro-positive mothers with no apparent history of thrombocytopenia. Despite this, the presence of thrombocytopenia raises some questions as to whether antiplatelet antibodies rather than antibodies to SSA/Ro-SSB/La are targeting the surface of fetal cells. These manifestations, while secondary to passively acquired autoimmunity (and therefore part of NLS), may be more akin to the neonatal thrombocytopenia of idiopathic thrombocytopenic purpura (ITP). The disparate fetal and adult vulnerability appears more pronounced in NLS than in ITP.

Kanagasegar *et al*. [59] reported an infant with neutropenia and mildly abnormal liver functions, but no cardiac or cutaneous manifestations of NLS, born to a mother with anti-SSA/Ro-SSB/La antibodies. The child's neutropenia improved as maternal antibody was metabolized. Sera from this child and mother, as well as sera from two registry mothers who had given birth to infants with CHB and neutropenia, were shown to bind the cell surface of intact neutrophils [59]. Binding to neutrophils was then inhibited (>80%) by incubating the sera with the 60-kDa Ro antigen, suggesting that anti-60-kDa SSA/Ro is directly involved in the pathogenesis of neutropenia.

Wolach *et al*. [60] extended the hematologic spectrum of NLS. They describe a 5-month-old infant with anti-SSA/Ro antibodies and typical cutaneous involvement in the setting of complete marrow aplasia, which recovered at 8 months with the disappearance of anti-SSA/Ro antibodies. However, before this complication is added to the "official list" of manifestations, it is curious that the mother herself was said to have "tested negative" for anti-SSA/Ro antibodies. The child died at 16 months from gram-negative sepsis.

CANDIDATE ANTIGEN–ANTIBODY SYSTEMS IN NLS

Target Autoantigens of the SSA/Ro-SSB/La System

Antibodies to SSA/Ro ribonucleoproteins in the maternal sera, often in association with SSB/La, have been almost universally demonstrated when isolated CHB develops in an offspring [9–11]. Anti-SSA/Ro antibodies are characteristically found in the majority of patients with SS [61] and close to half of those with SLE [62] but can also be detected in asymptomatic individuals [63, 64]. Fritzler *et al*. [63] detected a 0.5% frequency of anti-SSA/Ro positivity after testing several thousand healthy female blood donors of childbearing age. A similar frequency was detected by Harmon *et al*. [64] in a study of 800 asymptomatic pregnant women. Reactivity against SSB/La is also strongly associated with the development of CHB and is frequently detected in patients with SS [65, 66]. Its prevalence in SLE is only about 15% [66].

The candidate autoantigens are ubiquitous and present in all cells. The major antigenic component of SSA/Ro was initially described as a polypeptide of 60 kDa. The gene has been cloned in several laboratories with accumulating evidence that there are isoforms in T-cell lines with at least two slightly different copies in the haploid genome [67–69]. The 60-kDa SSA/Ro contains an RNA-binding protein consensus motif [67, 68], which could account for its direct interaction with small cytoplasmic hY-RNAs [70]. More recent studies demonstrate that the "zinc finger" in human 60-kDa SSA/Ro is not conserved across species [71]. It has been

suggested that 60-kDa SSA/Ro may function as part of a novel quality control or discard pathway for 5S rRNA production in *Xenopus* oocytes [72].

Anti-SSB/La antibodies recognize a 48-kDa polypeptide that does not share antigenic determinants with either 52-kDa or 60-kDa SSA/Ro [73]. The SSB/La polypeptide is composed of at least two structural domains on the native protein, each of which contains a distinct antigenic-binding site [74]. SSB/La facilitates maturation of RNA polymerase III transcripts, directly binds a spectrum of RNAs, and associates at least transiently with 60-kDa SSA/Ro [75, 76].

In addition to the well-characterized 60-kDa SSA/Ro and 48-kDa SSB/La antigens, another target of the autoimmune response in mothers whose children have CHB is the 52-kDa SSA/Ro protein [77]. The full-length protein, 52α, has three distinct domains: an N-terminal region rich in cysteine/histidine motifs containing two distinct zinc fingers known as RING finger and B-box; a central region containing two coiled coils with heptad periodicity, one being a leucine zipper with potential for intramolecular dimerization; and a C-terminal "rfp-like" domain [78, 79]. The 52-kDa SSA/Ro protein has a high degree of homology with the ret finger protein, *rfp*, which is part of the transforming gene *ret*; this raises the question of whether the 52-kDa SSA/Ro protein might have similar transforming potential [78]. Moreover, the *ret* protein has the structure of a cell surface receptor.

An alternatively spliced transcript of full-length 52-kDa SSA/Ro has been identified, 52β [80], in which exon 4 encoding amino acids 168–245, inclusive of the leucine zipper and an immunodominant epitope [81, 82], is deleted. Although there is no evidence that the newly described 52β directly contributes to the pathogenesis of CHB, two requisite conditions for its potential involvement have been satisfied. First, 52β is recognized by autoantibodies from the sera of mothers whose children have CHB [80], consistent with reports of an additional N-terminal epitope on 52α, which is present in 52β [81, 82]. Second, 52β is present in cardiac tissue [80]. In contrast to 52α, 52β mRNA is preferentially expressed between 14 and 16 weeks of gestation, which precedes the clinical detection of CHB by several weeks [83]. Curiously, the increased expression of 52β is not observed in all 14- to 16-week hearts. This could simply reflect inaccuracies in dating the gestational age by sonogram. Alternatively, some fetal hearts may express more 52β at the same gestational age than others, which contributes, in part, to the low percentage (1–2%) of affected fetuses born to mothers with candidate antibodies [12, 84–86].

Cloning and sequencing of a novel autoantigen identified by sera containing predominant reactivity with a 60-kDa SSA/Ro RNA binding protein were found to be >96% identical to rabbit calreticulin [87, 88]. Preliminary work demonstrated that many sera from mothers of children with CHB react with human calreticulin by ELISA [89]. This finding may be of potential relevance, as calreticulin is an acidic high-affinity calcium-binding protein of M_r 46,567 common to both sarcoplasmic reticulum membranes in muscle and endoplasmic membranes in nonmuscle tissues. The carboxyl-terminal end of calreticulin contains the tetrapeptide Lys-Asp-Glu-Leu (KDEL) salvage or endoplasmic reticulum retention signal [88]. Future work on the association of CHB and antibodies to proteins of the endoplasmic reticulum should be of considerable interest.

Eftekhari *et al*. [90] reported that antibodies reactive with the serotoninergic 5-hydroxytryptamine $(5\text{-HT})_{4A}$ receptor, cloned from human adult atrium, also bind 52-kDa SSA/Ro. Moreover, affinity-purified 5-HT_4 antibodies antagonized the serotonin-induced L-type Ca channel activation in human atrial cells. Two peptides in the C terminus of 52-kDa SSA/Ro, amino acids 365–382 and 380–396, were identified that shared some similarity with the 5-HT_4 receptor. The former was recognized by sera from mothers of children with neonatal lupus, and it was this peptide that was reported to be cross-reactive with peptide amino acids 165–185, derived from the second extracellular loop of the 5-HT_4 receptor. These findings are of particular importance, as over 75% of serum from mothers whose children have CHB contain antibodies to 52-kDa SSA/Ro as detected by ELISA, immunoblot, and immunoprecipitation [91, 92].

Given the intriguing possibility that antibodies to the 5-HT_4 receptor might represent the hitherto elusive reactivity, which could contribute directly to atrioventricular block, the 5-HT_4 receptor was examined as a target of the immune response in these mothers. Initial experiments demonstrated mRNA expression of the 5-HT_4 receptor in the human fetal atrium. Electrophysiologic studies established that human fetal atrial cells express functional 5-HT_4 receptors. Sera from 116 mothers enrolled in the research registry, whose children have CHB, were evaluated. Ninety-nine (85%) of these maternal sera contained antibodies to SSA/Ro, 84% of which were reactive with the 52-kDa SSA/Ro component by immunoblot. In sum, none of the 116 sera were reactive with the peptide spanning amino acids 165–185 of the serotoninergic receptor. Rabbit antisera, which recognized this peptide, did not react with 52-kDa SSA/Ro. Accordingly, although 5-HT_4 receptors are present and functional in the human fetal heart, maternal antibodies to the 5-HT_4 receptor are not associated with the development of CHB. These results are in agreement with the findings of Cavill *et al*. [93].

Novel Antigen/Antibody Systems

Maddison and colleagues [94] described a novel antigen of 57 kDa recognized by 8 (38%) of 21 mothers whose children have NLS. Partial sequencing of p57 DNA demonstrated that this antigen is distinct from SSA/Ro and SSB/La. Supporting a potential pathogenic role of this antibody was its absence in the cord blood of an infant with CHB despite readily detectable circulating maternal levels. The authors proposed that this finding could be explained by selective cardiac depletion due to deposition on fetal cardiocytes. Alternatively, the antibody may not have been transported effectively across the placenta.

Although it is not known how maternal antibodies influence the development of cardiac versus cutaneous manifestations of NLS, antibodies to U1RNP in the absence of reactivity to anti-SSA/Ro and/or SSB/La have never been reported in children with CHB. Sheth and colleagues [95] have added two cases to eight reported previously in which anti-U1RNP antibodies but not anti-SSA/Ro-SSB/La antibodies were present in infants with cutaneous disease alone. Furthermore, Solomon *et al.* [96] described anti-U1RNP-positive, anti-SSA/Ro-SSB/La-negative dizygotic twins discordant for cutaneous manifestations of NLS (neither twin had cardiac disease). The segregation of anti-U1RNP antibodies with cutaneous disease may be a useful maternal marker and should guide research efforts in sorting out cardiac versus cutaneous susceptibility to antibody-mediated injury.

Evaluation of the Fine Specificities of the Maternal SSA/Ro-SSB/La Autoantibody Response

Important from the clinician's perspective are issues regarding the management of a pregnancy and the outcome of both the mother and her child. Can our rapidly expanding knowledge of SSA/Ro and SSB/La autoantibodies and their cognate antigens help define the mother at highest risk for having a pregnancy complicated by NLS? While seemingly straightforward, the task is a challenging one. Several laboratories from the United States and abroad have tackled this problem using various techniques, including immunodiffusion, immunoblot of various tissues and cell lysates, ELISA employing recombinant and purified proteins, and immunoprecipitation of radiolabeled *in vitro* translation products and cell lysates.

Our laboratory has used gel separation methods, which vary the quantity of acrylamide to bis-acrylamide to obtain a more precise molecular characterization of the relevant antigenic structures identified by the immune response in women whose children have NLS [17, 91, 97]. Specifically, increasing the ratio of monomer to cross-linker from 37.5 (used in a standard Laemmli buffer system [98]) to 172.4 in a 15% acrylamide solution readily separates the 48-kDa SSB/La polypeptide from the 52-kDa SSA/Ro component. Figure 4 demonstrates representative reactivities (48-kDa SSB/La, 52-kDa SSA/Ro, 60-kDa SSA/Ro) in an immunoblot (using a high ratio gel) of a human fetal heart lysate

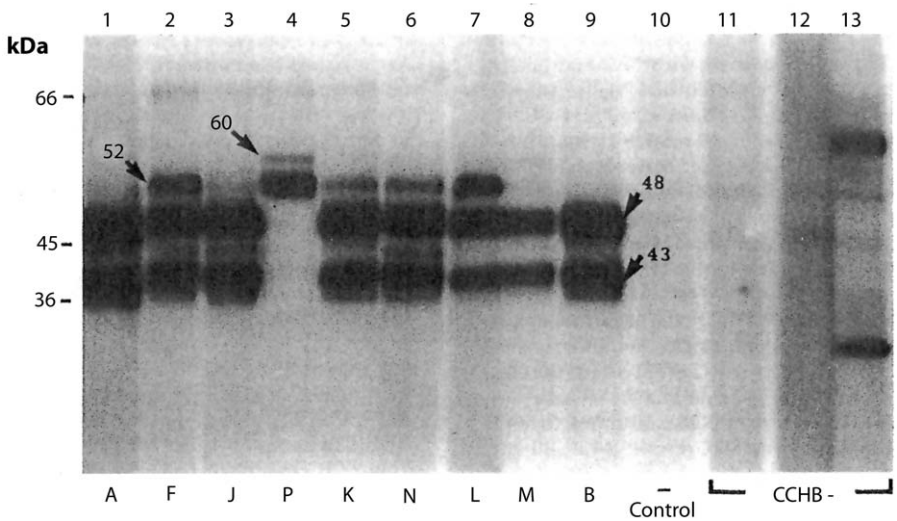

FIGURE 4 Representative immunoblot using fetal cardiac tissue aged 18 weeks and probed with sera from mothers of affected and unaffected offspring. Letters under lanes 1–9 correspond to sera of mothers of children with CHB. Lane 10 was probed with serum from a normal donor. Lanes 11–13 were probed with sera from three pregnant lupus patients carrying healthy fetuses. From Buyon *et al.* [17], with permission.

probed with antisera from mothers of children with CHB.

We have employed this method of gel separation for immunoblot, as well as ELISA, to evaluate antibody frequency, titer, and fine specificity in the sera from four groups of mothers segregated according to the status of the child: 57 whose children had CHB, 12 whose children had transient dermatologic or hepatic manifestations of NLS but no detectable cardiac involvement, 152 with SLE and related autoimmune diseases who gave birth to healthy children, and 30 with autoimmune diseases whose pregnancy resulted in miscarriage, fetal demise, or early postpartum death unrelated to NLS [91]. Anti-SSA/Ro antibodies were identified by ELISA in 100, 91, 47, and 43% of mothers of infants with CHB, transient NLS, healthy children, and fetal demise, respectively. High titers of anti-SSA/Ro antibodies were present more often in mothers of children with cardiac or cutaneous manifestations of NLS than in either of the other two groups. Maternal antibodies to SSB/La were detected by ELISA in 76% of the CHB group, 73% of the cutaneous/hepatic group, 15% with healthy children, and 7% with fetal demise. On immunoblot, 91% of the heart block group who had antibodies to SSA/Ro but not to SSB/La recognized at least one SSA/Ro antigen, with significantly greater reactivity against the 52-kDa component. In contrast, 62% of the anti-SSA/Ro-positive–SSB/La-negative responders in the healthy group recognized either the 52-kDa and/or 60-kDa components. Although there was no profile of anti-SSA/Ro response unique to the mothers of children with heart block or cutaneous manifestations of NLS, only 1% of normal infants were born of mothers with antibodies directed to both the 52-kDa SSA/Ro and 48-kDa SSA/La antigens and not to the 60-kDa SSA/Ro antigen, compared to 21% with cardiac and 25% with cutaneous manifestations of NLS.

Dörner *et al*. [99] investigated quantitative and qualitative differences of anti-SSA/Ro-SSB/La antibodies by ELISA in sera from 16 infants with CHB and their mothers compared to 8 healthy anti-SSA/Ro-positive infants born to SLE mothers. No serum sample contained IgM autoantibodies. All 16 (100%) CHB infants had anti-52-kDa SSA/Ro antibodies, 14 (88%) had anti-SSB/La, and 9 (56%) had anti-60-kDa SSA/Ro compared to 6 (75%) anti-52, 3 (38%) anti-48, and 2 (25%) anti-60 in the control infants. The anti-52-kDa SSA/Ro and anti-SSB/La antibody levels were significantly higher in CHB infants than in the controls. The anti-60-kDa SSA/Ro IgG levels of sera from infants and mothers from the CHB and control groups were similar.

Based on analysis by immunoblot and ELISA of sera from 14 mothers of children with CHB and 12 lupus patients with healthy offspring, Meilof *et al*. [100] concluded that the fine specificity of the autoantibody response to SSA/Ro and SSB/La proteins does not predict the occurrence of CHB. These results are not surprising, as it can be predicted from the disparity of disease expression in twins and the low recurrence rate in subsequent pregnancies (see later) that another factor (probably fetal) is operative and that the discovery of a unique risk profile is unlikely.

In a study of sera from 31 mothers of children with CHB, Julkunen *et al*. [92] demonstrated 97% reactivity with 52-kDa SSA/Ro by ELISA, 77% with 60-kDa SSA/Ro, and 39% with SSB/La. Compared to 45 mothers with SLE and healthy children, mothers of CHB children had higher titers of antibodies to recombinant 52- and 60-kDa SSA/Ro proteins. However, compared to 19 mothers with primary SS and healthy offspring, the autoantibody responses were similar. No differences in the titer of anti-SSB/La antibodies were found between mothers within either of these three groups. In agreement with previous data, these investigators did not find a specific antibody profile unique to CHB.

Silverman and colleagues [101] evaluated the maternal antibody profile in two groups of sera: 41 obtained from mothers whose children had manifestations of NLS (21 CHB, 20 cutaneous) and 19 from lupus patients known to have anti-SSA/Ro and/or anti-SSB/La antibodies and healthy children. Significantly higher levels of anti-SSB/La and anti-52-kDa SSA/Ro antibodies were demonstrated in the mothers of affected children. Mothers whose children had cutaneous manifestations had higher titers of anti-SSB/La antibodies than mothers whose children had CHB. Fine delineation of the anti-SSB/La responses revealed that a small carboxyl terminus polypeptide of recombinant SSB/La, DD, was recognized by 30% of mothers whose children had NLS but none who had healthy children.

Defining the risk of CHB based on a particular antibody profile depends in part on the control group chosen. For example, if the control group is mothers with SLE, as in our study done in 1993 [91] and that of Dörner *et al*. [99], it would not be surprising to find a greater frequency of anti-48-kDa SSB/La and 52-kDa SSA/Ro in CHB mothers. It has been reported previously that anti-60-kDa responses predominate over anti-52-kDa responses in SLE [102]. If the control mothers have SS, the antibody profiles of the CHB mothers and those with healthy offspring might be equivalent as supported by the studies of Julkunen *et al*. [92, 103]. In effect, these observations reinforce the findings of most studies that the serologic profile of mothers whose children have CHB closely resembles that of SS. One approach to defining risk would be to subset the mothers of children with CHB and compare "SS-CHB" to "SS-healthy" and "SLE-CHB" to "SLE-healthy."

However, because many mothers are asymptomatic and only identified by the birth of their affected child, an appropriate control group is difficult to assemble.

The fact that SDS immunoblot favors the recognition of denatured epitopes complicates the interpretation of antibody reactivity. It is likely that all anti-SSA/Ro responses would include reactivity with the 60-kDa SSA/Ro component if immunoprecipitation of the native protein was the assay employed [104]. Perhaps instead of defining a high-risk profile we should define a low-risk profile. In the author's experience, mothers who do not have anti-SSB/La antibodies and have anti-SSA/Ro antibodies of low titer that do not recognize either the 60-kDa or the 52-kDa component on SDS immunoblot appear to be at lower risk [105]. As of this writing, sera have been evaluated from 150 mothers whose children have CHB. All had antibodies to SSA/Ro or SSB/La by ELISA. An isolated response to the denatured 60-kDa component on immunoblot was observed in one (<1%) serum and only two sera (<2%) did not recognize any component of SSA/Ro or SSB/La on immunoblot (unpublished observation). However, this response represents only a small fraction of the anti-SSA/Ro responders in general.

A note of caution: reporting of antibody profiles is highly dependent on the assays employed. For example, Neidenbach and Sahn [106] reported an infant with cutaneous manifestations of NLS associated with maternal antibodies to SSB/La in the absence of associated antibodies to SSA/Ro. Testing was done by ELISA and immunoblot. In the author's experience and that of others, immunoprecipitation of the native 60-kDa SSA/Ro antigen has always been positive when anti-SSB/La antibodies are present [105], and such may well be the case in this "unique" infant.

Isacovics and Silverman [107] have utilized limiting dilution experiments of Epstein–Barr virus (EBV)-infected peripheral blood mononuclear cells to examine the frequency of anti-SSA/Ro and anti-SSB/La antibody secreting cells in mothers whose children have NLS [107]. These authors reported that a low anti-SSA/Ro or anti-SSB/La antibody B-cell precursor frequency tends to be associated with the birth of a child with NLS. Additionally, mothers of children with NLS who later developed SLE have higher anti-SSA/Ro and anti-SSB/La antibody-committed B cells than mothers who remained asymptomatic.

PROPOSED MECHANISMS OF IMMUNE INJURY

This model of passively acquired autoimmunity offers an exceptional opportunity to examine the effector arm of immunity and to define the pathogenicity of an autoantibody in mediating tissue injury. A molecular scenario in which maternal anti-SSA/Ro-SSB/La antibodies convincingly contribute to the pathogenesis of cardiac scarring has yet to be formulated. Two points, one clinical and the other cellular, are particularly difficult to reconcile. Only 2% of neonates born to mothers with the candidate antibodies have CHB [86], yet these antibodies are present in over 85% of mothers whose fetuses are identified with conduction abnormalities in a structurally normal heart [105]. Accordingly, the antibodies are necessary but insufficient to cause CHB. The final pathway leading to fibrosis may be variable, kept totally in check in most fetuses (normal sinus rhythm), subclinical in others (first degree block), and fully executed in very few (advanced block). The intracellular location of the target antigens raises questions regarding accessibility to maternal antibodies.

An overview of a proposed cascade to cardiac injury initiated by maternal anti-SSA/Ro-SSB/La antibodies, novel autoantibodies unique to the conduction system, or cross-reactive antibodies is shown in Fig. 5.

Accessibility of Fetal Antigen to Maternal Antibody

A mechanism whereby antibodies might interrupt critical intracellular events in fetal cardiomyocytes or specialized Purkinje cells is largely unknown. As stated previously by Tan [108], "the question is whether autoantibody reacts with intrinsic antigens to perturb the biologic function of normal cells." For anti-SSA/Ro and -SSB/La antibodies to be causal in the development of NLS, three basic requirements should be satisfied: (1) the candidate antigens must be present in the target fetal tissues; (2) the cognate maternal autoantibodies must be present in the fetal circulation; and (3) these antigens must be accessible to the maternal antibodies.

Earlier studies have firmly demonstrated reactivity of anti-SSA/Ro antibodies with fetal cardiac tissues, including the conduction system [17, 38, 109] (see Fig. 4). The preferential vulnerability of the fetal heart versus the adult heart is addressed by a study demonstrating that a 23-week fetal heart contained a greater quantity of SSA/Ro per milligram protein than 18- to 22-week hearts or an adult heart [110]. The presence of SSA/Ro and SSB/La antigens in the fetal heart is well established and therefore satisfies the first requirement. Similarly the second requirement has been fulfilled by studies demonstrating anti-SSA/Ro-SSB/La antibodies in the fetal circulation as assessed by measurements in cord blood [36, 111].

The third requirement, accessibility, has been more difficult to establish. It has been suggested that autoantibodies can penetrate living cells, subsequently alter

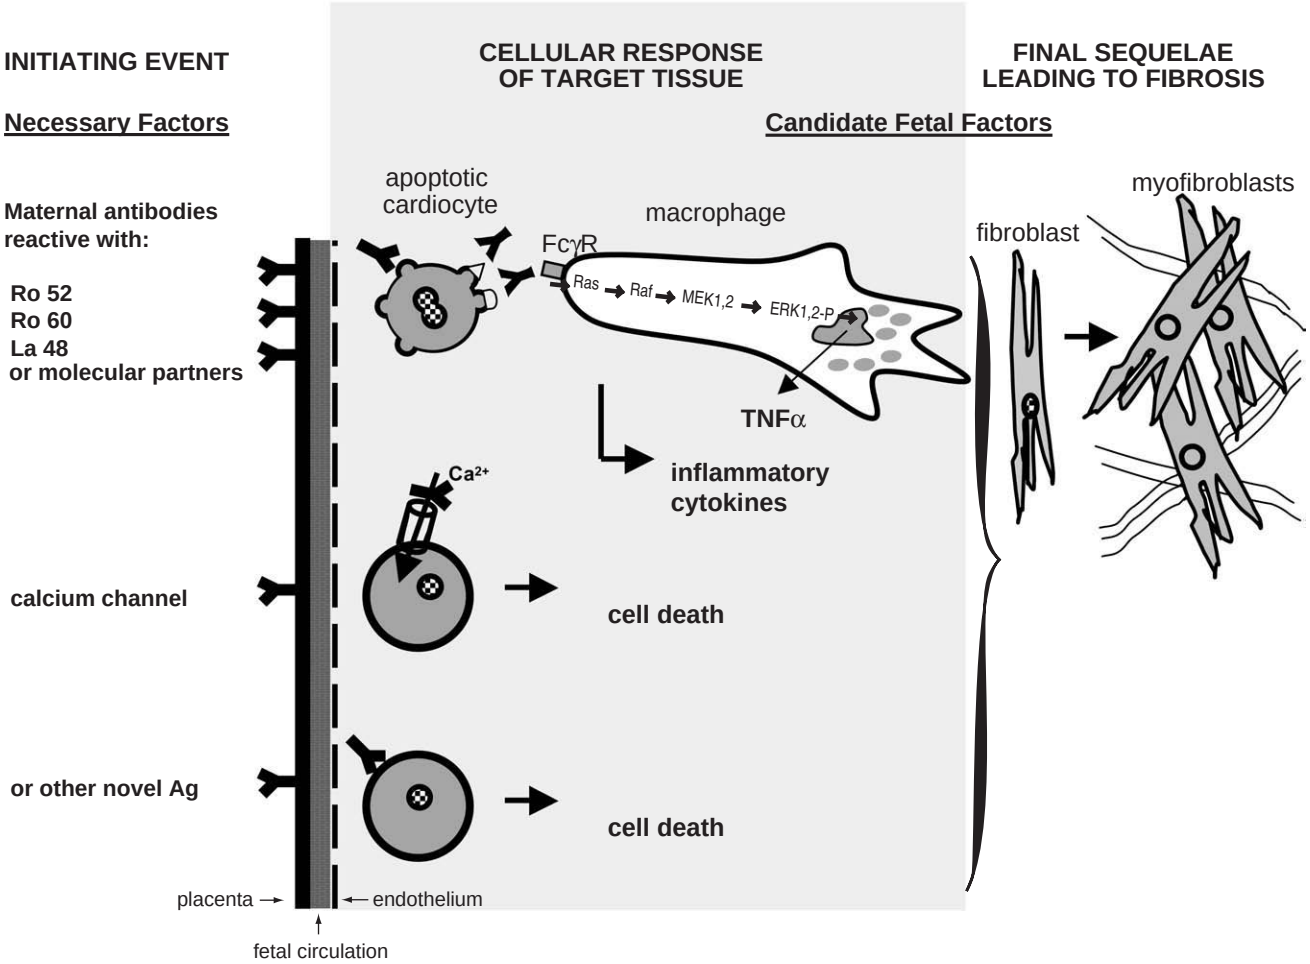

FIGURE 5 Putative mechanisms of autoantibody-induced injury leading to CHB. An overview of a proposed cascade to cardiac injury initiated by maternal anti-SSA/Ro-SSB/La antibodies, novel autoantibodies unique to the conduction system, or cross-reactive antibodies.

function, and cause cell death [112], but this notion still remains controversial. Alternatively, if the antibody cannot cross the cell membrane, then is the antigen trafficked to the cell surface? Finally, anti-SSA/Ro-SSB/La antibodies could cross-react with other surface cardiac antigens.

Several lines of evidence have been advanced to support the possibility that otherwise sequestered intracellular autoantigens can be expressed on the cell surface. Baboonian *et al*. [113] have demonstrated the sequential expression of the SSB/La antigen from the nucleus through the cytoplasm and ultimately on the cell surface of Hep 2 cells infected with adenovirus. Accumulating data support the surface expression of SSA/Ro in keratinocytes, after exposure to ultraviolet light [114–116] or following incubation with TNF-α [117]. Perhaps most relevant to NLS, 17β-estradiol at 10^{-7} M, a concentration reached during the third trimester of pregnancy [118], enhances binding of anti-SSA/Ro antibodies to keratinocytes [119] and induces up to five-fold increases in the expression of 52α and 60Ro mRNA [120]. Biologic significance is strengthened by the reports of estrogen receptors in cardiac tissue [121, 122]. Furthermore, one mismatch consensus estrogen response element was identified upstream of the transcriptional start site in the gene encoding 52-kDa SSA/Ro, and an estrogen response element similar to that of c-*myc* was detected in the human gene encoding 60-kDa SSA/Ro [120].

Reichlin *et al*. [123] have bolstered support for the accessibility of the candidate antigens to the respective maternal antibodies by the finding of antibodies to native 60-kDa SSA/Ro and denatured 52-kDa SSA/Ro in acid eluates of a heart from a fetus with CHB who died at 34 weeks gestation. The enrichment was apparently selective, as these antibodies were not detected in

eluates from the brain, kidney, or skin. Furthermore, Horsfall *et al*. [124] have demonstrated maternal IgG-bearing anti-SSB/La idiotypes on the surface of fetal myocardial fibers on autopsy of a neonate with CHB.

Apoptosis has been traditionally conceptualized from an immunologic point of view as either a means of maintaining B- and T-cell tolerance [125, 126] or as a mechanism for providing accessibility of intracellular antigens to induce an immune response [127]. Casciola-Rosen *et al*. [127] have demonstrated that autoantigens are clustered in two distinct populations of surface blebs on keratinocytes. The larger blebs, so-called apoptotic bodies derived from the apoptotic nucleus, contain both SSA/Ro and SSB/La proteins with SSB/La detected at the cell surface surrounding large blebs in the later stages of apoptosis. The 52-kDa protein was not specifically identified but rather deduced, as evaluation was done with a patient serum considered "monospecific" for 52-kDa SSA/Ro antibodies. The smaller blebs, arising from fragmented rough endoplasmic reticulum and ribosomes, contain SSA/Ro presumably of cytoplasmic origin. SSB/La was not contained in these blebs.

Apoptosis may be relevant in the pathogenesis of NLS. It is a selective process of physiological cell deletion in embryogenesis and normal tissue turnover and plays an important role in shaping morphological and functional maturity [128]. Apoptosis is a process that affects scattered single cells rather than tracts of contiguous cells. In the normal adult myocardium, apoptosis has been observed only rarely [129, 130]. In contrast, apoptosis does occur during the development of the heart. In the 1970s, Pexeider [131] extensively characterized the temporal and spatial distribution of cell death in the hearts of chicken, rat, and human embryos. Major foci included the AV cushions and their zones of fusion, the bulbar cushions and their zones of fusion, and the aortic and pulmonary valves. Albeit much of the cell death was noted in nonmyocytes, a focus of myocyte death was apparent in the muscular interventricular septum as it grew toward the AV cushions in midgestation. Takeda and colleagues [132] demonstrated apoptosis in midgestational rat hearts using terminal deoxynucleotidyl transferase dUTP nick end labeling, an *in situ* technique that detects DNA strand breaks in tissue sections. Although not coincident with the precise timing of CHB, it has also been suggested that apoptosis contributes to the postnatal morphogenesis of the SA node, AV node, and His bundle [133]. Perhaps a novel view of apoptosis is that it facilitates the placing of cardiac target autoantigens in a location accessible to previously generated maternal autoantibodies. Tissue damage might be a consequence of being in the right place at the wrong time.

To investigate the hypothesis that apoptosis indeed facilitates the accessibility of SSA/Ro and SSB/La in the heart, cultured human fetal cardiac myocytes were incubated with staurosporine or 2,3-dimethoxy-1,4-naphthoquinone (DMNQ) [134]. Using phase-contrast microscopy, morphologic signs of early apoptosis were observed in 40% of the cardiocytes after approximately 4 h and increased to 95% after 7 h. The cellular topology of SSA/Ro and SSB/La was evaluated with confocal microscopy and was determined in nonapoptotic and apoptotic cardiocytes by indirect immunofluorescence using two previously characterized antisera: one "monospecific" anti-SSB/La and the other recognizing both 52- and 60-kDa SSA/Ro with goat antihuman IgG-FITC as the secondary antibody (Fig. 6). In nonapoptotic cardiocytes, SSA/Ro was predominantly nuclear with minor cytoplasmic staining and SSB/La was confined to the nucleus. In early apoptotic cardiocytes, condensation of the SSA/Ro- or SSB/La-stained nucleus was observed accompanied in some cells by a "ring" of bright green fluorescence around the periphery. In the later stages of apoptosis, nuclear SSA/Ro and SSB/La staining became weaker. Blebs could now be seen emerging from the cell surface, stained with both SSA/Ro or SSB/La. Scanning electron microscopy unambiguously confirmed the surface expression of SSA/Ro and SSB/La on cultured human fetal apoptotic cardiocytes (Fig. 7).

In vivo studies have confirmed the observations made *in vitro*. Tran and colleagues [135] have demonstrated the translocation of SSB/La in apoptotic cardiocytes in the conduction system of the unmanipulated mouse fetal heart. Clustering of SSB/La near the surface of apoptotic bodies occurs *in vivo* under physiological conditions. To access proof of concept and examine whether SSB/La and/or SSA/Ro epitopes on apoptotic cells are accessible for binding by Abs *in vivo*, these same investigators have exploited a murine passive transfer model in which the fate of human autoantibodies actively transported across the placenta could be traced in fetal tissues known to have high rates of apoptosis [136]. Specifically, BALB/c pregnant mice were injected with human anti-SSA/Ro-SSB/La serum, monospecific anti-Ro60 serum, affinity-purified anti-SSB/La, anti-dsDNA, or normal human serum. Apoptotic cells identified in the fetal conducting tissue (present under normal physiologic conditions of remodelling) showed redistribution of SSB/La from the nucleus to the surface of apoptotic bodies. Fetuses from anti-SSA/Ro-SSB/La Ab-injected mothers showed a striking colocalization of human IgG with apoptotic cells in the atrium, AV node, liver, skin (with particulate epidermal deposition), and newly forming bone. The IgG–apoptotic cell complexes were organ specific and

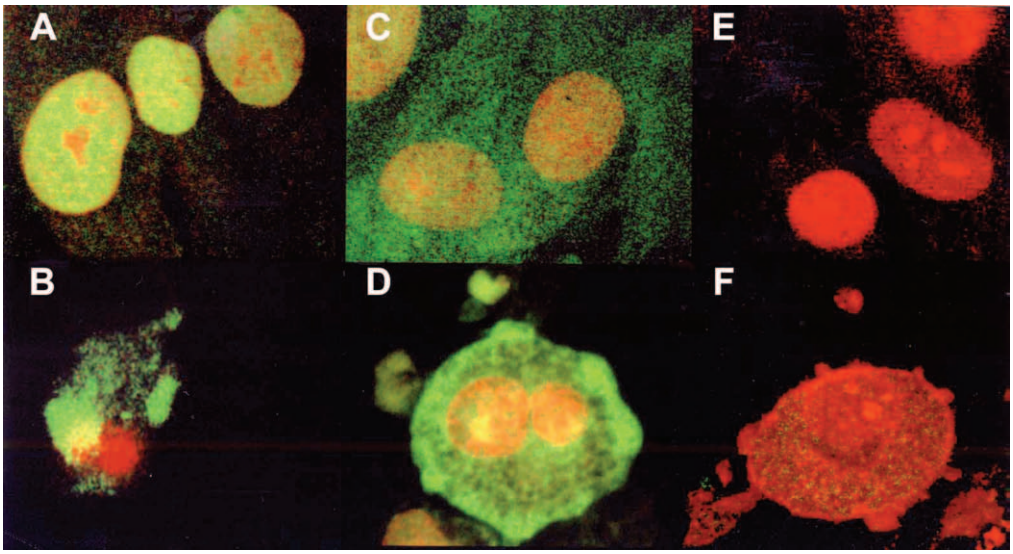

FIGURE 6 Cellular topology of SSA/Ro and SSB/La in nonapoptotic and apoptotic cultured human fetal cardiocytes. Cells were doublelabeled with PI (red) and antisera (FITC). (**A**) SSB/La stains the large nuclei in nonapoptotic cells. (**B**) It can be appreciated that SSB/La is increased in the cytoplasm and also concentrates in blebs. (**C**) SSA/Ro stains the nuclei and cytoplasm of nonapoptotic cells, whereas in apoptotic cells (**D**) there is translocation of SSA/Ro to the cell periphery and strong staining of blebs. (**E** and **F**) Normal human serum did not stain control or apoptotic cells as evidenced by the absence of green fluorescence.

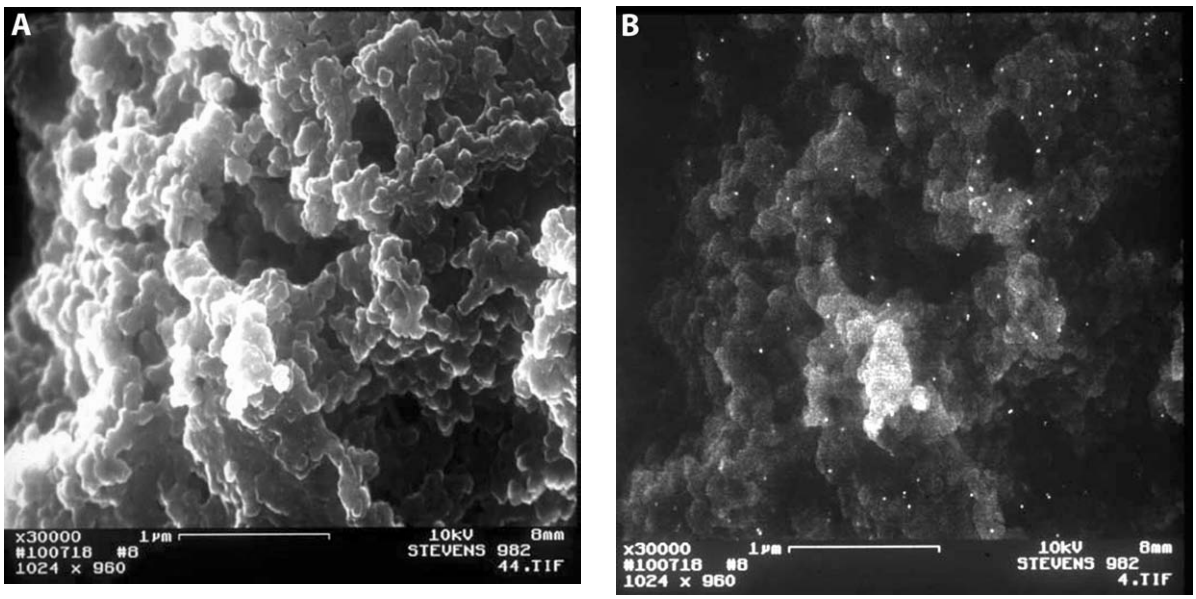

FIGURE 7 Scanning electron micrographs of cultured human fetal cardiocytes labeled with immunogold attached to a maternal serum containing anti-52-kDa and -60-kDa SSA/Ro. (**A**) High-power magnification showing the topography of an apoptotic human fetal cardiocyte. (**B**) Backscatter image demonstrating that the apoptotic surface is bound by sera containing anti-48-kDa SSB/La.

were not detected in thymus, lung, or gut. No IgG deposits were identified in fetuses from mothers injected with anti-dsDNA, anti-Ro60, or normal sera. Experiments with affinity-purified anti-SSB/La and anti-SSA/Ro-SSB/La Abs absorbed with SSB/La confirmed the specificity of deposited IgG as anti-SSB/La.

The demonstration (*in vitro* and *in vivo*) of antigen–antibody binding at the cell surface [135–137] supports the hypothesis that maternal antibodies to components of the SSA/Ro-SSB/La complex are not simply markers of disease but play an active part in the pathogenesis of CHB. A molecular explanation for subsequent damage to the specialized cells of the conduction system and working myocardium remains speculative. In this context, a mechanism is envisioned whereby unexpected circumstances convert the physiologic process of apoptosis into one in which an inflammatory component is evoked. Perhaps the unexpected event is opsonization. These findings suggest that circulating maternal autoantibodies opsonize cells undergoing physiological apoptosis, which then changes otherwise innocent degradation products into proinflammatory stimuli. This cascade could result in damage and ultimately permanent scarring in those tissues with low regenerative capacity.

To address the functional consequences of opsonization of apoptotic cardiocytes, we designed coincubation experiments with human macrophages [138]. The Th1 cytokine, TNF-α, was chosen as a readout of inflammation. Basal production of TNF-α by the macrophages was 9.7 ± 0.9 SEM pg/ml and decreased to 3.3 ± 0.3 SEM pg/ml after coincubation with apoptotic cells, which was not observed in initial experiments using cardiocytes rendered necrotic after hypotonic lysis. Apoptotic cardiocytes preincubated with normal human IgG acted functionally as nontreated apoptotic cells; TNF-α production by the macrophages was 5.7 ± 0.9 SEM pg/ml. In contrast, when macrophages were cocultured with apoptotic cardiocytes incubated with affinity-purified antibodies to each of the components of the Ro/La complex, TNF-α production was increased by 3- to 5-fold over basal levels and 10- to 14-fold over that secreted after culture with apoptotic cells alone. Nonapoptotic cardiocytes incubated with medium alone or serum containing antibodies reactive with 48-kDa SSB/La, 52-kDa SSA/Ro, and 60-kDa Ro did not modify the basal production of TNF-α by the macrophages. Preliminary studies demonstrated that macrophage-derived factors induce phenotypic changes in cardiac fibroblasts supportive of scarring [139].

Li and colleagues [140] reported that affinity-purified anti-SSB/La antibodies but not anti-52-kDa SSA/Ro antibodies recognize laminin, a high molecular weight, noncollagenous structural glycoprotein present on the sarcolemmal membrane of cardiocytes [140]. Several anti-SSB/La antibodies bound to the sarcolemmal membrane of human fetal cardiocytes aged 9–15 weeks of gestation as demonstrated by immunofluorescence on frozen sections. In contrast, binding to adult hearts was not observed. Experimental data suggested that the cros-sreactivity was dependent on the native SSB/La structure, as laminin was not recognized on the SDS immunoblot. These results support the hypothesis that molecular mimicry between laminin and SSB/La may account, in part, for the vulnerability of the fetal and not adult heart.

Complement Regulatory Proteins

With regard to the mechanism of tissue injury, consideration should be given to the possibility that protective molecules may be diminished on the surface of fetal cells. In adulthood the cells of an organism are protected from complement-mediated damage by membrane-bound proteins such as decay accelerating factor (DAF, CD55), protectin (CD59), and membrane cofactor protein (MCP, CD46) [141–143]. DAF regulates C3/C5 convertases, and CD59 regulates assembly of the terminal components of the membrane attack complex. MCP patrols cell membranes, inactivating the C4b and C3b that is bound inadvertently by acting as a cofactor for their factor I-mediated cleavage [144]. MCP is expressed on a wide variety of cells, including those of the epithelial, fibroblast, and endothelial cell lineage [145].

To examine fetal characteristics that might influence autoantibody-mediated diseases acquired *in utero*, such as heart block in NLS, the tissue expression of MCP was studied [146]. Immunoblots of organs from six fetuses (aged 19–24 weeks) probed with rabbit anti-MCP antibodies revealed a band at 60 kDa in addition to the known 65- and 55-kDa isoforms that comprise the codominant allelic system of MCP. Five fetuses expressed the most common MCP polymorphism (predominance of the 65-kDa isoform, upper band α phenotype) in the kidney, spleen, liver, and lung. In contrast, all hearts from these five fetuses demonstrated a different pattern in which there was a marked decrease in the intensity of the 65-kDa band and accentuation of the lower molecular weight bands. In a sixth fetus that expressed the second most common polymorphism (equal expression of the 65- and 55-kDa MCP isoforms, αβ phenotype), the heart was similar to the other tissues. Preferential expression of the MCP β isoform in five of six fetal hearts, irrespective of the phenotype of other organs, suggests tissue-specific RNA splicing or posttranslational modification. The clinical significance of this tissue-specific phenotype is unknown at present

but may provide an important clue to the susceptibility of the fetal heart to antibody-mediated damage.

Arrhythmogenicity of Maternal Autoantibodies and Perturbation of L-Type Calcium Channels

Two earlier publications, both in animal models, indirectly invoked arrhythmogenic effects of anti-SSA/Ro-SSB/La antibodies. Alexander *et al.* [147] reported that superfusion of newborn rabbit ventricular papillary muscles with IgG-enriched fractions from sera containing anti-SSA/Ro-SSB/La antibodies specifically reduced the plateau phase of the action potential consistent with an alteration of calcium influx. Using isolated adult rabbit hearts, Garcia *et al.* [148] showed that IgG fractions from women with anti-SSA/Ro-SSB/La antibodies induced conduction abnormalities and reduced the peak slow inward current (I_{Ca}) in patch-clamp experiments of isolated rabbit ventricular myocytes. Because conduction in the AV node is essentially dependent on calcium electrogenesis, an AV block would be expected to result from treatments leading to reduction of the I_{Ca} in ventricular myocytes. The L-type calcium channel is mainly responsible for I_{Ca} in ventricular myocytes and for the propagation of the action potential in the AV node.

These intriguing publications led to a collaborative effort with Dr. Mohamed Boutjdir (Brooklyn VA Medical Center, Brooklyn, NY) in which attention focused on the human fetal heart [149]. To assess the effect of IgG fractions and affinity-purified antibodies on conduction and heart rate, EKG recordings were obtained from whole human fetal hearts, aged 18–24 weeks (Fig. 8). Baseline EKGs were recorded after a stabilization period of 30–45 min. Perfusion of the heart for 27 min with purified anti-52-kDa SSA/Ro antibodies from three mothers whose children had CHB resulted in bradycardia associated with widening of the QRS complex that could represent a bundle branch block or an intraventricular defect in the conducting system. The average increase in R-R and P-P interval corresponded to 32 and 30%, respectively. At 33 min of perfusion, a complete AV block was diagnosed with the presence of only P waves and missing QRS complexes. Reperfusion of the heart with antibody-free Tyrode's solution for 48 min resulted in partial and slow recovery. In contrast, IgG from four control mothers did not have any measurable effect on AV conduction. These findings were further characterized by studying the effects of IgG fractions and affinity-purified anti-52-kDa SSA/Ro antibodies on whole cell L-type I_{Ca} recorded by the patch-clamp technique [150]. As seen in Fig. 9B, IgG from a mother whose children had CHB,

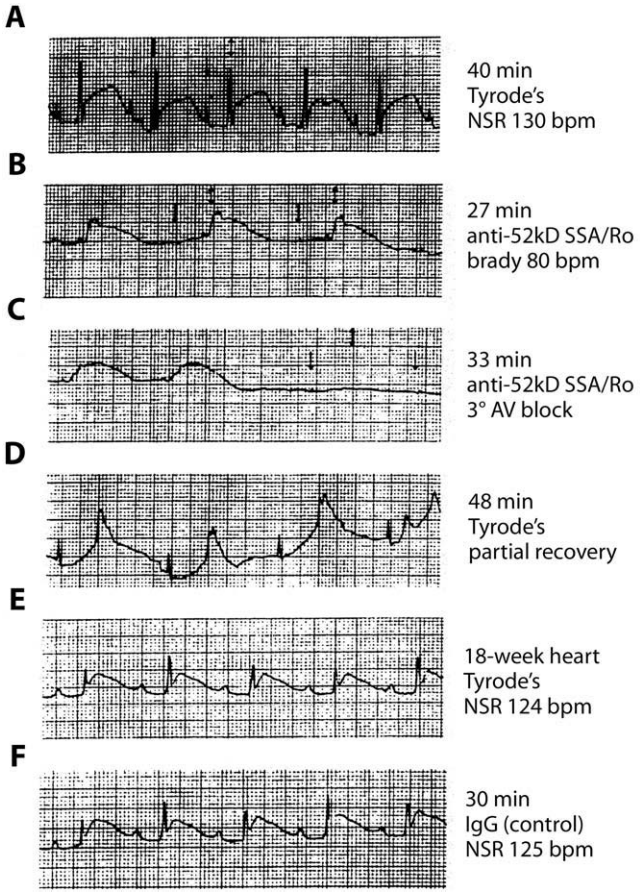

FIGURE 8 Effect of affinity-purified anti-52-kDa SSA/Ro antibody on the EKG recording of a 24-week human fetal heart. After 40 min of stabilization in Tyrode's solution, a regular sinus rhythm at 130 bpm (**A**) was recorded (lead I: horizontal scale, 50 mm/s; vertical scale, 10 mm/mV). Twenty-seven minutes after infusion of anti-52-kDa SSA/Ro antibody (800 µg/ml), there was significant bradycardia (80 bpm) associated with a widening of the QRS complex (**B**) that could represent bundle branch block or an intraventricular defect in the conducting system. (**C**) After 33 min, complete AV block was diagnosed with the presence of only P waves (indicated by single-headed arrows) and missing QRS (indicated by double-headed arrow). Perfusion of the heart with antibody-free Tyrode's solution for 48 min resulted in partial recovery (**D**). (**E** and **F**) EKG recordings from an 18-week human fetal heart during control conditions (**E**) and after 30 min of perfusion with 800 µg/ml of normal IgG (**F**). Normal IgG did not induce any conduction abnormalities or change in heart rate (124 bpm during control vs 125 bpm with normal IgG). From Boutjdir *et al.* [149], with permission.

but not from a control mother, inhibited peak I_{Ca} at all voltages tested. The average inhibition at 0 mV was 59%. Similarly, affinity-purified anti-52-kDa SSA/Ro antibodies from three CHB mothers inhibited peak I_{Ca} by 56% at 0 mV (Fig. 9C). Accordingly, inhibition of I_{Ca} by the autoantibodies in isolated myocytes further

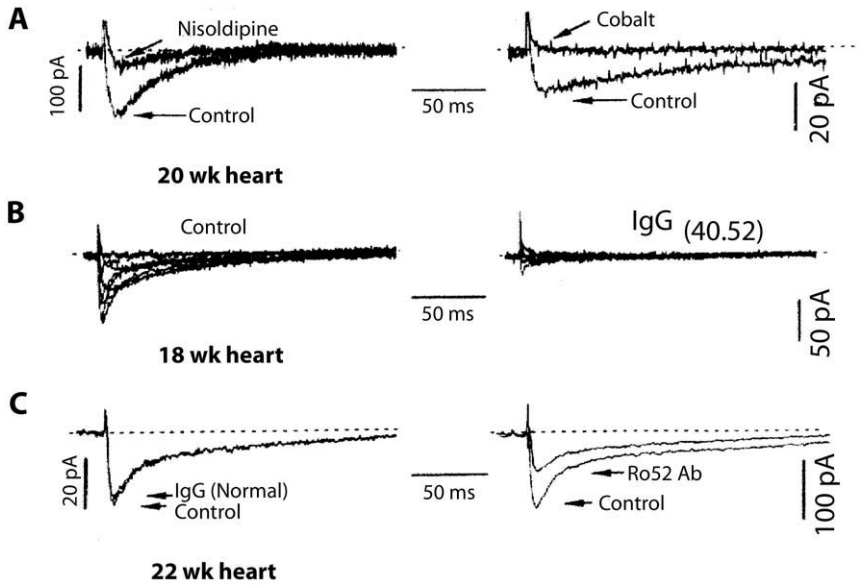

FIGURE 9 Effect of IgG and affinity-purified anti-52-kDa SSA/Ro antibodies on whole cell I_{Ca}. (**A**, left) I_{Ca} tracings elicited by a 200-ms test pulse to 0 mV preceded by a 100-ms prepulse to -40 mV from a holding potential of -80 mV every 10 s. I_{Ca} on the left and right were recorded from a cell of 20- and 18-week hearts, respectively. Application of nisoldipine (2 μmol/liter) or cobalt (5 mmol/liter) inhibited I_{Ca}. (**B**) A series of time- and voltage-dependent I_{Ca} tracings recorded from a cell of an 18-week heart at voltages ranging between –30 and 160 mV with a 10-mV increment during control and during the steady-state effect of 80 μg/ml of IgG from a mother whose child has CHB. (**C**) The lack of IgG effect from a control mother on I_{Ca} in a cell from a 22-week heart. However, the affinity-purified anti-52-kDa SSA/Ro antibody from a second CHB mother inhibited peak I_{Ca} by 46% in another cell from a 22-week heart. From Boutjdir *et al.* [149], with permission.

supports the contribution of Ca^{2+} channels to the conduction abnormalities observed in the whole heart.

The biophysical properties by which the autoantibodies inhibited whole cell I_{Ca} were then investigated at the single channel level using the cell-attached configuration of the patch-clamp method [150]. Barium currents were recorded through Ca^{2+} channels as described [151]. Bath application of affinity-purified anti-52-kDa SSA/Ro antibody from two CHB mothers produced a significant decrease in the Ca^{2+} channel activity and the ensemble average current. The ensemble average currents decreased from 0.23 to 0.13 pA (–43%, $P < 0.02$). Similar inhibition was obtained with IgG from two CHB mothers, but no significant effect was observed with IgG from three control mothers. Analysis of single channel kinetics indicated that this inhibition was the result of shorter open times and longer closed times, which could also explain the basis of the whole cell I_{Ca} inhibition by the autoantibody. The effect of the affinity-purified antibody and IgG from mothers whose children have CHB was less pronounced in the cell-attached than the whole-cell recordings, suggesting involvement of a diffusible cytosolic constituent in mediating the response to autoantibodies. Xiao and colleagues [152] have extended this work and reported a direct interaction of maternal anti-SSA/Ro-SSB/La antibodies with the pore-forming α (1)-subunit of Ca channels using transfected *Xenopus* oocytes, a finding of interest that remains to be confirmed.

Given data in the rabbit and human heart it is tempting to conclude that inhibition of L-type Ca^{2+} channels explains the pathogenicity of anti-SSA/Ro (perhaps anti-SSB/La) antibodies in the development of CHB. Several facts are highly supportive of this conclusion. AV nodal electrogenesis is dependent on L-type Ca^{2+} currents. Ca^{2+} channel density is lower and sarcoplasmic reticulum less abundant in fetal compared to adult cardiac cells, increasing the dependency on transsarcolemmal Ca^{2+} entry [153]. Prolonged exposure of fetal Ca^{2+} channels to maternal anti-SSA/Ro-SSB/La antibodies may lead to internalization and degradation of the channel, cell death, and ultimately fibrosis. Inhibition of ventricular Ca^{2+} channels may result in decreased contraction and congestive failure. Alternatively, antibody binding to the channel may result in opsonization and phagocytosis by macrophages with inflammatory/fibrotic sequelae (similar to the apoptosis theory described earlier).

SA nodal electrogenesis is also dependent on L-type Ca^{2+} currents [154]. Interestingly, detailed evaluation of autopsies done on children in the Research Registry for Neonatal Lupus revealed pathology in some cases at the SA node (as described earlier) [30]. Mazel *et al.* [155] observed sinus bradycardia in a murine model of passive immunity with anti-SSA/Ro antibodies. Highly relevant to these histologic and functional observations is Brucato's identification of sinus bradycardia in 4 of 24 EKGs from otherwise healthy newborns born to the cohort of mothers with SSA/Ro antibodies [86]. Of 187 cases in the research registry [41], atrial rates from postnatal EKGs were available for 40 neonates; the mean rate was 137 bpm ± 20 SD (range 75–200). The one slow rate of 75 bpm was obtained during sleep and increased to 140 bpm when awake. In an additional child, the records stated sinus bradycardia; however, no EKG was available and subsequent records were not sent to the registry. In both the author's review and the study by Brucato the sinus bradycardia was not permanent. Although this suggests that the nature of the initial insult and/or the subsequent reparative processes may be different for the SA and AV nodes, normal atrial rates may reflect the functioning of other pacer foci in the atria.

Murine Model of CHB

While clinical data leave little doubt regarding the association of anti-SSA/Ro and/or SSB/La antibodies with the development of CHB, and experimental data are beginning to suggest pathogenicity, efforts to establish an animal model have been limited. Kalush *et al.* [154] reported that offspring of BALB/c mice immunized with the monoclonal anti-DNA idiotype 16/6 had conduction abnormalities. Of 31 pups born to mothers with experimental SLE, 8 had first-degree heart block, 2 had second-degree heart block, 2 had complete block, 10 had bradycardia, and 8 demonstrated widening of the QRS complex. None of these disorders could be detected in the 20 offspring of healthy control mice. One of the difficulties in interpreting these findings is that the immunized mothers synthesized a variety of autoantibodies, including antibodies reactive with 16/6 Id, ss/dsDNA, Sm, RNP, cardiolipin, SSA/Ro, and SSB/La. Accordingly, it was not possible to segregate out which specific antibody might be responsible for the arrhythmias detected in these pups. The electrocardiographic data are provocative; however, no histologic data were provided to assess the status of the SA or AV node or the presence of myocarditis.

To further establish an antibody-specific murine model to correlate arrhythmogenic effects of maternal autoantibodies with the *in vivo* genesis of CHB, female BALB/C mice were immunized with 100 µg of one of the following 6× His human recombinant proteins purified by Ni^{2+} affinity chromatography: 48-kDa SSB/La, 60-kDa SSA/Ro, 52-kDa SSA/Ro (52α full-length), and 52β [157]. Control animals were given the same injections with a Ni^{2+} affinity-purified polypeptide encoded by pET-28 alone. Following primary immunization in complete Freund's adjuvant and two boosters (50 µg) in incomplete Freund's adjuvant, high-titer immune responses to the respective antigens were established by ELISA and immunoblot of recombinant antigens, and immunoprecipitation of [^{35}S]methionine-labeled *in vitro* translation products. Sera from mice immunized with either 52α or β immunoprecipitated radiolabeled murine 52-kDa SSA/Ro, confirming that these mice were specifically reactive with the murine homologue. Moreover, immunoblot of a newborn murine heart demonstrated the presence of 52-kDa SSA/Ro. Mice were mated and boosters continued every 3 weeks to ensure continued high-titer antibody responses. EKGs were performed on all pups using standard limb leads at birth or within 2 days postpartum. Maternal antibodies to the primary immunogens were detected by ELISA in the pups.

Results are summarized in Table 2. Of 54 pups born to six fertile mice immunized with 60-kDa SSA/Ro, none had CHB; of 27 pups born to three fertile mice immunized with 48-kDa SSB/La, none had CHB. In contrast, of 78 pups born to five fertile mice immunized with 52α and 86 pups born to five fertile mice immunized with 52β, 1 and 5 pups, respectively, had CHB. Accordingly, this antibody-specific animal model provides strong preliminary evidence for a pathogenic role of antibodies reactive with 52-kDa SSA/Ro, particularly the 52β form, in the development of CHB. Moreover, analogous to the frequency of 1–5% given for women with SLE who have anti-SSA/Ro and/or SSB/La antibodies [84–86], this model suggests that additional factors promote disease expression.

Lessons from Monozygotic and Dizygotic Twins

The study of twin gestations further emphasizes the complexity of NLS. These informative *in vivo* experiments of nature provide clues to the true relevance of the maternal antibody and host factors. Discordance of disease expression in monozygotic twins would be particularly intriguing because the placenta is shared and the fetal genetics are identical. Twins born to mothers with anti-SSA/Ro-SSB/La antibodies provide a unique opportunity to gauge the effect of a specific antibody profile on disease phenotype. Regardless of whether twins share a common placenta or not, it is likely that

TABLE 2 Murine Model of CHB

Immunogen	Mothers immunized (*N*)	Mothers fertile (*N*)	Pups (*N*)	AV block		
				I (*N*)	II (*N*)	III (*N*)
48-kDa SSB/La	10	3	27	2	0	0
52α SSA/Ro	8	5	78	3	1	1
52β SSA/Ro	5	5	86	5	0	5[a]
60-kDa SSA/Ro	7	6	54	10	0	0
β-Galactosidase	3	2	11	0	0	0
Vector	4	4	43	0	0	0

[a] One 52β mother had three pups with CHB in the same litter; another mother had one CHB pup.

even if a mother had three types of antibodies (type A causing CHB, type B causing skin rashes, and type C being nonpathogenic) the proportion of these antibodies should be similar in each fetal circulation. Types A and B by definition must be of the correct subclass and isotype (*i.e.,* IgG, subclasses 1–4) to be transported across the trophoblast, whereas type C might not be transported at all. One might envision quantitative differences in each twin, but it is difficult to conceive of a mechanism to explain why one placenta would transport antibodies more selectively than another unless Fc receptors were expressed differentially.

Of 23 twin pairs and one triplet set published [3, 6, 10, 39, 85, 96, 110, 158–169], only 6 are entirely concordant for disease expression (summarized in Table 3). Gawkrodger and Beveridge [158] described disparate disease expression in male twins who were in the same amniotic sac and shared a common placenta. The mother had anti-SSA/Ro and anti-SSB/La antibodies. One infant presented at 8 weeks of age with Stokes Adams attack and second-degree heart block, a facial rash, and evidence of hemolytic anemia, whereas his twin brother had merely a "peeling" facial rash at 15 weeks of age. Cooley *et al.* [159] reported two sets of monozygotic twins discordant for CHB. Watson *et al.* [163] performed HLA studies and C4 phenotypes on dizygotic twins discordant for isolated CHB. Both infants had identical HLA (DR4,DR7) and C4 phenotypes (C4A3.QOB1.1). Serum from the mother and both cord bloods demonstrated anti-SSA/Ro and SSB/La antibodies with no significant difference in titer noted in the cord blood of either twin when compared with maternal titers. Brucato *et al.* [164] reported a second pair of HLA identical twins discordant for CHB, and a third such pair was reported by Kaaja *et al.* [165]. In the research registry there were three sets of twins [39]. Two sets were dizygotic, with only one twin in each set having CHB. Histologic and genetic analysis of the third set revealed a twin placenta (diamniotic, dichorionic) and monozygosity. One twin had CHB and the other was completely healthy.

Certainly these observations support a fetal contribution to the development of neonatal lupus, but perhaps even more intriguing is that in two sets of twins [158, 162] and the set of triplets [169], all children were affected but with discordant manifestations. Accordingly, even if the antibody profile is an important predictor of risk for one manifestation of neonatal lupus versus another, the fetus (perhaps density of calcium channels, impaired healing, exuberant fibrosis) and/or its immediate environment (low oxygen) provides an additional factor(s) required to convert susceptibility to overt disease. The logical inference from these reports is that developmental events *in utero* strongly contribute to the susceptibility of a particular fetus.

IMMUNOGENETICS OF THE MOTHER AND HOST

The majority of studies to date have documented the near universal presence of DR3 alleles in the mothers of affected offspring, frequently associated with the extended haplotype A1,B8 [11, 103, 110, 170–172]. In addition to the reports of others, 10 of 11 affected mothers studied at our institution were HLA DR3. The one exception was DR7. For comparison, of 25 women with SLE or SS who gave birth to healthy offspring, 48% were DR3, (odds ratio = 16, $P < 0.003$). Several investigators have noted an increased frequency of HLA-DR2 in anti-SSA/Ro-positive mothers of normal infants [11, 171]. This is not surprising, as sera from the majority of mothers whose offspring have CHB contain both anti-SSA/Ro and -SSB/La antibodies and not anti-SSA/Ro alone [14, 17, 91]. It is the former subgroup that is more strongly associated with the linked HLA alleles B8, DR3, DRw52, DQw2 and the latter subgroup with DR2, DQw1 [173].

[a] One, 2 and 3 arbitrarily refer to the twin or triplet siblings but do not imply sequence of birth.
[b] Both twins had CHB recognized at birth; twin 2 had associated fibroelastosis and was asymptomatic at 1 year of age, twin 1 had L-transposition, ventricular septal defect, coarctation, and hypoplastic right ventricle, and died at 15 days of age.

As has been suggested for other HLA-linked diseases, it is possible that several genes within a particular haplotype may contribute to enhanced susceptibility. Arnaiz-Villena *et al.* [174] found that class III antigens BS and C4QOB1 are increased together with the A1;B8;DR3 haplotype in SSA/Ro-positive mothers whose offspring have CHB. Moreover, these class II genes were not increased significantly in a group of SSA/Ro-positive mothers whose offspring did not have CHB. Of particular interest was the observation that the most common DR3-bearing haplotype found in the Spanish population for adult SLE (A30; B18; DR3; BfF1; C2C,; C4ABQ) was not increased among the mothers of offspring who had CHB. This study did not find an increased frequency of DR2 in the anti-SSA/Ro-positive mothers of healthy offspring, *i.e.,* $DR2^+ = 3/15$ (20%) versus 23% in their normal population.

Brucato *et al.* [172] reviewed the literature and reported that of 28 mothers whose children have CHB, 50% were A1, 62% were B8, and 96% were DR3. In their own cohort of 15 Italian mothers of children with CHB, Brucato and co-workers [172] found a significantly increased prevalence of DR3 and DQ2 and B8/DR3, DR3/DQ2 and A1/Cw7/B8/DR3/DQ2 haplotypes. In a study of 31 Finnish mothers (all anti-SSA/Ro and/or SSB/La positive) of children with CHB, HLA B8 and DR3 were present in 71 and 74% of the affected mothers, respectively [103]. Thus, the genetic background of CHB mothers is similar in Anglo-Saxon populations and populations from southern and northern Europe [103]. The same Finnish study demonstrated that as a group, CHB mothers were genetically related more closely to primary SS than to SLE [103].

At the present time a role for fetal genetic differences in the major histocompatibility complex influence susceptibility is not firmly established. In five earlier reports of affected neonates, only two were DR3 [11, 110, 170, 171]. These data emphasize the passive nature of NLS and the difference between acquiring manifestations of lupus and actually developing the disease. However, continued investigations of larger numbers of affected mothers add complexities to the picture. In the study of Arnaiz-Villena *et al.* [174], four of five offspring with CHB were DR3 positive compared to two of five unaffected siblings [174].

Perhaps fetal HLA, not as an isolated risk factor, but as it relates to maternal HLA, is a fetal factor contributing to injury. A plausible hypothesis might be that tissue damage occurs when the HLA relationship between the fetus and mother is either bidirectionally compatible or unidirectionally compatible from the child's perspective. Relevant to the hypothesis that macrophage phagocytosis of apoptotic cardiocytes opsonized by autoantibodies initiates an inflammatory cascade leading to CHB, HLA class II compatible maternal Th1 cells would be able to provide help to fetal macrophages. In support of this notion, Miyagawa and colleagues [175] reported on a limited study of 13 Japanese families in which children with CHB shared both HLA class II alleles with their mothers significantly more often than children without CHB (4/9 CHB vs 0/12 healthy siblings, $P < 0.02$). Furthermore, Stevens *et al.* [176] demonstrated maternal cells in the AV node, myocardium, and liver of two infants with NLS who died shortly after birth, possibly representing alloreactive hematopoietic cells that trigger inflammation leading to tissue distruction.

MATERNAL DISEASE AT IDENTIFICATION OF NEONATAL LUPUS AND PROGRESSION

In 1987, McCune and colleagues [177] assessed the health status of 21 mothers and their children with NLS. This study suggested that all mothers eventually developed symptoms of a rheumatic disease but larger series have not reached similar conclusions [92, 178–180].

To date, 110 mothers of children with CHB enrolled in the research registry have been evaluated; at the time CHB was identified, 39 mothers were asymptomatic, 17 had an undifferentiated autoimmune syndrome (UAS), 20 had SLE, 24 had SS, 5 had SLE/SS, and for 5 the diagnosis is unknown. At a mean follow-up of 8.4 years, 14 (36%) of the 39 initially asymptomatic mothers had developed symptoms of a rheumatic disease: 1 developed UAS, 5 SLE, 7 SS, and 1 SLE/SS. Twenty-five (64%) remained asymptomatic. Of the 17 mothers initially diagnosed with UAS, 1 developed SLE and 4 SS. Three mothers with SS at the birth of the affected child progressed to SLE/SS at follow-up.

Similar results were reported by Julkunen *et al.* [92]. Fifteen (48%) of 31 mothers whose children had CHB were asymptomatic before the index delivery, 7 of whom remained asymptomatic after a mean follow-up of 8 years. Two mothers had SLE, 1 mother had definite primary SS, 1 had probable SS, 1 had autoimmune hypothyroidism, and 1 had Grave's disease. Six (19%) gave a self-reported diagnosis of a chronic autoimmune disease antedating the index delivery. Of 2 mothers who died, 1 subsequently developed SLE and died of a fatal cardiac arrhythmia 5 years after the birth of the affected child. The other died of alcoholic liver disease and had developed SLE after 11 years. No patient with SLE had nephritis. Importantly, these authors noted that as a group, mothers of CHB children had clinical and immunologic characteristics more closely related to primary SS than SLE.

In a study of 64 CHB mothers from Toronto, 42 (66%) were asymptomatic, 2 (3%) had SLE, 2 (3%) had linear scleroderma, 2 (3%) had RA, 3 (5%) had a history of rheumatic fever, 1 (2%) had SS, and 12 (2%) had UAS [178]. Three of the 12 mothers with UAS progressed to SLE and 2 developed SS. Thirty-six of the 42 initially healthy mothers remained well, 1 developed SLE, 1 hyperthyroidism, 1 ankylosing spondylitis, and 3 UAS. Unlike the other larger studies, not all mothers included in this cohort were documented to have anti-SSA/Ro-SSB/La antibodies.

Taken together, it can be concluded that asymptomatic mothers do not invariably become ill (at least over 8 years or more of follow-up) and if an asymptomatic mother does develop SLE, it is not likely to be life-threatening. Although a more formal epitope analysis of the autoantigens has not been done with regard to clinical outcome, the fine specificity of anti-SSA/Ro-SSB/La antibodies as assessed by immunoblot is highly stable for years, independent of the maternal clinical status [179].

Maternal health status may also be of interest with regard to the discordant clinical manifestations of neonatal lupus. A link between the health status of the mother and child might aid to the researcher in defining risk for a given mother, an enormous benefit to the practitioner faced with family counseling, and in identifying a pathogenetic mechanism of injury. Maternal disease might reflect the fine specificity of an antibody response, which in turn could account for the preferential vulnerability of one particular organ versus another. Lawrence *et al.* [180] compared a cohort of 24 women with anti-SSA/Ro-SSB/La antibodies whose children

have only cutaneous manifestations of neonatal lupus to their previously published cohort of 32 mothers with similar antibodies whose children have only cardiac manifestations [178]. Maternal health status was considered as either symptomatic (inclusive of varied rheumatic diseases such as systemic lupus erythematosus, Sjogren's syndrome, and undifferentiated autoimmune diseases) or completely asymptomatic. A significantly greater number of mothers whose children had CHB were asymptomatic (75%) compared to mothers of children with skin rash alone (42%). At follow-up, mothers of children with CHB were more likely to remain asymptomatic (59%) than were mothers of children with skin rash (25%).

This same question has also been addressed by review of data in the research registry [39]; included were 105 mothers whose children had only CHB and 47 whose children had only a skin rash [181]. All mothers had documented antibodies to SSA/Ro and/or SSB/La. Initially, 37% of the "CHB mothers" and 28% of the "skin mothers" were asymptomatic. After at least 5 years of follow-up, 24% of the 105 "CHB mothers" and 13% of the 47 "skin mothers" remained symptom-free. There was a trend to more symptomatic disease in the mothers whose children had cutaneous manifestations, but the differences between "skin mothers" and "CHB mothers" in the registry did not reach statistical significance. These data are not completely in accord with those of Lawrence *et al*. [180], the difference being in the distribution of maternal disease in the CHB groups. There was a significantly greater proportion of symptomatic "CHB mothers" in the registry than in Toronto. Interestingly, when Fisher's exact test was used to compare the "skin mothers," the proportion of symptomatic individuals did not differ significantly between the Toronto and registry databases. The referral patterns of the two studies could plausibly explain their divergent findings with regard to the health of "CHB mothers." All subjects in the Toronto database are from within a single city catchment area, not from outside sources; the research registry, in contrast, includes the entire United States. While the referral source for the Toronto patients is not included in the report by Lawrence *et al*. [180], 42% of the registry CHB cases and 54% of registry skin cases were referred by rheumatologists (P = NS, CHB vs skin). Data from two separate studies suggest that mothers who have children with cutaneous disease are more likely to be symptomatic than asymptomatic. However, this could be explained by the fact that recognizing a neonatal rash as NLS is more likely in a mother with rheumatic disease. Whether maternal health status (i.e., absence of clinical disease) is a marker for heart disease remains to be established.

IDENTIFICATION AND MANAGEMENT OF THE HIGH-RISK PREGNANCY

An overall schema for management is presented in Fig. 10. These recommendations are considered experimental, based on the author's experience, and have not been tested in a controlled trial.

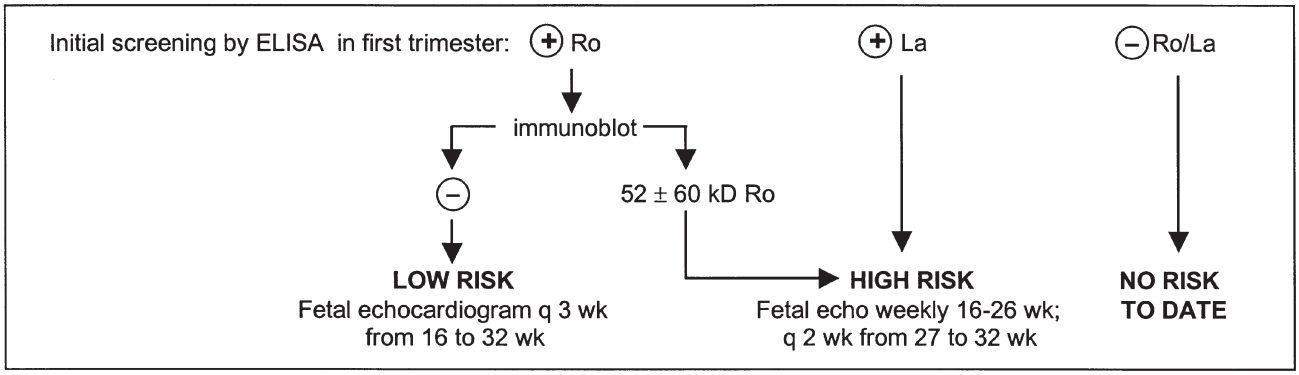
Prenatal Considerations

Ideally, because CHB is identified most often from 18 to 24 weeks of gestation, intrauterine therapy should eventually be possible. The clinical approach to cardiac manifestations of NLS includes obstetric and rheumatologic management of (1) the fetus identified with CHB and (2) the fetus with a normal heart beat but at high risk of developing CHB.

To address the treatment of identified CHB, one needs to know if the presence of bradycardia represents an irreversible fibrotic process and if continued autoimmune tissue injury will cause progressive damage. McCue *et al*. [6] reported a neonate described with first-degree heart block at birth that resolved at 6 months. In contrast, Geggel and colleagues [182] reported an infant born with second-degree heart block that progressed to third-degree block by 9 weeks of age. As discussed in preceding sections, data from the research registry also emphasize that an incomplete AV block is not always fixed and the degree of block is variable [39, 41]. There is a spectrum of conduction abnormalities even at the time of initial detection and *in utero* injury can have continued sequelae in some cases, despite clearance of maternal antibodies from the neonatal circulation.

The rationale for the treatment of identified heart block and the prevention of potential heart block is to diminish a generalized inflammatory insult and reduce or eliminate maternal autoantibodies. Accordingly, several intrauterine therapeutic regimens have been tried, including dexamethasone, which is not metabolized by the placenta and is available to the fetus in an active form, and plasmapheresis. Although there is not yet documentation in the literature regarding the reversal of third-degree heart block (complete fibrosis of the AV node would not be reversible) by maternal treatment with dexamethasone alone, the potential for diminishing an inflammatory fetal response attacking the myocardium is plausible. This would be an effect independent of a decrease in antibody titer. A precedent for this therapeutic rationale is the resolution of associated pleuropericardial effusions and ascites reported in separate investigations [13, 23, 183]. In the largest retrospective study published to date, it was observed that fluorinated glucocorticoids ameliorated

A. Laboratory evaluation of pregnant women with autoimmune disorders, and guidelines for management



B. Therapeutic approach to CHB diagnosed *in utero*

Situation	Treatment
1. Degree of block at presentation	
• 3rd degree (>3 wk from detection)	• Evaluate by weekly echocardiography and obstetrical sonography; no therapy is initiated.
• 3rd degree (<3 wk from detection)	• 4 mg p.o. dexamethasone daily for 6 wk. If no change, taper dose to discontinue. If reversal to 2nd degree or better, continue until delivery, then taper.
• Alternating 2nd/3rd degree	• 4 mg p.o. dex daily for 6 wk. If progression to 3rd degree, taper. If reversal to 2nd degree or better, continue until delivery, taper.
• 2nd degree • Prolonged mechanical PR interval (1st degree)	• 4 mg p.o. dex daily until delivery, then taper. If progression to 3rd degree, taper after 3rd degree persists for 6 wk.
2. Block associated with early signs of myocarditis, congestive heart failure, and/or hydropic changes	• 4 mg p.o. dex daily until improvement, then taper.
3. Severely hydropic fetus	• 4 mg p.o. dex daily, with apheresis as a last resort to rapidly remove maternal antibodies, or consider terbutaline, digoxin, diuretics, direct fetal pacing. **Deliver if lungs are mature.**

FIGURE 10 Current laboratory evaluation and clinical management of neonatal lupus.

incomplete atrioventricular block and hydropic changes in autoimmune-associated congenital heart block but did not reverse established third-degree block [184]. Specifically, data included 47 mothers whose sera contained anti-SSA/Ro-SSB/La antibodies and their 50 children diagnosed with isolated CHB *in utero* and in whom at least four echocardiograms were performed thereafter. In 28 pregnancies, the mothers were treated with 4–9 mg/day dexamethasone for 3–19 weeks or with 12–24 mg/week betamethasone for >6 weeks (group A). In 22 pregnancies, fluorinated steroids were not used (group B). Third-degree block was present in 21 fetuses in group A and in 18 fetuses in group B; none were reversible despite steroids. Three fetuses in group A and two in group B progressed from second-degree block alternating with third-degree block to permanent third degree at birth and postnatally. Notably, of four fetuses in group A with second-degree block at presentation, all reverted to first degree by birth. Of two fetuses in group B with second-degree block at presentation, both progressed to permanent third-degree block postnatally. Initial echocardiographic evaluation revealed pericardial effusions in 13 group A vs 4 group B (P = NS), pleural effusions in 2 group A vs 0 group B (P = NS), ascites in 8 group A vs 0 group B ($P < 0.007$), hydrops in 8 group A vs 0 group B ($P < 0.007$), and intrauterine growth restriction (IUGR) in 1 group A vs 1 group B (P = NS). Pericardial effusions resolved and reappeared

in both groups. Steroid therapy was most effective in the sustained resolution of pleural effusions (2/2), ascites (6/8), and hydrops (5/8). Oligohydramnios ensued in 9 group A and 2 group B (P = NS). Although fetuses in group A had more associated complications at initial presentation than those in group B, there were no significant differences between the groups in the duration of pregnancy (35.7 weeks vs 37.0 weeks), number of deaths (4 vs 1), final degree of block, or requirement for permanent pacing (14 vs 11).

In the author's experience and that of others, apheresis in addition to dexamethasone has not reversed third-degree heart block [13, 23], although titers of maternal anti-SSA/Ro-SSB/La have been decreased profoundly [185]. Maternal risks of dexamethasone are similar to any glucocorticoid and include infection, osteoporosis, osteonecrosis, diabetes, hypertension, and preeclampsia. Fetal risks include oligohydramnios, intrauterine growth retardation, and adrenal suppression. Intervention with glucocorticoids might decrease acute inflammation but not necessarily prevent subsequent fibrosis.

Available data support serial cardiac monitoring of all fetuses with any bradyarrhythmias detected *in utero* and of neonates with incomplete blocks at birth whose mothers are previously known or currently identified to have anti-SSA/Ro-SSB/La antibodies. Fetal echocardiogram is essential to diagnose and follow the course of disease and may suggest the presence of an associated myocarditis by the finding of decreased contractility in addition to the secondary changes associated with myocarditis, such as an increase of cardiac size, pericardial effusions, and tricuspid regurgitation. The obstetric management should be guided by the degree of cardiac failure noted on the ultrasound images. The *in utero* environment is preferred as long as possible because of the low resistance circulatory pathways, thereby affording minimal work to maintain cardiac output.

The initiation of dexamethasone or plasmapheresis as a preventative measure has been considered. With regard to prophylactic therapy of the high-risk mother (documentation of high-titer anti-SSA/Ro and SSB/La antibodies, anti-48-kDa SSB/La and 52-kDa SSA/Ro on immunoblot, and a previous child with NLS), administration of prednisone, dexamethasone, or plasmapheresis is not justified at the present time. Maternal prednisone (at least in low and moderate doses) early in pregnancy does not prevent the development of CHB [186]. This might be anticipated, as prednisone given to the mother is not active in the fetus [187] and levels of anti-SSA/Ro and anti-SSB/La antibodies remain relatively constant during steroid therapy. However, Shinohara *et al.* [188] published uncontrolled data suggesting that prenatal use of maternal glucocorticoids has prophylactic merit. This recommendation was based on the finding that 15 of 61 infants born to 40 mothers with anti-SSA/Ro antibodies who did not receive glucocorticoids had CHB. The unexpectedly high prevalence may be explained by the retrospective nature of the study and potential referral bias. Conversely, CHB did not occur in any of 26 fetuses whose mothers were given steroids prior to the 16th week of gestation. If one accepts the rate of 2%, then at least 40 mothers with anti-SSA/Ro antibodies may need to be followed to find one infant with complete block.

With regard to plasmapheresis as a prophylactic therapy, Barclay and colleagues [189] initiated plasmapheresis during the late second trimester in a woman with anti-SSA/Ro antibodies and a history of four unsuccessful pregnancies, including a 32-week stillbirth with unexplained antenatal bradycardia. The pregnancy resulted in a healthy birth, and the titer of anti-SSA/Ro antibodies was decreased by 75%, although detectable antibodies were present in the cord blood [189]. The author similarly utilized "prophylactic" plasmapheresis in a pregnant woman with SS and a previous child with CHB [185]. In this case the fetus, despite having circulating levels of these antibodies detectable at birth, was exposed to only 10% of the potential maternal antibody load during the second and third trimesters. The child, now 8 years of age, never had any manifestations of NLS. In the absence of controlled studies, which may never be feasible given the rarity of CHB, plasmapheresis should be considered highly experimental and only reserved for those cases where the fetus is in a life-threatening situation with hydrops and deteriorating cardiac function.

The best approach for a mother with a previous offspring with CHB is unknown. It is suggested that all mothers with anti-SSB/La antibodies or antibodies to components of SSA/Ro (particularly the 52-kDa) on immunoblot should have serial fetal echocardiography done by an experienced pediatric cardiologist weekly from 16 to 26 weeks and every other week until about 34 weeks. Thereafter auscultation should be sufficient. Major advances have been made in fetal echocardiography. Until recently, the *in utero* detection of first-degree block was not technically feasible. However, the EKG equivalent of the PR interval can now be measured by echocardiography [190]. A prospective NIH-supported multicenter study, PR Interval and Dexamethasone Evaluation (PRIDE), in CHB is underway to examine the mechanical PR interval weekly in pregnant woman with anti-SSA/Ro and/or anti-SSB/La antibodies. One of the goals of this trial is to identify the prevalence of first-degree block and to determine whether it is a marker for more advanced destruction of the conducting system. Such information will provide the optimal opportunity for reversibility. It

is strongly recommended that all neonates born to mothers with anti-SSA/Ro-SSB/La antibodies have an EKG at birth to detect first-degree block.

Breast Feeding

Mothers often ask about the risks of breast feeding. Askanase and colleagues [191] have addressed whether human breast milk contains antibodies to components of the SSA/Ro-SSB/La complex and, if so, whether breast feeding might be associated with the postnatal manifestations of neonatal lupus. To accomplish these goals, breast milk from nine mothers with serologic evidence of anti-SSA/Ro and/or SSB/La antibodies was examined by ELISA and immunoblot for the presence of these same antibodies. Five of these breast-fed infants were healthy without any manifestations of neonatal lupus, one had an isolated cardiomyopathy and died, two had cutaneous manifestations of neonatal lupus, and one had both CHB and rash. IgA and IgG antibodies to all components of the SSA/Ro-SSB/La complex were present in breast milk. Not unexpectedly, the antibody profiles of the breast milk paralleled those observed in the serum.

Of 237 mothers enrolled in the registry as of September 2000, 129 mothers answered a questionnaire regarding breast feeding of their 266 children. Neonatal lupus was present in 149 of the children (55 with a skin rash alone, 72 with CHB alone, and 22 with both manifestations) and 117 were unaffected. The frequency of breast feeding in the mothers enrolled in the Research Registry for Neonatal Lupus was slightly lower (51%) than the national average (60%) of mothers breast feeding upon leaving the hospital [192]. This might be explained by the fact that mothers with anti-SSA/Ro-SSB/La antibodies are discouraged from breast feeding by their physicians or, in some cases, may be too ill or on other medications. Overall, a total of 136 children (51%) were breast fed. Of 55 children with neonatal skin rash, 33 were breast fed. Of 22 with both rash and CHB, 12 were breast fed. For the unaffected siblings, 60 of 117 were breast fed. Fisher's exact test revealed no significant differences between breast-fed and nonbreast-fed children with isolated skin rash, or those with rash and CHB, compared to unaffected children. Although there was a trend for the children who were breast fed to have cutaneous manifestation of neonatal lupus appear at a later age than those who had rashes and were formula fed, the difference in mean age of presentation of the rash did not reach statistical significance: 9.69 weeks vs 7.55 weeks (P = NS). The duration of the rash was not influenced by breast feeding: 14.7 weeks in the breast-fed group vs 19 weeks in those not breast fed (P = NS). Not unexpectedly, of 72 children with isolated CHB, 31 were breast fed, which did not differ significantly from unaffected children. Of 7 infants in whom cardiomyopathy was detected after birth, 4 were breast fed.

Accordingly, available data do not suggest that breast feeding has pathologic consequences. Specifically, children with skin rashes were not breast fed more frequently than those who remained healthy. Furthermore, prematurity was not a factor contributing to the development of skin rash in breast-fed infants. There was a trend toward later presentation of the rash in the children who were breast fed but there was no increase in duration compared to children who received formula. Because maternal antibodies transferred to the fetus during gestation would still be present for several months postpartum, the additional contribution of antibodies from breast milk may be inconsequential even if intestinal transport is effective. Mothers should be advised that autoantibodies are present in their breast milk but reassured that, at least within the limits of published literature, breast feeding is not associated with neonatal lupus. However, given the potential for intestinal transport of the maternal antibodies in the unusual circumstance of a worsening skin rash or developing cardiomyopathy, consideration should be given to the discontinuation of breast feeding.

Treatment of Cutaneous Manifestations

Infants with CHB should be protected from excessive sun exposure, as they are at risk for developing skin lesions until 8–12 months of age. In the absence of precise information regarding specific pathogenicity of the maternal antibody response, it is reasonable to consider all offspring of mothers with antibodies to components of the SSA/Ro-SSB/La ribonucleoproteins at risk for cutaneous disease in the first few months of postnatal life. Topical steroids, preferably those that are nonfluorinated, have been recommended for babies who develop lesions [42]. High-potency topical steroids to the skin of an infant can result in systemic effects. Because the lesions are transient and generally benign, systemic therapies such as antimalarials, which have a low toxic-to-therapeutic ratio in young children, have not been recommended [42].

Neiman and colleagues [45] reported on therapy and outcome of 57 infants (20 males, 37 females) diagnosed with cutaneous NLE (absent heart disease) between 1981 and 1997. Thirty-four (60%) were treated. Thirty-one were given only low to medium potency topical corticosteroid preparations. Three children were initially given topical antifungal agents and then treated subsequently with topical steroid preparations. None received systemic glucocorticoid therapy. The active

rash resolved in all children regardless of treatment. In 51 children for whom reliable follow-up data were available, 37 rashes completely resolved without sequelae, of which 21 were treated and 16 received no therapy except avoidance of sun exposure. However, in 14 there were residual skin abnormalities: 10 had telangiectasias, 2 had hyperpigmentation of the affected areas, and 10 had what was described as pitting, scarring, or atrophy after at least 2 years of follow-up. Of these 14 children, 10 were treated and 4 were untreated. Although there was no significant difference in outcome between treated and untreated children by Fisher's exact test, firm conclusions are limited by the small number of cases.

Recurrence Rates

In the research registry as of June 2003, 91 mothers have had pregnancies (lasting longer than 6 months) subsequent to the birth of child with CHB (Table 4). In 65 (71%) of these pregnancies there were no AV conduction abnormalities or reported cutaneous manifestations of NLS in the children. Seventeen (19%) next pregnancies resulted in a second child with CHB, 3 in association with a skin rash. It is of note that in one of these families the first child had first-degree block detected at age 10 and the second child had CHB detected *in utero*. In 7 (8%) next pregnancies, the offspring had cutaneous manifestations alone. Thus, the probability of having a second affected child with any manifestation of NLS was 25%. One subsequent pregnancy ended at 30 weeks, but the fetus was not known to have any conduction abnormalities. Another subsequent pregnancy resulted in the birth of a boy who died at age 2 months. While there were no documented conduction abnormalities, he had severe aortic stenosis and cardiomyopathy, which on biopsy was found to be associated with immunoglobulin deposition [30].

TABLE 4 Outcome of 83 Pregnancies Immediately Subsequent to the Birth of a Child with CHB

Outcome	*N*	%
Healthy	65	71
Manifestations of NLS		
CHB only	14	13
CHB and rash	3	4
Rash only	7	8
Fetal demise	1	2
Neonatal death[a]	1	2

[a] Aortic stenosis and severe cardiomyopathy.

It is also important for the clinician to consider the outcomes of pregnancies subsequent to the birth of a child with NLS rash. Among registry mothers, as of June 2003, there have been 33 pregnancies (lasting longer than 6 months) following the birth of a child with NLS rash (Table 5). In 13 (39%) of the offspring, there were no cardiac or cutaneous manifestations of NLS; 12 (36%) had NLS rash alone. It is striking that 8 (24%) next pregnancies resulted in a child with CHB, 5 in association with rash.

FETAL OUTCOME

Data published from the research registry revealed that 22 (19%) of the 113 offspring with CHB whose mothers were documented to have anti-SSA/Ro and/or SSB/La antibodies have died (12 boys, 10 girls), as illustrated in Fig. 11. Six of these deaths occurred *in utero.* Ten neonates died in the first 3 months of life. Six children died between 3 months and 3 years of age. None of the 67 children between 3 and 10 years old remaining in the cohort have died. Twenty-two children are older than 10 years. However, the mortality is reduced markedly in those children born at later gestational ages. Specifically, only 8 (9%) of 86 children born at or after 34 weeks have died [39]. Those infants who survive the neonatal period have an excellent prognosis. The cumulative probability of survival at 3 years is 79%.

With regard to the morbidity of CHB, 67 (63%) of the 107 children born alive have required pacemakers, 35 within the first 9 days of life. Fifteen additional children have been paced in the first year and 17 after 1 year. One infant has had a cardiac transplant at 8 months of age because of intractable cardiomyopathy. Moak *et al.* [193] underscored the need to recognize late-onset cardiomyopathy as a sequela of CHB with their report of 16 cases that developed despite adequate pacing.

In a study of 15 CHB patients followed by Silverman *et al.* [14] there were 3 neonatal deaths, 2 late deaths due

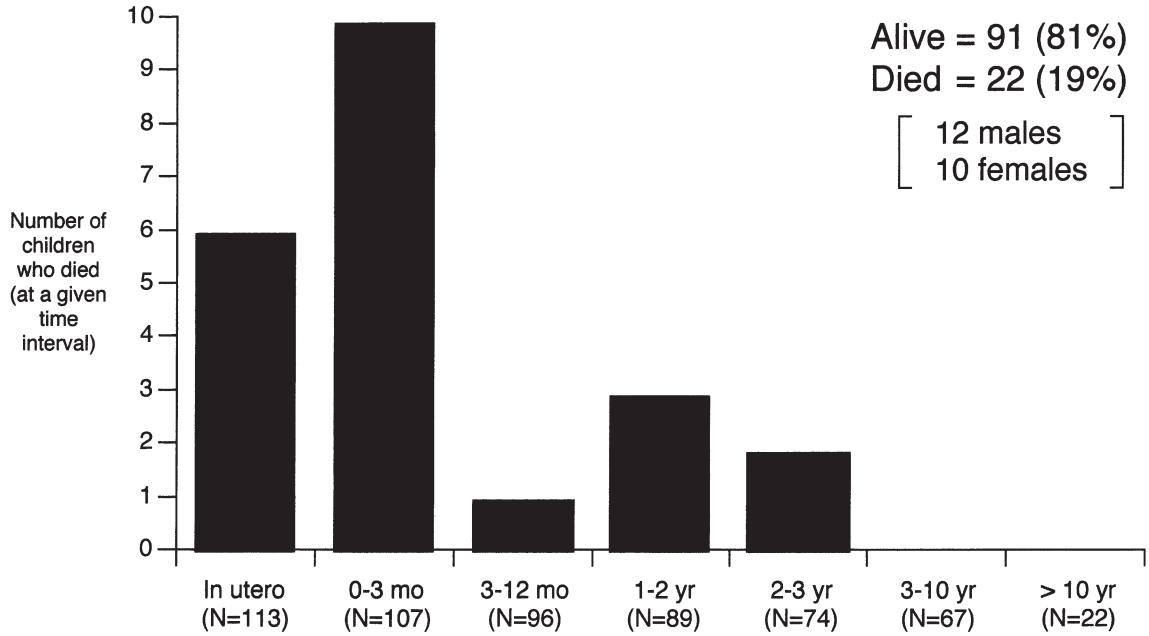

FIGURE 11 Mortality of CHB at different ages. Along the horizontal axis, N is the number of children in this cohort alive at the age specified (0–3 months indicates children up to and including age 3 months, 3–12 months indicates children older than 3 months up to and including age 12 months, etc.)

to pacemaker failure, and 6 who have required pacemaker therapy. Similarly, McCune *et al.* [177] reported a follow-up of 14 neonates with CHB of whom 5 required pacemakers.

Long-Term Follow-up of Children with Varied Manifestations of NLS

Given the rarity of the disease, little information is available on the health outcome of children with neonatal lupus and their unaffected siblings. This is of interest from several perspectives. There is a genetic susceptibility for the development of SLE [194–198], and relatives of SLE patients can have autoantibodies in the absence of clinical disease [199]. Perhaps in addition to autoantibodies, the expression of SLE in the mother increases the risk of autoimmune disease in her offspring independent of whether the child has neonatal lupus or not. This generates the hypothesis that children with neonatal lupus, as well as their unaffected siblings, whose mothers have SLE might be at greater risk for the development of subsequent disease than children whose mothers are asymptomatic. Perhaps vulnerability to neonatal lupus is a marker for susceptibility to, or protection from, the development of actively acquired autoimmunity.

Martin and colleagues [200] reported on the health of children 8 years of age or older who had manifestations of neonatal lupus (affected group) and their unaffected siblings (unaffected group). Questionnaires were sent to mothers (with anti-SSA/Ro-SSB/La antibodies) enrolled in the research registry and to a control group comprising children of healthy mothers referred by the registry enrollees. Responses to the questionnaires were confirmed and expanded by a review of medical records. Fifty-five mothers enrolled in the registry returned questionnaires on 49 children with neonatal lupus and their 45 unaffected siblings. Six children were identified with definite rheumatologic/autoimmune diseases: 2 with juvenile rheumatoid arthritis, 1 with Hashimoto's thyroiditis, 1 with psoriasis and iritis, 1 with diabetes mellitus and psoriasis, and 1 with congenital hypothyroidism and nephrotic syndrome. All had manifestations of neonatal lupus and their mothers have manifestations of autoimmune diseases: 4 SS, 1 SLE/SS, and 1 UAS. In 4 of 55 sera tested, the ANA was positive (2 of 33 affected children and 2 of 22 unaffected children). No serum contained antibodies reactive with SSA/Ro or SSB/La antigens. These data suggest that children with neonatal lupus require continued follow-up, especially prior to adolescence and if the mother herself has an autoimmune disease. While there was no apparent increased risk of SLE, the development of some form of autoimmune disease (systemic or organ specific) in early childhood may be of concern. During adolescence and young adulthood, individuals with

neonatal lupus and their unaffected siblings do not appear to have an increased risk of developing systemic rheumatic diseases.

In one small series, Brucato *et al*. [164] found that at a mean follow-up of 18 years none of 13 children with CHB developed clinical symptoms or serological abnormalities suggesting immune disease.

Despite these encouraging results, there have been seven cases published in which an autoimmune disease developed in a child with manifestations of neonatal lupus. All the children were female and in each instance except one the mother had SLE. Specifically, Esscher and Scott [201] reported a female with CHB who developed SLE at age 15 years. Jackson and Gulliver [202] reported an infant with cutaneous neonatal lupus who developed SLE at age 13, and Fox *et al.* [203] described a similar patient who developed SLE at age 19 years. In a patient described by Waterworth [204], CHB was identified at age 6 years and SLE diagnosed at age 13 years; no information was provided on the mother. Lanham *et al*. [205] reported two children with CHB; one subsequently developed primary SS at age 23 years and the other arthritis, positive ANA, and antibodies to dsDNA at age 19 years. Hübscher *et al.* [206] reported the development of scleroderma of the face, puffy hands, and Raynaud's phenomenon in a 13-year-old girl with CHB. At age 15 she was found to be seropositive for anti-SSA/Ro and U1 RNP. It should be emphasized that maternal anti-SSA/Ro-SSB/La antibodies were not actually documented for any of these mothers.

CONCLUSIONS

The presence of antibodies reactive with several components of the SSA/Ro-SSB/La ribonucleoprotein particle, notably the 48-kDa SSB/La and the 52-kDa SSA/Ro antigens by immunoblot, is to date a near-universal characteristic of all mothers giving birth to offspring with NLS. Although NLS is rare, its discussion is an integral part of all pregnancy counseling of women with SLE, SS, and undifferentiated autoimmune syndromes. Overall, studies suggest that there is an unacceptable morbidity and mortality. A major clue to defining the pathogenesis of antibody-mediated damage is the selective vulnerability of the fetal heart. Vulnerability could relate to a direct or indirect antigen target expressed differentially in the developing human heart. Alternatively, but not mutually exclusively, biologic events operative during fetal life, such as apoptosis, could facilitate accessibility of intracellular antigens to the extracellular environment. Opsonization of apoptotic cardiocytes might alter the normal events of cell removal by macrophages. Inadvertent activation of the macrophage and subsequent dysregulation of the fibroblast may lead to permanent injury. Perturbation of L-type calcium channels, which propagate the action potential in the AV node, provides a clue to a definable pathogenetic effect of anti-SSA/Ro antibodies. How apoptosis and calcium channel dysfunction relate, if at all, is not intuitive; there may be more than one mechanism involved in pathogenesis. A reproducible murine model of CHB would be a critical tool to define antibody pathogenicity at the histologic and molecular levels with subsequent application for testing prophylactic and therapeutic interventions. The availability of a research registry devoted to NLS should provide an invaluable resource for basic and clinical research. The reporting of recurrence rates, mortality and morbidity, and maternal outcomes in a large number of patients has facilitated family counseling greatly. We eagerly await the results of the PRIDE study in the hope that with more detailed echocardiographic data, risk can be better defined and reversibility of early injury a reality.

Acknowledgments

The work reported herein has been supported in part by NIH/NIAMS Contract NO1-AR-4-2220 (Research Registry for Neonatal Lupus), NIH Grant RO1 AR42455, the S.L.E. Foundation, Inc., and the American Heart Association New York chapter. The author thanks Ann Rupel for her continued labor of love in preparation of the manuscript, Peg Katholi for tireless work for the registry, and the Lee and Driscoll families for their generous support.

SYSTEMIC LUPUS ERYTHEMATOSUS IN CHILDHOOD

Paul J. DeMarco
Ilona S. Szer

INCIDENCE

Approximately 25% of all cases of systemic lupus erythematosus (SLE) begin in the first two decades of life [1] but the disease is extraordinarily rare in children under the age of 5. Of 108 patients who developed the disease before the age of 18, 6 became ill before their 5th birthday [2] and of 23 children who had onset prior to their 10th birthday, only 3 were less than 5 years old [3]. After the age of 5, the incidence of the disease increases progressively through adolescence. The average annual incidence rate of SLE in individuals under the age of 24 is 5 in 100,000 compared to the annual rate of 0.53 in children under the age of 14 [4–6]. In the first decade of life, the ratio of girls to boys with SLE is 3:1, increasing to 6:1 in adolescence.

Family studies reveal that relatives of children with SLE exhibit the disease more frequently than family members of adults with SLE. Seventeen percent of children have an affected first-degree relative and 27% of children have an affected first- or second-degree relative [2]. Moreover, 33% of the parents and 39% of the sisters of pediatric patients have positive antinuclear antibodies, specifically antihistone antibodies [7]. Those sisters are also found to have activation of the complement system and may be the relatives at highest risk for the later development of SLE [8–10]. In addition, familial occurrence of increased peripheral blood B cells actively secreting immunoglobulins has been observed [11]. These data suggest that the genetic determinants involved in influencing susceptibility to SLE are more pronounced in childhood-onset disease.

A concordance of 57–69% is reported for identical twins [12–15]. The second twin generally develops the disease within a mean of 3.6 years after the first [15]. Similarly, siblings with SLE are more likely to develop their disease within a few calendar years of each other than they are to develop their disease at approximately the same chronological age [16]. The mean interval in years between the onset of disease in siblings is about the same as that interval in identical twins.

Observations for an underlying etiology for juvenile SLE continue to suggest a complex interaction of a genetically predisposed individual under specific circumstances. Some infectious vectors described in children include Epstein–Barr virus [17] and parvovirus [18]. Children with SLE have a higher seroconversion rate for Epstein–Barr virus than age-matched controls; these same autoantibodies demonstrated cross-reactivity with elements of the viral particle. Reports of parvovirus infection in children reveal induction of antinuclear antibodies (ANA) as well as induction of other autoantibodies, including Sm, RNP, Ro, and La. This report suggests a prolonged lupus-like illness without persistence of symptoms of SLE.

MANIFESTATIONS OF CHILDHOOD SLE

The classification criteria established for SLE have been applied successfully to children. The overall clinical manifestations of SLE occurring in children resemble those in adults (Table 1), although involvement of the reticuloendothelial system has appeared

more prominent in children [2, 19–34]. The most recent reevaluations of the differences between adults and children have varying information regarding which clinical manifestations are more likely to be seen in children; however, these recent reports seem to support a much earlier notion that juvenile SLE is more severe than its adult counterpart. Although a study by Manthorpe *et al.* [35] demonstrated a high prevalence of lupus nephritis of 82% in children <11 years versus 53% in adults, two earlier studies reported a similar prevalence in adults and children [19, 36]. Tucker *et al.* [30] reported a statistically significant incidence of hematologic manifestations and double-stranded (ds)DNA as well as a greater prednisone requirement. The greater number of renal manifestations, 27% children versus 17% adults, was not statistically significant. Font *et al.* [31] reported nephropathy to be statistically more common, 20% versus 9% in adults, as well as fever and lymphadenopathy. Rood *et al.* [32] reported arthritis, anemia, and seizures to be the most frequent manifestations, which the author accounted for the 2.6–3.9 times higher chance of more severe disease. Double-stranded DNA was also more common in children than adults in this population, 93% in children versus 63% in adults [32]. Finally, although finding no difference in immunologic markers, Carreno *et al.* [33] found more frequent vasculitis (44% vs 27%), seizures (18% vs 7.6%), and nephropathy (67% vs 48%) in juvenile versus adult SLE. When taken together, these observations seem to suggest the notion from the 1960s that childhood SLE is more severe than adult SLE, specifically regarding hematologic, renal, and possibly neurologic manifestations of the disease.

Mode of Onset

Arthritis, fever, and rash are the three most common presenting complaints, followed by general systemic symptoms of anorexia, weight loss, fatigue, weakness, and malaise. Perhaps because of this mode of onset, half of the patients described by Meislin and Rothfield [19] in the late 1960s had initially been diagnosed as having diseases other than SLE, including acute rheumatic fever, juvenile rheumatoid arthritis (JRA), discoid lupus, sickle cell anemia, idiopathic thrombocytopenic purpura, and Hodgkin's disease. Similarly, initial diagnoses summarized by Deare *et al*. [28], whose patients were studied between 1947 and 1958, included acute glomerulonephritis, hemolytic anemia, leukemia, allergic rash, epilepsy, infectious mononucleosis, rubella, acute rheumatic fever, and septic arthritis. Only 3 of the 15 children in this ancient series received the diagnosis of SLE at the initial evaluation; the lag in diagnosis averaged 10 months.

Early diagnosis has been aided greatly by laboratory tests for ANA, serum complement and anti-DNA antibodies, the relative infrequency of acute rheumatic fever in modern clinical practice, and increased awareness among pediatricians that SLE occurs in children. Conversely, physicians must interpret a positive ANA in an adolescent female with probable intercurrent illness cautiously because the majority of such patients fulfill fewer than four classification criteria and do not develop SLE [29].

Clinical Manifestations

Fever

The most common presenting sign is fever, which occurs in 70–100% of patients. It is usually insidious and low grade, reaching 102°F daily and returning to normal. High spiking fevers of 104°F have also been reported, with a pattern similar to that observed in systemic onset JRA [30].

Arthritis

Arthritis in childhood SLE is manifested as pain, stiffness, or swelling of the joints and may be difficult to distinguish from other causes of synovitis in children (Table 2). Every series of children with SLE includes some patients whose prominent joint involvement made the clinical picture indistinguishable from that of polyarticular juvenile rheumatoid arthritis, either before other manifestations of SLE became apparent or before laboratory studies established the diagnosis of SLE [30]. The presence of rheumatoid factor in a child with arthritis is more common in SLE than in JRA and can be a source of confusion for the clinician. Unlike JRA, particularly when it is associated with the rheumatoid factor, arthritis in SLE rarely causes significant cartilage destruction, bony erosion, premature epiphyseal fusion, or growth disturbance. When deformities such as swan neck or ulnar deviation of the phalanges are seen, they are usually due to periarticular inflammation and are readily reducible. Intrinsic muscle atrophy may decrease grip strength and affect hand function adversely. Joint aspiration usually reveals a paucicellular fluid with low levels of protein and complement. A distinctive deformity of the hands has been reported in both adults and children with SLE. These hand deformities, described elsewhere in the text, have the eponym of Jaccoud's arthritis and were initially thought to represent chronic rheumatic fever [35]. The association of Jaccoud's deformity and increased occurrence of antibodies to UI RNP has been made [36].

Weight Loss and Anorexia

Weight loss and anorexia have been reported in 35% of patients. Usually weight loss does not exceed 10% of total body weight. Although uncommon, some children may present in an emaciated state, having lost 25–30% of their body mass [30].

Skin Disease

The typical macular or papular erythematous eruption in a butterfly distribution that extends across the bridge of the nose but spares the nasolabial folds is seen in about 50% of children. Crusted scaling lesions that cover the face, neck, upper torso, and arms as well as facial and truncal discoid lesions are also frequent. Nodular, vesicular, and even bullous lesions may occur on the face and extremities in addition to the more common fixed red macular eruptions. Some children have only an erythematous blush or palmar erythema. Subungual hemorrhages and vasculitis are characteristic. These lesions are prone to breakdown and suppuration, cause considerable local problems, and lead to systemic infection [2]. These have been associated frequently with Raynaud's syndrome.

Some children have petechial or purpuric lesions unrelated to thrombocytopenia or trauma, which suggest cutaneous vasculitis. Diffuse hyperpigmentation may appear at sites of previous skin lesions, especially in black children, whereas discoid lesions may resolve with scarring and depigmentation. Sometimes the skin lesions ulcerate and crust. Ulcerated, infarcted lesions are frequent on the hands, especially on the palms. Subcutaneous nodules caused by panniculitis are seen, and nodules that superficially resemble those seen in indi-

TABLE 2 Differential Diagnosis of Childhood Arthritis[a]

- Acute rheumatic conditions
  - Acute rheumatic fever
  - Henoch–Schonlein purpura
  - Kawasaki disease (mucocutaneous lymph node syndrome)
  - Serum sickness and drug reactions
  - Mucha–Haberman disease
  - Sweet's syndrome
- Chronic rheumatic conditions
  - Juvenile chronic polyarthritis
  - Juvenile chronic pauciarthritis
  - Juvenile spondyloarthritis
  - Systemic lupus erythematosus
  - Dermatomyositis/polymyositis
  - Vasculitis
  - Progressive systemic sclerosis
  - Mixed connective tissue disease
  - Neonatal onset lupus
  - Juvenile multisystem disease
- Infectious arthritis
  - Gonnococcal arthritis–dermatitis–tenosynovitis syndrome
  - Bacterial arthritis
  - Syphilis
  - Mycobacterial arthritis
  - Viral arthritis
  - Arthropod-borne arthritis (Rocky Mountain spotted fever, Lyme disease)
  - Acute osteomyelitis with joint effusion
- Inflammatory disorders
  - Inflammatory bowel disease with arthritis
  - Familial Mediterranian fever
  - Relapsing polychondritis
  - Cortical hyperostosis (Caffey's disease) and idiopathic hyperostosis (Goldbloom's syndrome)
  - Sarcoid arthritis
- Hypertrophic osteoarthropathy
  - Secondary to pulmonary, cardiovascular, gastrointestinal or endocrine disorders and neoplasms
  - Cystic fibrosis
  - Biliary atresia
  - Primary hypertrophic osteoarthropathy
- Traumatic arthritis
  - Acute chondrolysis of the hip
  - Child abuse
  - Congenital indifference to pain
  - Frostbite
  - Foreign body synovitis (rose thorn, palm frond)
- Degenerative disorders
  - Avascular necrosis of bone
  - Chrondromalacia patella
  - Osteochondritis dessicans
  - Slipped capital femoral epiphysis
- Metabolic diseases
  - Diabetic cheiroarthropathy
  - Abnormalities of amino acid metabolism (alkaptonuria, homocystinuria, sulfite oxidase deficiency)
  - Abnormalities of lipid metabolism (familial hyperlipoproteinemia, Fabry's disease, Gaucher's disease, Farber's disease)
  - Endocrinopathies (Cushing's syndrome, Addison's disease, thyroid disease, myxedema)
  - Purine/pyrimidine metabolism (gout, Lesh–Nyhan's disease)
  - Heavy metal poisoning
  - Hemochromatosis
  - Hematologic disease (hemogloblinopathies, hemophilia, deficiencies of white cell killing ability)
  - Bone metabolism (rickets, dysplasia, hyperparathyroidism, vitamin A and D poisoning, fluorosis)
- Heritable disorders with joint laxity
  - Marfan's syndrome
  - Ehler–Danlos syndrome
  - Benign hypermobility syndrome
- Neoplasms
  - Benign tumors of bone and cartilage (osteiod osteoma, hemangioma, villonodular synovitis)
  - Malignant tumors of bone (synovial sarcoma, epithelioid sarcoma)
  - Hodgkin's and non-Hodgkin's lymphoma
  - Neuroblastoma
- Immunodeficiency syndromes
  - Selective IgA deficiency
  - Agammaglobulinemia and hypogammaglobulinemia
  - Complement component deficiencies
- Psychiatric disorders
  - Psychogenic rheumatism
  - Reflex sympathetic dystrophy
  - Munchausem's syndrome and factitious fever

[a] Modified from Jacobs [29], with permission.

viduals with rheumatoid arthritis have been described as well. An erythematous blush may be observed on the palms regardless of disease activity. Erythematosus or bullous lesions of mucocutanous areas were present at initial evaluation in 21% of children reported by King *et al.* [2] and 10% of those reported by Jacobs [29]. These shallow ulcers occur on the buccal mucosa, lips, gums, and palate and may be found on the vulva. In some instances the lesions are painless, although patients usually complain of mouth pain or a "sore throat." Both rash and oral lesions reappear from time to time with increased activity of the disease. The skin rash is reportedly photosensitive in about 40% of white females and less often in other patients. In some cases, sun exposure exacerbates or initiates systemic disease. The majority of patients, however, do not exhibit overt cutaneous sun sensitivity. Livedo reticularis is another frequently observed skin manifestation, recently linked to anticardiolipin antibodies in patients with both SLE and the antiphospholipid syndrome [37].

Alopecia

Hair loss as a presenting complaint can be elicited in the history of most children with SLE. Total alopecia does not occur. In many instances the most notable feature is simply a noticeable increase of hair on the pillow after a night's sleep. In addition to generalized hair thinning or patchy loss, the texture of the hair may become altered. Hairs just above the forehead are brittle and prone to breaking off, leaving short "frizzy" hairs at the hairline.

Myalgia

Myalgia is a common manifestation of childhood SLE. Occasionally frank myositis with evident weakness due to muscle inflammation and necrosis with serum enzyme elevation is encountered. Some children with severe myositis who exhibit criteria of mixed connective tissue disease probably represent a subset of SLE; they are discussed later in the section on mixed connective tissue disease (MCTD).

Raynaud's Phenomenon

Raynaud's phenomenon is present in a significant number of children with SLE but its absence does not exclude the diagnosis of the illness. Raynaud's phenomenon may precede the onset of other symptoms of SLE by many years, but it should be emphasized that in children, as in adults, there are many causes of Raynaud's phenomenon and most patients with isolated Raynaud's phenomenon may never develop SLE or any other rheumatic disease [38, 39]. Of 27 children with Raynaud's phenomenon with and without associated symptoms referred to the Pediatric Rheumatology clinic, 14 (52%) had a connective tissue disease, 4 (15%) had a probable rheumatic illness, and 9 (33%) had no underlying disease [40]. Circulating ANA and an abnormal nail-fold capillary pattern correlated strongly with secondary Raynaud's. In our clinics we evaluate children with isolated Raynaud's phenomenon with no serologic abnormalities only if new symptoms appear (Table 3).

TABLE 3 Evaluation of Children with Raynaud's Phenomenon

CBC, differential, ESR	History: systemic symptoms, pain, numbness, drug exposure, sicca symptoms, muscle weakness

Hematologic Manifestations

Hematologic abnormalities in children with SLE are frequent and reported to have increased prevalence in pediatric SLE; 38% of pediatric patients versus 16% of adults developed hemolytic anemia and/or thrombocytopenia (<100,000 plts/liter) by 2 years [30]. The leukocyte count in approximately 60% of the patients is reduced below 5000 cells/mm^3; in one series [28], 90% of patients had leukopenia. Leukopenia in lupus is due to lymphopenia and can be differentiated from virally induced leukopenia, which is usually associated with a lymphocytosis. Circulating antilymphocyte antibodies have been documented in 30% of patients [9]. Autoimmune thrombocytopenia occurs in less than 10% of pediatric patients and may be the presenting complaint [41]. Up to 75% of children have a hemoglobin level of <10 g/100 ml [28]. The etiology of the anemia is diverse and may include general causes such as chronic illness, blood loss, nutritional deficiencies, malabsorption, or bone marrow suppression. Hemolysis, classically due to antierythrocyte antibodies manifested as a direct Coombs-positive state, is common and may require folate supplementation.

Thrombotic thrombocytopenic purpura (TTP) in childhood bears a dramatic resemblance to systemic lupus erythematosus. In one retrospective chart and literature review, 9 of 35 (26%) patients diagnosed with TTP fulfilled criteria for SLE and 8 of 35 (23%) were diagnosed with SLE after clinical follow-up [42]. Proteinuria was significantly associated with the development of coexistence of SLE. This stands in contrast to the adult experience. An additional case report of the hemolytic uremic syndrome presenting with juvenile SLE seems supportive of this observation [43].

Elevation of factor VIII-related antigen (FVIIIRAg) has been documented in children with SLE, as well as in children with other rheumatic diseases associated with vasculitis [44]. It is speculated that a high level of circulating FVIIIRAg reflects the presence of vascular endothelial injury and may correlate with increased disease activity.

Lymphadenopathy

Twenty-five to 70% of children develop lymphadenopathy at some time during the course of the illness and 40% have diffuse glandular enlargement at initial evaluation. The classic cases of SLE in young women with striking cervical adenopathy reported by Klemperer *et al*. [45] illustrate this aspect of SLE in the pediatric age group. Biopsy of lymph nodes reveals reactive adenopathy, sometimes with vasculitis. Edema, sinus hyperplasia, and occasionally necrosis with hematoxyllin bodies are found [46]. A disproportionately elevated LDH with fever and adenopathy, usually posterior cervical, should raise the suspicion of necrotizing histiocytic lymphadenitis (NHL), or Kikuchi–Fujimoto disease. Although most patients with Kikuchi syndrome have a self-limiting illness, NHL may complicate SLE and MCTD, as well as herald a life-threatening flare of SLE [47–49] (unpublished observation).

The presence of lymphadenopathy in a young patient with constitutional symptoms raises the possibility of lymphoma and leukemia. While both Hodgkin's lymphoma and acute leukemia have been reported to coexist with or mimic childhood SLE [50–52], this is distinctly uncommon, and in the vast majority of children with lupus, adenopathy represents an integral component of the illness. Of note, children who present with lymphadenopathy often have it again during subsequent flares. A biopsy should be discouraged if there is reasonable likelihood of the diagnosis of SLE because this group of patients frequently requires high-dose prednisone therapy, and notable problems may be encountered with wound healing and infection.

Splenomegaly

Enlargement of the spleen occurs in 25–30% of children with SLE at initial evaluation. The incidence is lower in the older series perhaps because the diagnosis of idiopathic thrombocytopenic purpura or Evan's syndrome excluded SLE. Pathologic findings are the same as in adults and are discussed in Chapter 36. Functional asplenia has been reported in children and represents a potentially serious complication predisposing the patient to overwhelming pneumococcal sepsis [53].

Hepatomegaly

In most series, hepatomegaly is noted at the time of presentation in 25–40% of patients and represents another relatively unique aspect of childhood SLE. Sixty-nine percent of patients described by Meislin and Rothfield [19] had hepatomegaly. Minor abnormalities of liver function are very common, noted in 90% of Cook's patients [54], but clinical jaundice is rare. The absence of significant liver chemistry abnormalities distinguishes SLE from chronic active hepatitis and the special subset of chronic hepatitis affecting young women described by Baehr *et al*. [55] that is associated with arthritis, hypergammaglobulinemia, and striking levels of autoantibodies. Very rarely, both illnesses have been reported to coexist [56].

Gastrointestinal Manifestations

Gastrointestinal manifestations are present in 25–40% of patients; abdominal pain and diarrhea are the most common initial signs. Painful intercurrent abdominal crises may occur frequently in the course of childhood SLE and have diverse causes that are of varying importance. Serositis, vasculitis, pancreatitis, splenic infarcts, lymphadenitis, and peritonitis represent the mechanisms for these episodes [57] and require differentiation from acute appendicitis; "atypical pain," normal bowel sounds, and lack of white blood cell elevation suggest that surgery is not required. Vasculitis of the mesentery and bowel wall may progress to hemorrhage, infarction, and frank perforation with secondary peritonitis [54, 58, 59]. Pancreatitis may be either a presenting sign of SLE [60] or a complication of prednisone therapy [61]. Acute pancreatitis of SLE may rarely be associated with the acute respiratory distress syndrome resembling hyaline membrane disease [61]. Retroperitoneal fibrosis [62], ascites [63], concomitant ulcerative colitis [64], and protein-losing enteropathy [65–67] have all been reported as unusual presenting manifestations of childhood SLE.

Renal Manifestations

Renal involvement can be documented in about 70% of pediatric patients or in as many as 90% reported by Cook *et al*. [54]. Although the older literature associates more severe renal disease with childhood compared with adult-onset SLE [19], studies of children continue to vary in their assessment of this feature of the disease [31–34, 68–70]. Our experience suggests that approximately 50% of children have evidence of renal involvement at the time of diagnosis based on urinalysis and assessment of renal function. Acute renal failure as an isolated initial manifestation of SLE [71], distal renal tubular acidosis preceding lupus glomerulonephritis [72], and nephrotic syndrome preceding SLE [73] are exceedingly rare but have been reported in children. Routine urinalysis should be examined carefully for the presence of red blood cells, white blood cells, cellular casts, and oval fat bodies; the latter suggests the pres-

ence of the nephrotic syndrome. A helpful, early manifestation of renal pathology is the presence of white cells in the urine in the absence of infection [30]. Consideration should be given to the presence of chronic interstitial cystitis as a manifestation of active SLE in the assessment of hematuria [74, 75].

Proteinuria should be quantitated in grams excreted over a 24-h period. This is especially important in children because orthostatic proteinuria is common among pediatric patients [76]. Accurate 24-h collections are understandably difficult for a young patient when it interferes with the school day. In lieu of the 24-h collection analyzed every 6 months for total protein, the spot urine creatinine to protein ratio can be used [77].

Elevation of serum creatinine is a relatively late sign and not useful as an early predictor of outcome. An accurately determined creatinine clearance, however, can be used as a sensitive therapeutic indicator. Decreases in creatinine clearance suggest the need for more vigorous treatment when other guidelines of disease activity are equivocal.

A sudden onset of massive proteinuria in a child with SLE requires an evaluation for renal vein thrombosis [78–80]. Because proteinuria due to renal vein thrombosis does not respond to either steroid or cytotoxic therapy, the physician must distinguish between increased proteinuria as a consequence of renal vein thrombosis and increased proteinuria as a sign of advancing renal disease. Duplex Doppler ultrasound examination may reveal the presence of renal vein thrombosis. If thrombosis is demonstrated, treatment with anticoagulants should be initiated [79].

Evaluation of a child with SLE must include a blood pressure determination during each visit. Elevated blood pressure suggests either vasculitis or diffuse proliferative glomerulonephritis. Hypertension as a presenting sign of childhood SLE is rare but develops in 40–60% of children during the course of the illness [54, 81]. Seizures may be the presenting symptom in children who have developed renal insufficiency or failure and present with hypertensive encephalopathy. In one study, African-American children, particularly boys, had significantly more hypertension than Caucasian patients [81]. The same authors found that chronic renal failure or end-stage renal disease developed more frequently in hypertensive children than those without hypertension, suggesting that early renal involvement with hypertension may be predictive of later renal failure. In addition to improving renal outcome [81, 82], control of hypertension decreases the risk of hypertensive encephalopathy (more common in children than adults), strokes, and premature coronary artery disease.

The frequency of the occurrence of histologic subtypes in children with lupus nephritis is difficult to report. Diffuse proliferative glomerulonephritis is reported in 40–70% of children, possibly due to selection of the most severely affected children. The second most common subtype is focal glomerulonephritis, found in 10–20% of individuals; membranous disease occurs in 5–10% of patients [68]. Baqi *et al*. [83] performed a comprehensive evaluation by biopsy of all children with lupus nephritis to show 42.9% WHO IV, 21.4% WHO III, 19.6% WHO IIB, 5.4% WHO IIA, 3.6% WHO V, and 1.8% WHO I. Although pathologic descriptions may not be useful for predicting transformation or progression of one lesion into another [84, 85], the grading of morphologic changes according to indices of activity and chronicity is considered a sensitive predictor of renal outcome [83, 86–88], particularly in conjunction with persistant hypertension [83, 89]. Those patients progressing to end stage renal disease had persistant hypertension, anemia, nephrotic syndrome, and high chronicity indices [89].

Neuropsychiatric Manifestations

Neuropsychiatric manifestations of childhood SLE reportedly occur in 9–60% of patients [1, 2, 68, 90–92]. The mean age of onset of neurologic disease is approximately 13.3–14 years of age [93, 94] with the majority of patients having excellent recovery and response to treatment and a duration of symptoms of less than 3–4 weeks. Severe neuropsychiatric lupus manifestations in children, such as psychosis, vasculitis, optic neuritis, and transverse myelitis, have responded favorably to intravenous methylprednisolone and cyclophosphamide [95]. Central nervous system (CNS) lupus is discussed in Chapter 26. Comments here are limited to special considerations concerning children.

Neuropsychiatric symptoms in any patient with SLE may be caused by the primary illness, the administered steroids, infectious complications, or an emotional stress. The psychologic impact of SLE is particularly great in adolescence when hormonal and physiologic changes reach their peak. Adolescents, concerned with their body image, become anxious and depressed when their bodies are disfigured by disease or treatment [96]. The fear of peer rejection may lead to feelings of isolation and depression, further compounded by the chronicity of the illness and uncertainty about the future [97].

The diagnosis of neuropsychiatric involvement relies heavily on clinical acumen. Although the presence of elevated serum level of ribosomal P protein may help distinguish between SLE-related psychosis and primary psychosis of childhood, it is not a specific finding in patients with SLE [98]. Some observers reported serum antineuronal antibodies at symptom

onset; these antibodies decline with symptom improvement [99]. Single photon emission-computed tomography (SPECT) analysis appears to be a useful tool for the initial assessment of CNS involvement [100–102]. While SPECT identified the initial extent of CNS damage, it failed to correlate with the patients' subsequent clinical improvement during longitudinal follow-up [103, 104].

Headache is a prominent symptom in children with active SLE and a frequent presenting complaint [58]. The headache usually subsides after other disease manifestations become controlled. Brandt and Lessel [105] reported migrainous phenomena in 10% of their patients with SLE. In children with SLE, headache may be a manifestation of hypertensive encephalopathy, intracranial hemorrhage, meningitis, or pseudotumor cerebri [106–108]; rarely, pseudotumor cerebri is an initial presentation of pediatric SLE [109].

Seizures as a presenting manifestation of SLE are rare. Most cases reported as SLE beginning with seizures represent drug-induced lupus in children receiving anticonvulsant therapy for a primary seizure disorder. The observation that these children had milder disease and a better prognosis prompted the study of anticonvulsant drugs as potential inducers of childhood lupus [30, 110]. A detailed discussion of drug-induced lupus may be found in Chapter 44. When a child known to have SLE has a seizure, as seen in 17% of children, bacterial meningitis must first be presumed to be the cause and the diagnosis of CNS lupus may be made only after infection has been excluded [106]. In one case series of 25 children with neurologic symptoms, all but 1 had an established diagnosis of lupus and 7 children had neurologic symptoms when the diagnosis of SLE was established [111].

Chorea is an unusual symptom of SLE [112–126]. Prior to 1985, chorea was encountered in childhood-onset disease much more frequently than in adults with lupus: 53% of all reported cases of chorea-associated with SLE had been in children [113–120]. In one report of 68 children with SLE, 10% had chorea [116]. Chorea can be a diagnostically important initial manifestation of SLE and rarely develops late in the course of the disease [112–115]. Thirteen children have been described in whom chorea was the sole manifestation of lupus [117–126].

Chorea in SLE likely represents another manifestation of the antiphospholipid antibody (aPL) syndrome [115, 127, 128] and may respond best to anticoagulation. A review of chorea and aPL summarized all cases from 1985 to the present [115]; 40% of patients were less than 18 years old. Similarly, of those patients who had SLE, aPL, and chorea, 37% were children. This is a larger proportion than the reported incidence of SLE in the total population (37% versus 25%, respectively). Of note, all of the children with chorea had circulating lupus anticoagulant.

Other neuropsychiatric manifestations of aPL antibodies in juvenile SLE patients include stroke, cerebral ischemic events [128–130], transverse myelitis [131, 132], cerebral vein thrombosis [133], retinopathy [130, 134], and parkinsonism [135].

Pulmonary Manifestations

Pulmonary manifestations occur in up to 60% of children with SLE [30, 136–138]. Like adults (see Chapter 33), children may develop complications related to the underlying illness, such as pneumonitis, pleuritis, pleural effusion, interstitial fibrosis, vasculitis, diaphragmatic muscle dysfunction, and hemorrhage, as well as complications related to therapy or other organ dysfunctions, including uremia, congestive heart failure, thromboembolism, and infection such as pneumocystis carinii [136–141]. In the past, both acute and chronic interstitial lung diseases were considered minor problems in childhood SLE. Currently, with improved survival, several studies of children with SLE who had no clinical evidence of lung involvement documented pulmonary function abnormalities consistent with a restrictive pattern in up to 67% of patients [136–138, 142]. A longitudinal study of pulmonary function tests (PFT) in 15 children with SLE who were asymptomatic for respiratory disease revealed 40% of patients have at least one abnormality, including significant reductions in FVC and diffusing capacity; on serial reevaluation at 6 and 12 months, there was no change and the patients remained asymptomatic [143]. Our experience, based on annual PFT, suggests that at 2–5 years of follow-up less than 20% of children have had abnormalities. We no longer advocate annual PFTs for children with SLE.

Pulmonary hemorrhage has been recognized as a major cause of death for children with SLE [2, 144, 145] often noted at autopsy [146–148]. Ample evidence suggests that in some cases, acute pulmonary hemorrhage is secondary to pneumonitis caused by the deposition of immune complexes and complement in the interstitium of alveolar walls and along the alveolar capillary walls [149–152]. Clinically, the syndrome of pulmonary hemorrhage is characterized by a sudden onset of dyspnea, with hypoxemia, anemia, and bilateral alveolar infiltrates [153, 154]. Hemoptysis is usually present but is not an invariable feature [146, 155]. Pulmonary vasculitis may be distinguished in children on high-resolution computed tomography from other pathologic states through the presence of a centrilobular pattern, which may obviate the need for biopsy confirmation [156].

Cardiac Manifestations

Cardiovascular abnormalities have been documented in up to 60% of children with SLE [2, 14, 28, 30, 54, 157, 158], an incidence similar to that reported for adults [58, 159–163]. Findings span the gamut of cardiac pathology from nonspecific heart murmurs to acute chronic constrictive pericarditis, arrhythmias, and myocardial infarction. Valvular abnormalities are most common and include Liebman–Sacks vegetations, rigid and thickened valves with stenosis, regurgitation, or both, and miscellaneous valvular abnormalities such as thickening of leaflets, calcification, and mitral valve prolapse [163]. While the presence of carditis seems to be associated with antiphospholipid or anticardiolipin antibodies in adults [164, 165], myocarditis and/or pericarditis is more common in children who have anti-Ro/SS-A and anti-La/SS-B antibodies [166, 167]. Cardiac complications of both systemic and pulmonary hypertension may occur. These are discussed in detail elsewhere in this text; only coronary artery involvement as it affects children is reviewed here.

Unusually early atherosclerotic coronary artery disease and myocardial infarction have been documented in young patients with SLE [168–177]. Contributing factors include associated high levels of serum triglycerides, diabetes, and hypertension [178]. The strongest predictor in these children appears to be nephrotic range proteinuria; ultrasonographic evidence of premature atherosclerosis was evident before clinical hypertension, although blood pressure readings were higher than matched controls [179]. Coronary arteritis has been documented in some of these patients and may represent the initial event [180]. Nonatheromatous coronary vasculopathy without coronary arteritis has been reported to cause fatal myocardial infarction in a child with antiphospholipid antibody syndrome and Raynaud's phenomenon [181], suggesting an additional mechanism of myocardial damage. One prospective study of 26 asymptomatic patients with SLE addressed the issue of prevalence of the coronary artery involvement using exercise thallium-201 cardiac scintigraphy [182]. Eight of the patients were 25 years old or younger and 6 demonstrated myocardial perfusion abnormalities; 5 had abnormal thallium-201 imaging findings and 1 had abnormal M-mode echocardiographic findings. There was no correlation with corticosteroid therapy, particular organ involvement, serologic parameters, or duration of the disease. Dedicated studies in childhood lupus have shown a greater presence of cardiac abnormalities in asymptomatic children using screening electrocardiograms, echocardiograms, and myocardial perfusion studies [183, 184]. These studies also failed to demonstrate a corrolation with corticosteroid dose but suggested a relationship to antiphospholipids and abnormal lipid profiles. Older and earlier studies, however, reported an association with the duration of corticosteroid therapy [168–171, 174] and with the presence of coronary arteritis [172, 180]. Whether alternate-day administration of corticosteroids would lessen the risk of premature ASHD through lipid and glucose metabolism as well as blood pressure regulation is not clear. Abnormal lipid metabolism has been documented in patients with SLE prior to starting steroids [185]. However, diabetes and hypertension, both known risk factors for atherosclerotic heart disease, occur less frequently in patients receiving alternate-day therapy. Until long-term prospective studies answer these questions, it seems prudent to use the alternate-day regimen in children whenever possible to minimize known risk factors.

Endocrinologic Manifestations

Autoimmune thyroid disorders are well recognized in systemic lupus erythematosus. Both thyroid abnormalities and autoantibodies are more common in children with SLE than in healthy children. In a study of 35 children with SLE, 6 (17%) had thyroid abnormalities; 4/6 had overt hypothyroidism. In total, 43% demonstrated antithyroid antibodies, 31% had antimicrosomal antibodies, and 29% had antithyroglobulin antibodies [186]. This finding mimics the adult experience [187]. A second systematic review of thyroid function in 42 patients with juvenile SLE confirmed a higher incidence of thyroid autoantibodies (14%) versus 4.4% in a control population [188]. This study also screened patients with ultrasonography and found found four patients (9.3%), with evidence of thyroiditis. The study only identified one SLE patient with active thyroid disease. Some investigators advocate a high index of suspicion for evolving SLE in pediatric patients with either hypothyroidism or hyperthyroidism and antinuclear antibody positivity based on anecdotal experience of pediatric SLE presenting with thyroid disease [189].

The effect of pituitary and gonadotrophic hormones on the clinical course of SLE is discussed elsewhere (Chapter 7). When FSH and LH physiology in juvenile SLE has been compared to healthy controls, baseline levels of both gonadotrpic hormones were higher than the 51 healthy controls yet the difference did not reach statistical significance [190]. One study suggested improvement in malar rash following oral hormone therapy [191]. This benefit should be considered carefully in the context of the potential risk of a flare of systemic manifestations such as nephritis. Although one dedicated study did not find any evidence of

elevated prolactin levels in juvenile SLE [188], a second suggests a trend toward a baseline elevation that did not reach statistical significance. Elevated prolactin in pediatric SLE has been correlated with CNS disease [192], but the clinical significance has not been determined.

Avascular Necrosis of Bone

A detailed discussion of osteonecrosis can be found in Chapter 37. Several reports suggest that avascular necrosis of bone is more frequent in childhood disease, with up to 40% of patients affected; most patients are symptom free, and the lesion is found during a radiologic survey [193, 194]. Radiographs reveal mottling of the trabecular bone pattern, subchondral demineralization, depression or fragmentation, and irregular areas of lucency with sclerosis [1, 194, 195]. When only symptomatic patients are reported, the incidence of avascular necrosis of bone falls to 4.5% in children, equaling that in adults with SLE [196]. Clinically, osteonecrosis is manifested with severe joint pain and with limitation of motion and ambulation. Some patients progress rapidly to total joint destruction requiring replacement. The risk of collapse appears lower in growing children presumably because of increased blood supply to the growing epiphysis.

Joint replacement and "core decompression" pose special problems in the growing child. Surgery may damage the open physis and alter the growth pattern of the affected bone. Treatment, therefore, is limited to nonsteroidal anti-inflammatory agents approved for children, such as tolmetin, at a dose of 20–30 mg/kg/day or naproxen at a dose of 10–15 mg/kg/day [30, 197]. Limitation of activities and rest help relieve pain but it is unlikely that nonweight bearing alters the natural history of osteonecrosis. Our philosophy, based on experience with chronically ill children, is to allow normal activity limited only by the child.

LABORATORY FINDINGS

Laboratory findings in children with SLE are essentially the same as those found in adults (Chapter 15). As in older patients, circulating antinuclear antibodies detectable by immunofluorescent techniques and elevation of all immunoglobulins, particularly IgG, are found in virtually all children [198]. Various patterns of nuclear staining have been described and correlate with the presence of specific autoantibodies [199]. Reactions with nuclear antigens such as double-stranded (native) DNA and single-stranded (denatured) DNA as well as nonhistone proteins (Sm) and proteins associated with small RNAs (SSA/Ro, SSB/La) have all been documented in children with SLE [199–201]. Antinuclear cytoplasmic antibody staining and ELISA for PR3-IgG, MPO-IgM, lactoferrin-IgG and IgM, cathepsin G-IgG and IgM, and elastase-IgG can also be detected. As ANA and extractable nuclear antigen antibodies patterns can complicate the detection of ANCAs, the pathophysiologic role of ANCA in SLE is unclear [202]. Antibody to double-stranded DNA is the most specific finding and is detected in 78% of children at the time of the diagnosis [203] (Table 1).

A rise in antibody to dsDNA is associated with a concomitant fall in the level of total hemolytic complement; this is observed in 70% of children with SLE [204] (Table 1) and is abnormally low in approximately 90% of patients with renal disease [205, 206]. Low complement can also reflect partial or complete deficiency of the classical pathway [207]. Both of these laboratory tests reflect and may predict changes in disease activity [208–212]. They have become important tools in the management of the disease in children who appear to develop abnormal immune phenomena prior to clinical flares more frequently than adults [213–216]. In our experience, virtually all children with active SLE have circulating antibodies to native (ds)DNA compared with 70% adults reported by Tan [217].

Autoantibodies to ribosomal P proteins (anti-P) in juvenile SLE appear to have a higher prevalence than in adult SLE; one study revealed a prevalence in juvenile SLE of 42% while the adult cohort had a prevalence of 7.7% [218]. Children with SLE with both dsDNA and anti-P had a significant odds ratio for the presence of nephritis as well as the concomitant presence of U1-RNP and Sm autoantibodies. Additionally, titers of anti-P and dsDNA varied in accordance to observed changes in the SLEDAI. Taken together, these observations suggest a critical role of anti-P in juvenile SLE.

The IgM rheumatoid factor can be demonstrated in up to 30% of children with lupus, a frequency exceeding the incidence of rheumatoid factor positivity in juvenile rheumatoid arthritis [30]. The rheumatoid factor in SLE is frequently monoclonal or oligoclonal and, because of its more acidic pH optimum, may not be demonstrated by latex fixation. The rheumatoid factor is often associated with a small cryoglobulin with a cryocrit rarely exceeding 0.5–1%. It should be distinguished from cryofibrinogenemic states or heparin-precipitable material, which is found frequently in SLE plasma [219]. The rheumatoid factor containing cryoprecipitate may be the cause of complement consumption that sometimes occurs during transport of the sample.

CLINICAL COURSE AND PROGNOSIS

SLE in children is a chronic multisystem disease characterized by unpredictable exacerbations and remissions of both systemic symptoms and specific organ involvements. The complexity of clinical manifestations calls for a highly individualized approach to each patient.

Mild SLE in children is rare [1, 2, 19, 30, 68, 90], but with increased awareness among primary care providers, improved diagnostic testing, and early referral, the detection of mild disease may become more common. Assessment of disease severity in 108 children with SLE revealed that 5% of children had mild disease without clinical evidence of major organ involvement, complement consumption, and anti-DNA antibodies. These children were primarily symptom free and did not require steroids to control mild exacerbations of cutaneous or musculoskeletal symptoms. The second group, about 10% of patients, included children exhibiting severe symptoms of generalized SLE at its onset, including biopsy-documented renal disease. These children required high-dose prednisone therapy during the first several years; remission was sustained successfully for many years after the stormy initial course [2]. In our experience this subset accounts for 25–30% of patients. However, the majority of children with SLE have a chronic low-grade disease interrupted by irregular, often intense episodes of exacerbation of function of one major organ or another. These episodes, often described as lupus crises, may result in death and call for immediate and often heroic measures (see later). Most of these children have renal involvement that waxes and wanes concomitant with serologic activity; it may, however, progress slowly and independently of immune phenomena to chronic renal failure [1, 2, 19, 68, 89, 204, 206, 220]. Repeated exacerbations of nephritis and uncontrolled hypertension accelerate this process [222]. As discussed in the section on laboratory findings, the presence of antibody to native DNA and the fall in the level of serum complement may correlate with disease activity and predict exacerbations. These parameters should be followed regularly. If they correlate in a given patient, they are used in the prevention of future exacerbations [197, 205, 209–215, 223]. Regular evaluation of urinalysis, creatinine clearance, and protein excretion may reveal the progression of renal disease and call for more aggressive therapy.

The reported prognosis for children with SLE has improved dramatically over the past two decades. The estimated 5-year mortality of 75–80% in the 1960s [30, 54] became 75–85% survival after 10 years of disease in the 1970s [1, 30, 204, 224]. Increasing age at onset, noncompliance, black race, low socioeconomic status, and thrombocytopenia appear to have a negative impact on survival [225, 226]. During the 1980s, management of compliant children with SLE at major medical centers and under the direction of pediatric rheumatologists achieved 95–100% 5-year survival. The 10-year survival is anticipated to be close to 100% as well [30]. Certainly treatment with high doses of corticosteroids and cytotoxic agents has improved the survival of patients with life-threatening SLE crises and has prevented major organ failure in many patients [227–229, 230]. A favorable course of lupus nephritis has been correlated with the long-term normalization of serum complement [231] and cyclophosphamide therapy. The existence of intensive care units, hemodialysis, and transplantation, the effective treatment of infectious complications (the commonest cause of death in many series), and hypertension, as well as the diagnosis of mild cases, have all resulted in higher survival rates. Recent discovery that acquired hypogammaglobulinemia, treatable with IV gammaglobulin and relieved with increased immunosuppression, is not rare in pediatric patients has also contributed. Aggressive, early treatment of serologically predicted exacerbations enables children with SLE to lead essentially normal lives, attend schools, and stay out of the hospital.

DISCOID LUPUS ERYTHEMATOSUS IN CHILDREN

Although chronic discoid lupus erythematosus is less frequent than SLE in childhood, it is estimated that 2–3% of the reported cases of discoid lupus erythematosus have their onset before 15 years of age [232]. As in adults, cutaneous lesions of discoid lupus consist of well-defined erythematous patches with a frequent occurrence of adherent scales and follicular plugging. Older lesions often show atrophic scarring, although involution of the lesions without scarring can occur. Sun-exposed areas are involved most commonly, and in many patients the lesions disseminate or exacerbate upon exposure to ultraviolet light. Patients with discoid lupus may have mild laboratory abnormalities such as positive ANA, high IgG, and mild leukopenia but they do not have systemic disease [233, 234]. It is not known how many children will progress from discoid lupus erythematosus to SLE, but in our experience this is extremely rare. In studies of all age groups, 7% of patients with discoid lupus erythematosus have progressed to SLE over a period of 5 years from the onset of skin lesions [58]. The patients should therefore be aware of the small risk of progression to a more threatening, systemic illness. A thorough evaluation is recom-

mended once a year or at any time that unusual signs develop.

DRUG-INDUCED LUPUS ERYTHEMATOSUS IN CHILDREN

A syndrome resembling or identical to SLE can be induced by the administration of certain drugs. The illness usually subsides following discontinuation of the offending agent. This subject is discussed in detail in Chapters 12 and 44; the role of anticonvulsant drugs in inducing this syndrome in children is discussed here.

The first report implicating hydantoins as inducers of SLE appeared in 1953 [235]. Many subsequent cases have been reported implicating diphenylhydantoin, methylphenylhydantoin, trimethadione, ethosuximide, and clobazam [236–241]. In 1963, Jacobs reported seven children who developed SLE-like symptoms while receiving anticonvulsants, either alone or in combination [30]. All children had positive LE cells and polyarthritis. More recent reports [242–244] suggest that most children with anticonvulsant-induced lupus have fever, rash, and polyarthritis. Although pleuropericarditis is common and cardiac tamponade is disproportionately frequent and life-threatening [30, 245, 246], CNS disease has not been reported, and most authors emphasize the lack of clinical signs of renal involvement [244, 247].

In the study on the incidence of positive ANAs in children receiving anticonvulsant therapy, Singsen *et al*. [242] found that 14 of 70 children receiving ethosuximide and/or diphenylhydantoin had positive ANAs; 2 of 14 had anti-DNA antibodies. Serum ANA titers in the symptomatic children with drug-induced disease did not differ significantly from those in asymptomatic patients. ANAs were also found in the sera of 5 of 23 children receiving phenobarbital alone. Follow-up studies at 10 months showed no symptoms of SLE in any of the ANA-positive patients, suggesting that asymptomatic children who develop ANAs should be followed carefully but need not discontinue their anticonvulsant therapy [242]. The incidence of antibodies against individual histones and histone complexes is greater than 95% in adults with drug-induced lupus (Chapter 12). This has not been studied systemically in children.

In addition to induction of lupus with anticonvulsant drugs, children, like adults, can develop SLE while receiving hydralazine [248], chlorpromazine [30], oral contraceptives [249, 250], zafirlukast [251], sulfonamides, and sulphasalazine [30]. Due to its use for the treatment of acne, minocycline has become increasing recognized as a cause of drug-induced lupus in adolescents [252]. Unlike other types of drug-induced lupus, these children have been reported to develop hepatitis as well as dsDNA and ANCA serologies [253, 254]. ANCA serologies have been perinuclear patterns associated with antimyeloperoxidase and antielastase autoantibodies [255, 256]; in one study, these patients had either HLA-DR4 or -DR2 and all had an HLA-DQB1 allele encoding for tyrosine at position 30 of the first domain [255].

Exacerbation of SLE has reportedly followed the ingestion of alfalfa tablets [257]. Drug-induced SLE in a 12-year-old boy after long-term and interferon-α and -γ included induction of nephritis and double-stranded DNA [258]; prompt discontinuation of interferon and treatment with prednisone and cyclophosphamide were met with full recovery. This case raises the issue of the role of interferon in the induction of SLE.

Studies of adult patients with drug-induced lupus erythematosus reveal increased susceptibility in individuals with a slow acetylator phenotype [259, 260] and with the presence of the HLA/DR4 antigen [261]. Data are not available on the incidence of the slow acetylator phenotype and the presence of genetic susceptibility in markers in children receiving anticonvulsants who develop lupus erythematosus. It is known, however, that although females are more susceptible to drug-induced lupus than males, drug-induced lupus is the most common form of this disease in adult males [261]. Moreover, patients with a positive family history of rheumatic disease are more prone to develop drug-induced lupus, as are individuals with Klinefelter's syndrome [262, 263].

MIXED CONNECTIVE TISSUE DISEASE IN CHILDHOOD

In 1972, Sharp *et al*. [264] described 3 children and 22 adults with clinical and laboratory features of SLE but with overlapping prominent features of dermatomyositis and scleroderma. Patients' sera contained a newly identified antibody to the extractable nuclear antigen system and the term mixed connective tissue disease was applied to the syndrome. It was later determined that the extractable nuclear antigen (ENA) is composed of two different antigens: Sm and RNP; patients with SLE may have both anti-Sm antibodies and anti-RNP, whereas patients with mixed connective tissue disease are characterized serologically by the presence of anti-ENA antibodies consisting solely of anti-RNP [265, 266]. Although initially children with mixed connective tissue disease were considered to have a worse prognosis than adult patients, this may not be so. Clearly there are children who fulfill the diagnostic criteria for mixed connective tissue disease whose manifestations overlap

various rheumatic conditions and may include arthritis, pericarditis, Raynaud's phenomenon, rash, or sclerodermatous skin changes and whose symptoms can be controlled either with nonsteroidal anti-inflammatory drugs (NSAIDS) alone or with relatively small, alternate-day doses of prednisone [267]. Of the original 43 children with MCTD described in the literature, however, 9 (20%) have died [267–272]. Detailed analysis of all case series (Table 4) [267, 269, 273, 274] revealed that the predominant clinical symptoms were fever, polyarthritis (at times crippling), and rash, either malar and SLE-like or scaling and reminiscent of dermatomyositis. Weight loss and fatigue were common. Raynaud's phenomenon occurred in all patients, and sclerodermatous skin changes with sausage-shaped fingers and myositis occurred in over 75%, a considerably higher rate than in series of childhood lupus [30]. Abnormal esophageal motility was observed in two patients. Pulmonary disease, usually restrictive with or without pulmonary hypertension, occurred in 60% of patients. Salivary gland involvement, manifested by recurrent parotid gland swelling (Sjögren's syndrome), was significant in 30% of children. This is now a recognized, albeit rare, presentation of AIDS in childhood, which may simulate SLE/MCTD [275]. Myocarditis and/or pericarditis was found in 50%. Renal involvement, initially considered rare in mixed connective tissue disease, was present in 30%; when biopsy findings are available, analysis reveals glomerular scarring, membranoproliferative pattern, focal proliferative glomerulonephritis, and mesangial proliferation [270]. CNS disease—rare in adult patients—was seen in 26% of children. All of the children had hypergammaglobulinemia, positive ANA in a speckled pattern, and high titers of anti-RNP antibodies. The total hemolytic complement was usually normal. Severe thrombocytopenia was noted in 6 of 14 children reported by Singsen *et al.* [270]; others did not report this. Two of these 6 children subsequently died, one of hemorrhage and the other of overwhelming sepsis following splenectomy [270]. The initial report that this subset of SLE was mild and not fatal was clearly overly optimistic; when the original cohort of adult and pediatric patients was restudied 5 years later, 36% had died [272]. As time went on, each patient took on more and more of the clinical pattern of one disease, dermatomyositis, scleroderma, or SLE. It was necessary to individualize therapy; initially one of the advantages of separating out patients with mixed connective tissue disease from SLE or dermatomyositis was to identify a group who may require less aggressive therapy. Unfortunately, this approach may have resulted in excess mortality in patients with mixed connective tissue disease who evolved into "ordinary" SLE. We are now on guard for such evolutions and manage children

TABLE 4 Summary of Clinical Features of MCTD in Children

	Incidence (%)

with MCTD using the same guidelines as those applied to SLE [276, 277]. Interestingly, even with this information available, one study of long-term follow-up of these children documented such varied clinical courses as to question whether MCTD is a distinctive disorder [273].

The largest retrospective study of adult and pediatric patients with MCTD suggested different clinical presentations between these two groups [274]. Seventy-two children and 914 adult patients were evaluated by questionnaire in 1984 and 1992 to follow long-term outcomes. Frequency of pericarditis, renal involvement, and thrombocytopenia were lower than previously reported: 16, 20–28, and 10–19%, respectively. Furthermore, mortality from 1983 to 1990 was 3% for juvenile-onset MCTD versus 8% for adult-onset MCTD. Forty-nine percent of the children versus 29% of the adults fulfilled criteria for SLE, a statistically significant difference between the two groups. In contrast to previous smaller studies, this study suggests that pediatric MCTD has a more favorable outcome with more SLE-like characteristics and fewer cases of systemic sclerosis.

JUVENILE SJÖGREN'S SYNDROME

Sjögren's syndrome is a disorder characterized by kerato-conjunctival sicca in the presence of specific autoantibodies (ANA, SSA, SSB, and RF) or a confirmatory minor salivary gland biopsy [278]. It occurs either as an isolated syndrome, termed primary Sjögren's syndrome, or in association with a defined connective tissue disorder, termed secondary Sjögren's syndrome. Although rare, primary Sjögren's syndrome has been described in children [279–281] and termed juvenile Sjogren's syndrome (JSS). Clinical manifestations are similar to those seen in adults. Serum anti-α-fodrin antibodies have been detected in JSS patients before sicca symptoms [282], as well as before other autoantibody markers [283]. This suggests that α-fodrin antibodies may be an early diagnostic marker for JSS. In adults, secondary Sjögren's syndrome is commonly associated with rheumatoid arthritis and scleroderma [284]; in contrast, secondary Sjögren's syndrome in children has historically been associated more intimately with SLE and MCTD [285, 286]. One study suggests that most children with Sjögren's syndrome will develop SLE or MCTD [286].

The spectrum of JSS is evolving as the area undergoes further study. Earlier reports, reviewed by Deprettere *et al*. [287], revealed that out of 28 children with JSS, 17 had primary JSS and 11 children had secondary JSS; 5/11 children had SLE and 4/11 had MCTD. Parotid gland enlargement, sicca symptoms, ANA > 1:160, and abnormal salivary gland biopsy specimens were the most common findings. In 1995, Anaya *et al*. [281] reported 5 new patients and reviewed 34 cases of primary JSS and 31 cases of secondary JSS. In primary JSS, parotitis was a more common presenting feature in children than in adults (62.5% vs 12.8%, respectively); parotitis and the presence of ANA and RF were the principal findings. In contrast, extraglandular features, sicca complex, occurrence of ANA, and articular symptoms were less common in children than in adults. In secondary JSS, 42% of the patients had JRA, whereas 29 and 26% had SLE and MCTD, respectively. Secondary JSS preceded SLE with a range of 1–9 years in 57%; the diseases appeared concurrently in the remaining children.

With parotitis as a principal presentation of JSS in childhood, an evaluation for all potential infectious etiologies is important prior to the diagnosis of juvenile Sjögren's syndrome. In addition to mumps in young children, the diffuse infiltrative lymphocytosis syndrome can mimic both Sjögren's syndrome and SLE [288] and should be considered in the differential diagnosis of atypical kerato-conjunctival sicca or parotitis [289]. Children with HIV disease can present with parotitis [290], but the increased prevalence of pulmonary involvement and infrequent occurrence of autoantibodies should suggest this infectious etiology [275]. The presence of SLE does not rule out parotitis from HIV [291].

Therapy is largely supportive [285, 286] with artificial tears and saliva substitutes to palliate sicca symptoms. Parotitis has been treated effectively with short courses of corticosteroids [281]. Trials of oral pilocarpine, topical cyclosporine, and SNI-2011 are ongoing in adults [292]. Treatment of extraglandular symptoms is covered in appropriate sections.

ANTIPHOSPHOLIPID ANTIBODY SYNDROME

The relatively new syndrome of antiphospholipid antibodies and thrombotic phenomena has long been observed in children [293–296]. The lupus anticoagulant (LA), an antibody that acts as an inhibitor of the thromboxinase complex and *in vitro* prolongs both intrinsic and extrinsic clotting pathways, does not cause bleeding unless there is a coexistent prothrombin deficiency or thrombocytopenia [296–298]. Rather, the presence of the circulating anticoagulant is associated with a tendency to thrombosis presumably due to initial endothelial injury [299–305]. The LA has been demonstrated in children by the presence of a prolonged partial thromboplastin time (PTT) that fails to correct with 1:1

dilution, the kaolin cephalin clotting time (KCT), Russell viper venom time (RVVT), and the platelet neutralization time. The LA has been demonstrated by KCT in the absence of a prolonged PTT in pediatric SLE, however, suggesting that KCT may be a more sensitive screening test [306]. Antiphospholipid antibodies may also present as IgM and IgG anticardiolipin antibodies (aCL) as well as a false-positive syphilis serology.

The presence of antiphospholipid antibodies alone may neither suggest the diagnosis of SLE nor correlate with the risk of thrombosis in children. Children who fulfill the criteria for primary aPL syndrome may not fulfill the ACR criteria for SLE [307]. Further, aPL in children with other autoimmune disorders tend to occur in lower titers and may not be associated with thrombosis [306]. Children with SLE and their first-degree relatives both have increased incidence of aPL; 38% of young SLE patients had at least one aPL and 19% of the first-degree relatives had at least one aPL [308]. Although the aPL positive proband had a 21% incidence of thrombotic events, no thrombotic events occurred in the first-degree relatives [309].

The antiphospholipid antibody syndrome is defined by specific laboratory parameters and clinical manifestations (Chapter 43); criteria have been applied successfully to children. Unfortunately, studies of aPL in children with SLE use different combinations of aCL and LA tests with and without the false-positive syphilis serology to evaluate the incidence and clinical manifestations of aPL syndrome. Thus, the reported incidence of aPL ranges from 9 to 87% [127, 306, 310, 312]. Associated clinical manifestations mirror the adult experience and include thrombocytopenia, Coombs positive hemolytic anemia, vascular thrombosis or digital ischemia, stroke syndromes, chorea, pulmonary vasoocclusive disease, Addison's disease, partial seizures, movement disorders, and hemidystonias [307, 312–316]. Antiphospholipid antibodies apparently have little to no role in the evaluation or sequelae of lupus nephritis [317]. A catastrophic antiphospholipid antibody syndrome has also been described [318]. Hemorrhage can occur if a patient with aPL syndrome develops factor II deficiency reported in the presence of the LA [319, 320] (personal communication). The mechanism of this association is not clear but may be secondary to rapid hepatic clearance of the antigen/antibody factor II complex and usually responds to corticosteroids with or without vitamin K and factor replenishment.

Neurologic events correlate with elevated IgG-aCL in most studies [321] but not all [312]. Although the LA is likely a better marker for thrombotic risk than aCL [321], there are no longitudinal randomized studies for prophylaxis; many pediatric rheumatologists, however, support the use of low-dose aspirin for children with SLE and serologic evidence of IgG aCL antibodies [322]. The current standard of care supports the use of pharmacotherapeutics only after a thrombotic event. Although no randomized trials are available for treatment guidelines, Silverman [323] reported treatment of thrombotic events with heparin followed by coumadin for 6 months to maintain the INR at 2.5. Thereafter, his patients were committed to indefinite coumadin to maintain the INR at 1.5–2.0. Neither recurrent thrombus nor adverse bleeding was reported [323]. Carbamazepine has been reported to treat this type of chorea [324].

GENERAL APPROACH TO MANAGEMENT OF CHILDREN WITH SLE

The treatment plan for children with SLE must be based on a careful assessment of the extent and severity of the disease versus the risk of treatment, while keeping in mind the need for growth and normal function at home and in school. Symptoms of children with mild disease can be managed with NSAIDS: tolmetin (20–30 mg/kg/day) or naproxen (10–15 mg/kg/day) [30, 325, 277] to control fever and reduce joint inflammation. Regular monitoring of liver enzymes is indicated, although the frequency of drug-induced hepatotoxicity is much less with NSAIDs than that associated with the use of salicylates, which occurred frequently in children with SLE [327]. Rash and minor constitutional symptoms, with or without arthritis, may respond to hydroxychloroquine (<6.5 mg/kg/day) [2, 277, 328, 329]. To prevent worsening of the rash, the use of sunscreens, visors, and parasols, as well as avoidance of direct sun exposure, cannot be overemphasized. If minor constitutional symptoms cannot be controlled, low-dose, alternate-day prednisone can be used.

As stated earlier, many children with SLE present with active nephritis, are seriously ill, and develop evidence of advancing disease while treated conservatively. For those children, prednisone, up to 2 mg/kg/day in divided daily doses, is used to alter or abolish the specific mechanism of disease responsible for the life- or organ-threatening process. In general, high-dose prednisone therapy (2 mg/kg/day in divided doses) should be reserved for acute life-threatening episodes and maintained for the briefest possible time, using both clinical and laboratory parameters of disease activity, specifically elevation of antibodies to double-stranded DNA and fall in the serum complement levels [276, 277, 330, 331]. Usually, significant clinical improvement occurs within 2 to 6 weeks, and the dose is consolidated to a single morning regimen. Once normalization of immune abnormalities is achieved, the dose may be adjusted to

an alternate-morning regimen by doubling the daily dose and adding another 20–40% [28]. While maintaining control, the drug may be tapered slowly over 2–3 years to the minimum level required for the control of symptoms and serologic parameters. Whenever possible after the acute period, administration of hydroxychloroquine and nonsteroidal anti-inflammatory drugs may allow for further reduction in the steroid. Hydroxychloroquine at a dose not exceeding 6 mg/kg/day is well tolerated for many years with nominal risk of retinal toxicity [332] and has been associated with fewer flares of SLE in adulthood [329].

If the disease cannot be controlled adequately with alternate-day prednisone, the use of azathioprine (2–3 mg/kg/day) or pulse intravenous cyclophosphamide (500–1000 mg/m^2) may be indicated for individual patients [30, 276, 277, 333–335] as steroid-sparing agents. A gradual reduction in prednisone can usually be accomplished after control has been achieved with the addition of the cytotoxic agent. Methotrexate has been used successfully as a steroid-sparing agent for pediatric patients failing either prednisone or prednisone–cyclophosphamide; in both cases, improvement in laboratory and clinical end points, such as nephritis, was seen [336]. Cyclosporine A has been used successfully in adults and children [324, 337, 338]. Autologous stem cell transplantation (ASCT) for pediatric rheumatic diseases continues to receive increasing attention as protocols are developed and indications established [339]. Children with SLE have been the successful recipients of ASCT, with the first two patients reported to have complete remissions and increases in growth curve velocity [340]. The role of ASCT in the treatment of rheumatic diseases has yet to be completely defined.

Glucocorticoid-induced osteoporosis requires special attention and can be stabilized with appropriate nutritional support with at least 1 of calcium carbonate and 400 IU vitamin D daily [340a].

TREATMENT OF SPECIFIC PROBLEMS AND LONG-TERM COMPLICATIONS

Children who are in an emergent situation, are comatose, hypertensive, or hemorrhaging require vigorous intervention, such as pulse steroid therapy (30 mg/kg of methylprednisolone daily for 3 days) and intravenous cyclophosphamide (750 mg/m^2) or lymphoplasmapheresis three times a week, concomitant with a cytotoxic agent. Specifically, the treatment of pulmonary hemorrhage, an often fatal early complication of childhood SLE [2], should include intravenous steroid, cyclophosphamide, and plasma- or lymphoplasmapheresis [154, 341–343]. This approach, although successful only anecdotally, appears to have promise [344, 345].

Indications for the use of cytotoxic therapy in the treatment of SLE in children neither immediately threatened with a fatal complication nor exhibiting active lupus nephritis have not been firmly established. Patients with certain neurologic manifestations of SLE, as well as several with gastrointestinal vasculitis and pneumatosis intestinalis, have been treated successfully with intravenous boluses of cyclophosphamide [346, 347]. Patients with severe thrombocytopenia or myositis may be candidates for such treatment [348], although intravenous immunoglobulins have also been successful in controlling SLE complicated by thrombocytopenia in both children and adults [349, 350]. Other authors report successful management of CNS crises, including transverse myelitis, with massive doses of methylprednisolone (30 mg/kg/day) for 6 days [351–353]. A lack of prospective placebo-controlled trials makes the decision-making process extremely difficult and underscores the need for randomized studies of different treatment modalities in the management of SLE in children.

Abdominal Crises

A sudden onset of even mild abdominal pain and low-grade fever in a patient whose SLE is well controlled with corticosteroids or cytotoxic therapy may represent sepsis with peritonitis [354–356]. Immediate treatment with broad-spectrum intravenous antimicrobials is indicated while defining the nature of the problem. The organisms involved are most frequently pneumococci, staphylococci, or streptococci followed by gram-negative bacteria, *Salmonella*, and fungi [30, 356, 357]. General supportive measures—maintenance of fluid and electrolyte balance, blood pressure, and ventilation, as well as stress levels of steroids—are essential to the patient's survival. Early surgery may be life saving in cases of perforation [358], but may significantly worsen the course in a child with sepsis and peritonitis or acute SLE. Once careful evaluation has ruled out perforation and sepsis, prednisone (1–2 mg/kg/day) may be used until symptoms are brought under control.

Hypertension and Renal Disease

The control of hypertension should be vigorously pursued whenever this complication occurs [81, 359]. In addition to antihypertensive agents, azathioprine or cyclophosphamide may be added to the steroid regimen. This permits modification of steroid therapy to alternate mornings, a regimen resulting in less blood pressure elevation [360]. The management of renal

disease should be highly individualized [361, 362]. High-dose prednisone should be used whenever renal biopsy reveals active glomerular involvement. Because patients with mesangial or focal glomerulonephritis have a relatively good prognosis in terms of potential for renal failure, low-dose, alternate-day therapy is probably adequate [363]. If this principle is not strictly adhered to, deaths from treatment of patients with insignificant renal involvement may exceed fatalities from the disease [364]. Acute deterioration in renal function may be reversed with immediate pulse methylprednisolone therapy, 30 mg/kg/day for 3–6 days [365–367] or monthly cyclophosphamide boluses [361, 368]. The potential exists, however, for life-threatening sepsis disseminating from an occult site with these aggressive therapies [369]. Since the recognition of the potential for histologic change [85, 87, 370], the index of activity and chronicity has been used to estimate prognosis for individual patients. As expected, the higher the activity index, the more likely the reversal of the inflammatory lesion. Patients with high-activity and low-chronicity indices, therefore, reportedly have a good outcome if they are treated with any one of the various regimens: oral corticosteroids, cyclophosphamide, or azathioprine; high-dose intravenous cyclophosphamide plus steroids; high-dose steroids; or even low-dose steroids [361, 368, 371]. Refractory lupus nephropathy remains a clinical challenge, which has been managed successfully with either cyclosporine [372] or mycophenolate mofetil [373, 374]. It is prudent to choose the least toxic regimen for such patients but one that will ultimately eliminate the activity without resulting in scarring. Prednisone alone may be enough to accomplish this.

Patients with a moderate degree of scarring seem to be appropriate candidates for cytotoxic therapy, either alone or in combination with corticosteroids [334, 361, 368, 375]. Long-term prospective studies designed without consideration for the activity and chronicity index rating have shown that cytotoxic therapy is superior in the treatment of diffuse proliferative glomerulonephritis [163, 376–385]. Patients with a high chronicity index already destined for renal failure and dialysis or transplantation may benefit little from immunosuppressive therapy and only suffer from its toxicity. For these patients, a less vigorous therapy should be considered [361]. Nevertheless, studies currently in progress suggest that intravenous boluses of cyclophosphamide may have beneficial effects on some renal lesions with a high degree of chronicity [361]. While the pharmacokinetics and side effects of bolus oral cyclophosphamide appear similar to those of intravenous cyclophosphamide, neither the degree of potential benefit nor toxicity has been fully evaluated [378].

Chronic Renal Failure

Eventually, children with renal failure secondary to SLE require dialysis, renal transplantation, or both [386]. Retrospective analysis has revealed that DPGN (WHO class IV) and hypertension are significant predictors of progression to ESRD [387, 388]. Baqi *et al.* [388] suggest that a creatinine level >1.6 mg/dl associated with a C3 level <63 U/ml at presentation are also predictive of progression to ESRD [388]. The ultimate prognosis for those patients who do not have significant active extralegal disease is similar to that for patients with idiopathic renal failure [389]. The overall function and survival of children treated with chronic hemodialysis were considered favorable; one study reported a 5-year actuarial patient survival of 95% [388]. More recently, however, McCurdy *et al.* [387] reported only 50% survival of children with SLE receiving chronic dialysis.

In addition, chronic dialysis is associated with retarded linear growth [391–394], osteodystrophy [393], hypertension, chronic anemia, neurologic dysfunction, hepatitis, and psychosocial disturbances [396–398]. Although children may be able to attend school regularly, the great amount of time and effort required to give dialysis treatments precludes full rehabilitation. Vitamin D analogs have been used successfully to improve intestinal calcium absorption, reverse secondary hyperparathyroidism, and support and/or improve bone mineral density, as well as improve linear growth in some patients [340a, 399, 400]. Either calcium carbonate or calcium lactate provides both calcium and a source of alkali [401–404].

The optimal treatment for all children with renal failure is renal transplantation; a successful transplant provides the best opportunity for normal growth and development, as well as a better acceptance of living with chronic disease [405]. Renal transplantation has been successfully undertaken in young children [406]. Thus far, few children have been reported to develop glomerulonephritis in the donor kidney [407]. A less aggressive disease course that often accompanies renal failure and the posttransplantation regimen of immunosuppression most likely accounts for the low frequency of disease in the donor kidney.

SPECIAL CONSIDERATIONS IN THE ADOLESCENT WITH SLE

Adolescence is a stage of growth and development marked by “great emotional upset with wide fluctuations in behavior” [408]. Body image is fragile and the need for acceptance by peers is at its peak. The

emotional strain of chronic disease is intensified by the disfiguring stigmata of both disease and, more importantly, its treatment [409]. Among the manifestations most disturbing to the teenager are dermatitis, hair loss, and vasculitic lesions frequently involving the face. Control of the disease usually results in improvement; to control the disease, however, the young patient often exchanges disease-related symptoms for even more upsetting cushingoid stigmata of mood facies, obesity, striae, and fine tremors [410]. Because peer acceptance is so highly valued, the young patient may not comply with therapy in order to avoid cushingoid appearance, acne, hair loss, and weight gain. One study revealed noncompliance in 59% of adolescent patients required to take steroids [411]. Alternate-day steroid regimen should be used as early as possible to lessen the risk of infection, to avoid grotesque cushingoid appearance, and to avoid growth retardation, diabetes, and hypertension [412].

The young patient with SLE quickly learns that his or her chronic disease is punctuated by exacerbations and must be monitored every 1–3 months with blood and urine studies. During the initial active stage, weekly follow-up may be required, significantly interfering with school and social activities. It is important to ensure that the patient does not become estranged from his or her peer group; it has been documented that patients who isolate themselves from their peers tend to have exacerbations of disease twice as frequently as those who remain socially active [413, 414], although cause and effect here are difficult to determine.

As with any chronic illness, the adolescent may exhibit a wide range of psychological reactions [408]. The intensity of these responses will depend on the degree of illness, particular symptoms, and the psychological makeup of the individual patient [415]. The fear of inability to meet goals, such as working and raising a family, and the fear of death need to be brought out and discussed openly. Education about the nature and course of the disease often leads to acceptance and alleviation of unfounded fears. Structured psychiatric intervention is advisable if the patient develops depression or has suicidal tendencies. With proper emotional support in the form of group or individual discussion with professionals trained to care for children with chronic disease, adolescents with SLE can make a successful adjustment to their illness [416].

Finally, physicians caring for adolescent patients must address the issues of contraception and pregnancy. Estrogen-containing oral contraceptives have been associated with exacerbation of SLE, whereas progesterone, equally effective in contraception, does not induce flares [249, 250, 417]. The inability to bear children often concerns young women with SLE and those adolescents who require prolonged treatment with cyclophosphamide. Although pregnancy is fully covered elsewhere in this book, it is important to mention here that when the disease is controlled, the chances of conceiving and bearing a child without inducing a flare approach those for healthy women [30, 418–421]. While cyclophosphamide therapy may lead to oligomenorrhea [422] and ovarian and testicular failure [423], ovarian failure is much less common in younger women than those in their middle age. Monthly intramuscular GnRH analogs have been shown to be protective in eight of eight female SLE patients receiving cyclophosphamide, whereas five of nine control patients developed premature ovarian failure [424]. The youngest SLE patients in this study were ages 20–23 years; however, the same group has administered GnRH analogs to preserve ovarian function in children as young as 15 years who were treated for malignancies with cytotoxic agents [425]. Sperm should be stored in sperm banks for the males, who are at high risk of sterility. In addition, bimonthly intramuscular testosterone begun 1 month prior to and continued during treatment with cyclophosphamide has been shown to preserve sperm count in young adults [426] and could be considered for adolescent males with documented skeletal maturation.

IMAGING OF SYSTEMIC LUPUS ERYTHEMATOSUS: STATE OF THE ART[1]

Lorraine G. Shapeero

Systemic lupus erythematosus (SLE) is a relatively common chronic inflammatory disease that affects bones and joints, skin, lungs, serous membranes (pleura, pericardium, and peritoneum), kidneys, gastrointestinal tract, cardiovascular and nervous systems, and a variety of other organs. Since the mid-1970s, the author has evaluated the various imaging modalities for diagnosing SLE from conventional radiography, sonography, and scintigraphy to the more advanced techniques such as magnetic resonance imaging (MRI), single photon emission computed tomography (SPECT), positive emission tomography (PET), computed tomography (CT), and power Doppler. This chapter describes and illustrates the current role of imaging for SLE and its complications in each organ system.

IMAGING OF MUSCULOSKELETAL SLE

General Radiographic Features

The radiographic manifestations of SLE vary with the organs affected and with the duration of the disease. The most frequent presenting symptom is joint involvement [1, 2]. The symmetric polyarthritis of lupus, often nondeforming and nonerosive, affects particularly the small joints of the hand and often the wrists, the knees, and the shoulders [3]. In a review of 62 hands of patients with established SLE who fulfilled the American Rheumatism Association criteria, nondeforming arthritis was seen in 74% of patients. Five patients (16%) with severe disease had deformities of the hands and wrists; of these, four had flexible or reducible changes. Deforming arthritis was mentioned frequently in the early descriptions of SLE [1]; however, when more specific criteria for the classification of SLE were established, the prevalence of this type of arthritis was considerably less (5%), although occasionally it could range from 5 to 50% [1, 3]. Even the most disfiguring arthritis of the hands can usually be reduced when the hands are pressed firmly against an X-ray cassette (Fig. 1) [3]. In some instances, the joint deformities are not correctable (Fig. 2).

The common types of hand involvement are swelling at the proximal interphalangeal (PIP) joints and metacarpophalangeal (MCP) joint of the thumb (hitchhiker's thumb), swan neck deformities (Fig. 3), subluxations of the MCP joints, and ulnar deviation of the fingers [1, 2].

Fusiform swelling of the fingers is a manifestation of inflammatory changes in the pericapsular soft tissues rather than a joint effusion, which is usually unimpressive in this disease. Juxta-articular osteoporosis of the hands has been reported in 50% of lupus patients [2]. In the authors' experience, it was found less frequently, in only 16% of patients. Atrophy of the thenar and

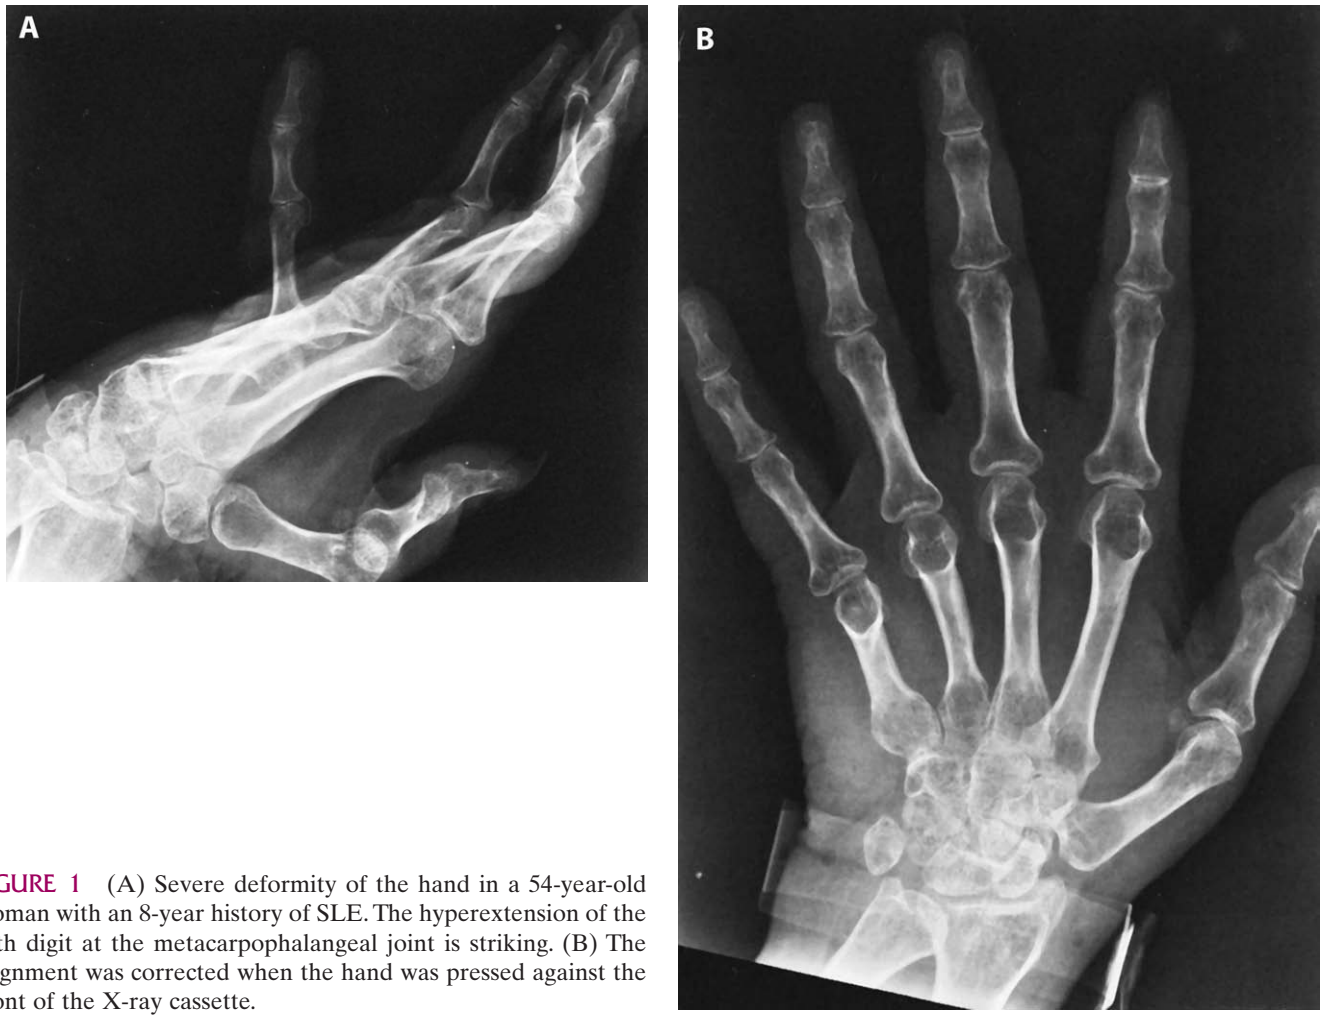

FIGURE 1 (A) Severe deformity of the hand in a 54-year-old woman with an 8-year history of SLE. The hyperextension of the fifth digit at the metacarpophalangeal joint is striking. (B) The alignment was corrected when the hand was pressed against the front of the X-ray cassette.

FIGURE 2 This 52-year-old woman with SLE has severe irreducible hand deformities simulating a mutilating arthritis. The profound osteoporosis, the "hitch-hiker's" thumb (*arrow*) and the metacarpal subluxations are pronounced.

FIGURE 3 This 37-year-old woman with SLE since childhood has subluxations at the metacarpophalangeal joint and a pronounced swan neck malalignment of the fifth finger. Despite the severity, the deformities are reducible.

hypothenar muscles is rare but occasionally can be a prominent feature of SLE [2]. Even when deforming arthritis is present, loss of articular cartilage and erosive changes are unusual [3–5]. Age appears to have no significant influence on the frequency of this finding [4].

Advanced Arthropathy (Jaccoud's Arthritis)

Bywaters [6] noted a striking similarity between the arthritic deformities of SLE and Jaccoud's arthritis—an entity originally thought to result from rheumatic fever. Clinically, Jaccoud-like arthritis may simulate rheumatoid arthritis [3–6] but patients show little functional disability despite the severity of the deformities. Although Jaccoud-like arthropathy may have a variable appearance, the more characteristic features are symmetric arthritis, ulnar deviation of the fingers, MCP subluxation, swan neck deformities of the digits [hyperextension at the PIP joints and flexion at the distal interphalangeal (DIP) joints], and boutonnière deformities (flexion at the PIP joints and hyperextension at the DIP joints). As mentioned earlier, pressure on the hands by firm placement on a radiographic cassette can correct the malalignment of the fingers on radiographs even when patients clinically present with severe deformities [1] (Fig. 1). Rarely, radiographs demonstrate cyst-like lesions and hook defects in the metacarpal heads.

The prevalence of Jaccoud's syndrome is reported as 2.4–7% [1, 7–10]. Perhaps as the survival rate of patients with SLE increases, this prevalence will also increase. Jaccoud's disease appears to be a long-standing arthritis (average duration of 22 years), whereas the classical arthritis of SLE is a nondeforming arthropathy of short duration (average of 7.2 years).

Occasionally, Jaccoud's arthritis may affect the knees and elbows. De la Sota *et al*. [7] reported a Jaccoud's arthritis of the knees with an unusual severe functional impairment accompanying the nonerosive deformity. In a few of the patients in their series, Esdaile *et al*. [1] described a fixed flexion contracture of the elbows as an atypical finding in Jaccoud's arthritis. This subtype is distinctive from classical Jaccoud's disease and probably represents a variant.

The pathogenesis of Jaccoud's arthritis is not clearly understood, but fibrosis is a prevalent feature in the reparative response. In addition, the frequent association of mitral stenosis in Jaccoud's arthritis suggests that fibrosis is more generalized than suspected. The association with rheumatoid arthritis is rare [2, 3, 10, 11].

Subchondral Cysts and Erosions

Cystic bone lesions in SLE are typically located in the subchondral region in the small joints of the hands and feet. In one series of 141 patients [12], 41% of lupus patients had subchondral cysts predominantly in the metacarpal heads and carpal bones, although most authors state that it occurs less frequently. Cysts are usually multiple and show progressive development over the course of the disease. No correlation is found with other manifestations of SLE, such as pleuritis, pericarditis, and joint and central nervous system (CNS) disease involvement. These subchondral cysts may simulate the "punched-out" lesions of gouty arthritis (Fig. 4) and occasionally may be accompanied by erosions and overhanging edges. Several investigators have discussed the coexistence of gout and SLE [13–15]. The clinical picture is that of classic gout, particularly affecting the great toe. The diagnosis should not be confused with a flare-up of SLE or with cellulitis of the foot. Radiographs reveal the typical gouty erosions with an "overhanging edge" of the interphalangeal joint of the great toe. Aspiration of the MCP joint shows sodium urate crystals in the fluid and elevated serum uric acid levels of 10–11 mg/100 ml. Investigators have also discussed an association among SLE, nephritis, and gout [14, 15], and one author mentioned the coexistence of SLE, gout, and Paget's disease [15]. These reports stress the problem of

FIGURE 4 (A) A well-circumscribed cyst-like defect of the scaphoid simulates tophaceous gout in this patient with SLE. The absence of joint space narrowing is frequently seen with intraosseous tophi. (B) This patient has SLE with erosions of the metatarsal head, soft tissue masses, and a mild loss of joint space, features typical of gout. The uric acid levels, however, were normal.

diagnosis when coexisting arthritic or osseous conditions are present.

Hook-like erosions, an unusual finding in SLE [2, 16, 17], develop in the wrists (Fig. 5A), shoulders (Fig. 5B), metacarpal heads, and, occasionally, in the metatarsal heads. Rarely, erosions have been reported in the temporomandibular joints [17a]. Erosions may be unilateral or bilateral. The defects are characteristically on the volar-radial surface of the bone and are difficult to distinguish from the erosions of rheumatoid arthritis, pseudogout, osteoarthritis, gout, and hemosiderosis [1–4, 6, 10].

Acral Sclerosis–Tuft Resorption and Periarticular Calcifications

In one series, radiographs showed acral sclerosis in 17% of lupus patients. Focal sclerotic changes, however, are not specific for SLE; 8% of normal patients have this finding. Tuftal sclerosis is also associated with rheumatoid arthritis, psoriatic arthropathy, sarcoidosis, scleroderma, and dermatomyositis [2, 18, 19]. Because radiographs show acral sclerosis and osteoporosis in lupus patients with and without Raynaud's phenomenon, it is not possible to separate patients with Raynaud's phenomenon by radiographic features alone. However, in one study, all lupus patients who had radiographic findings of terminal tuft resorption or periarticular calcification had clinical Raynaud's phenomenon [2].

Soft tissue calcifications (calcinosis universalis and calcinosis cutis) [20, 21] are discussed later in the section on dermatological imaging of SLE. When radiographs show the triad of periarticular calcification, acral sclerosis, and joint deformity without erosions, SLE should be considered, and patients should be evaluated by the American Rheumatism Association criteria. One should also consider the possibility of an overlap syndrome, namely SLE and scleroderma or mixed connective tissue disease. A diagnostic feature of mixed connective tissue disease is the elevation of antinuclear

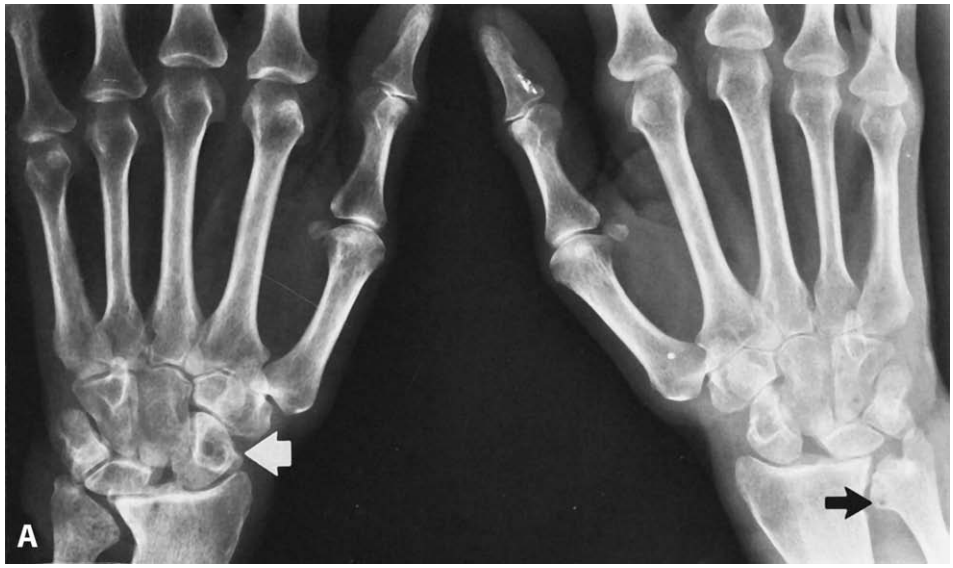

FIGURE 5 (A) Erosions in the wrists of a 32-year-old patient with SLE involve the radioulnar joints (*arrow*), the distal ulna, and the articular ends of the thumb metacarpals. Note the widening of the scapholunate articulation consistent with bilateral scapholunate ligamentous tear. (B) A large, scooped-out erosion is present in the greater tubercle of the humerus.

antibody titers with specificity for nuclear ribonucleoprotein (extractable nuclear antigen) [2].

Sacroiliitis

Sacroiliitis is an infrequent manifestation of SLE [22–24, 24a]. Usually, radiographs show early changes such as loss of the cortical "white line" of the iliac side of the joint and small erosions. The late findings of sclerosis and joint fusion that are found in the spondyloarthropathies are distinctly unusual in SLE. Tc-99m methylene diphosphonate (^{99m}Tc MDP) bone scans show elevated radiopharmaceutical uptake ratios of the affected sacroiliac joint(s) in lupus patients [25]. Currently, MRI, especially with contrast enhancement and fat suppression, is considered to be the most sensitive

method for detecting sacroiliitis and is superior to CT for identifying active bone erosions and cartilaginous abnormalities.

Abnormalities of Tendons and Ligaments

Tendinous or ligamentous interstitial, partial or complete tears, tenosynovitis, and tendonitis are not unusual in rheumatic disorders, including SLE, and occasionally herald the onset of the disease [27, 27b]. For example, the incidence of rotator cuff tears in patients attending a rheumatic disease clinic can be as high as 50% (Fig. 6).

When available, MRI is the modality of choice for defining globally the extent of tendinous and ligamentous inflammation or tear and abnormalities of the adjacent bones, labra and other soft tissues [27c–30].

MRI creates images based on the response of atomic nuclei (protons) to radiofrequency pulses in a strong magnetic field with absorption of energy for resonance and subsequent emission of energy for relaxation. Each nucleus has a nuclear spin that is proportional to its angular momentum. For spin-echo sequences (T1- and T2-weighted sequences), the radiofrequency pulse flips the vectors of the nuclei 90° to create the conditions for excitation, resonance, and spin coherence (spins are in phase). The T1–relaxation or spin–lattice relaxation reflects the process whereby excited nuclei give off energy to their environment, the lattice, and thereby relax back to their original stable state. T2–relaxation or spin–spin relaxation is the process whereby the spins lose their phase coherence and become out of phase.

FIGURE 6 The marked 3-mm narrowing of the acromiohumeral space signifies a complete tear of the rotator cuff in this patient with SLE. Note the erosion of the greater tubercle. The similarity to rheumatoid arthritis is striking.

The ability to recognize abnormalities on MR images depends on tissue contrast. T2-weighted images can show excellent contrast between *high-signal-intensity (hyperintense) pathologic tissue* such as inflammation, cysts, edema, cysts, or tumor and *low-signal-intensity (hypointense) normal muscle and fibrous tissue*. On T2-weighted sequences, fat in marrow and subcutaneous tissue will appear medium or high signal intensity depending on the standard or fat sequence. Therefore, differentiation between fat and pathologic processes may be difficult. To improve lesion conspicuity, fat suppression (saturation) is added with the result that fat-containing tissue becomes hypointense and separable from hyperintense pathologic lesions.

T1-weighted images are used to demonstrate anatomic relationships, but not for delineating pathologic lesions because there is low tissue contrast within and among tissues on this sequence. Only fat, proteinacious material (e.g., abscesses), and subacute hemorrhage are hyperintense on T1-weighted sequences. Other tissues (e.g., muscle and fibrous tissue) and pathologic processes display low signal intensity and therefore may not be differentiated easily. The addition of contrast medium and fat suppression to the T1-weighted sequence can improve lesion identification because pathologic tissue often displays intense enhancement and is therefore separable from the nonenhancing normal fat and fibrous tissue and mildly enhancing muscle.

With musculoskeletal MRI, the normal tendon or ligament shows low signal intensity on T1- and T2-weighted images. In contrast, tendonitis or intrasubstance tear produces a focal area of high signal intensity within the tendon, and tenosynovitis is associated with peritendinous hyperintense fluid (Fig. 7). With complete rupture, hyperintense fluid separates the disrupted ligament (Fig. 8). In the lupus patient on corticosteroid or immunosuppressive therapy, MRI cannot distinguish between the infected tenosynovitis (Fig. 9) and the noninfected inflammation. Sonographic localization of fluid and sonographically-guided aspiration enhance rapid diagnosis and appropriate treatment [31].

Duplex sonography, when performed by experienced musculoskeletal sonologists or sonographers, is useful for studying individual tendons (e.g., Achilles tendon,

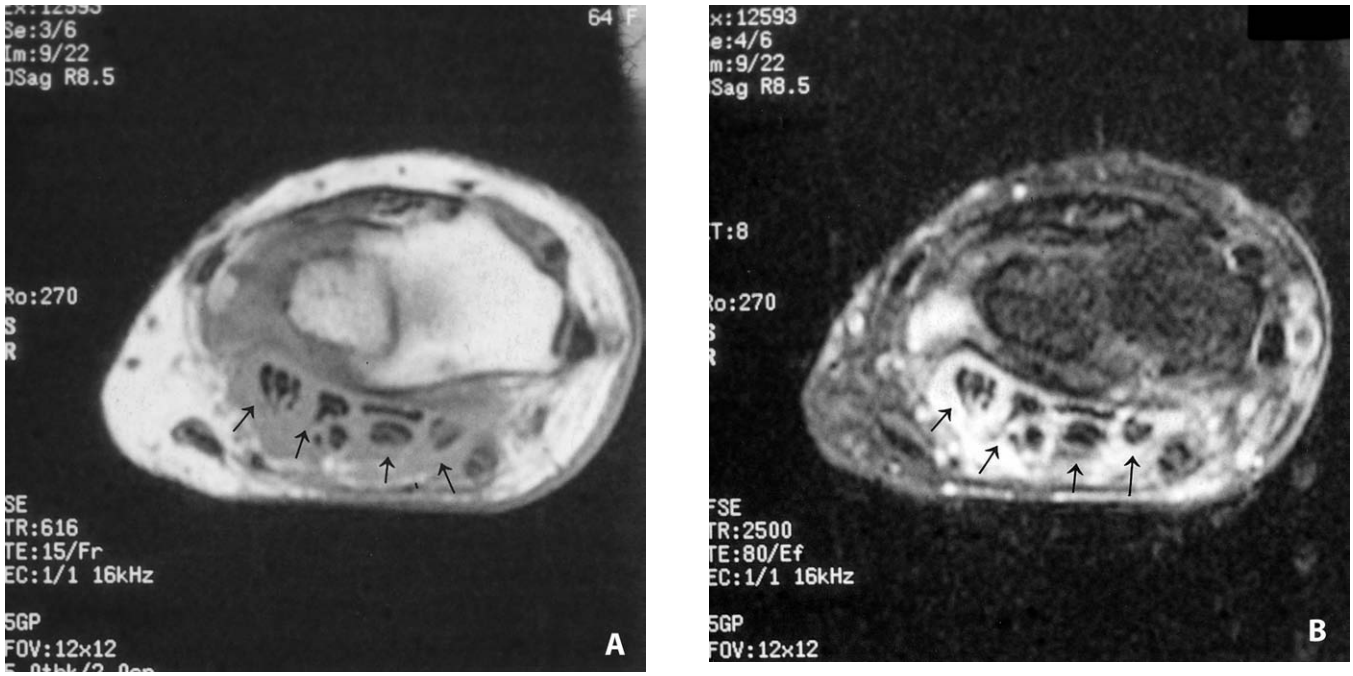

FIGURE 7 (A) Axial T1-weighted MR image (616/15) of the distal ulna and radius shows low-signal-intensity fluid (*black arrows*) surrounding the flexor tendons in a 46-year-old woman with SLE. (B) T2-weighted MR image with fat saturation (2500/80) shows high-signal-intensity fluid (*black arrows*) surrounding the flexor tendons consistent with a tenosynovitis and some high signal intensity within the tendons consistent with tendonitis.

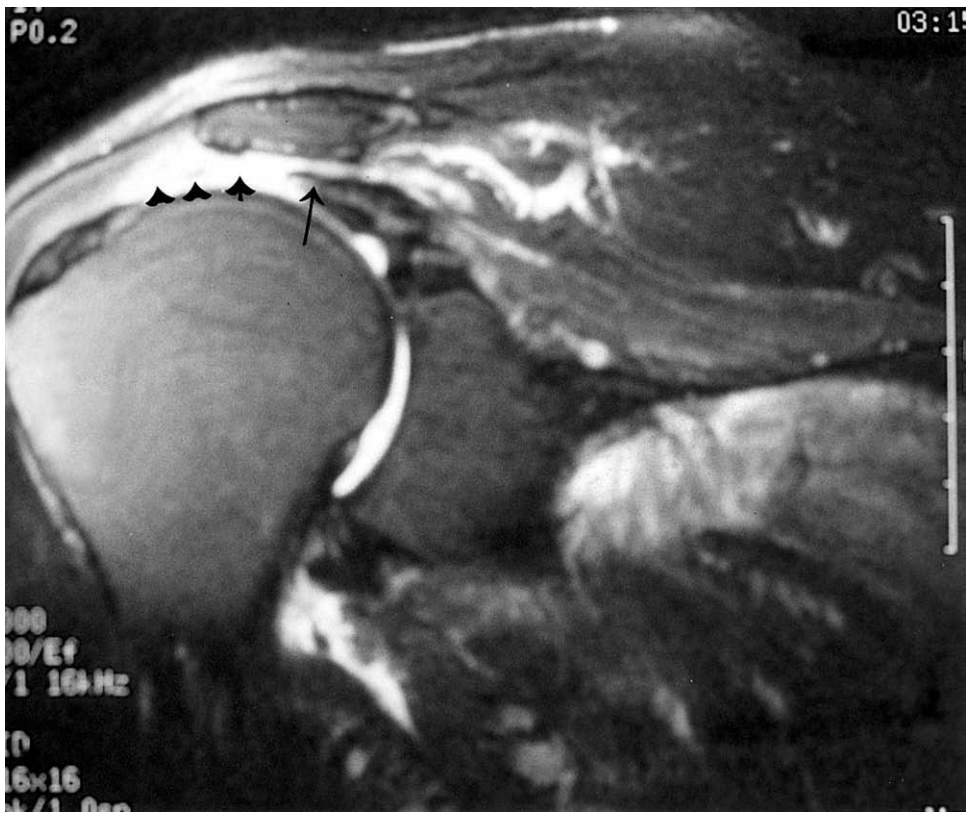

FIGURE 8 Coronal oblique T2-weighted MR image with fat saturation (3000/100) of the right shoulder of a 54-year-old woman with SLE who developed shoulder pain while on long-term steroids. High-signal-intensity fluid communicates between the subacromial bursa and the shoulder joint and defines the point of tear (*arrowheads*) and the retracted rotator cuff (*arrow*).

FIGURE 9 (A) Axial T1-weighted MR image (650/16) of the fingers shows low signal intensity around the deep and superficial flexor tendons of the third digit and the adjacent soft tissues, which becomes high signal intensity on (B) axial T2-weighted with fat saturation MR images (5000/84) This 67-year-old woman with SLE, who had received high-dose corticosteroids, presented with fever and a swollen finger. Axial (C) and sagittal (D) contrast-enhanced T1-weighted with fat saturation MR images (586/18) show enhancement (*arrows*) of the tendons and soft tissues. The tenosynovitis was biopsied, and the culture grew slow-growing mycobacterium.

biceps tendon) or groups of tendons (e.g., rotator cuff), although adjacent osseous structures cannot be evaluated [32, 33] More recently, the addition of tissue harmonic sonographic imaging, extended field-of-view imaging, and power Doppler to standard sonography have improved the detection of tears and inflammation [33a–33c]. Tissue harmonic sonographic imaging shows better spatial and contrast resolution of normal and pathologic tissues than standard sonography [33a]. Extended field-of-view imaging shows the full extent of a particular tendon or ligament or focus of inflammation or abscess on one image [33b]. Power Doppler

sonography is more sensitive than conventional Doppler for depicting increased blood flow in areas of inflammation in and around tendons, ligaments, bursae, and muscles [33c].

SLE is not the only etiologic factor predisposing to ligamentous or tendinous tears. Corticosteroids, even in the absence of ligamentous disease, may cause detritic structural changes that result in rupture. Histologic examination of the ligament shows features of collagen damage. Resnick [3] reported spontaneous rupture of tendons in SLE patients and indicated that these patients typically had received corticosteroids. Attrition of the periarticular capsular structures may be an explanation for laxity and joint deformities.

Carpal instability in SLE is not uncommon and occurred in 14.5% of our series and was associated with bilateral scapholunate dissociation in 9.7% of the patients. At radiography, a 3-mm or greater widening of the scapholunate joint is a sign of this instability and has been named the "Terry Thomas" or, more recently, the "David Letterman" sign (Fig. 10) [34]. Radiographs of the hand in the neutral position may be normal. However, when the patient is examined at fluoroscopy, transient carpal subluxation or "popping" of a carpal bone may be seen during ulnar–radial and flexion–extension movement of the wrist. Radiographs taken in ulnar deviation are a useful static method for showing instability. Intraarticular contrast-enhanced wrist arthrography can delineate the ligamentous tears by showing communication between wrist compartments [35]. More recently, high-resolution MRI, especially with intraarticular contrast enhancement, has been useful for delineating tears of the ligaments and tendons of the wrist [36] and may replace conventional arthrography in the future. The newer modalities of ultrafast electron beam CT and fast (echoplanar) MRI have potential application for dynamic cross-sectional imaging of joint kinematics and stability [37, 38].

FIGURE 10 This patient with SLE presented with clicking and instability of the wrist. Anteroposterior radiograph of the wrist shows widening of the scapholunate joint consistent with rupture of the scapholunate ligament.

Complications of Treatment of SLE

Osteonecrosis

One of the more serious complications of SLE is osteonecrosis of the articular ends of the bones followed by secondary joint degeneration (osteoarthritis). In 1960, Dubois and Cozen [39] described the association of "avascular (aseptic) bone necrosis" and SLE. They reported a series of 400 patients with SLE; 10 patients (2.5%) developed osteonecrosis. All except 1 patient had received corticosteroids before the appearance of ischemic necrosis. Osteonecrosis may involve three or more anatomic sites and may be unifocal or multifocal. In a retrospective study of patients with osteonecrosis of various etiologies, 3% (32 of 1032 patients) had multifocal disease. Thirteen of the 32 patients were lupus patients treated with chronic corticosteroid therapy [40]. The spontaneous onset of osteonecrosis in SLE is rare [40a].

Since the initial report of Pietrogrande and Mastromarino in 1957 [41], corticosteroid-induced osteonecrosis has become a well-established entity. The prevalence of osteonecrosis in adult patients with SLE varies from 5 to 6% [3, 39, 42] to 32% (our series). All of our patients were receiving prednisone. However, the prevalence of osteonecrosis in children with lupus appears to be higher at 40% [43–45]. MRI [46–49] is the most sensitive modality for detecting early osteonecrosis and infarcts and also should be used for following response to medical or surgical therapy for osteonecrosis (e.g., changes with nonweight-bearing, core decompression, osteotomy, fibular graft placement).

Klipper *et al.* [50] reported Raynaud's phenomenon in 61% of patients with SLE and osteonecrosis, especially those who had received high or sustained dosages

of corticosteroids. However, Griffiths *et al*. [51] found no significant difference in the prevalence of Raynaud's disease when osteonecrosis complicated SLE.

Osteonecrosis has a predilection for the femoral head (Fig. 11) but also involves the humeral head, the femoral and tibial condyles, the talus, and the smaller tubular bones of the hands and feet. Weight-bearing joints are typically more affected than nonload-bearing joints of the upper extremities. In the lower extremity, the most commonly affected site is the head of the femur and the least frequently are the bones of the foot and ankle. Similarly, in the upper extremity, the head of the humerus is involved most commonly and, considerably less frequently, the smaller bones of the wrist and hand. Diaphyseal infarctions are less common than osteonecrosis at the articular ends of the bone. The clinical onset of osteonecrosis may be insidious. The onset of pain and limitation of motion in patients with chronic osteonecrosis may alert the clinician to the development of detritic synovitis, secondary osteoarthritis, or both [52]. However, osteonecrosis in SLE may be occult.

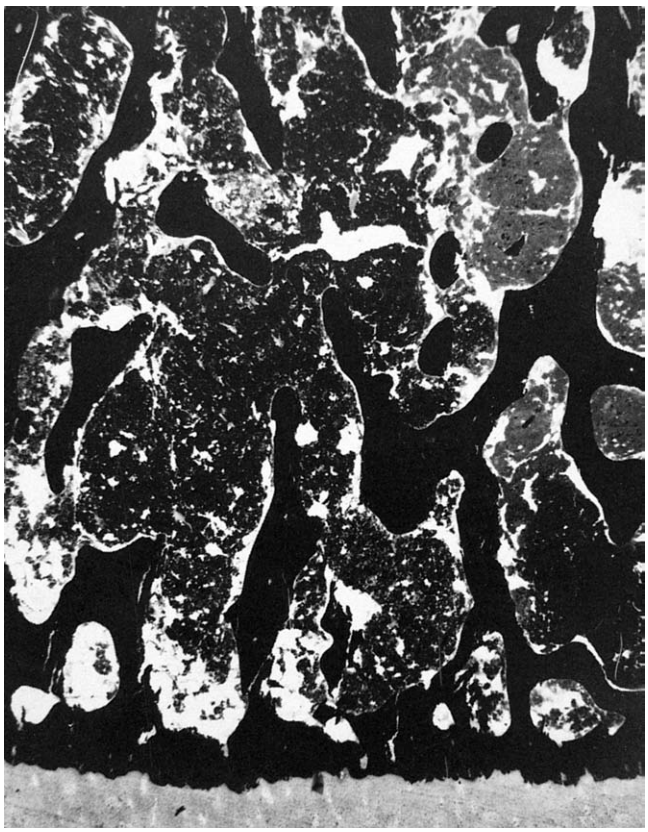

FIGURE 11 A photomicrograph of the femoral head from a 34-year-old man with SLE shows a corticosteroid-induced osteonecrosis. The increased density in the subchondral region results from extensive calcification in the marrow (undecalcified bone, von Kossa's stain) (magnification ×26).

In a study of 66 lupus patients who had received at least 5 mg/day prednisone for longer than 6 months, 8% of patients had asymptomatic osteonecrosis of the hip documented at MRI, which was metabolically inactive as evidenced by normal radiopharmaceutical uptake on ^{99m}Tc MDP bone scans. The lesions did not show progression or regression on clinical or imaging examination during a 1-year interval. The authors suggested that the stability of the lesions may also be related to the stability of prednisone dosages and disease activity during the time period studied [53a].

The radiographic features of osteonecrosis in SLE are identical to those seen in other conditions (e.g., trauma, corticosteroids, Gaucher's disease, sickle cell disease, and decompression bone disease). Regardless of the underlying cause, the radiographic findings and pathogenesis are the same. Histologic examination of osteonecrosis shows that, after the vascular insult, the subarticular bone and fatty marrow become necrotic and that calcifications are deposited in the nonviable marrow (saponification of fat). In the early stage, when the calcification is deposited minimally in the marrow, radiographic findings are often absent because the foci of calcification cannot produce adequate density. However, at this stage, MRI demonstrates early high-signal-intensity edema and hemorrhage. When calcification of the marrow is more extensive, the medullary bone will appear denser at radiography. Once the reparative process begins and vascular granulation tissue erodes the subchondral zone (e.g., femoral head), bone is resorbed and the articular cortex becomes structurally weakened and can collapse under the strain of weight-bearing. At radiography, the subchondral fracture is a crescent of radiolucency that parallels the articular cortex of the bone (Fig. 12). This crescent sign is pathognomonic of osteonecrosis [53]. The radiolucent crescent subtends the necrotic zone like an umbrella covering the area of infarct. Ultimately, the dead cancellous bone in the involved area undergoes microfractures, with the result that osteochondral fractures of the articular surface are detected radiographically. Appositional new bone scaffolding on necrotic trabeculae is a significant process that contributes to the increased density of the ischemic portion of the bone (Fig. 13) [3, 53]. This process of repair is what Pfemister called *creeping substitution*. The infarcted area is composed of three zones: (1) a central "yellow zone" of necrotic trabeculae and detritic marrow, (2) a "red zone" of fibrovascular granulation tissue delimiting the necrotic tissue, and (3) the "white zone" of reparative sclerosis around the periphery of the ischemic infarction. The greater the repair response in the infarcted bone, the denser it appears. In order of importance, the following factors contribute to the radiodensity of the bone: (1) the appo-

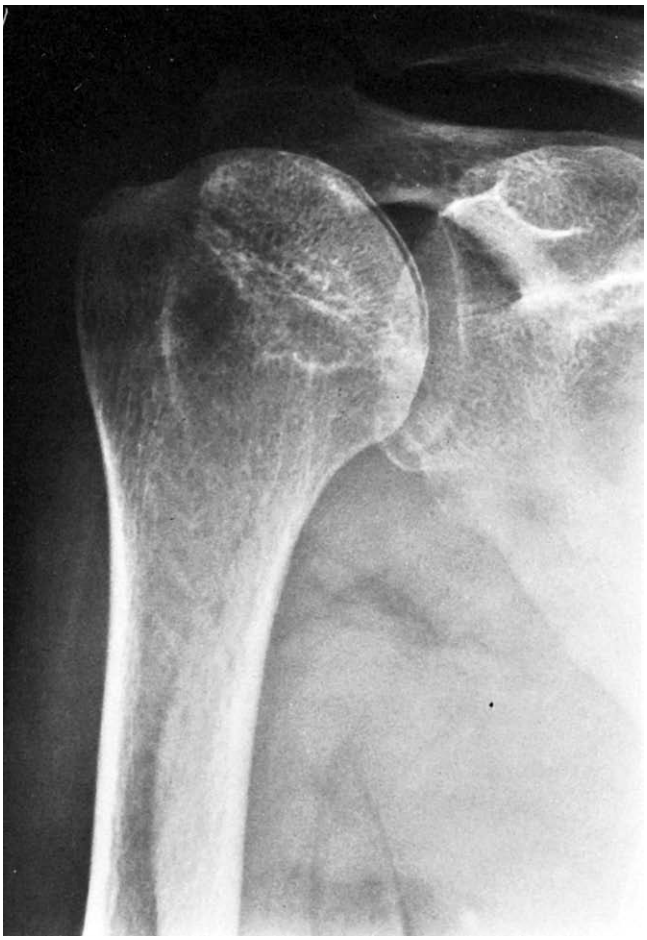

FIGURE 12 The radiolucent crescent of subchondral bone is the hallmark of osteonecrosis on this radiograph of a shoulder of a patient with SLE. Initially, the joint space is unaffected.

sition of new bone on nonviable trabeculae, (2) the calcification of necrotic fatty marrow (see Fig. 11), (3) microfractures and compression of the dead trabeculae, and (4) the apparent increased bony density because of the surrounding osteoporotic viable bone. In addition to epiphyseal osteonecrosis, medullary infarcts may develop in lupus. Often, however, the infarcts may not be visible on radiographs but are well defined at MRI (Fig. 14). Laminar periostitis is another radiographic finding occasionally associated with vascular complications of SLE [54, 55].

Prior to MR imaging, ^{99m}Tc MDP bone scans were the preferred modality for identifying osteonecrosis. When the blood flow to the necrotic zone is deficient (ischemic), the bone scan focally becomes photopenic because of an absent uptake of the radiopharmaceutical. When the reparative process begins, scintigraphy shows increased radiopharmaceutical uptake.

MRI is the most sensitive test for early recognition of osteonecrosis (Fig. 15) [47–49]. Different stages of osteonecrosis show different characteristics. With early osteonecrosis, 85% of patients may have no symptoms or only mild symptoms, radiographs are normal, and bone scans are false negative in 15% of studies. At this early stage, T2-weighted MR images, especially with fat saturation, are positive with high-signal intensity in areas of acute inflammation, edema, hemorrhage, or vascular engorgement in the affected bone. Recognition at this early stage is essential to prevent the complications of collapse and secondary osteoarthritis. As edema resolves, osteonecrosis may then show a "double line sign" consisting of a hypointense, fibrotic, peripheral, reactive rim around hyperintense marrow fat. In later stages, osteonecrosis becomes low signal intensity on T2-weighted MR images because hypointense fibrous tissue replaces marrow fat. These MRI features correlate with the radiographic findings of subchondral collapse. In addition to necroses in the epiphyses, MRI can also demonstrate well-demarcated medullary bone

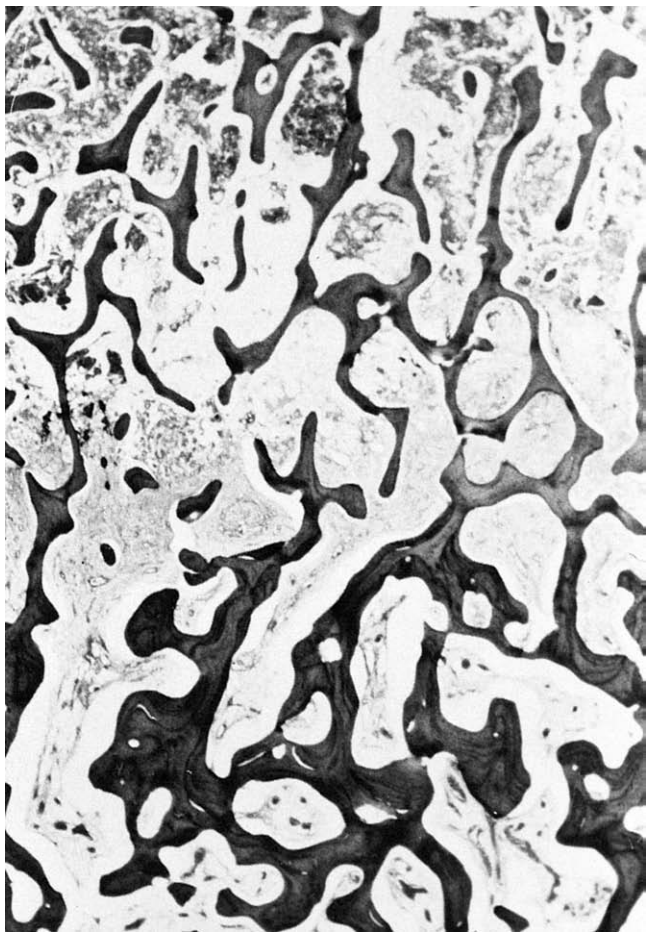

FIGURE 13 A major factor contributing to the increased density of the bone is the apposition of new bone upon necrotic trabeculae (creeping substitution) as seen on this photomicrograph.

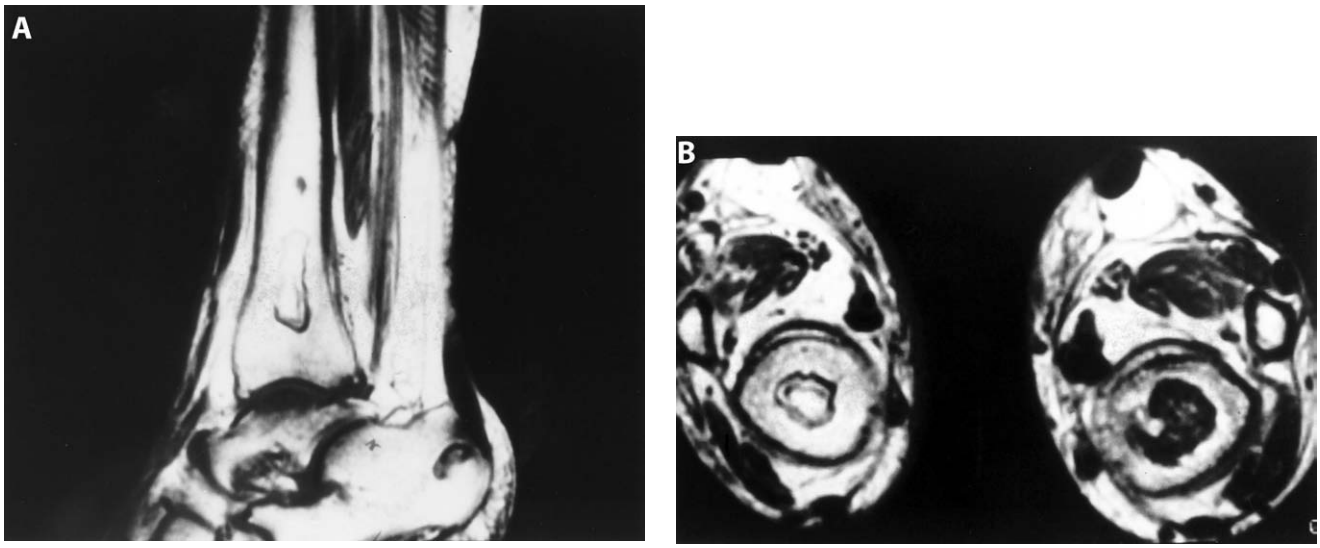

FIGURE 14 (A) Sagittal and (B) axial T1-weighted MR images (500/30) of the tibia show well-demarcated infarcts in the metadiaphysis in a 33-year-old woman with SLE who had received corticosteroid therapy for several years.

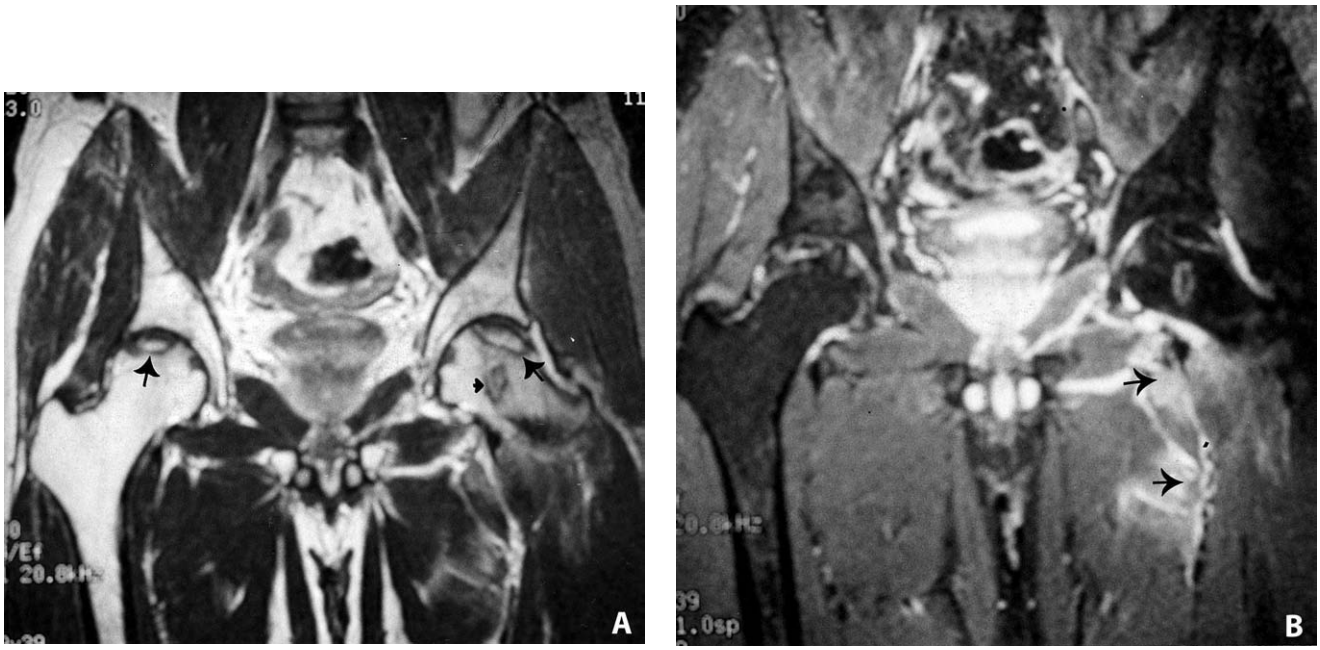

FIGURE 15 This 36-year-old man with SLE had bilateral hip and left thigh pain. (A) Coronal T1-weighted MR image (566/16) of the hips shows crescentic bilateral osteonecrosis of femoral heads (*large arrows*) and a well-defined medullary infarct (*arrowhead*) of the neck of the left femur. The left adductor magnus muscle displays heterogeneous signal intensity. (B) Coronal short tau inversion recovery (STIR) MR image (4900/89/150) shows the osteonecroses surrounded by high signal intensity (*arrowhead*). Normal marrow fat is low signal intensity. Fluid is present in the hip joints. The feathery pattern of high signal intensity in the left adductor magnus muscle (*arrows*) is consistent with myositis.

infarcts (Fig. 14). Although T1- and T2-weighted MR images in orthogonal planes are the standard sequences for evaluating osteonecrosis and infarcts, the addition of intravenous contrast medium can improve differentiation between acute medullary bone infarct and osteomyelitis (see section on osteomyelitis) [49a].

The complications of osteonecrosis are often more serious than the condition itself. In the later stages of ischemic necrosis, deformity of the articular surface may develop with risk of secondary osteoarthritis, which, when severe, necessitates arthroplasty. Norman [52] reported the conditions that predispose to secondary osteoarthritis as osteonecrosis (30%), "burnt-out" inflammatory arthritis (i.e., rheumatoid arthritis, ankylosing spondylitis) (28%), congenital dislocation of the hip (26%), and epiphysiolysis (9%). In osteonecrosis, the articular cartilage remains intact for a longer period of time than in idiopathic osteoarthritis. This explains why the joint is not affected initially in the degenerative process, whereas in primary osteoarthritis, the cartilage is the first tissue to undergo degeneration with cartilage loss and joint space narrowing. After the joint narrows, osteophytes form as part of the repair response. They ring the articular surface away from the zone of heavy weight-bearing. Within the pressure segment, the cartilage surface is denuded, and sclerosis, subarticular cysts, or pseudocysts form in the subchondral zone (Fig. 16A). The pseudocysts are metaplastic foci of cartilage and fibrous tissue. Characteristically, foci of articular cartilage remain intact in osteonecrosis, even in the weight-bearing segment. The pattern of joint cartilage destruction in secondary osteoarthritis is decidedly different from that of idiopathic osteoarthritis. When the hip, shoulder, or any other joint is put through a range of motion, some retention of joint space is likely to be present in the different positions. This radiographic sign may help differentiate osteoarthritis resulting from osteonecrosis from idiopathic osteoarthritis (Fig. 16B). When arthroplasty is performed for severe osteoarthritis, the stability of the arthroplasty or the presence of loosening, subsidence, and failure are evaluated on sequential radiographs. ^{99m}Tc MDP bone scans are also useful for evaluating infection, and arthrography can delineate areas of abscess formation.

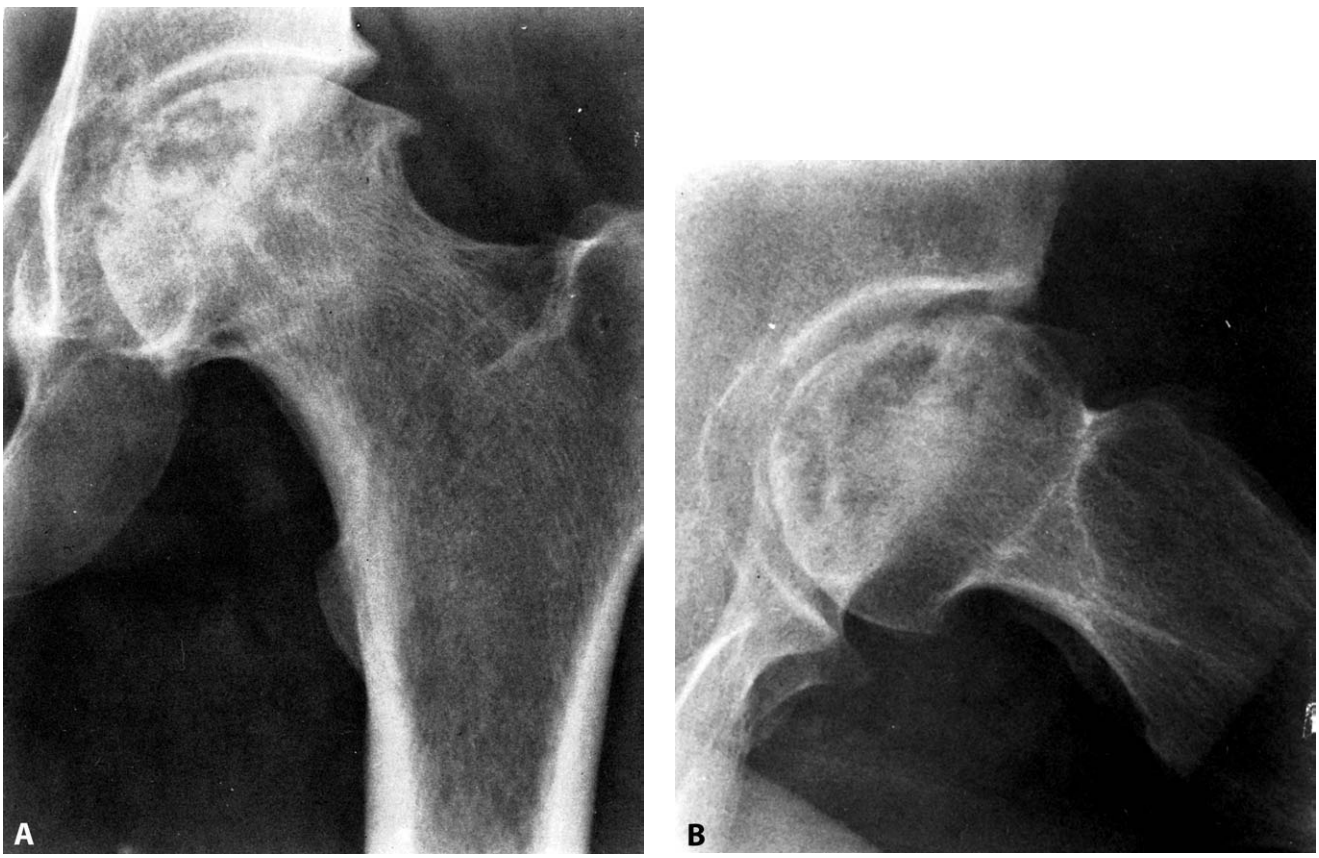

FIGURE 16 (A) Anterior–posterior radiograph shows secondary osteoarthritis complicating steroid-induced osteonecrosis in a 20-year-old woman with SLE. (B) The oblique radiograph of the hip shows retention of the joint space despite osteophytes. This would suggest persistence of articular cartilage.

Intravertebral Vacuum Cleft

The intravertebral vacuum cleft sign (Fig. 17), reported by Maldague *et al.* [56], represents a sign of osteonecrosis of the vertebral body. The radiographic gas shadow (cleft) within the vertebra associated with vertebral collapse is a rare but distinctive finding and aids in excluding a space-occupying lesion such as infection or tumor as the cause of the vertebral collapse. Often, these patients have been on corticosteroids. In one series, 7 of 10 patients with the vacuum cleft were receiving corticosteroid therapy.

Insufficiency Fractures

Patients with SLE who develop osteoporosis on long-term corticosteroid therapy are susceptible to insufficiency fractures that result from loads applied to weakened bones [57].

Radiographs may be negative for fracture in 50% of patients, but ^{99m}Tc MDP-delayed bone scans demonstrate increased uptake in areas of stress fracture. When bone scans are indeterminate, MRI can be useful for delineating the fracture as focal linear areas of high signal intensity on T2-weighted MR images, often associated with extensive high-signal-intensity edema in the adjacent bone marrow [57a].

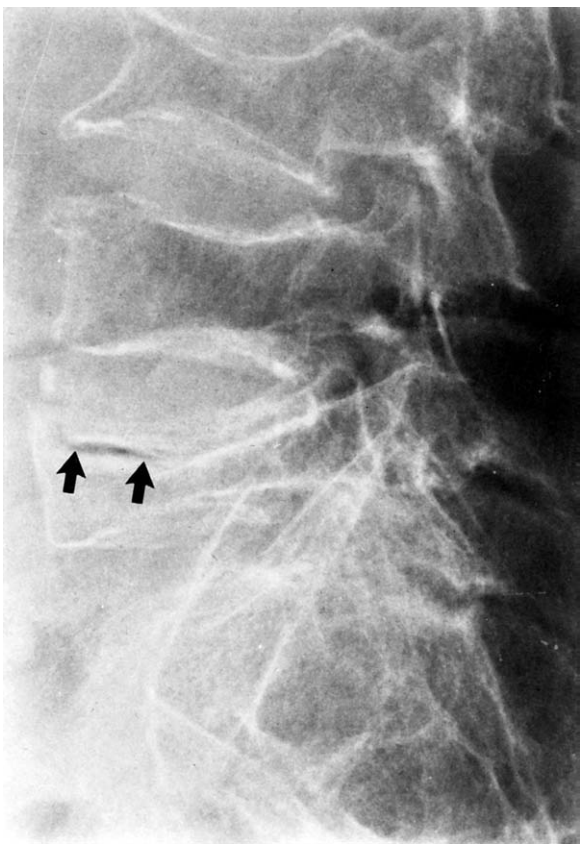

FIGURE 17 A rare finding of an intravertebral vacuum sign (*arrows*) in a lupus patient treated with corticosteroids.

Infections of Bones and Joints

Corticosteroid and immunosuppressive therapy predispose lupus patients to infection [58–60]. Investigators have shown that infection was the primary cause of death in 40% of patients with SLE [58]. When the daily dosage of prednisone is maintained above 40 mg/day, there is a five- to sevenfold increase in infection. The most common of sites of bacterial infection are the urinary tract, lungs, and skin. A small number of patients, however, develop infectious arthritis [58], osteomyelitis, or both. Septic arthritis can be monoarticular or polyarticular, and the onset is usually acute (within 24–72 hours). Suppurative arthritis associated with SLE can be a serious problem. One must be alert to the features of possible infection in order to establish the diagnosis, identify the organism, and institute appropriate treatment promptly. The knee is the most commonly affected joint, but other joints involved are the hip, ankle, and elbow, in descending order of frequency. *Neisseria* or gram-negative bacilli are often cultured from the infected joints of patients with SLE. In contrast, in rheumatoid arthritis, the characteristic organism is *Staphylococcus aureus* in 75% of patients [60]. Initially, radiographs may be normal or show periarticular osteoporosis without erosions. With progression, radiographs may demonstrate joint effusions and focal erosions at the periphery of the articular surface of the bone [58], or, with acute suppurative arthritis, joint destruction and pathologic subluxation [61, 62]. ^{99m}Tc MDP bone scans demonstrate increased radiopharmaceutical uptake of the involved joint. MRI shows the joint effusions that are sometimes loculated and thickened synovium (Fig. 18). High-signal-intensity edema may also develop in the adjacent bone. Power Doppler can detect the inflammatory tissue by showing increased blood flow [33c], and duplex sonography helps localize joint fluid for aspiration.

Suppurative osteomyelitis as an isolated complication of SLE is not as common as infectious arthritis. Hematogenous spread is the usual route of infection. In the past, ^{99m}Tc MDP scintigraphy was used extensively for detecting osteomyelitis. Currently, MRI, when available, is the preferred modality. MRI is as sensitive as bone scintigraphy in the early detection of osteomyelitis, but because of its superior spatial resolution, MRI is more specific for distinguishing osteomyelitis from arthritis, cellulitis, and soft tissue abscess [63, 63a]. On T2-weighted MR images, particularly on fast spin echo sequences, fatty marrow and osteomyelitis both appear hyperintense, and osteomyelitis may be obscured. With fat saturation (suppression), fatty marrow becomes low

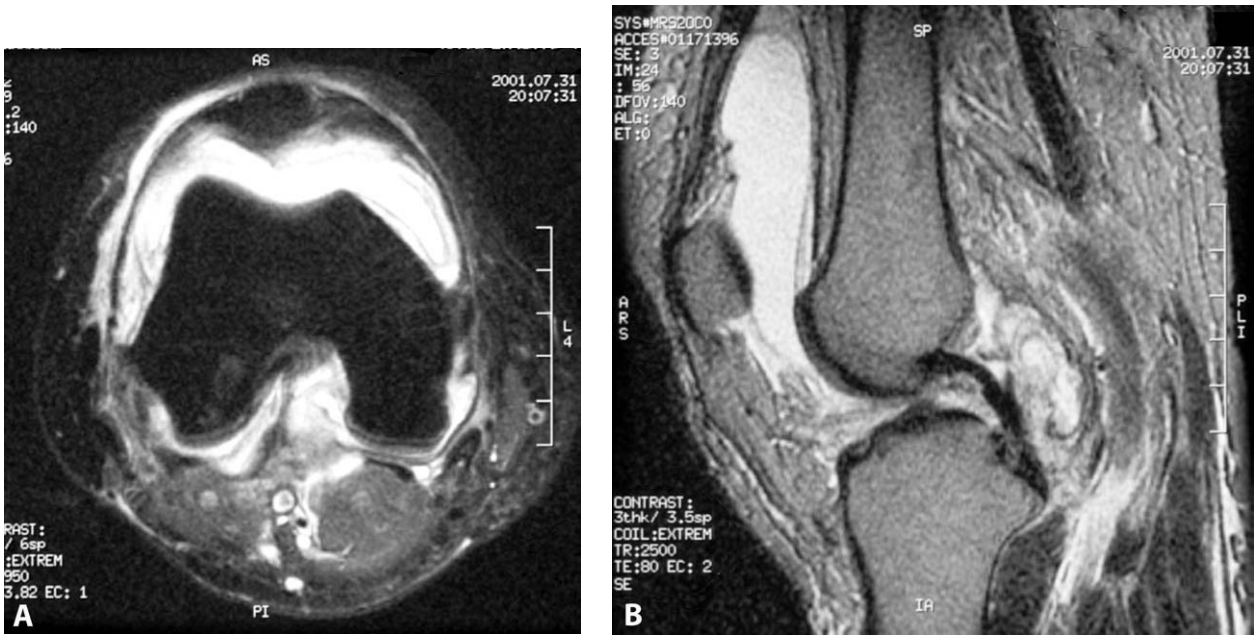

FIGURE 18 (A) Fast spin echo axial T2-weighted with fat saturation (3950/34) and (B) sagittal oblique T2-weighted MR images (2500/80) show a large effusion with thickened synovium and posterior loculation in this lupus patient with knee pain and infective arthritis. Culture from a biopsy grew out *Cocciodiomycosis immitis*.

signal intensity on the T2-weighted sequence. In contrast, osteomyelitis is hyperintense and conspicuous. The addition of contrast medium and fat saturation to the T1-weighted sequence also enhances the detection of osteomyelitis because intensely enhancing osteomyelitis contrasts with nonenhancing yellow marrow and mildly enhancing red marrow. Contrast-enhanced MRI also separates necrotic, gangrenous tissue that does not enhance from the cellulitis that does (Fig. 19). The identification of both necrosis and cellulitis assists the surgeon in selecting the areas for surgical debridement. Contrast-enhanced T1-weighted MR sequences may

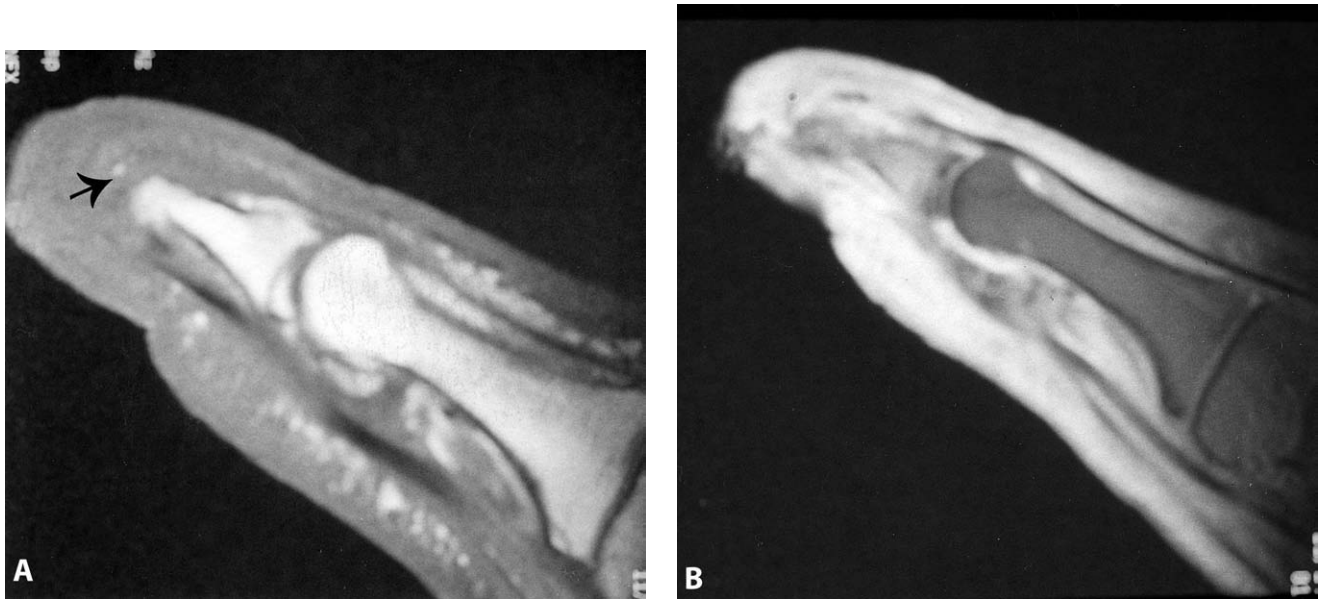

FIGURE 19 (A) Sagittal T1-weighted MR image (500/14) of the great toe shows extensive low signal intensity in the soft tissues and in the region of the poorly-defined distal phalanx (*arrow*) of a 53-year-old woman with SLE and a markedly swollen tender toe. (B) Sagittal contrast-enhanced T1-weighted with fat saturation MR image (566/14) shows the enhancing soft tissues, middle phalanx, and partially destroyed distal phalanx consistent with cellulitis and osteomyelitis.

also be helpful for differentiating the acute infarct with thin linear rim enhancement from osteomyelitis with more geographic and irregular marrow enhancement [49a]. Occasionally, radiographs can show findings of bone and soft tissue destruction in patients with severe vasculitis and gangrene of the fingers and toes and superimposed pyogenic infection (Fig. 20).

Osteomalacia

A rare complication of lupus treatment is the development of osteomalacia. One patient in our series had severe SLE with extensive vasculitis of the bowel and infarction of the intestines. A major resection of the diseased loops of bowel was performed to control her disease and symptoms. The sacrifice of a considerable length of intestine may result in malnutrition and severe osteomalacia.

Renal Osteodystrophy and Renal Failure

The lupus patient with renal osteodystrophy (with or without dialysis) may show multiple soft tissue and bone abnormalities, particularly soft tissue and vascular calcifications (Fig. 21), bone resorption, osteosclerosis, and osteoporosis at radiography [64]. Cortical thinning can be a manifestation of both secondary hyperparathyroidism and osteoporosis. In lupus patients with renal osteodystrophy and secondary hyperparathyroidism, ^{99m}Tc MDP bone scans may show the "super scan" or "metabolic bone scan" with diffuse increased radiopharmaceutical osseous uptake, although this is not as commonly seen as in primary hyperparathyroidism.

In lupus patients with renal failure, delayed ^{99m}Tc MDP whole body bone scans can demonstrate increased uptake in soft tissues as well as decreased renal parenchymal uptake because of decreased renal excretion of radiopharmaceutical (Fig. 22).

Myopathy

Eighteen of 228 lupus patients (8%) who were followed for at least a 6.5-year period manifested muscle disease. In another study, 50% of patients with SLE had muscle involvement [65]. The myopathy appeared to parallel the activity of the patient's disease. Most patients with lupus myositis experience myalgia, weakness, and tenderness in the muscle groups, especially around the shoulder and hip. In the pediatric age group, patients with SLE frequently have pain in the muscles of their extremities, which is almost as frequent as arthralgias. Local swelling in the muscle bellies is often circumscribed and transient.

The exact etiology of lupus myopathy is controversial. Other factors that may contribute to muscle symptomatology are referred pain from adjacent joints or a proximal myopathy developing as a complication of high-dose corticosteroid therapy. Isenberg and Snaith [65] studied the muscle biopsies specimens from 20 lupus patients with myopathy, 10 of whom had abnormal histology. They concluded that the findings were nonspecific.

MRI defines the extent of the myositis and the response to treatment. However, lupus patients who are on corticosteroids may also show atrophy with fatty infiltration of their muscles. On newer, fast spin echo T2-weighted MR images, both fatty atrophy of muscle and myositis produce linear areas of high signal intensity within the muscle. When fat suppression is used, fat in atrophic muscle will appear hypointense and the remaining hyperintense areas in muscle represent myositis (Fig. 23). Likewise, on contrast-enhanced, fat-suppressed T1-weighted MR images, areas of myositis will enhance intensely in contrast to normal or atrophic muscle, which shows only mild enhancement (Fig. 23). Pyomyositis [66] must always be excluded in SLE and cannot be differentiated from noninfected, inflammatory myositis unless associated abscesses are identified. Sonography or CT provides guidance for abscess localization and drainage.

IMAGING OF DERMATOLOGIC SLE

Soft tissue calcification, although more common in dermatomyositis and scleroderma, is occasionally seen in SLE [20, 21, 67–76]. Budin and Feldman [75] described the four different patterns of calcifications in SLE at radiography as diffuse, linear, streaky, and nodular. They emphasized that soft tissue calcifications may be present in the skin and subcutaneous tissues and in the peripheral vasculature in lupus patients without renal osteodystrophy (Fig. 24). Calcifications are usually localized (the circumscripta type) but may be generalized (universalis type). Shapeero and Miller [20] found only 1 of 141 patients with the generalized form, with subcutaneous calcifications of the chest, abdomen, and extremities (Fig. 25). Different factors have been proposed to explain soft tissue calcification in SLE, including infection, vasculitis, and autoimmune response at the cell membrane with resultant cell necrosis and dystrophic calcification [75]. Soft tissue calcification in the lupus patient may also be a manifestation of renal osteodystrophy as discussed in that section (Fig. 21).

Increased uptake of ^{99m}Tc hydroxydiphosphonate in extraosseous sites has also been reported in SLE

FIGURE 20 This 59-year-old woman had a 30-year history of SLE. She developed severe vasculitis complicated by gangrene of the digits of both hands. (A) The status at onset. (B) Loss of soft tissue at the peripheral parts of the digits.

FIGURE 20 (*Continued*) (C) Severe gangrene and slough of the soft tissue of the index and middle fingers. The right thumb was amputated because of gangrene. (D) One year later, an osteomyelitis destroyed the terminal phalanx of the little finger. (E) Two years, later the osteomyelitis has progressed to involve the proximal phalanx of the index finger, with more extensive involvement of the infection into the little digit and more extensive gangrene.

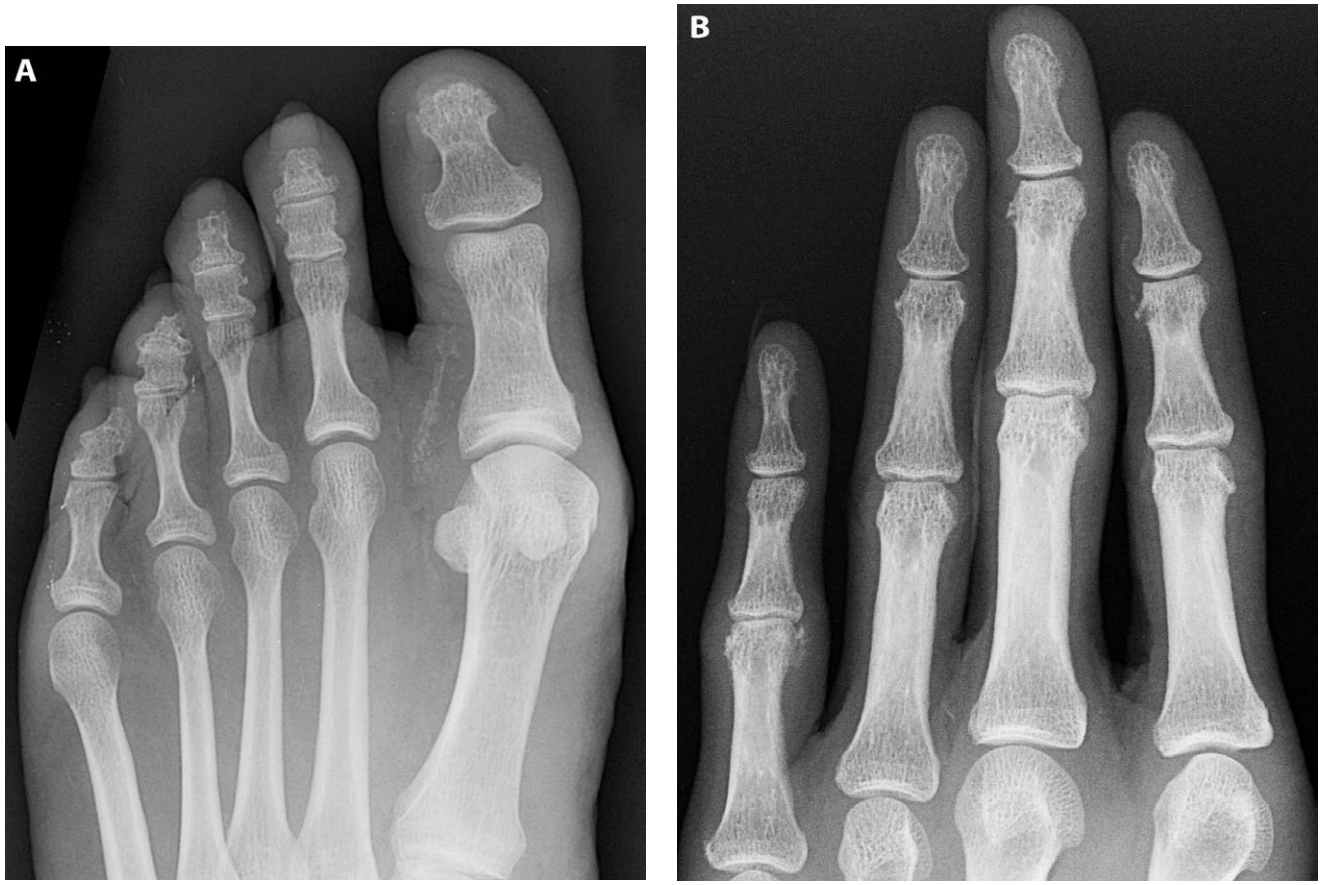

FIGURE 21 Anterposterior radiographs of the (A) foot and (B) hand show linear vascular and focal juxta-articular calcifications in the soft tissues and subperiosteal absorption of the radial aspect of the proximal phalanges in a 37-year-old dialysis patient with SLE and with renal osteodystrophy.

FIGURE 22 Whole body delayed anterior and posterior planar scintigraphic images 3 h after injection of 99m-Tc HDP show diffuse soft tissue uptake with bilateral decreased renal parenchymal uptake consistent with renal failure in this patient with lupus nephritis.

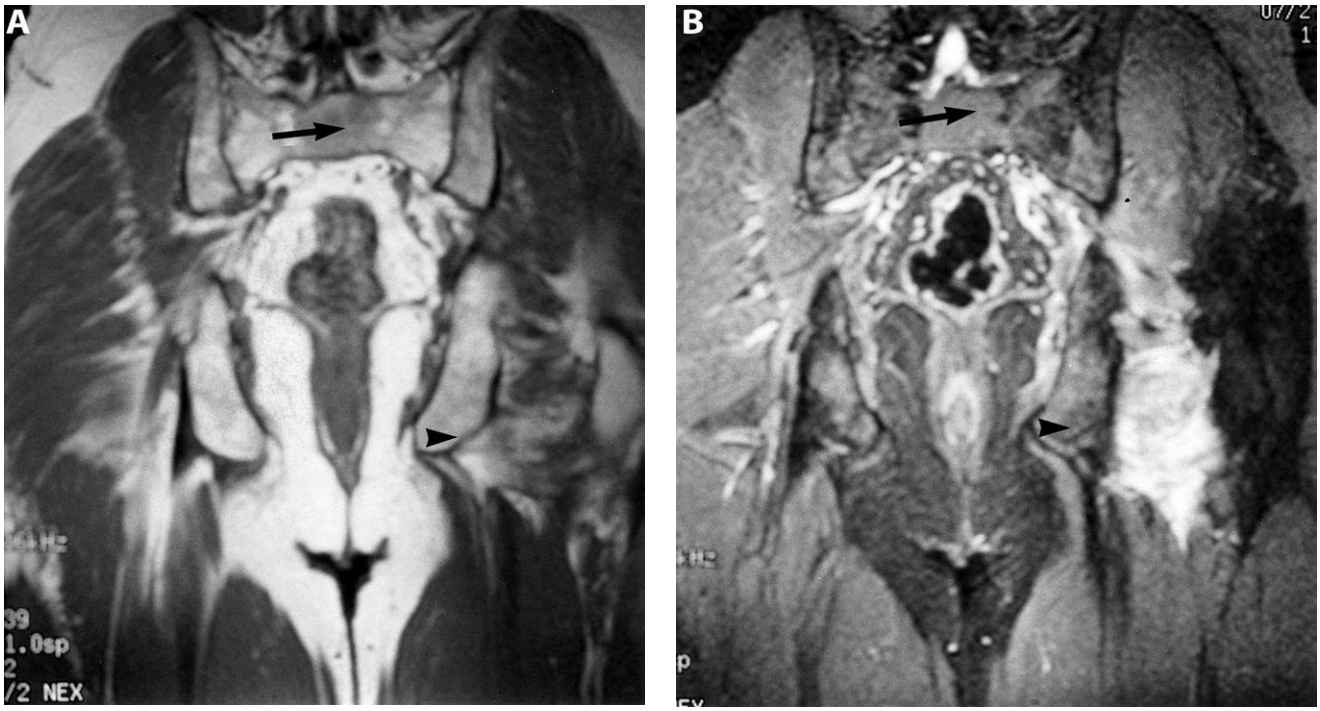

FIGURE 23 (A) Coronal T1-weighted MR image of the pelvis shows heterogeneous signal intensity of the left thigh muscles (obturator internus, obturator externus, gemelli, and adductor magnus) that could result from fatty atrophy or inflammation/hemorrhage in a patient with SLE. (B) Coronal short tau inversion recovery MR image (fat is low signal intensity) shows diffuse high signal intensity in this region consistent with myositis (*arrow*, sacrum; *arrowhead*, ischium).

FIGURE 24 Lateral radiograph of left knee shows calcific plaques and heavily calcified femoral and popliteal arteries in a 19-year-old woman with SLE without renal osteodystrophy From Budin and Feldman [75], with permission.

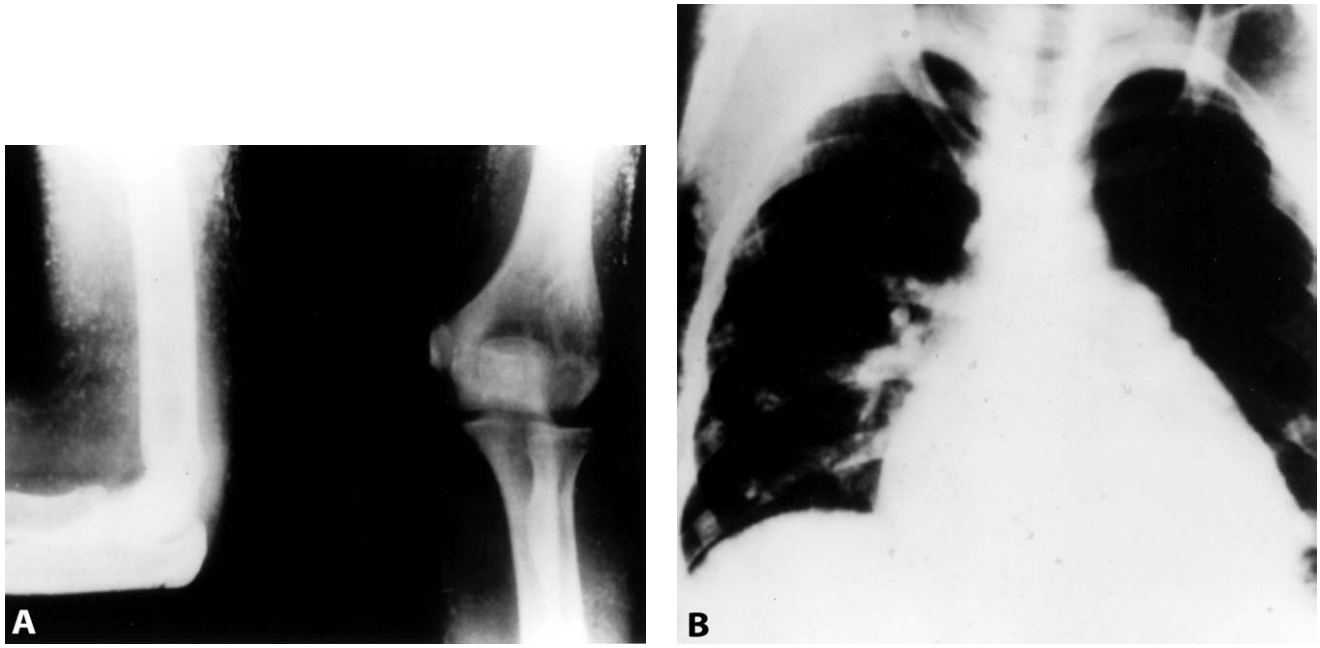

FIGURE 25 (A) Anteroposterior and lateral radiographs of a right elbow show multiple linear and nodular calcifications in the superficial and deep soft tissues. (B) Posteroanterior chest radiograph shows diffuse calcification of the soft tissues of the chest in an 18-year-old woman with SLE with calcinosis universalis and cutis. From Shapeero and Miller [20], with permission.

even though no abnormal soft tissue calcifications were seen on the radiographs. The basic mechanism for nonosseous uptake of radiopharmaceuticals is not known. Various mechanisms have been suggested: absorption to soft tissue calcium and immobile collagen, binding of the hormone or enzyme receptors, and tagging to denatured protein [76].

As discussed in the section on renal failure and musculoskeletal abnormalitites, diffuse increased radiopharmaceutical uptake in the soft tissues on delayed ^{99m}Tc MDP bone scans can occur in lupus patients with a decreased renal excretion of radiopharmaceutical (Fig. 22).

IMAGING OF PLEUROPULMONARY SLE

Pleural Effusions

Pleural involvement is the most common radiographic manifestation of SLE. Pleural effusions (Fig. 26) are often small, transient, recurrent, and bilateral [77–80] but may be massive and refractory to treatment [81]. Pleural effusions may also develop in the lupus patient with pulmonary infarcts, pulmonary infection, or congestive heart failure secondary to myocarditis, hypertension, or uremia. Lupus pleural effusions have normal glucose concentration in contrast to the low glucose level in infectious or rheumatoid pleural effusions. The majority of effusions reported in the literature are exudates; LE cells may be present [82, 83]. The posterior–anterior, lateral, and lateral decubitus radiographs identify the pleural effusion, and sonography may be useful for guiding thoracentesis.

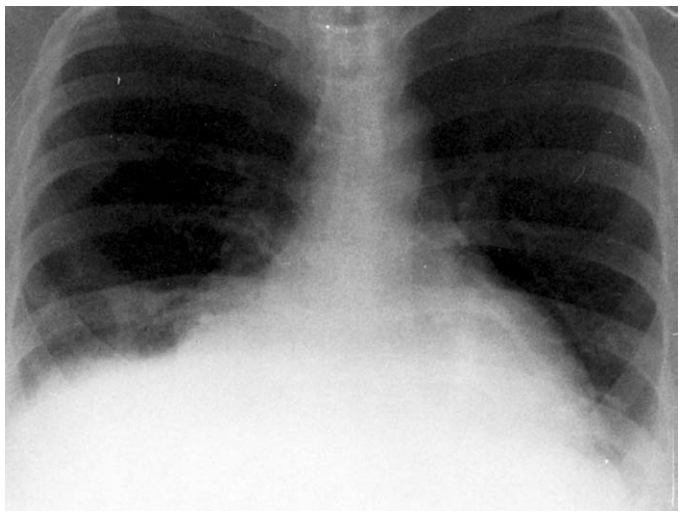

FIGURE 26 Posteroanterior chest radiograph shows bilateral pleural effusions in a 19-year-old woman with lupus pleuritis.

Lupus Pneumonitis

Radiographically, acute lupus pneumonitis usually appears as unilateral or bilateral basilar opacities (Fig. 27) that do not change with antibiotics but respond to corticosteroid or immunosuppressive therapy. Patients usually have high fevers, tachypnea, tachycardia, and cyanosis, but few physical findings [84–86]. Sputum cultures show no pathologic growth. The combined clinical and radiographic findings suggest the diagnosis of acute lupus pneumonitis. Histologic examination shows hyaline membranes, alveolitis with focal necrosis and ateletectasis, interstitial edema, interstitial lymphocytic infiltrate, bronchiolitis, and capillary and arteriolar thrombi [87–91]. Electron microscopy occasionally identifies microtubular structures within the cytoplasm of the pulmonary capillary endothelium similar to those seen in the kidney [92, 93]. This acute process, which occurs in 0.9–11.7% of lupus patients [86, 87], may resolve completely or regress to a more chronic interstitial pneumonitis and fibrosis.

Sudden development of bilateral infiltrates is not uncommon in SLE and may also result from hemorrhage, congestive heart failure, and uremia [94]. In addition, cytotoxic drug therapy, such as cytosine arabinoside, may produce a diffuse alveolar, interstitial, or a mixed pattern without signs of congestive heart failure (Fig. 28) [95]. After cessation of the drug, the alveolar consolidation regresses rapidly within 3–7 days whereas the interstitial pattern disappears more gradually [66].

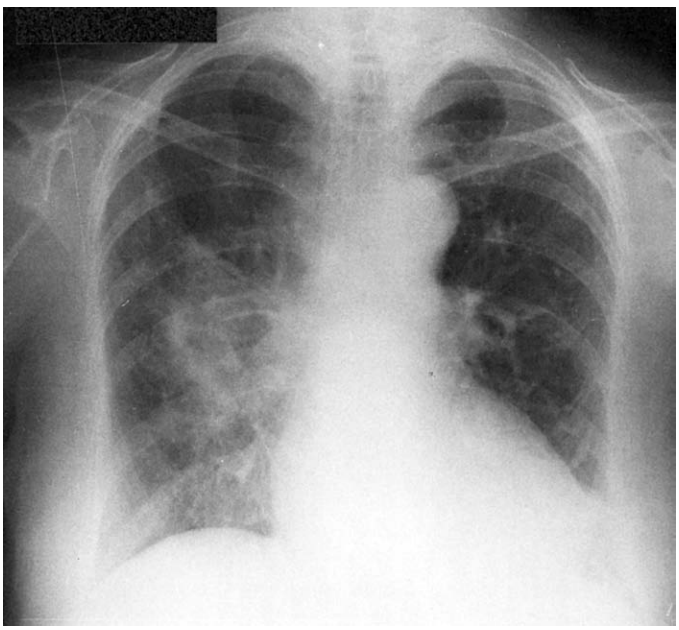

FIGURE 27 Posteroanterior chest radiograph demonstrates bilateral lower lobe lupus pneumonitis in a 43-year-old woman with tachycardia, high fevers, and negative sputum.

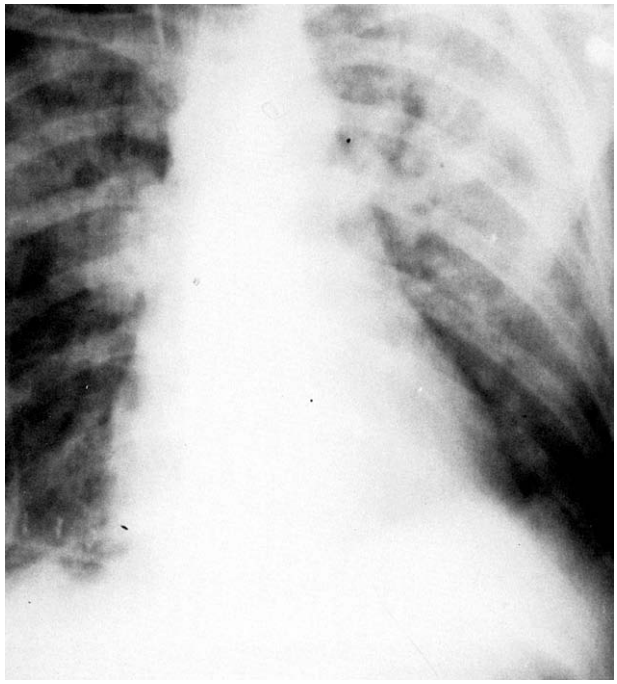

FIGURE 28 Anteroposterior portable chest radiograph shows a bilateral interstitial-alveolar pattern in a 27-year-old lupus patient with cyclophosphamide toxicity. The chest radiograph returned to normal with cessation of cyclophosphamide therapy.

However, in lupus patients, especially those on corticosteroid therapy, alveolar or interstitial patterns and cavitary nodules on radiographs most frequently represent infection, particularly secondary to opportunistic organisms, such as gram-negative organisms, fungi, cytomegalic inclusion disease, *Pneumocystis carinii*, and *Mycobacterium tuberculosis* [58, 77, 96–99]. Although the radiograph can demonstrate alveolar or interstitial pneumonia (Fig. 29A), CT may be needed to define cavitation (Fig. 29B). Contrast-enhanced CT and MRI, particularly with its triplanar capabilites, can delineate the extension of the abscesses into the soft tissues outside the thoracic cavity (musculature, neck including brachial plexus).

In SLE, other nonspecific pulmonary findings (fleeting, migratory, recurrent densities, honeycombing reticulation, parenchymal or subpleural cysts, and basilar linear shadows) develop in one-third to two-thirds of patients [58, 79, 80, 85, 86, 100, 100a]. Various authors have called these findings *diffuse interstitial lung fibrosis*, *fibrosing alveolitis*, and *interstitial pneumonitis* [58, 77, 101–104]. Some investigators have found 67-gallium scintigraphy useful for diagnosing active interstitial inflammation and for monitoring its response to treat-

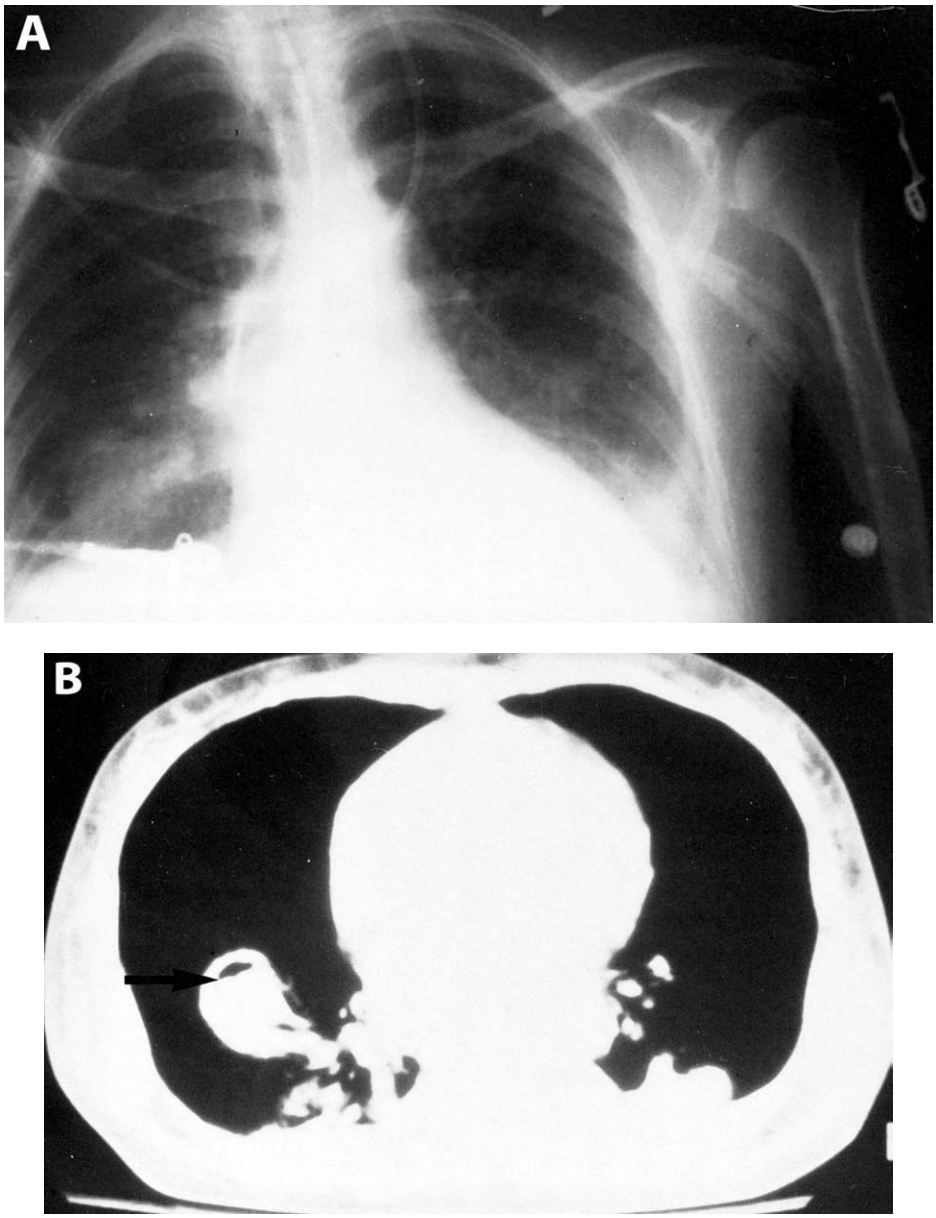

FIGURE 29 (A) Posteroanterior chest radiograph shows consolidation in both lower lobes. (B) Axial CT scan done on the same day as (A) shows a cavity in the right lower lobe. Brush biopsy showed *Aspergillus fumigatus*.

ment [105, 105a]. In fibrosing alveolitis, rupture of a bleb or cyst may lead to pneumothoraces and mediastinal emphysema [79, 106–109]. Radiographs sometimes may not identify the blebs, whereas they are easily defined at CT [109]. Hemopneumothorax has also been reported in SLE [110]. Both primary factors (alveolar hemorrhagic lesions, focal subpleural petechiae, pleuritis, mucopurulent mucous plugs with atelectasis, and ball valve effect) and secondary factors (pulmonary emboli, bacterial infection, and bleeding diathesis) may predispose to hemopneumothorax [110].

Mixed connective tissue disease may present with similar findings as SLE with basilar interstitial changes, pneumonitis, pleural effusions, and pleural thickening [111].

In addition to other pleuropulmonary findings in SLE, sequential chest radiographs may show progressive volume loss, the "shrinking lung," associated with high diaphragms and restrictive pulmonary function (Fig. 30) [112–117]. Some lupus patients with elevated diaphragms have normal diaphragmatic strength [117]; others have found weakened diaphragmatic muscle

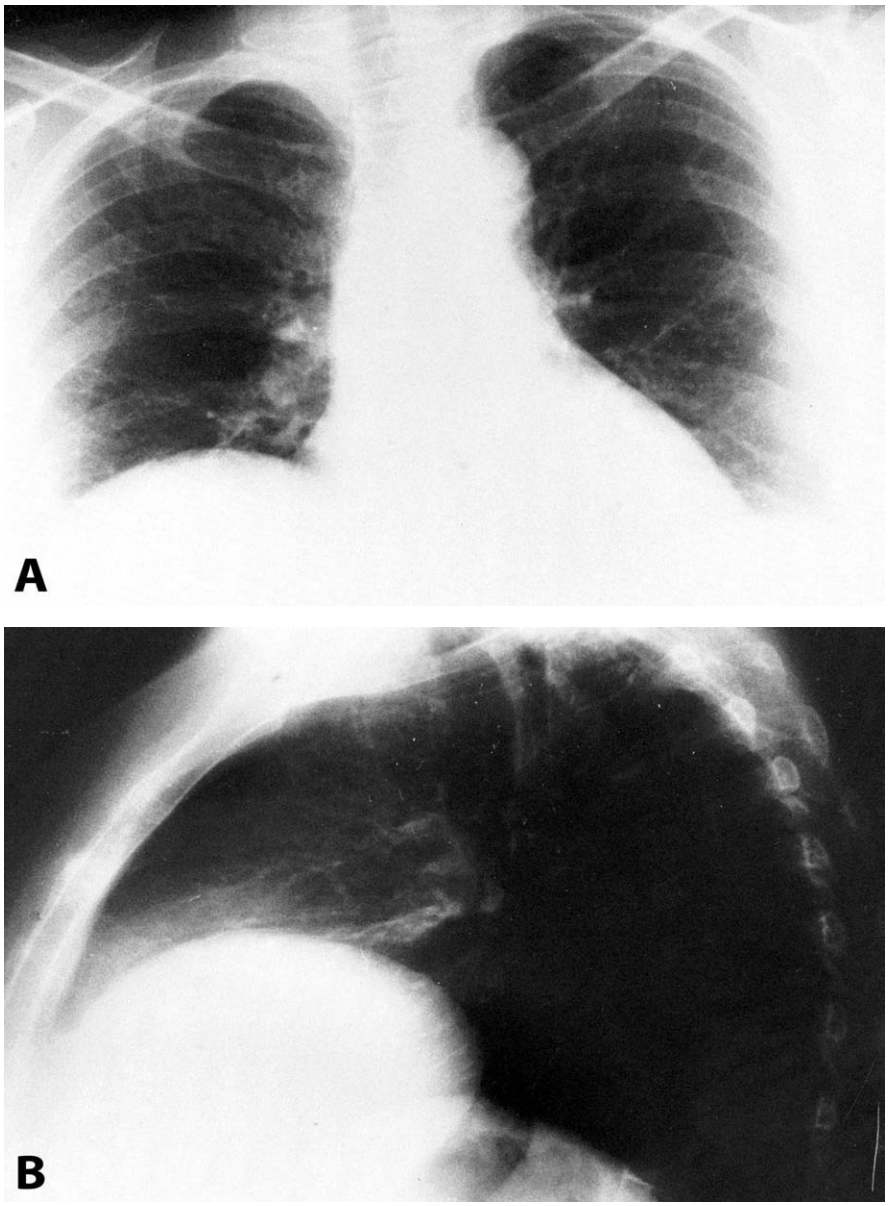

FIGURE 30 (A) Posteroanterior and (B) lateral chest radiographs show an elevated right diaphragm in a lupus patient with unilateral shrinking lung. Courtesy of Dr. M.-F. Kahn, University of Paris.

along with a restrictive pulmonary function pattern [92, 113]. In two patients, beta-agonists improved diaphragmatic performance [87, 114a]. Even when chest radiographs are normal, lupus patients may experience considerable impairment of pulmonary function, such as a restrictive respiratory pattern and low diffusing capacity [77, 118].

Thin-section, high-resolution CT is an important adjunct for the early assessment of pleuropulmonary disease in SLE. Several studies have shown that this technique identified lung disease in patients with SLE who had no clinical or radiographic evidence of lung involvement [119, 119a, 120]. Pulmonary abnormalities were identified in 38 to 72% of patients at high-resolution CT as compared with 6 to 34% at radiography, respectively. In one study [119], the interstitial changes correlated with decreased pulmonary function: decreased single-breath diffusing capacity for carbon monoxide (DLCO) ($r = 0.77$) and ratio of forced expiratory volume in 1 second to forced vital capacity (FEV^1/FVC) ($r = 0.8$) but did not correlate with the residual volume/total lung capacity (RV/TLC) ratio. A second study [120] found abnormal pulmonary function tests in only 41% of patients with abnormal high-resolution-CT findings. In a third series [120], a trend toward significance was found between disease activity

and interstitial lung disease on high-resolution CT, although no statistical significance was found between abnormal pulmonary function tests and interstitial lung disease. In these three studies, high-resolution CT demonstrated various findings of interstitial lung disease with "ground glass" appearance and interlobular septal and intralobular interstitial thickening associated with architectural distortion and bronchial wall thickening and dilatation. The "ground glass" appearance reflected two processes: (1) acute alveolitis and (2) fine reticular fibrosis, which appeared as an amorphous increase in lung attenuation because it was below the limits of CT resolution. In the nonlupus patient, certain interstitial findings at high-resolution CT appear to correlate with histology at open lung biopsy and may help predict response to therapy and patient outcome [120, 121]. The use of high-resolution CT as a prognostic indicator has yet to be proved in SLE.

In addition to its role for diagnosing and evaluating extent of disease, high-resolution CT is effective in guiding procedures such as lung biopsy and bronchoalveolar lavage to areas of specific SLE involvement.

Pulmonary Infarcts

Pulmonary infarcts in SLE result from thromboembolism [122, 122a], *in situ* vasculitis, or circulating anticoagulants and antiphospholipid antibodies [123, 123a, 124] and rarely are the presenting manifestation of SLE [124a]. Scintigraphy shows abnormal ventilation–perfusion defects discordant with ventilation defects, when present (Fig. 31). Radiographs may be normal or may show pleural effusions, atelectases (Fig. 32), or, infrequently, enlarged central pulmonary arteries in chronic embolism. In one case report [99], cavitary nodules proved to be necrotic pulmonary infarction at autopsy. It should be emphasized that because infection is common, cavitary pulmonary vasculitis should be a diagnosis of exclusion and a thorough investigation, including biopsy, should be performed before a final diagnosis of vasculitis is made [99]. Helical CT allows rapid evaluation of the pulmonary circulation with breath holding and gives improved demonstration of thrombi in pulmonary arteries [122a, 123a].

The imaging features of pulmonary "vasculitis" are best defined at high-resolution, helical CT but are not specific for SLE and may be also seen in other vasculitidies, such as Wegener's granulomatosis and scleroderma–polymyositis overlap syndrome. The inflamed pulmonary vessels produce a perivascular inflammatory infiltrate with hemorrhage and necrosis that appears as centrilobular, hazy densities at CT.

Pulmonary Hemorrhage

Pulmonary hemorrhage is an unusual and often fatal complication of SLE. Patients present with acute symptoms of hemoptysis, respiratory failure, tachycardia,

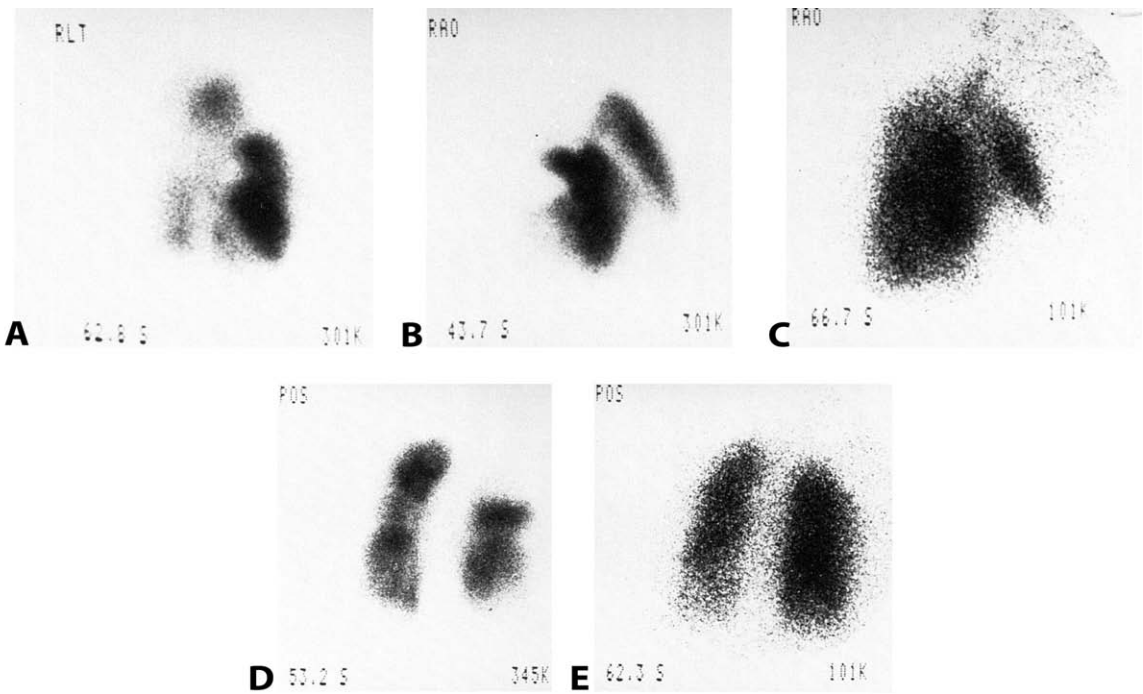

FIGURE 31 Lung scintigrams in a lupus patient with thromboembolism shows mismatch in perfusion (A, B, D) and ventilation (C, E) defects.

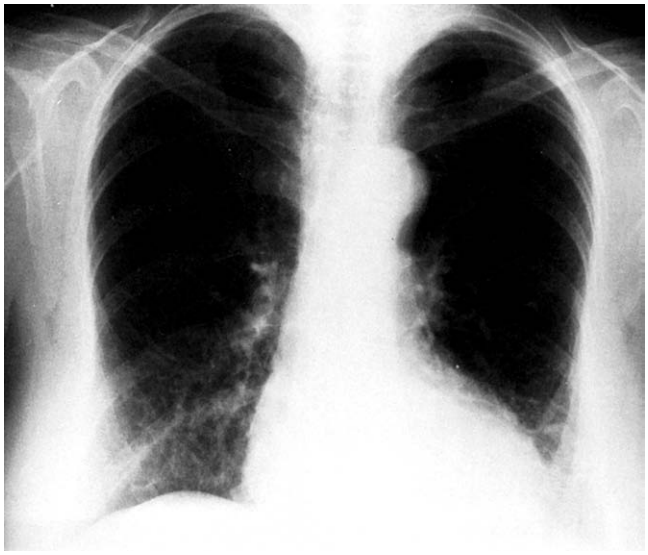

FIGURE 32 Posteroanterior chest radiograph shows subsegmental atelectases in the lower lobes in a patient with SLE and pulmonary emboli.

and high fevers and may survive for 2 hours to 3 years after the first hemorrhage [124–134]. In children, pulmonary hemorrhage may precede SLE and be indistinguishable from pulmonary hemosiderosis. Diffuse parenchymal abnormalities, especially with unexplained blood loss or signs and symptoms of connective disease in a child, should alert the clinician to consider this diagnosis [135].

When hemoptysis is absent, iron-laden macrophages on transbronchial biopsy may suggest the appropriate diagnosis [129]. Occult pulmonary hemorrhage can also be measured by inhaled carbon monoxide (CO) uptake $C^{15}O$ clearance studies, although this is performed infrequently. By this technique, extravascular blood takes up additional inhaled $C^{15}O$ so that the $C^{15}O$ uptake is elevated. In addition, when $C^{15}O$ is inhaled, extravascular blood labeled with the $C^{15}O$ is stagnant and slows radiopharmaceutical clearance. Thus pulmonary hemorrhage is characterized by increased $C^{15}O$ uptake and delayed $C^{15}O$ clearance [136].

The radiographic features of pulmonary hemorrhage are predominantly extensive, bilateral, homogeneous densities (the "ground glass" appearance) (Fig. 33) [127, 129] and nodular, acinar infiltrates [127, 132]. Ventilation-perfusion radionuclide scans are normal [132]. CT defines the character and distribution of pulmonary hemorrhage and efficacy of therapy more clearly than conventional radiography [137]. With effective corticosteroid, immunosuppressive, and sometimes plasmapharetic therapy, patients may improve with resolution of imaging findings. Despite therapy, patients with pulmonary hemorrhage may show rapid deterioration with demise.

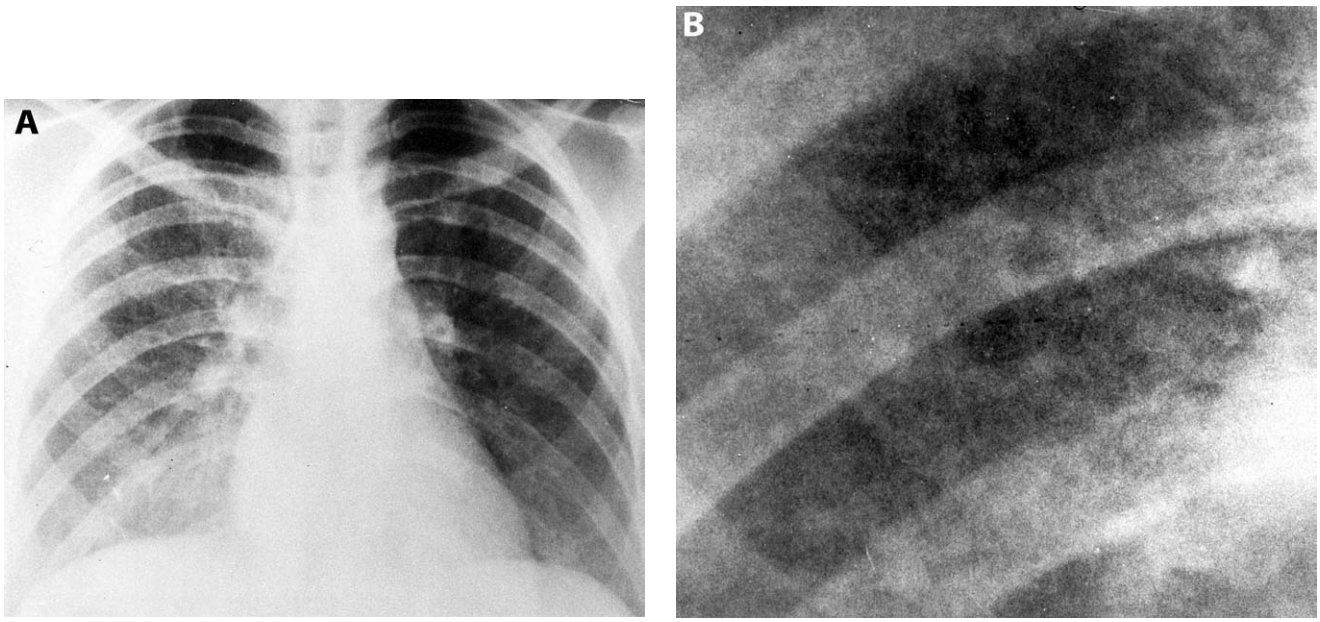

FIGURE 33 (A) Posteroanterior chest radiograph shows diffuse, bilateral increased lung density partially obscuring vessels with absence of air bronchograms. (B) Magnification of the right midlung: the typical ground-glass pattern sometimes seen in pulmonary hemorrhage partially obscures the pulmonary vessels in a 22-year-old patient with SLE. From Gamsu and Webb [129], with permission.

Pulmonary hemorrhage probably results from several mechanisms. An immune complex-mediated etiology has been suggested because electron microscopy identifies granular electron deposits (characteristic of immune complex aggregates) in the alveolar and vascular walls [77, 92, 127, 128, 131, 132]. Brentjzens *et al*. [138] also demonstrated similar deposits in experimental animal models of serum sickness-induced pulmonary disease. Other factors contributing to pulmonary hemorrhage are bleeding diathesis, intercurrent infection, hemorrhagic shock, and pulmonary embolism and infarction that are sometimes associated with lupus anticoagulants [92, 124, 127, 139, 140].

Pulmonary hemosiderosis with hemosiderin-laden macrophages has also been described in patients with SLE [141], but chest radiographs show no abnormalities.

Pulmonary Hypertension

Pulmonary hypertension may have an insidious onset, masquerade as pleuritis, pneumonitis, or recurrent emboli, and may be the terminal feature of lupus. Previously, pulmonary hypertension was thought to be an unusual manifestation of lupus, perhaps because prior techniques did not allow adequate diagnosis [142–153]. However, with current Doppler echocardiographic equipment, Simonson *et al.* [154] showed that pulmonary hypertension is common in SLE, progresses slowly over time, and is related to an increase in pulmonary resistance as evidenced by the change in prevalence from initial and final evaluations during a 5-year follow-up. On the initial echocardiographic studies, the prevalence of pulmonary hypertension was 14% and was clinically unsuspected in 80% of their patients. In 5-year follow-up studies, the prevalence had increased to 43% [155]. Doppler echocardiographic measurements of tricuspid insufficiency with saline contrast enhancement, when needed, were used to calculate pulmonary artery systolic pressure, Doppler echocardiographic calculations of cardiac output were done at rest for each patient, and pulmonary resistance was determined by dividing the pulmonary artery systolic pressure by the cardiac output. A significant increase in mean systolic pulmonary artery pressure was found in lupus patients at 5-year follow-up. Because pulmonary resistance increased between the initial and follow-up echocardiographic studies, it was suggested that the causal mechanism for pulmonary hypertension was increased pulmonary vascular resistance. Another Doppler echocardiographic study [156] evaluated the pulmonary artery pressure response to exercise in patients with SLE. Exercise duration was significantly reduced in lupus patients to 8.1 minutes in lupus patients in contrast to 14.4 minutes in control patients. Pulmonary artery pressure was significantly greater in lupus patients at rest and for each stage of exercise as compared with controls and may be a contributory factor to decreased exercise tolerance. Similar cardiac indexes at rest in normal and lupus patients further support the hypothesis that the mechanism for pulmonary hypertension is an increase in pulmonary vascular resistance.

Raynaud's phenomenon is more frequent in lupus patients with elevated pulmonary pressure (75%) than those with normal pressures (40%), although this is not of statistical significance. Pulmonary hypertension is also associated with Raynaud's phenomenon in patients with scleroderma [157] and MCTD [158].

In more severe pulmonary hypertension, echocardiography may show enlargement of the right atrium and right ventricle, midsystolic closure of the pulmonic valve, mild mitral and tricuspid valve prolapse, and paradoxical septal motion as a manifestation [143, 144] (personal communication, Nelson Schiller, University of California at San Francisco) (Fig. 34). Chest radiographs are frequently normal but may show cardiomegaly with right atrial and right ventricular hypertrophy and central pulmonary arterial enlargement (Fig. 35). An unusual cause of severe pulmonary hypertension is thrombosis of the main pulmonary arteries that can be detected at high-resolution helical CT [123a].

Although the pathogenesis of increased pulmonary vascular resistance is not clear, different mechanisms have been proposed: (1) loss of pulmonary vascular reserve secondary to interstitial lung disease, (2) narrowing of pulmonary vasculature resulting from pulmonary vasculitis, *in situ* thrombosis of pulmonary arterioles, or pulmonary emboli, (3) generalized vasoconstriction of pulmonary arterioles, (4) thrombosis of pulmonary arterioles because of a hypercoaguable state associated with antiphospholipid antibodies, (5) vasoreactivity of pulmonary arterioles due to antiphospholipid antibodies that cause decreased endothelial protacyclin formation, and (6) vasospasm of pulmonary arteries associated with the peripheral arterial vasospasm of Raynaud's phenomenon [123a, 144–154].

Hilar Adenopathy

Hilar lymphadenopathy [58, 159, 159a] is a rare manifestation of SLE and has been associated with mediastinal adenopathy on chest radiographs but is best detected at CT and MRI. Mediastinoscopy confirms the enlarged lymph nodes, and histologic examination shows areas of necrosis and intracellular and extracellular hematoxylin bodies compatible with the diagnosis of SLE [58]. Hilar lymphadenopathy with or without pulmonary nodules has also been

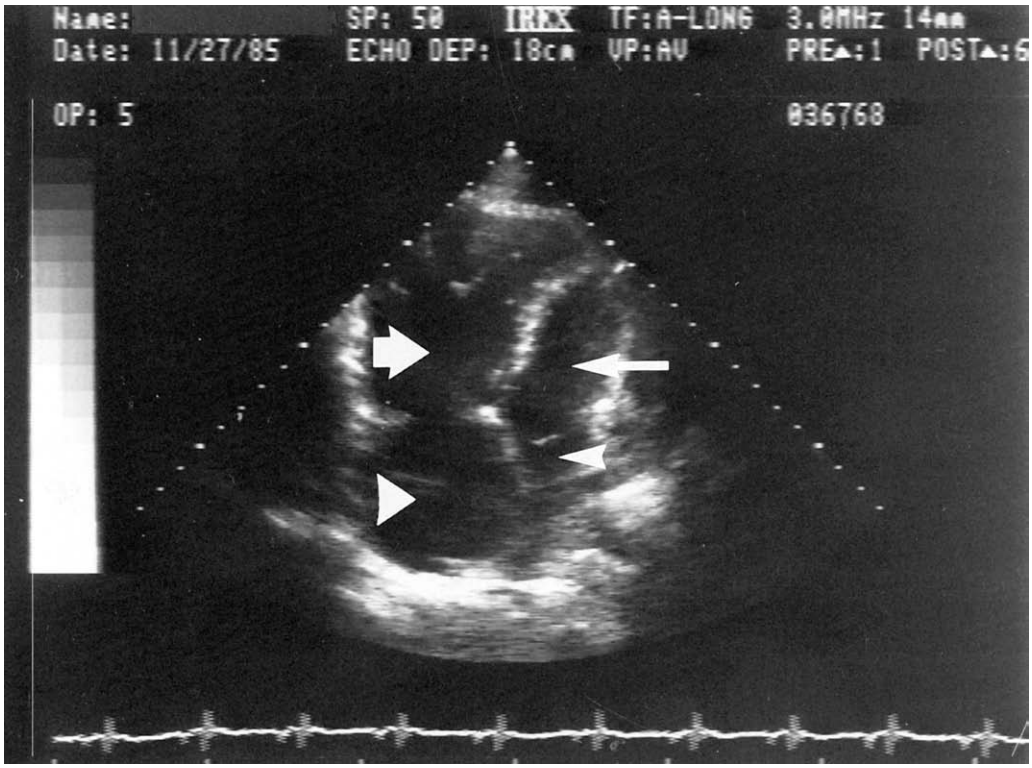

FIGURE 34 Apical four-chamber echocardiogram of a patient with long-standing SLE and pulmonary hypertension. The right ventricle (*large arrow*) and right atrium (*large arrowhead*) are considerably larger than the left ventricle (*thin arrow*) and left atrium (*thin arrowhead*) with bulging of the interatrial septum from right to left. Courtesy of Dr. N. B. Schiller, University of California, San Francisco.

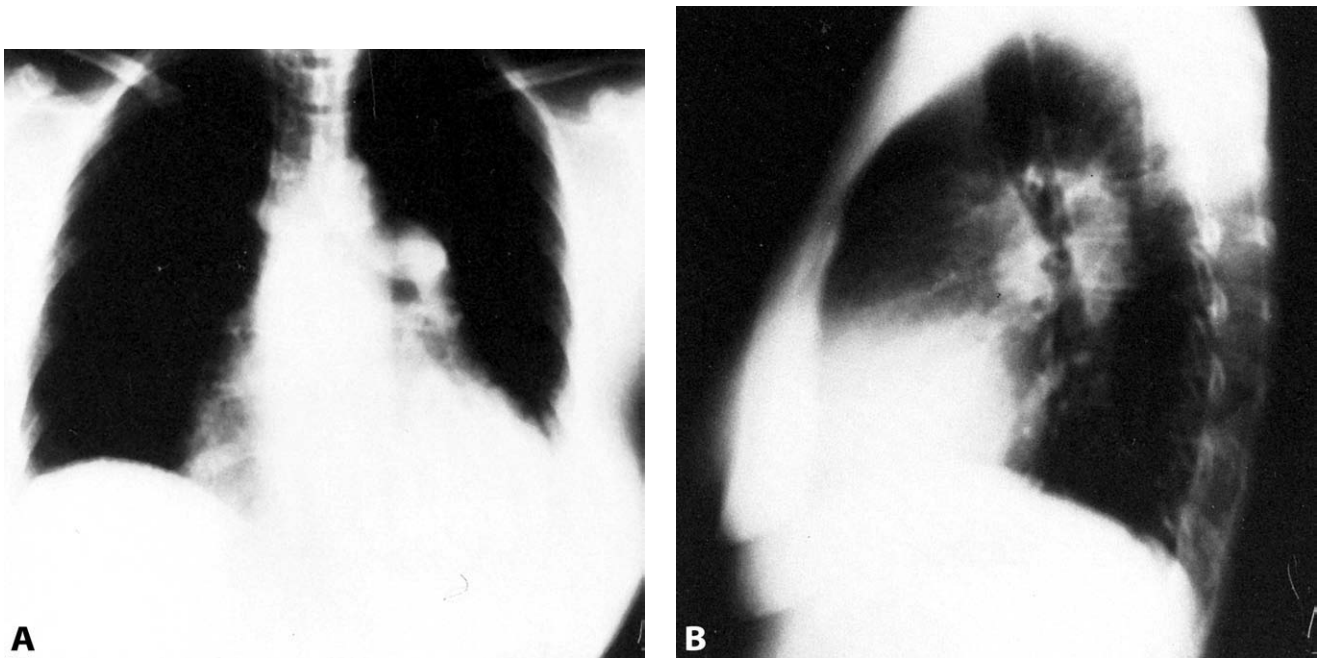

FIGURE 35 (A) Posteroanterior and (B) lateral chest radiographs show enlarged central pulmonary arteries in a 55-year-old patient with SLE and pulmonary arterial hypertension.

described in SLE associated with sarcoidosis [160, 161]. Furthermore, hilar lymphadenopathy may be the presenting manifestation of lymphoma in the lupus patient, and CT or MRI and, most recently, F-18-fluorodeoxyglucose positron emission tomography (FDG-PET) should be used for staging this disease and following its response to therapy (see section on reticulodendothelial SLE).

IMAGING OF CARDIOVASCULAR SLE

Pericardial Disease

Cardiovascular abnormalities of SLE develop in the majority of patients at some time during the course of their illness [162–177]. The most frequent clinical cardiovascular manifestation in SLE is acute pericarditis in 17–50% of patients [20, 77, 80, 166], although autopsy series reveal a higher prevalence of pericardial involvement ranging from 61 to 83% [176]. Pericardial effusions are associated significantly with active disease and pericardial pain. In only 14% of patients, the chest radiograph suggests the diagnosis when patients are symptomatic and pericardial effusions are large enough to displace the anterior fat pad. Without a positive anterior fat pad sign, a globular cardiac configuration may represent either a pericardial effusion or an acute myocarditis (Fig. 36) [20]. With an unusual sequela of pericardial effusion, constrictive pericarditis, radiographs show a marked decrease in the cardiac configuration (Fig. 37) [178]. MRI and echocardiography show pericardial thickening combined with a dilated inferior vena cava, hepatic veins, right atrium, and a normal or reduced volume right ventricle. In addition, an elongated narrow-shaped right ventricle with a S-shaped ventricular septum may be seen [178a].

Echocardiography detects pericardial effusions in 21–54% of lupus patients and is the most sensitive and inexpensive method for diagnosing and following most pericardial effusions (Fig. 38A) and thickening [162, 163, 166, 167, 171, 179–186]. Echocardiography depicts most effusions as anechoic fluid and pericardial fibrosis as an echogenic, thickened pericardium. Acute hemorrhage into the pericardium may cause an echogenic effusion. MRI (Fig. 38B) and CT occasionally may be used to evaluate pericardial effusions, particularly for delineating an anterior effusion or for defining a hemorrhagic effusion. Acute hemorrhage shows high attenuation at CT [187–189]. After the first 24–48 h, MRI is the most specific test for defining subacute hemorrhage, which characteristically is high signal intensity on electrocardiographic-gated, T1-weighted MR images. A rare manifestation of lupus, cardiac tamponade [190–193], can be recognized at echocardiography as right atrial collapse, right ventricular expiratory collapse, and paradoxical wall motion [165]. Cardiac tamponade may resolve with indomethacin [194] or may require sonographically-guided pericardiocentesis with its attendant risks of laceration of the myocardium and coronary arteries [194, 195]. Purulent pericarditis with or without tamponade is another unusual complication of SLE [165, 196].

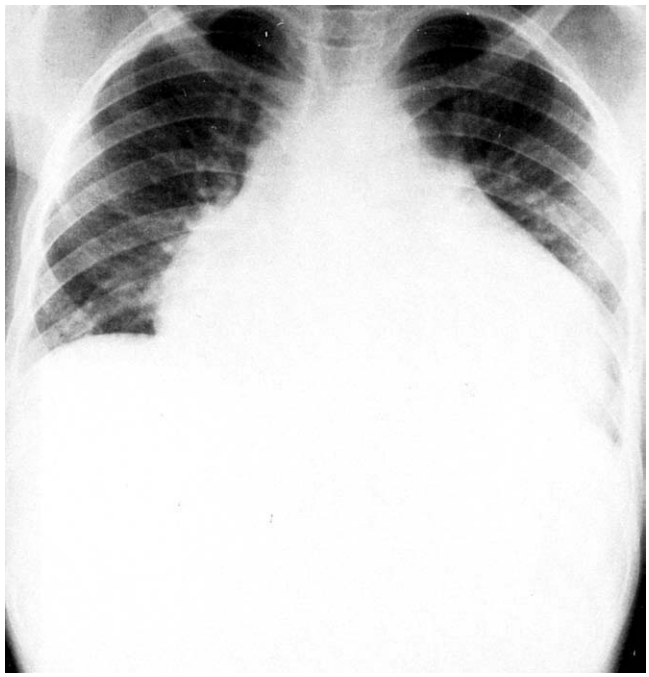

FIGURE 36 Posteroanterior radiograph shows a globular cardiac silhouette in a 10-year-old girl with SLE and a pericardial effusion.

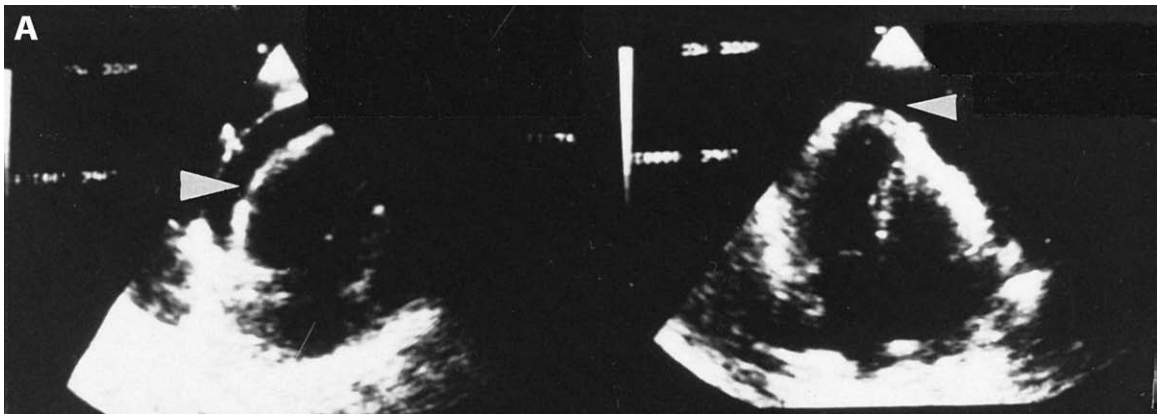
As with pleural effusions, pericardial fluid is usually an exudate, with numerous leukocytes, LE cells, antinuclear antibodies (ANAs), immune complexes, and antirheumatoid factor. Glucose levels are normal [165, 174, 197].

Cardiac Abnormalities

Conventional radiography shows both generalized and localized cardiomegaly that may be associated with various conditions: (1) myocarditis (Fig. 39) and Libman–Sacks endocarditis; (2) low or high output congestive heart failure; (3) pulmonary hypertension with right-sided enlargement; and (4) hypertensive cardiovascular disease secondary to corticosteroid therapy, accelerated arteriosclerosis, and lupus nephritis.

FIGURE 37 (A) Initial posteroanterior radiograph shows enlarged cardiac configuration in a 28-year-old man with SLE and pericardial effusion. (B) Posteroanterior chest radiograph taken 6 weeks later, when symptoms of pericardial constriction had developed, shows a decrease in the size of the cardiac silhouette. From Starkey and Hahn [178], with permission.



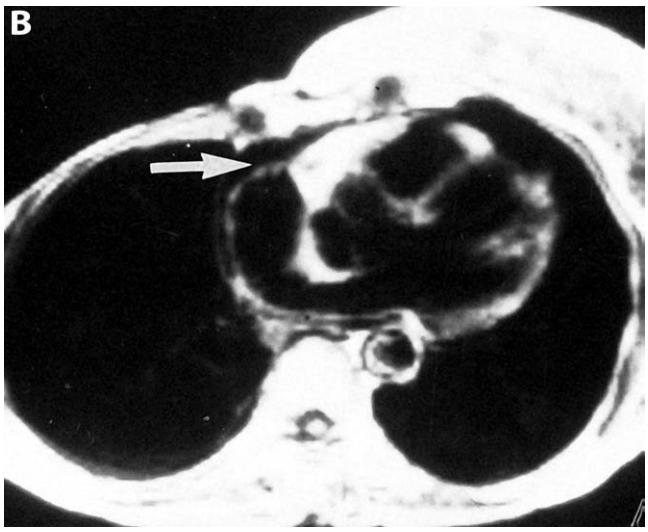


FIGURE 38 (A) Two-dimensional echocardiogram shows an anechoic anterior pericardial effusion (*arrow*) in a patient with SLE. (B) Axial ECG-gated T1-weighted MR image shows an anterior low-signal-intensity pericardial effusion (*arrow*).

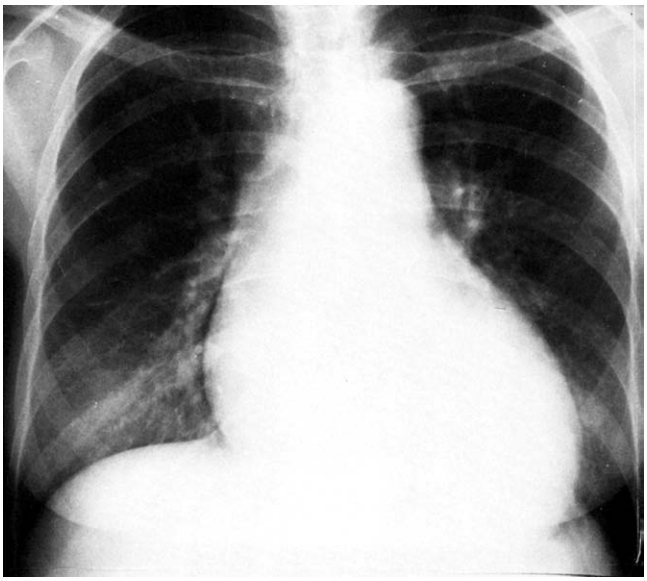

FIGURE 39 Posteroanterior chest radiograph demonstrates generalized cardiomegaly in a 28-year-old woman with SLE and myocarditis.

ECG, whether transthoracic or transesophageal, two dimensional (2D), three dimensional (3D), pulsed, or color flow Doppler, has become the primary method for defining anatomic and functional cardiac disease in SLE [162–171, 185, 186, 198–209]. Myocardial perfusion scintigraphy with ^{201}thallium alone or the ^{201}thallium/^{99m}Tc sestamibi (tetrofosmin) dual isotope technique is useful for detecting myocardial ischemia [210–211a]. The newer modalities of ultrafast, electron beam CT (EBCT), FDG-PET, and fast echoplanar MRI and magnetic resonance angiography (MRA) may add a new dimension to our understanding of the cardiac anatomy, dynamics, and ischemia in the lupus patient [212–219]. Prior to the development of these methodologies and ECG, cardiac catheterization was required to identify specific myocardial and valvular lesions [220–228] and is still used for the preoperative evaluation of coronary and endocardial abnormalities.

Endocardial Lesions

ECG readily detects anatomic and functional abnormalities of cardiac valves of patients with SLE [167, 201, 207, 229–243]. On radiographs, however, classic lupus endocarditis is difficult to diagnose because calcified vegetations are rarely seen. Senningen *et al*. [233] reported the radiographic findings of a Libman–Sacks endocardoma as an area of amorphous calcification just below the mitral valve (Fig. 40A) and the angiocardiographic findings as a multiobular intraventricular mass below the posterior mitral valve leaflet (Figs. 40B and 40C).

Transthoracic ECG (2D, 3D, and color flow Doppler) shows valvular abnormalities in 23–44% of lupus patients [165–167, 209, 243]. More recently, transesophageal (ECG) [207, 244] detected valvular lesions in 74% of lupus patients. The classic verrucous Libman–Sacks lesion (Figs. 41 and 42), when greater than 2 mm, appears as an irregular mass of heterogeneous echogenicity with diffuse valvular thickening. This thickening most commonly involves the mitral valve and sometimes the aortic valve with minimal involvement of the subvalvular apparatus. Any valve, however, may be affected [164, 179, 198, 201, 207]. When localized thickening is present, the midportion or base of the leaflet is involved more frequently. The overall prevalence of valvular regurgitation in SLE patients at transesophageal echocardiography is 61%, and moderate or severe regurgitation develops in 42% of patients. Libman–Sacks verrucae and focal myocardial scars affecting the papillary muscle may also lead to mitral prolapse, which was reported to have a significantly higher prevalence in SLE than in the general population [200].

The effect of corticosteroids on valvular disease in SLE remains a controversial tissue. Galve *et al*. [201] suggested that two types of endocardial valvular lesions, the verrucous mass and the fibrosed valve, may relate to corticosteroid usage differently. In their lupus patients, the verrucous lesion was usually seen in the younger patient, with active disease of shorter duration, who had received a smaller dose of corticosteroids. The rigid, fibrosed, thickened, and sometimes calcified valve was found more frequently in patients with disease of long duration who had received long-term corticosteroid therapy. Bulkey *et al*. [232] suggested that corticosteroids promoted healing of valvular vegetations, and scarring and cusp retraction subsequently may result. Another report, however, stated that valvular disease did not correlate with duration, activity, severity, or treatment of SLE [207], and that the extent of valvular disease at presentation did not predict permanent or progressive valvular dysfunction [207]. The incidences of valvular abnormalities at initial and follow-up evaluation (29 and 13 months later) were similar for valvular thickening for initial and follow-up studies (51 and 52%, respectively), but the incidences of initial and follow-up studies differed for vegetations (30 and 20%), for regurgitation (25 and 28%), and for stenoses (3 and 4%). Valvular lesions persisted or changed in size or appearance between the two studies but could also resolve. In addition, some new lesions appeared during the study.

Echocardiography should also be performed following biosynthetic valves to evaluate for postoperative

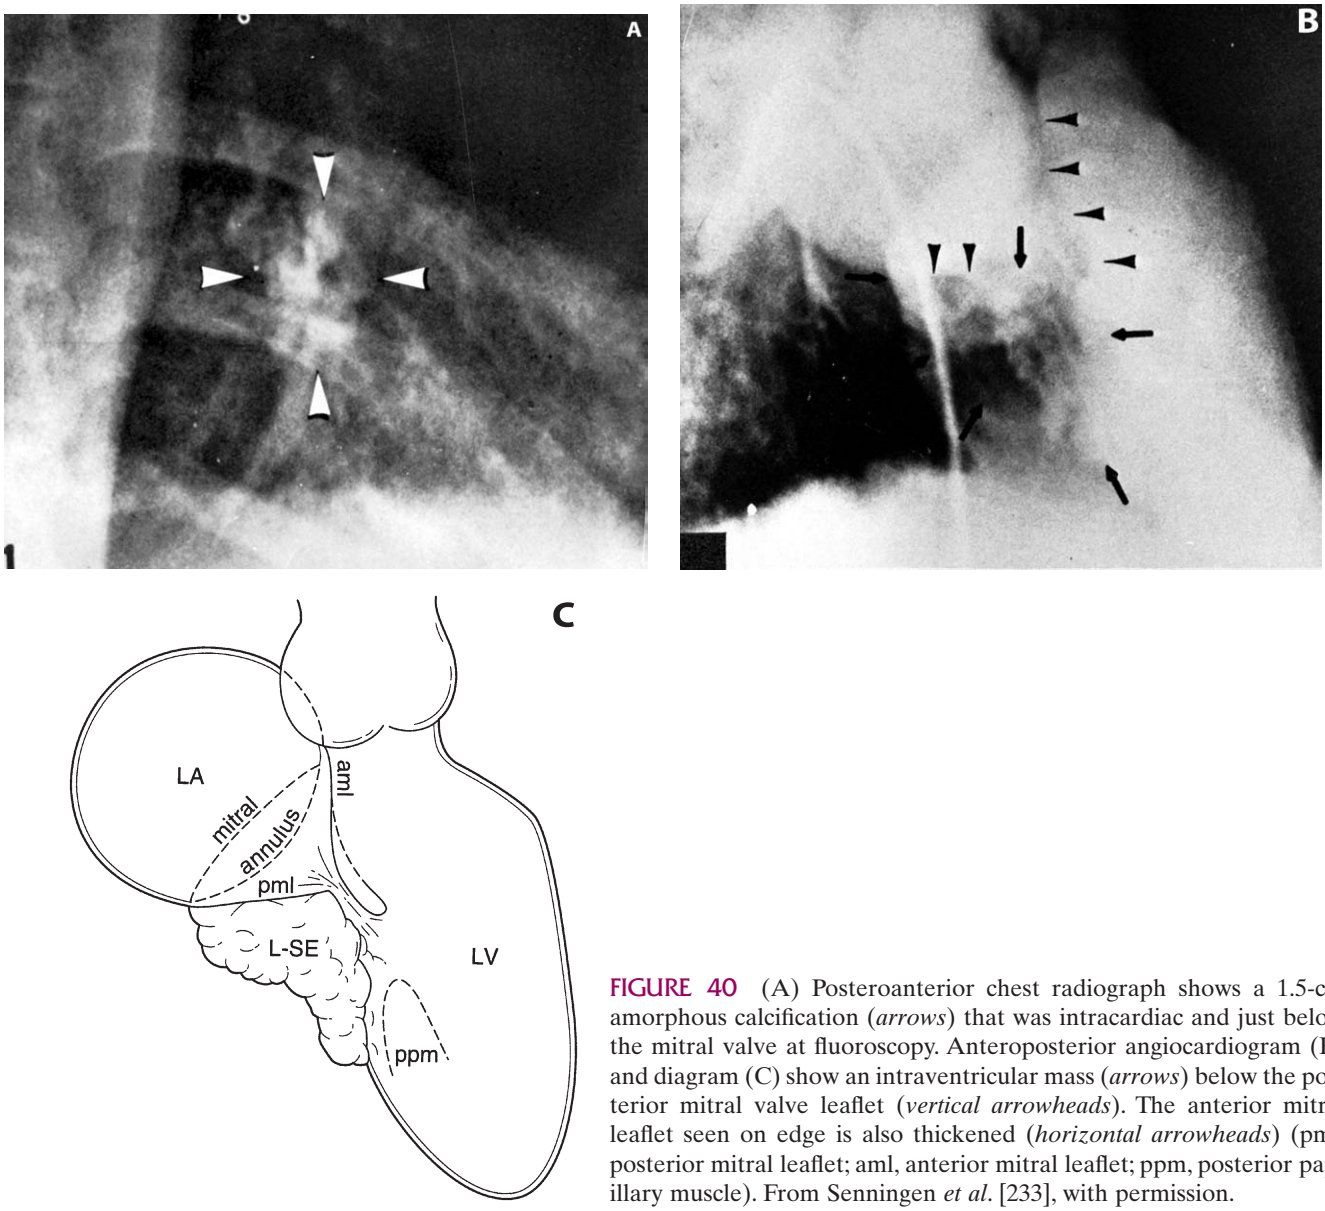

FIGURE 40 (A) Posteroanterior chest radiograph shows a 1.5-cm amorphous calcification (*arrows*) that was intracardiac and just below the mitral valve at fluoroscopy. Anteroposterior angiocardiogram (B) and diagram (C) show an intraventricular mass (*arrows*) below the posterior mitral valve leaflet (*vertical arrowheads*). The anterior mitral leaflet seen on edge is also thickened (*horizontal arrowheads*) (pml, posterior mitral leaflet; aml, anterior mitral leaflet; ppm, posterior papillary muscle). From Senningen *et al*. [233], with permission.

complications of dehiscence and for recurrent lupus valvulitis of the bioprosthetic valve [235].

Several investigators [166, 236–240, 243, 245, 246] have described a relationship among antiphospholipid antibodies, lupus anticoagulant, and valvular disease. In these studies, valvular vegetations, left ventricular hypertrophy, and cerebral arterial occlusions were more common among lupus patients with antiphospholipid antibodies than among those without elevated levels. Others have found that patients with SLE had a similar frequency and severity of valvular disease regardless of the presence or absence of antiphospholipid antibodies [242, 244].

Libman–Sacks endocarditis should be distinguished from rheumatic valvular disease. Lupus endocarditis usually presents as diffuse valvular leaflet thickening that infrequently calcifies. When thickening is present, the mid and base of the leaflet, rather than the tips, are more commonly involved. In contrast, in rheumatic fever, valvular masses predominate in the valve tips and are frequently calcified [201].

In SLE, infective endocarditis may simulate or complicate Libman–Sacks endocarditis and may cause significant morbidity and mortality and must be excluded in the febrile lupus patient with valvular disease [165, 201, 207]. Sometimes infected masses may differ from Libman–Sacks endocarditis in their location, appearance, and mobility [244]. Infective lesions usually are homogeneously echogenic, tend to be smaller, and attach to the valves at their line of closure without prolapsing into the cardiac cavity. In contrast, Libman–Sacks lesions display heterogeneous echogenicity, are more diffuse, and are located near the mid and base of the leaflet. Furthermore, lupus masses move parallel to the motion of the associated leaflet, whereas infected masses demonstrate vibratory or rotary motion partly independent from valvular motion [244]. Another complication of cardiac infection in lupus is the mural ventricular vegetation or thrombus [199–199b]. Intracavitary thrombi are usually associated with abnormal myocardial function [199a, 199b]. Rarely mural thrombi can develop as an isolated lesion without underlying myocardial abnormality [199c]. Intracavitary mural thrombi, whether infected or not, and Libman–Sacks endocarditis, when arising from the chordae tendinae and projecting into the outflow tract, may all present as echogenic intracardiac masses at echocardiography [199, 199a–c, 241].

Echocardiography also has an instrumental role in defining endocardial disease when clinically occult. For example, clinically silent valvular disease may be the source for thromboembolism in patients who present with cerebrovascular accidents or transient ischemic attacks.

Myocardial Functional and Anatomic Abnormalities

Echocardiography demonstrates multiple functional abnormalities in SLE: global left ventricular hyperkinesis, discrete segmental abnormalities of left ventricular wall motion, decreased end systolic volume index, prolonged isovolumic relaxation time, decreased left ventricular ejection fraction percentage and abnormal left ventricular diastolic filling dynamics, prolonged isovolumic relaxation time, reduced peak early diastolic flow velocity (peak E), increased peak late diastolic flow velocity (peak A), reduced E/A ratio, and lower deceleration rate of early diastolic flow velocity [168, 170, 171, 180, 184, 202, 204–206, 247, 248, 248a].

Anatomic abnormalities at echocardiography include left ventricular hypertrophy, left atrial dilatation and right ventricular enlargement, increased mass of the posterior left ventricular wall and interventricular septum, aneurysmal dilatation and intracavitary thrombus [171, 180, 184, 202, 206, 230, 241].

Winslow *et al*. [168] followed the natural history of left ventricular size and function in SLE in a 5-year echocardiographic study. Abnormalities of systolic and diastolic left ventricular function (increases in left ventricular mass index, mean wall thickness, end systolic volume, and decreases in ejection fraction) were increased significantly in patients with SLE as compared with a control population ($P \leq 0.05$). These findings progressed over the 5-year time period and were related to the coexistence of hypertension and coronary artery disease. In normotensive lupus patients, no significant differences in left ventricular mass index, volumes, or ejection fraction were found when compared with the control group. Primary lupus cardiac involvement did not lead to clinically significant changes in left ventricular size or function [168].

Myocardial infarction, once considered to be rare in lupus, is now recognized as a cause of late death [249–252]. Myocardial function is frequently depressed or abnormal [179, 184, 250] in some lupus patients who do not have clinical cardiac disease. In a prospective study, Hosenpud *et al*. [210] demonstrated a 38.5% prevalence of segmental myocardial perfusion abnormalities on exercise ^{201}thallium cardiac scintigraphy in SLE. Patients had reversible defects suggestive of ischemia, persistent defects consistent with scar, and both types of defects (reversible and irreversible). They found no correlation among several factors: a positive thallium study, the duration of disease, the quantity of corticosteroid therapy, major organ system involvement, or age. Only a history of pericardial disease was associated with positive scintigraphic findings.

For evaluation of cardiac dyskinesia, EBCT with cine-loop produces multilevel–multisecond continuous images of the beating heart. Intravenous injection of contrast media is required to allow differentiation between the blood pool and myocardium but would be contraindicated in the lupus patient with renal failure. EBCT can be performed during exercise stress and can characterize right and left ventricular performance because of a real-time technique [253].

Prior to the late 1990s, MRI, MR spectroscopy (MRS), and FDG-PET [214–218a] have been used in experimental protocols for evaluating the myocardium but not as part of standard clinical care. However, since the late 1990s, these modalities increasingly have become available and have been applied to the study of myocardial disease in populations at risk. In the only MRI myocardial study on lupus patients, the T1 relaxation times of myocardium were reported as longer in patients with active myocardial disease and decreased complement [214]. In patients without SLE and with unstable angina and infarction, T2-weighted MR images of the myocardium showed a hyperintense signal in the infarcted myocardium, which enhances on contrast-enhanced MRI [217]. Newer, faster contrast-enhanced MRI sequences (turbofast low-angle shot and echoplanar imaging) were developed to evaluate tissue perfusion [218, 218a] and the difference in viable and nonviable tissue in myocardium and other muscle and soft tissue [218, 218a]. These new MRI techniques can determine myocardial status, including myocardial perfusion reserve and region blood flow and volume. For example, during the first pass of contrast medium through the heart with fast contrast-enhanced MR sequences, the central region of infarcts may show hypoperfusion or no perfusion immediately consistent with irreversible injury as confirmed on electron microscopic examination. In contrast, the infarct periphery shows enhancement compatible with reversible injury and viable tissue [218a].

Metabolic abnormalities of the myocardium have been studied at FDG-PET and MRS. With its transverse tomographic images, FDG-PET allows spatial separation of different segments of the left ventricle so that differential radiopharmaceutical uptake reflects myocardial regional blood flow and metabolism. MRS, with ^{31}P and ^{13}C, produces spectra that correlate with changes of ischemia (e.g., lactate accumulation or depletion of phosphate high-energy stores) [215].

Coronary Artery Disease

Although accelerated arteriosclerosis is the predominant cause of myocardial infarction in SLE, vasculitis and thrombotic phenomena are also contributory factors [254–263a, 263b]. Cardiac catheterization has been the standard imaging modality for defining vascular abnormalities. Smooth, focal stenoses, aneurysmal dilatation, and lesions that change over a relatively short period of time characterize the vasculitis [260–262] and can be distinguished from the fixed, stenotic lesion of coronary arteriosclerosis. Heibel *et al*. [262] and Homcy *et al*. [260] emphasized that serial examinations should be obtained in order to differentiate the more rapidly evolving coronary vasculitis (Fig. 43) from the slowly progressing arteriosclerosis. A reversible arterial spasm has been documented at coronary angiography and may also be a factor in ischemic cardiac disease in SLE [264]. Although not reported in a cohort of lupus patients, three-dimensional contrast-enhanced ultrafast MRA, with a submillimeter resolution of structures, can be useful for evaluating coronary blood flow and flow reserve [264a].

EBCT has been applied to the detection of calcified coronary arteriosclerosis in the general population and in patients at risk including the patients with SLE [263a–263c]. In a pilot study on 13 patients (ages 33–48) with SLE with two or more risk factors, Von Feldt [263b] found that 2 patients had coronary calcification scores in the 70th percentile matched with women without known coronary disease and three had scores in the 90th percentile. In unpublished data in a review, Manzi and coworkers described the EBCT coronary artery findings in 40 patients with SLE, 20% of whom had a previous event (4 transient ischemic episodes or stroke, 3 myocardial infarction or angina, and 1 with both cerebrovascular and coronary events). The coronary calcification scores were significantly higher in women with a previous event than in those without a previous event [263c].

Coronary artery aneurysms (Fig. 44), a rare complication of SLE, are thought to result from accelerated arteriosclerosis or lupus vasculitis and have been described in the left main, left anterior descending, and right coronary arteries [265, 266]. Mycotic aneurysm of the coronary artery in patients with SLE is rare and was associated with salmonella infection in one report [266a]. With a coronary artery aneurysm, whether infected or not, new generation fast helical CT or electron beam CT and MRA or standard coronary angiography [262, 266] show the aneurysmal dilatation and its relationship to the remainder of the coronary vasculature and myocardium.

Aortic, Great Vessel, and Peripheral Arterial Occlusive Disease

Aortic root thrombus [267], aortic arch syndrome (thrombosis of a major arch vessels) [268, 269], aortic occlusion [270], aortoarteritis [271, 272], and superior

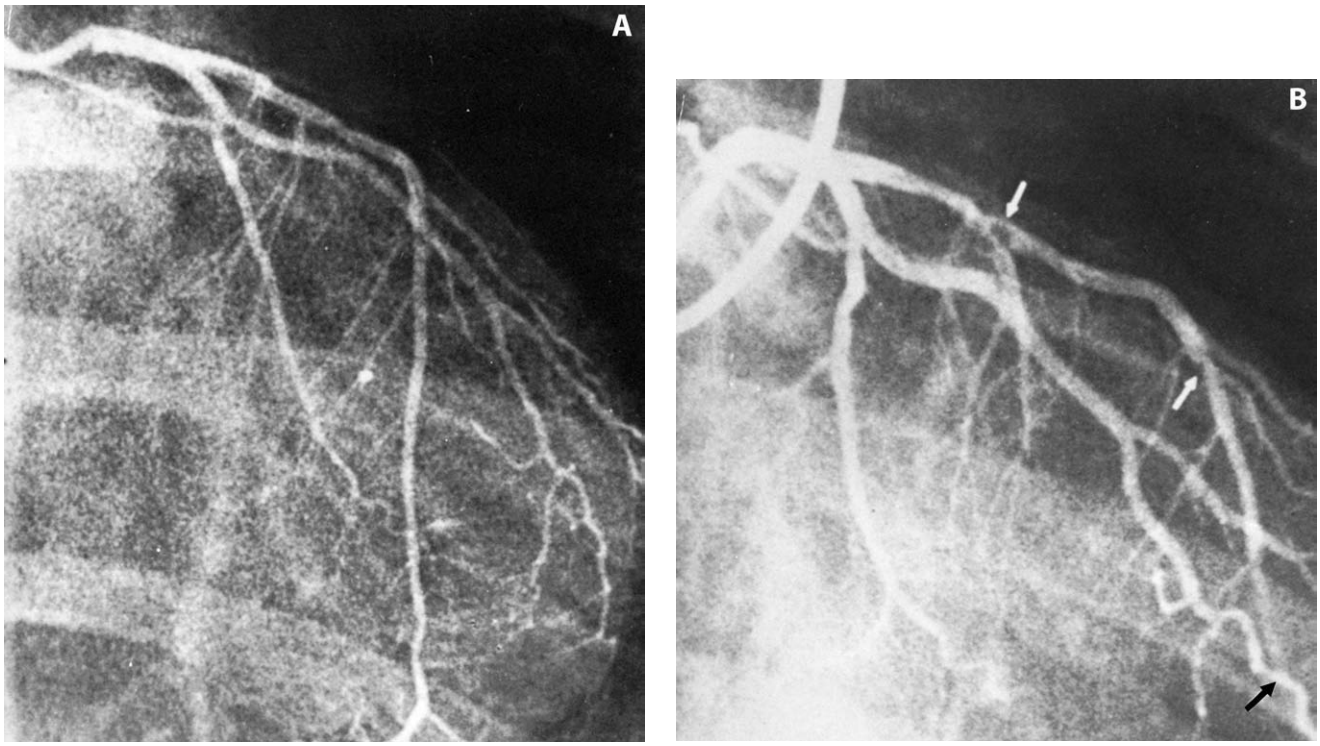

FIGURE 43 Selective arteriogram of the left coronary artery in right anterior oblique projection. (A) First study. No significant lesion of the left anterior descending coronary artery. (B) Second study, 18 days after (A) significant narrowing in the left anterior descending coronary artery at the origin of the large septal perforation (*uppermost arrow*), at the origin of diagonal branch (*middle arrow*), and in the distal portion of the vessel, consistent with coronary artery arteritis (*lowest arrow*). From Heibel *et al*. [262], with permission.

vena cava thrombosis [273] occasionally develop in lupus patients and may or may not be associated with antiphospholipid antibodies [268–270, 273]. Two-dimensional ECG, particularly with the transesophageal approach, can identify the aortic root thrombus, whereas conventional angiography and MRA define the aortic thrombosis in the thrombotic syndromes and the arteritis of the large vessels with alternating areas of narrowing and dilatation. Patients with SLE rarely develop dissecting aneurysms [274, 274a] (Fig. 45), which may be associated with atherosclerosis or Takayasu's aortitis [274b] or may be mycotic in etiology [275]. For rapid evaluation, helical CT or EBCT is carried out during the acute dissection or for the infected aneurysm that needs immediate treatment, and MRA is done for following the chronic dissection.

In SLE, peripheral arterial occlusion results from vasculitis or from thrombosis secondary to a hypercoaguable state associated with elevated lupus anticoagulant or antiphospholipid antibodies [276–281]. Ulceration and gangrene can follow. Vasospasm that may accompany the vasculitis is particularly associated with Raynaud's phenomenon (see sections on musculoskeletal and pleuropulmonary SLE). Conventional angiography and MRA (Fig. 46) show the peripheral vasculitis, thrombus, arteritis, and arteriosclerotic plaques [282–285].

Peripheral Venous Occlusive Disease

Thrombophlebitis and deep venous thrombosis occur in 4.6–12.2% of patients with SLE [77, 286]. Several factors predispose to deep venous thrombosis: chronic disseminated intravascular coagulation, small vessel angiitis with propagation of thrombus into larger vessels, venulitis, compensatory lupus anticoagulants, antiphospholipid antibodies, and prolonged patient immobility [276, 277, 286–290]. Conventional venography (Fig. 47) and, more recently, MRA and power Doppler/duplex sonography (Fig. 48) are usually used for studying the central veins. Previously, radiographic and radionuclide venography were the primary imaging modalities for evaluating extremity thrombosis [69, 288–291]. However, color flow Doppler/duplex

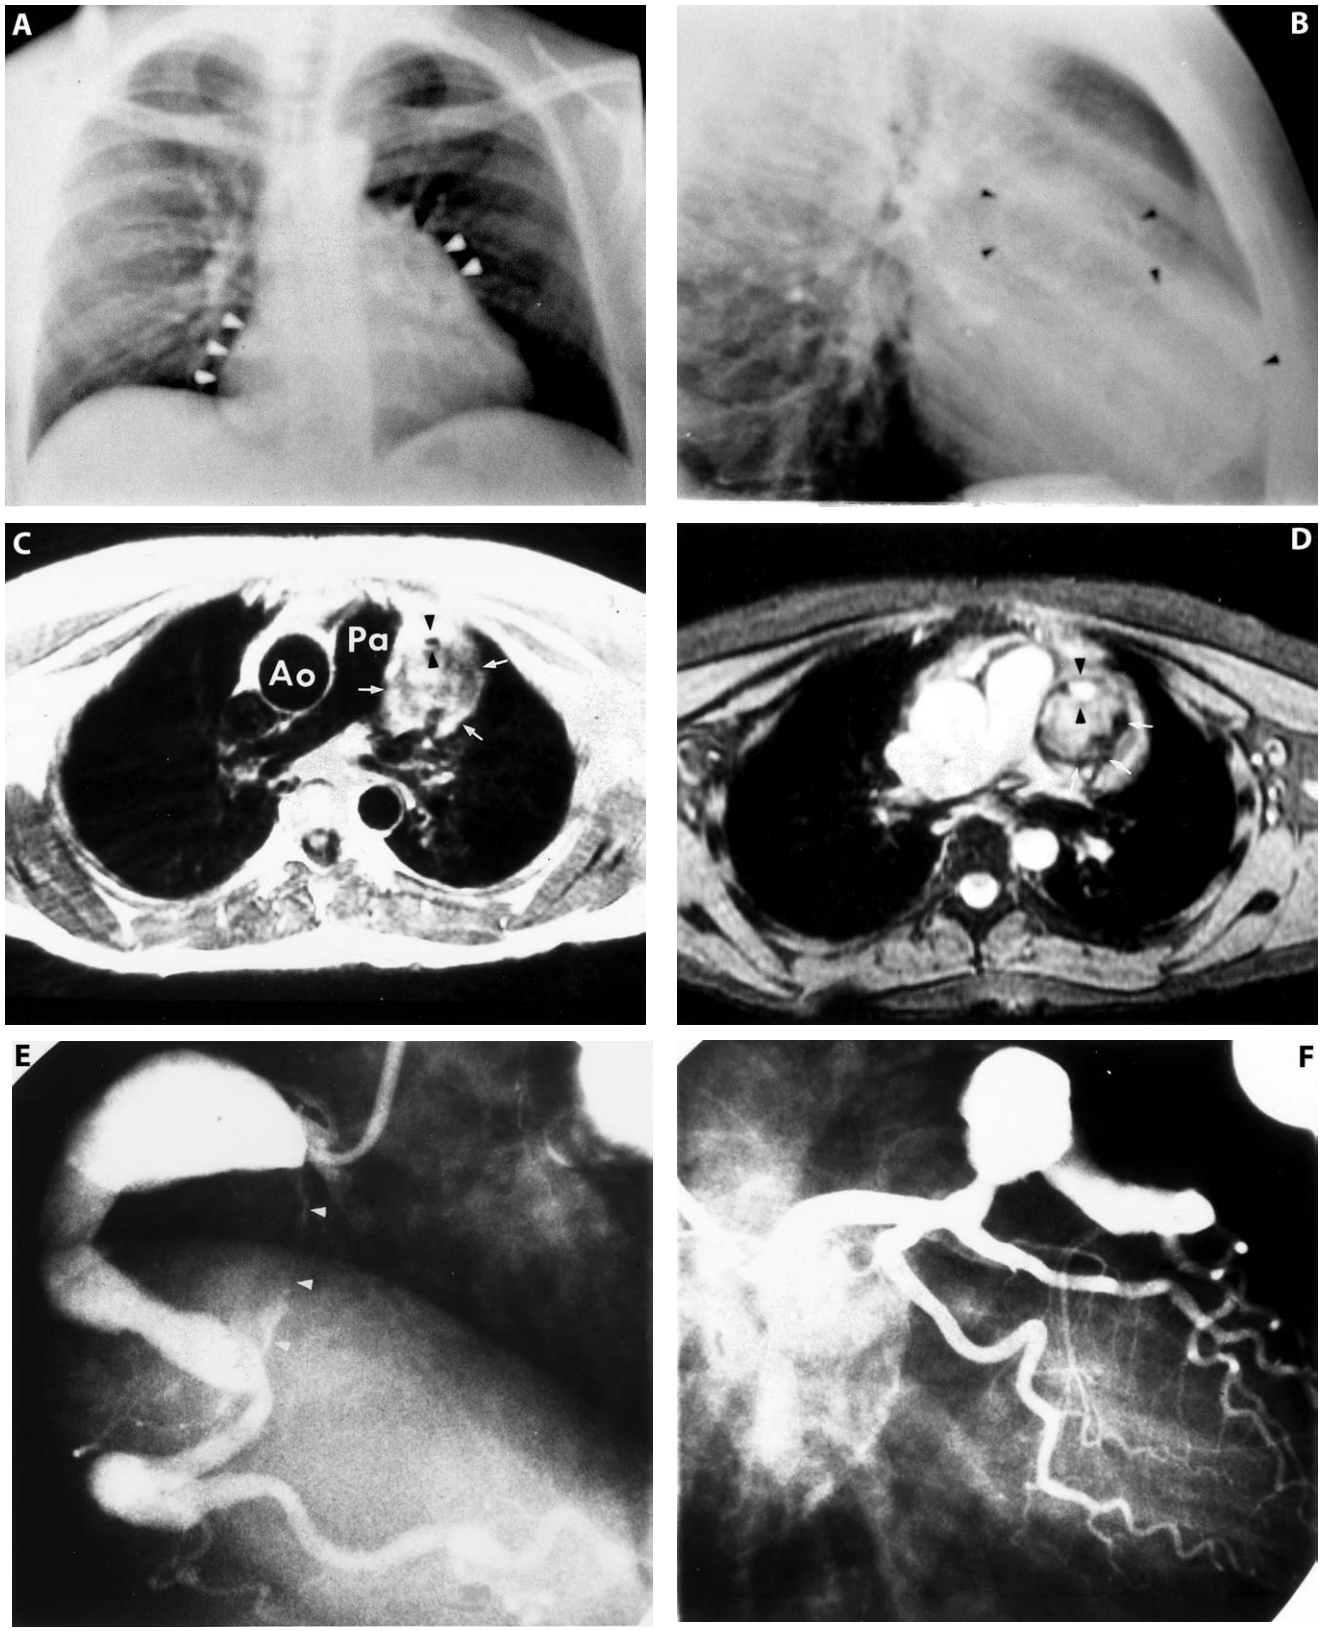

FIGURE 44 (A) Posteroanterior radiograph of a 26-year-old woman with SLE without cardiac symptoms shows a round calcified structure (*white arrowheads*) at the upper left margin of the heart and at the right atrial region. (B) Lateral radiograph shows that the upper calcifications are near the aortic root and the inferior calcifications overlie the right ventricle (*black arrowheads* outline the margin of the calcifications). Axial MR images (C and D) show an aneurysm of the left anterior descending coronary artery (*white arrows*). The aneurysm has an extensive thrombus that compresses the residual lumen (*black arrowheads*). The aneurysm is larger in diameter than both the aorta (Ao) and the main pulmonary artery (Pa). (E) Coronary angiogram in the left anterior oblique projection shows aneurysmal dilatation of the right coronary artery with peripherally calcified thrombus (*white arrowheads*). (F) Right anterior oblique projection shows a left anterior descending aneurysm. From Nobrega *et al.* [266], with permission.

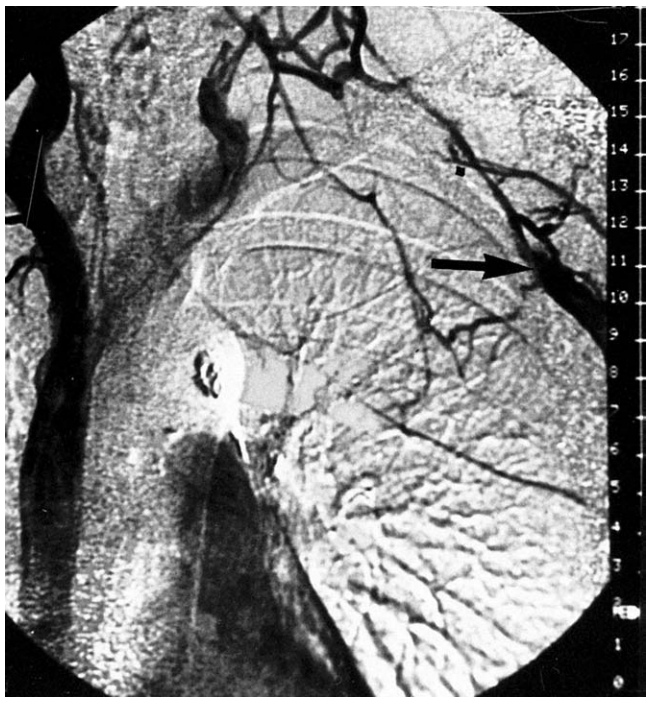

FIGURE 47 Venogram shows occlusion of the left axillary vein (arrow) with collateral filling of the innominate vein via the jugular collaterals in a patient with SLE. Courtesy of Dr. M.-F. Kahn, University of Paris.

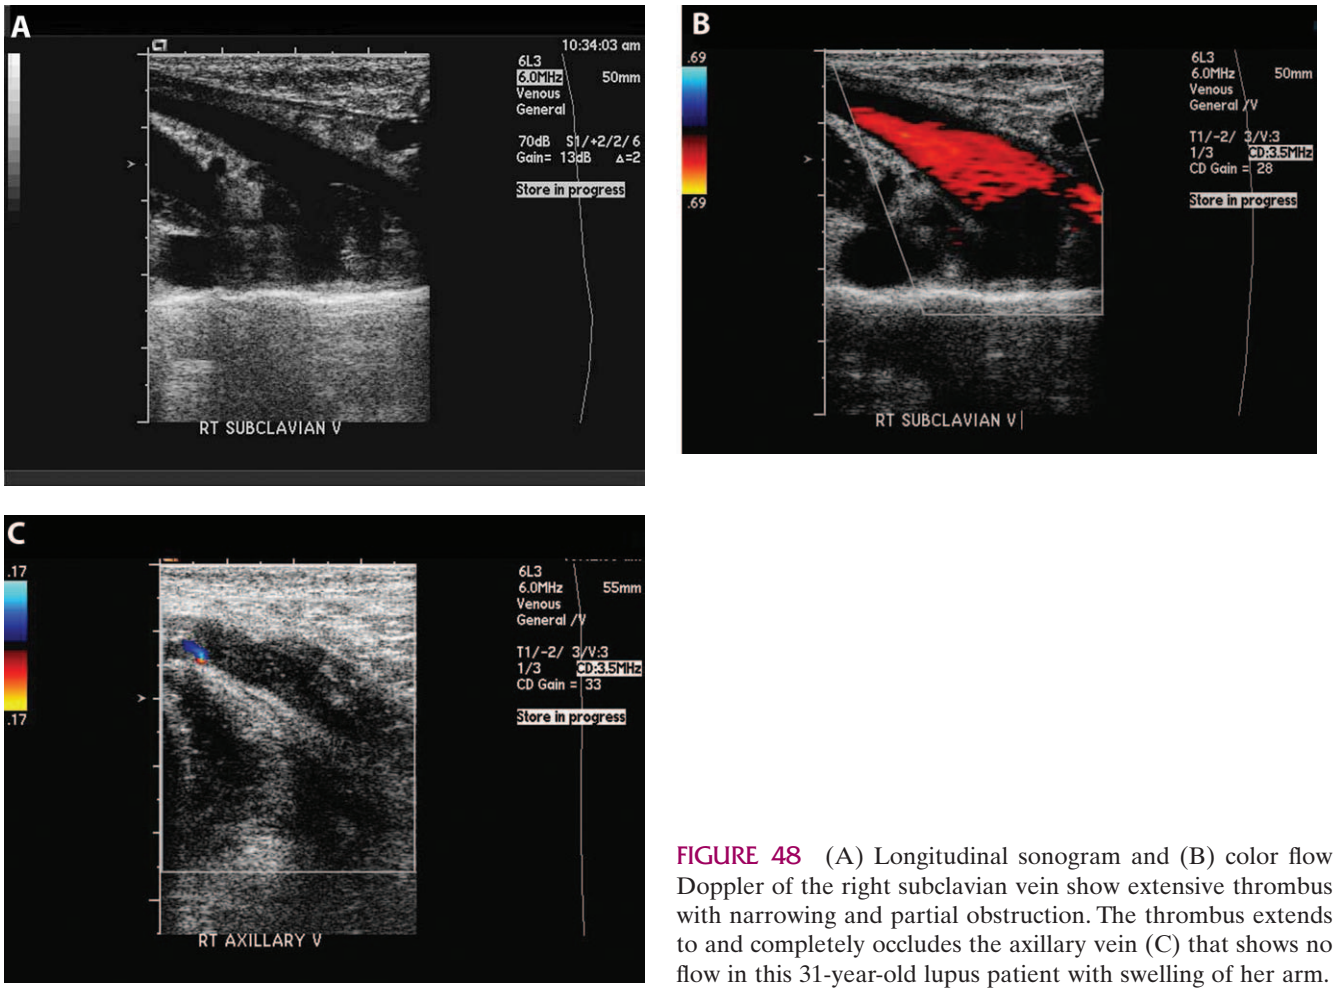

FIGURE 48 (A) Longitudinal sonogram and (B) color flow Doppler of the right subclavian vein show extensive thrombus with narrowing and partial obstruction. The thrombus extends to and completely occludes the axillary vein (C) that shows no flow in this 31-year-old lupus patient with swelling of her arm.

sonography (Fig. 49) and, more recently, power Doppler [33c], have replaced venography as the preferred initial test for deep venous thrombosis [69, 293–295] by demonstrating the noncompressible, thrombosed vein, the presence or absence of flow, and the areas of vein recanalization, when present. MRA should be reserved for situations where there is discordance between clinical and sonographic diagnoses.

In summary, a multimodality approach permits the best evaluation of cardiovascular disease in SLE. Echocardiography and color flow Doppler/duplex sonography should be the initial tests for evaluating cardiac anatomic and functional abnormalities, proximal aortic disease, and venous occlusive disease. Myocardial ischemia and perfusion can be evaluated by ^{201}thallium/^{99m}Tc sestamibi stress tests and potentially with dynamic contrast-enhanced MRI. EBCT can demonstrate coronary artery calcification. MRA has shown potential for evaluating noninvasively the coronary arteries and myocardial function. The rare aortic or coronary artery aneurysm and central venous thrombosis or dissecting aneurysm can be visualized at both CT and MRI, and conventional angiography and MRA can confirm the diagnosis, when necessary.

IMAGING OF GASTROINTESTINAL SLE

In 1885, William Osler [296] reported 11 patients with erythema exuditavum multiforme who had "gastrointestinal crises, colic, usually with vomiting and diarrhoea." Symptoms referable to the gastrointestinal tract are quite common in patients with SLE. Gastrointestinal upset may develop secondary to vasculitis, concurrent uremia, corticosteroid therapy, immunosuppressive or antimetabolite therapy, CNS involvement, or coincidental gastritis, hepatitis, pancreatitis, or peritonitis. Thus, at some time during the course of their illness, most patients with SLE report anorexia (47–82%) and nausea and vomiting (11–53.2%) and some have diar-

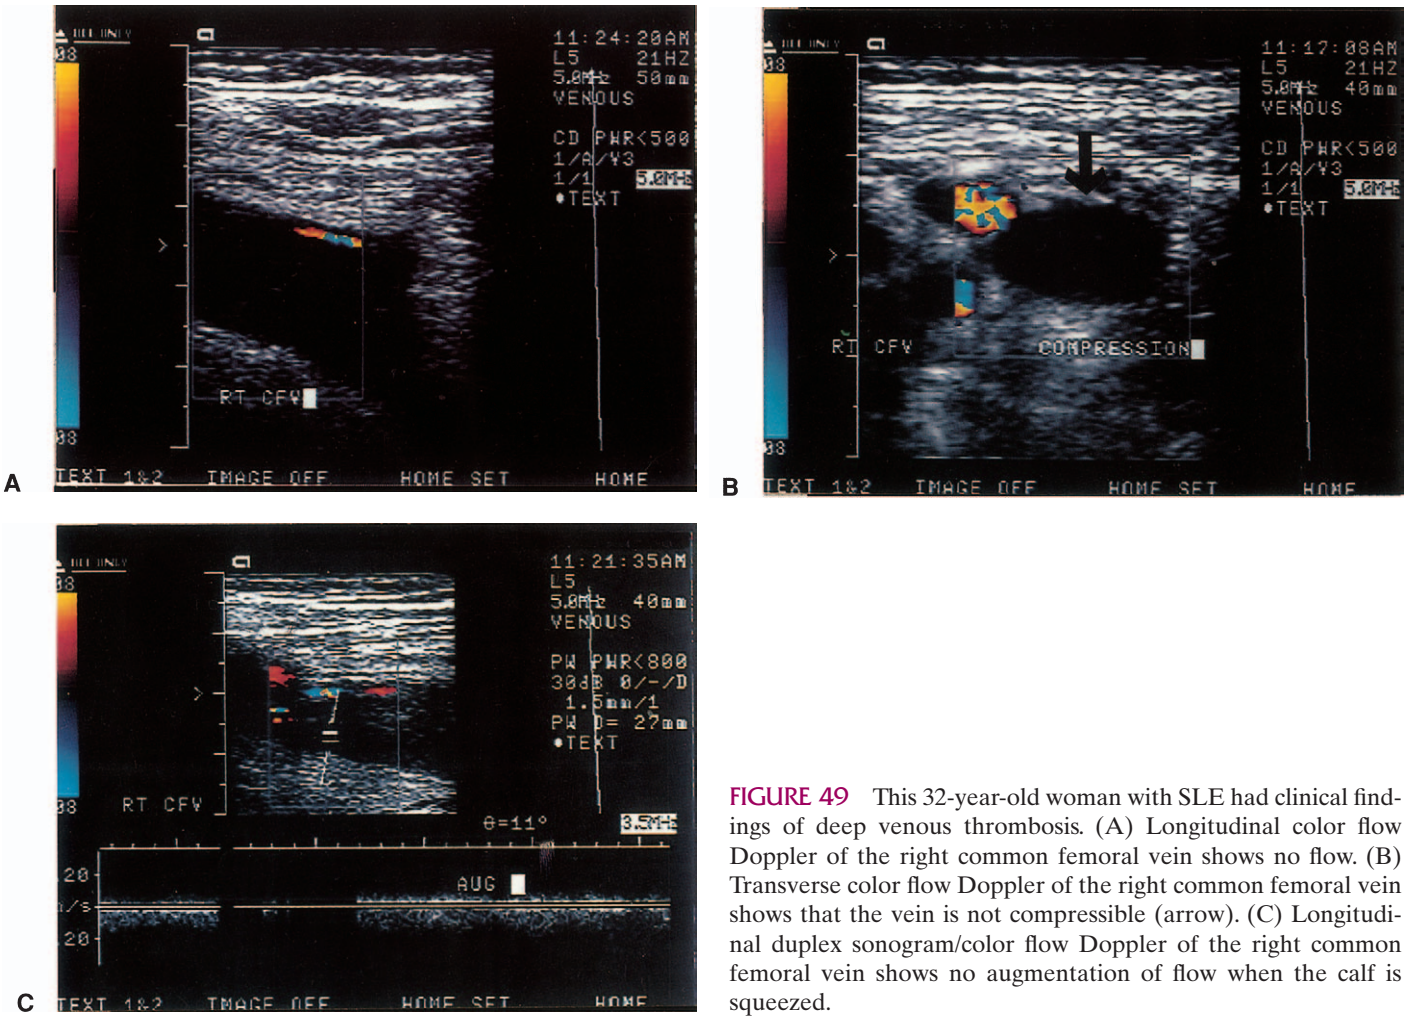

FIGURE 49 This 32-year-old woman with SLE had clinical findings of deep venous thrombosis. (A) Longitudinal color flow Doppler of the right common femoral vein shows no flow. (B) Transverse color flow Doppler of the right common femoral vein shows that the vein is not compressible (arrow). (C) Longitudinal duplex sonogram/color flow Doppler of the right common femoral vein shows no augmentation of flow when the calf is squeezed.

rhea (5.9–21%), bowel hemorrhage (5–6.3%), and abdominal pain (10–37%) [77, 80, 297–299].

Acute Reversible Lupus Gastrointestinal Ischemia

Acute reversible lupus ischemia of the gastrointestinal tract is a recognized but frequently misdiagnosed manifestation of SLE. A clinical picture consistent with reversible ischemia suggestive of vasculitis has been reported [80, 300–303]. It may be mistaken for various entities, as detailed earlier. In their series of 141 patients, Shapeero *et al.* [303] found 20 patients with ischemic disease compatible with a vasculitis that was reversed by corticosteroids. Nine had radiographic findings consistent with an ischemia: pseudo-obstruction of the gastric outlet (Fig. 50), duodenal stasis, effacement of mucosal folds, and thumbprinting (Fig. 51). Because the most common area of involvement is the small bowel, it is important to obtain a small bowel series as well as an upper gastrointestinal study to evaluate for changes of ischemia. The radiographic manifestations of gastrointestinal ischemia in SLE reflect the underlying pathologic process of a decrease in the blood supply and are similar to those of other types of ischemic bowel disease. The different layers of the bowel are not equally sensitive to a decrease in their blood supply [303–305]. The mucosa is most vulnerable to vascular compromise, followed by the muscular layers; the submucosa and serosa are least sensitive. The first changes to develop are superficial mucosal ulcerations that are radiographically not visible on small bowel series. In the colon, a fine pattern of ulceration may simulate ulcerative colitis [306–308]. When the muscular layer is impaired, an ileus may develop with fluid accumulation in the lumen of the gut. Unfortunately, at this stage, these changes are nonspecific. When submucosal hemorrhage and edema develop, as they frequently do, diffuse nodularity and

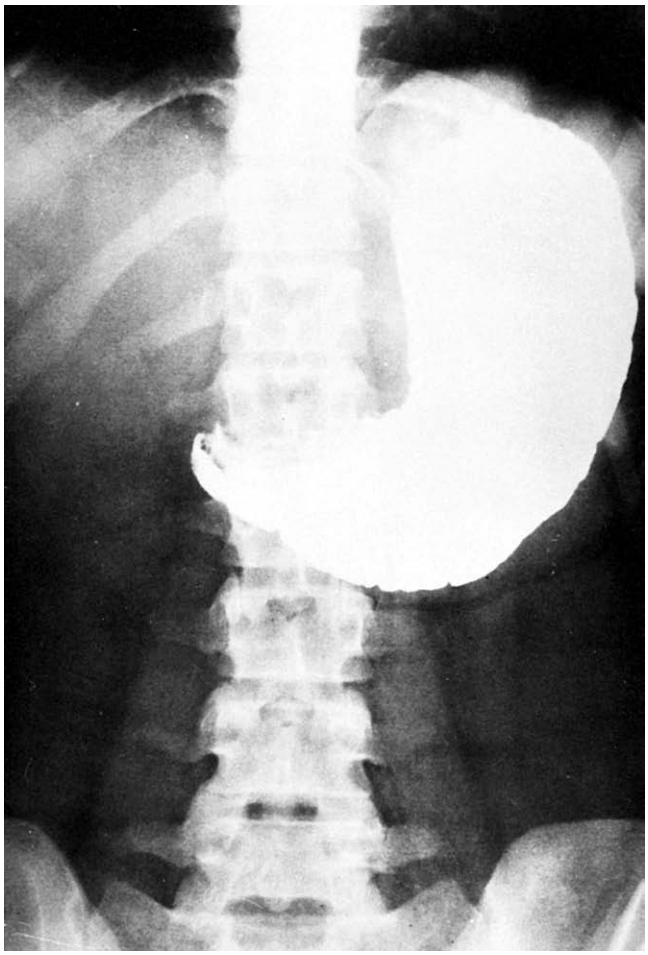

FIGURE 50 Upper gastrointestinal series shows a mildly dilated stomach with pseudo-obstruction of the gastric outlet in a 23-year-old woman with SLE. From Shapeero *et al.* [303], with permission.

thickening of the mucosal folds and the wall of the small bowel [303, 309] and colon strongly suggest the diagnosis of ischemia (Figs. 51 and 52). These findings may simulate other disease such as regional enteritis or submucosal hemorrhages from some other cause than ischemia; however, in the lupus patient, ischemia is the most probable diagnosis.

Phillips and Howland [310] described the angiographic findings of lupus arteritis as irregularities of the small mesenteric vessels. Asherson *et al.* [311] described mesenteric vascular occlusive disease at angiography and bowel infarction in lupus patients who have elevated antiphospholipid antibodies (Fig. 53). Although not yet reported in the lupus patient, MRA noninvasively can delineate the thromboses and irregularities of mesenteric vessels.

Ischemia secondary to vasculitis may have an acute or insidious onset. Chronic lupus vasculitis of the colon can rarely lead to stricture [312]. However, when ischemia is unrecognized, massive infarction, penetrating ulcers, intussusception, peritonitis, abscess formation, and perforation of the small and large bowel may result [312–320, 321, 321a] with the radiographic findings of ischemia, intramural air (pneumatosis intestinalis), air in the portal vein, and pneumoperitoneum. CT can demonstrate the findings of thickened ischemic bowel and its complications: pneumatosis intestinalis, air in the portal vein, abscess formation, intussusception, and ascites [322–324]. Management of the acute abdominal manifestations of SLE is a difficult therapeutic and surgical problem. Although some patients with ischemic episodes may respond to medical therapy and show improvement on barium studies and at CT [302, 324], the progression of clinical symptoms and signs, despite therapy, should indicate the need for laparotomy [320, 321].

Pneumatosis intestinalis does not always imply necrotizing lupus enterocolitis; a benign form [325–327]

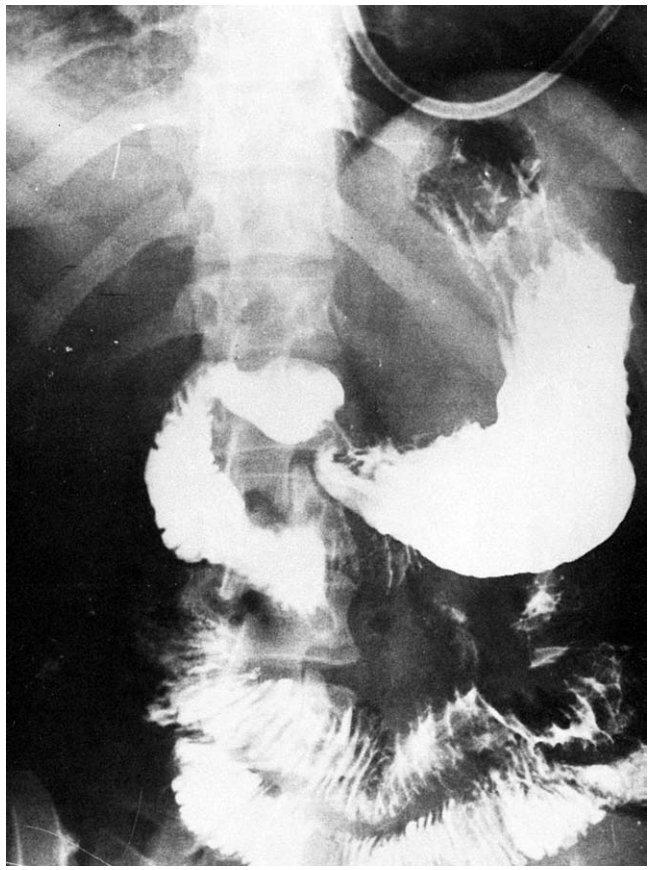

FIGURE 51 Small bowel series shows thickening and effacement of jejunal mucosal folds and thumbprinting in a 23-year-old woman with SLE. From Shapeero *et al.* [303], with permission.

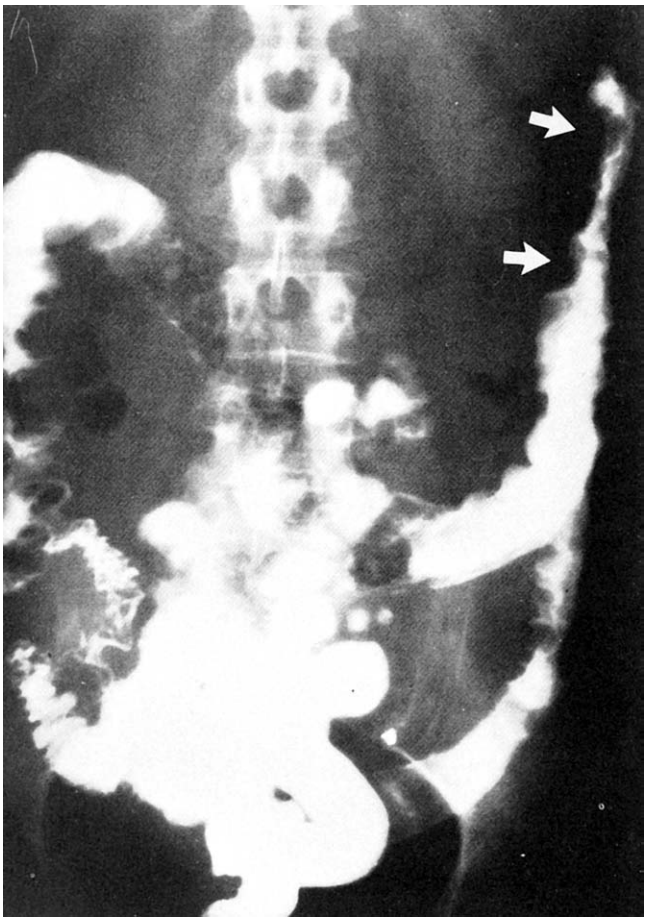

FIGURE 52 Barium enema shows thumbprinting of the entire colon (*arrow*) in a 26-year-old woman with ischemia lupus colitis. From Kistin *et al*. [307], with permission.

occurs and may resolve spontaneously (Fig. 54). In the benign form, the pathogenesis remains unclear and is not always associated with ischemia.

A rare gastrointestinal complication in SLE is colitis associated with neutropenia, a complication of immunosuppressive therapy [328]. In neutropenic colitis, barium studies should be avoided because of the risk for perforation. When cautiously performed, they show a thick-walled cecum with thumbprinting. CT, after oral contrast, also defines the cecal wall thickening and sometimes thickening of the ascending colon and the proximal portion of the transverse colon. Pneumatosis intestinalis, pericolonic fluid, and thickening of adjacent mesenteric fat may also be identified. As with acute reversible lupus gastrointestinal ischemia, bowel wall thickening in necrotizing enterocolitis can resolve with effective therapy. Bowel wall thickening and thumbprinting of neutropenic colitis cannot be differentiated from ischemia associated with SLE; however, the distribution of involvement in the cecum and right side of the colon should suggest neutropenic colitis in the appropriate clinical setting.

Chronic Gastrointestinal Lupus

Chronic gastrointestinal changes in lupus patients include esophageal dysfunction, gastric polyps, malabsorption syndrome, and protein-losing enteropathy [68, 329–341].

Esophageal abnormalities in SLE, which occur in 13–32% of patients [298, 329–334], more commonly affect the lower one-third of the esophagus and have been associated with Raynaud's phenomenon. Although the barium swallow may reveal aperistalsis, hypomotility, or esophageal dilatation, manometric

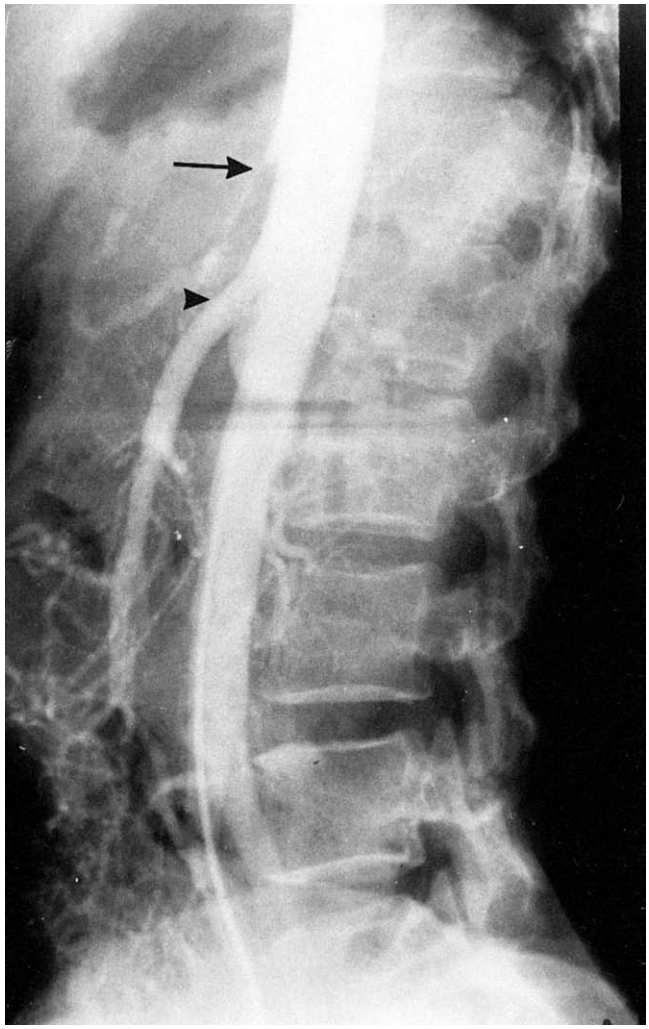

FIGURE 53 Lateral aortogram shows occluded celiac axis, patent superior mesenteric artery, and nonopacified inferior mesenteric artery in a 44–year-old patient with SLE and elevated antiphospholipid antibodies. From Asherson *et al*. [311], with permission.

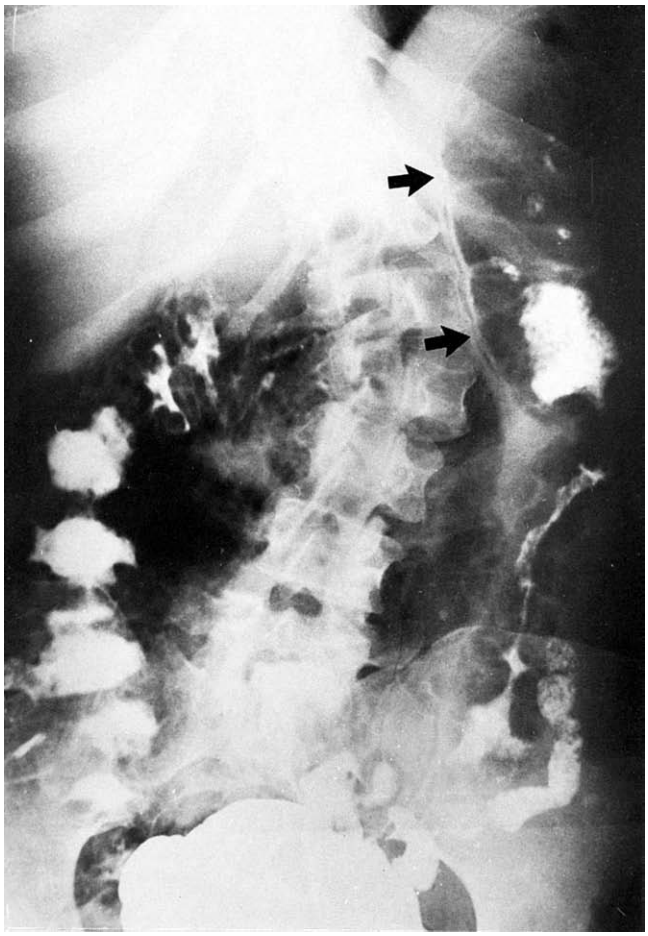

FIGURE 54 Postevacuation radiograph of barium enema shows linear air collections (*arrow*) in the splenic flexure and air bubbles in the wall of the ascending colon and in the mesocolon typical for pneumatosis intestinalis. From Freiman *et al*. [325], with permission.

studies are reported to be more sensitive for defining these changes [331, 332]. Esophageal motility disorders are less severe and less frequent in lupus patients as compared with scleroderma, mixed connective tissue disease, and polymyositis [331, 334].

Gastric polyps, seen as nodular-filling defects on gastrointestinal series, are a rare finding in lupus. Microscopic examination shows areas of chronic and acute inflammation with fibrinoid necrosis in the arteriolar walls associated with vasculitis [335].

Malabsorption was associated with SLE in several studies [336, 337, 337a]. Patients usually have abnormal d-xylose studies and/or increased fecal fat excretion [336, 337, 337a]. The radiographic pattern is similar to malabsorption in other entities with spiculation, fragmentation, and clumping of small intestinal loops. Biopsies may be normal or show blunting and loss of normal villi.

Lupus patients may also manifest a protein-losing enteropathy with coarsened and thickened intestinal folds (Fig. 55) and multiple smooth and nodular lesions predominantly in the proximal small bowel but occasionally in the stomach and colon [338–340, 340a, 341]. Jejunal endoscopy may show dilated lymphatics and submucosal edema [340a].

Ascites

Ascites may develop in patients with the nephrotic syndrome or with peritoneal inflammation secondary to primary lupus serositis, gastrointestinal lupus vasculitis, or infection. Ascitic fluid is easily identified on sonograms, CT, and MR images (Fig. 56) [342]. At sonography, thickened mesentery associated with serositis may appear as a "target sign" (echogenic rim with hypoechoic center) [343]. In addition to ascites, CT shows the significantly thickened bowel wall [342a].

Hepatic Abnormalities in SLE

The cross-sectional imaging modalities (MRI, MRA, CT, power Doppler, and duplex sonography) [287, 346–353] can play a major role in detecting thrombosis of the portal and hepatic veins as in the Budd–Chiari syndrome in SLE and for demonstrating the rare hepatic infarction secondary to hepatic artery occlusion. Occlusion of these vessels is associated with antiphospholipid antibodies and lupus anticoagulants [344–347, 353]. These modalities can delineate the thrombus in the affected vein, which is frequently enlarged, and the level and length of occlusion of the vein and the collateral vessels (Fig. 57). Conventional angiography [354] MRI and MRA not only identify the venous occlusions and the collateral circulation but also show abnormalities of the hepatic, mesenteric, and splenic arteries and veins (Figs. 58 and 59). Aneurysms, although rare (Fig. 60), may develop in hepatic artery branches and may rupture with resultant hematomas [354, 355]. CT, sonography, or MRI can localize the associated hematoma, and interventional angiographic procedures are used to embolize the leaking vessel to induce hemostasis.

In contrast to their definitive role for evaluating hepatic and mesenteric vasculature, the different imaging techniques cannot demonstrate characteristic parenchymal hepatic changes in SLE. Fatty liver, which may be found in lupus patients on corticosteroid therapy, appears echogenic on sonograms and low attenuation on CT. Generalized hepatomegaly without focal mass or changes in architecture on cross-sectional imaging, but particularly with ascites, has been described in SLE but has also been reported in a rare case of primary lymphoma in the SLE [80, 356].

An unusual, although important, complication of treatment for SLE is the development of hepatic adenomas and even hepatocellular carcinoma in patients on longterm danazol therapy [357]. Weill *et al.* [357] reported a lupus patient who had received danazol therapy for 4 years and developed anterior chest pain and right hypochondrial pain. Echocardiography showed no pericardial effusion, but two large hypoechoic hepatic masses were incidentally discovered (Fig. 61). α-fetaprotein was negative. CT and angiography confirmed the presence of the masses but could not exclude malignancy. A left lobectomy and segmental resection of the right lobe revealed a hepatocellular carcinoma in the left lobe and an adenoma in the right lobe. The patient is clinically well 5 years postoperatively. The clinician should be aware of this possible complication and consider screening sonography in patients on longterm danazol therapy.

IMAGING OF THE RETICULOENDOTHELIAL SYSTEM IN SLE

Lymphadenopathy

Generalized lymphadenopathy [360, 361] occurs in 36–57% of lupus patients and most commonly involves the cervical, mesenteric, axillary, and inguinal and rarely the hilar regions. Lymph nodes can show changes of necrosis and hematoxylin bodies.

Development of lymphadenopathy in SLE also may herald the onset of lymphoma [362–368]. For more than 15 years, CT and MRI with standard sequences have been used to identify the extent of the disease and to

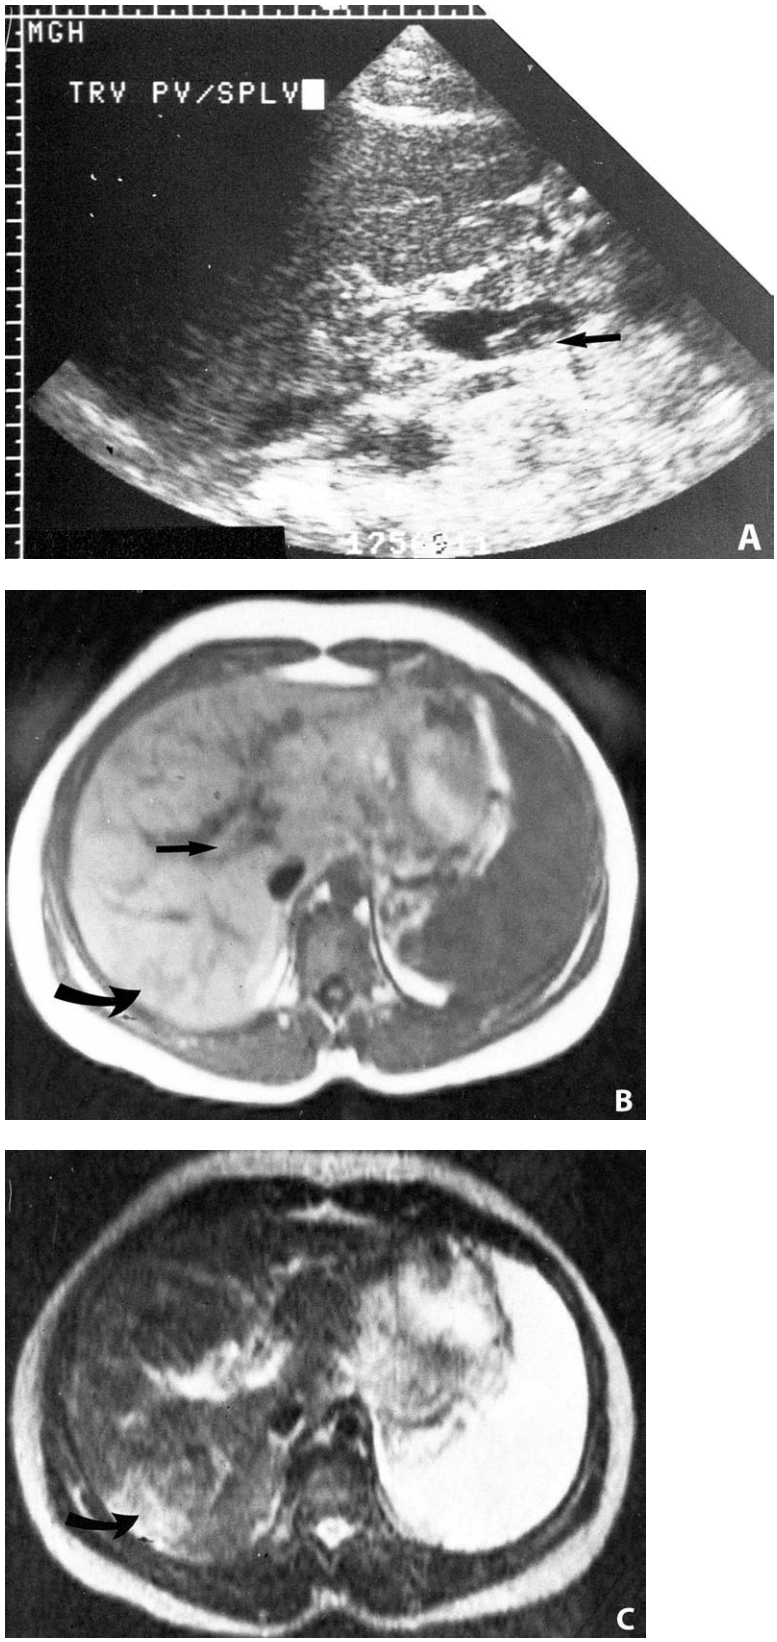

FIGURE 57 (A) Transverse abdominal sonogram shows echogenic thrombus (*arrow*) in the splenomesenteric confluence and occlusion of the intrahepatic portal vein. (B) Axial T1-weighted MR image shows the medium-signal-intensity thrombus in the portal vein (*arrow*) and a low-signal-intensity mass in the right lobe of the liver (*curved arrow*). (C) Axial T2-weighted MR image shows the high-signal-intensity thrombosed portal vein and the heterogeneous high-signal intensity right lobe lesion that probably represents hepatic infarction (*curved arrow*). FIGURE 61 A 30-year old lupus patient on long-term danazol therapy developed hypochondrial and anterior chest pain. Echocardiocardiography showed no cardiac abnormality but incidentally showed echogenic hepatic masses (*arrows*) of the right (A) and left (B) lobes of the liver. (C) An axial contrast-enhanced CT of the liver shows heterogeneously enhancing masses of the right and left lobes (*arrows*). Surgical exploration showed a hepatocellular carcinoma in the left lobe and an adenoma in the right lobe. Courtesy of Dr. Bernard Weill, University of Paris.

follow therapeutic response. MRI is the recommended modality for assessing cerebral lymphoma because of its excellent soft tissue contrast. In the spine, MRI can differentiate lymphomatous infiltration from normal marrow [368a]. The development of new fast MRI sequences allows total body imaging in 45 minutes and could be useful for rapidly evaluating the extent of lymphomatous involvement of both soft tissues and bones [368a, 368b]. In addition, FDG-PET has shown increasing utility for staging patients with lymphoma and following their response to treatment.

Splenic Abnormalities

Splenomegaly itself is a nonspecific finding in SLE and may be also a primary manifestation of lupus or be

associated with idiopathic thrombocytopenic purpura or neoplastic infiltration.

Functional asplenia/atrophy in SLE [369–372] is characterized by decreased radiopharmaceutical uptake at scintigraphy and atrophy at sonography, CT, and MRI. However, duplex sonography/color flow Doppler, CT, and MRA also may show splenic artery and vein and flow dynamics. A decreased radiopharmaceutical splenic uptake correlates with a depressed IgM level [369]. In SLE, functional asplenia seems to predispose to significant septic complications. In one study, 6 of 10 patients with SLE and functional asplenia developed pneumoccocal or salmonella sepsis [370, 371]. Only one of these patients survived the sepsis with return of splenic function [371].

In lupus patients who have lymphomatous involvement of the spleen, neither MRI nor CT is sufficiently sensitive to detect splenic involvement. Patients with splenic lymphoma may have a small or normally sized spleen as well as splenomegaly. Splenic infiltration and its resolution can be shown on sequential FDG-PET studies.

IMAGING OF GENITOURINARY SLE

Renal Manifestations

Most patients with SLE have normal urograms and sonograms. Significant findings are found in lupus patients with infarcts, chronic lupus nephritis, superimposed infection (both acute and chronic), and renal vein thrombosis.

When chronic renal failure develops, poor renal function precludes adequate urographic visualization of the kidneys. Contrast medium is contraindicated because it may aggravate renal failure. Sonography is the preferred imaging modality for evaluating renal size, echogenicity, and obstruction. In lupus nephritis, the kidney may be normal in size and echogenicity (equal to or less than that of the liver) for even months and years after diagnosis. However, in chronic lupus nephritis, the parenchyma becomes more echogenic [373] than the hepatic parenchyma (Fig. 62). The echogenic kidney is not specific for lupus nephritis and may be seen in other chronic medical renal disease, including chronic amyloidosis, a complication of SLE. Moreover, the increase in echogenicity does not correlate with the severity of the renal compromise [374, 375]. One report [375] described multiple focal hypoechoic areas within the renal cortex in diffuse active proliferative membranous lupus glomerulonephritis, but this has not been verified by other investigators. In chronic lupus nephritis, MRI may show loss of the normal corticomedullary differentiation on T1-weighted images (Fig. 63). As with sonography, these findings are not specific for SLE and may be seen in chronic renal disease and obstruction.

When renal function suddenly worsens, obstruction must be excluded, and sonography should be carried out (Fig. 64). When sonography shows no separation of the pelvocalyceal echoes, hydronephrosis can be excluded in 95% of the patients. When sonography demonstrates

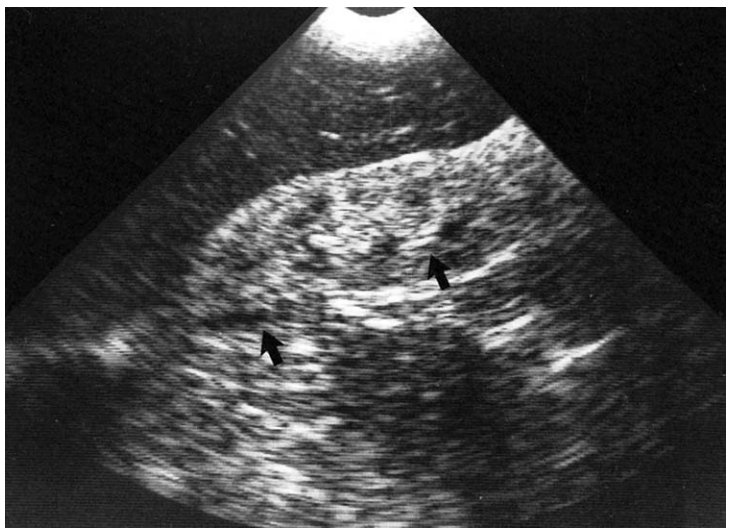

FIGURE 62 Longitudinal sonogram of the right kidney shows increased echogenicity of the kidney (*arrows*) as compared to the liver in a 27-year-old woman with SLE and chronic renal failure.

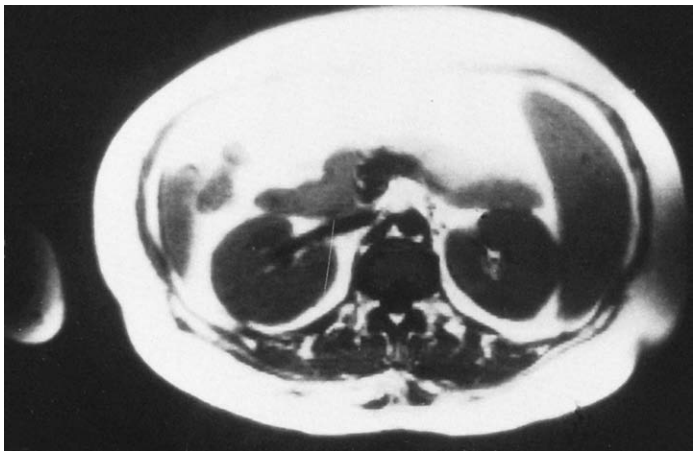

FIGURE 63 Axial T1-weighted MR image (500/30) shows loss of corticomedullary differentiation in chronic lupus nephritis.

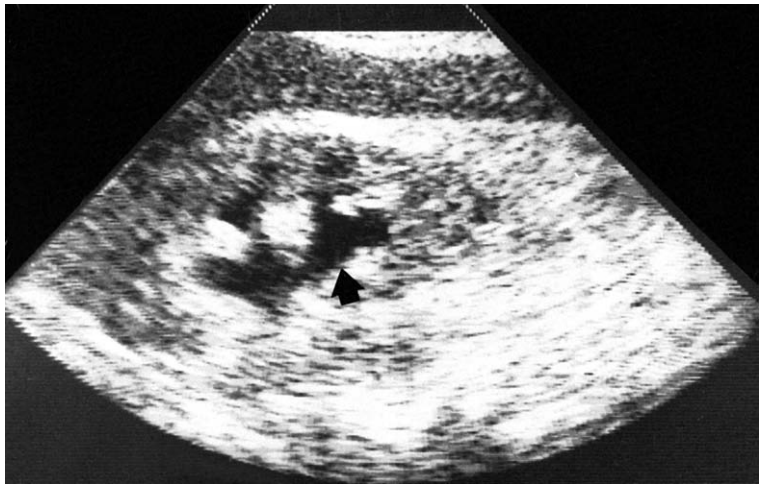

FIGURE 64 Longitudinal sonogram of an echogenic right kidney (*arrows*) shows hydronephrosis with separation of the pelvocalyceal echoes.

dilatation of the pelvocalyceal, 80% of patients will have hydronephrosis. False-positive diagnoses occur with the overdistended bladder, reflux, extrarenal pelvis, diuresis, and parapelvic cysts. When dilatation is present, renal scintigraphy after Lasix can differentiate obstructive from nonobstructive hydronephrosis.

Acute infarcts are hypoechoic, often wedge-shaped areas extending to the cortex at sonography. The peripheral wedge-shaped infarcts can also be identified at CT and MRI and appear as peripheral defects on renal Tc99m DMSA scans but are defined more clearly by the tomographic imaging of SPECT. With chronic infarcts and scarring, sonography, CT, MRI, and intravenous urography (IVU) demonstrate the cortical loss and renal contour deformities. Renal infarcts have been associated with anticardiolipin antibodies [376].

Because of their susceptibility to infection, patients with SLE may develop acute, generalized pyelonephritis. Usually, the kidneys are normal in size and echogenicity (sonography) and density (IVU). Occasionally, the IVU or sonogram may demonstrate a large edematous kidney [377]. IVU may also show diminished nephrographic density, delayed calyceal appearance time, faint visualization of the collecting systems, pyelocaliectasis, and ureterectasis. The focal form of acute pyelonephritis or lobar nephronia appears as a mass at IVU and may be indistinguishable from an abscess or even tumor. Sonography and CT aid in establishing the appropriate diagnosis [378–380]. Sonography, particularly with the newer techniques of tissue harmonic imaging sonography for improved resolution [33a], extended field of view [33b], and power Doppler,

depicts the focal pyelonephritis as a poorly marginated, hypoechoic mass with increased vascularity consistent with inflammation. Contrast-enhanced CT delineates a mass with ill-defined borders without frank liquefaction; noncontrast CT scans, however, may fail to disclose a lesion when it is isoattenuation with the renal parenchyma. When intrarenal abscesses evolve, CT, sonography, and MRI show well-circumscribed, often thick-walled intraparenchymal collections. Sonographically, the abscesses usually appear fluid-filled but may have internal echoes or even be echogenic. The presence of through transmission and refractive shadowing characterize the fluid nature of the abscess. At contrast-enhanced CT, abscesses show enhancing rims and central low attenuation necrosis [378]. At MRI, the abscess, when proteinacious, will be hyperintense on T1- and T2-weighted MR images, but, when nonproteinacious, the abscess is hypointense on T1-weighted MR images and hyperintense on T2-weighted MR images.

Infectious extension beyond the renal capsule causes pararenal and perirenal abscesses with thickening of these spaces and the adjacent psoas muscle. Both CT and MRI define the retroperitoneal extent of the abscess, but CT better identifies air in the abscess. Air bubbles in these soft tissues should alert the clinician to the possibility of a gas-forming organism. Sonography may be misleading because small air bubbles in the perirenal space are echogenic and may simulate fat and obscure the underlying small abscess.

In chronic pyelonephritis, all modalities show the small, atrophic kidney, but sonography is the most expeditious and least expensive. As with the acute process, the IVU may also demonstrate pyelocaliectasis and ureterectasis but is contraindicated in patients with compromised renal function.

In the lupus patient, the onset of renal vein thrombosis may be confusing. Frequently these patients have recurrent episodes of pleuritis. However, in the patient with a nephrotic syndrome, the sudden onset of chest pain may alert the clinician to the onset of pulmonary embolism secondary to thrombosis in the renal veins or veins of the extremities. Previously, angiography and venography [381] were (Fig. 65) and currently MRI [386] and MRA are the best tests for noninvasively studying thrombi in the renal vein and inferior vena cava and collateral circulation. Contrast-enhanced CT (Fig. 66A) can evaluate patency of the renal veins, but this study and standard venography are contraindicated with renal failure [381–385]. Renal veins can also be evaluated at duplex sonography (Fig. 66B) but may be obscured by bowel gas, particularly on the left side.

Renal arterial involvement in SLE affects primarily the small- and medium-sized arteries. At angiography, Ekelund and Lindholm [387] and Bookstein and coworkers [388] found impaired filling or nonvisualization of the interlobular arterioles on the arterial phase and absent glomerular granularity and indistinct corticomedullary junction on the nephrographic phase (Fig. 67) [387]. These angiographic changes reflect the histologic findings of diffuse glomerular involvement, partial obliteration of glomerular capillaries, and luminal narrowing of the interlobular arterioles by intimal and medial hyperplasia [388]. Occasionally lupus patients develop renal artery aneurysms (Fig. 68) [354]. Rupture of the aneurysms may result in acute retroperitoneal hemorrhage. The latter process may also develop as a complication of renal biopsy and presents as a perirenal and/or pararenal collection that may also involve the psoas muscle. As the hematoma changes from acute to chronic, the collection changes from hyperechoic to mixed to hypoechoic at sonography (Fig. 69) and from increased to normal to decreased attenuation at CT. At MRI, subacute hematomas are hyperintense on both T1- and T2-weighted MR images. Another complication of renal biopsies, arteriovenous (AV) fistulas, can be demonstrated at MRI (especially MRA) and power Doppler/duplex sonography. With AV fistulas, the renal vein develops an arterialized flow pattern.

Bladder Abnormalities

The differential diagnosis of bladder abnormalities of SLE includes lupus interstitial cystitis [389–393a], infectious cystitis, bladder tumor, and cystitis secondary to cyclophosphamide therapy [394, 395] and occasionally the neurogenic bladder [396]. IVU, sonography, and CT depict cystitis of various etiologies as bladders with thickened, sometimes irregular, walls with reduced capacity. Contrast-enhanced CT also shows an abnormally enhancing bladder wall [393]. Weisman *et al.* [389] described two patients with lupus cystitis who also showed pyelocaliectasis and ureterectasis (Fig. 70). Obstruction, when present, occurred at the ureterovesical junction. In one patient, immunofluorescent deposits were found in the blood vessel walls of the bladder, suggesting an immune etiology [389]. Recognition of this type of bladder involvement in SLE is important because it may be a partially reversible cause of renal failure. The acute radiographic and clinical findings usually improve with corticosteroid therapy. Bladder cancers, usually first evaluated at cystoscopy because of a history of hematuria, are staged at CT and MRI studies. The neurogenic bladder, as a complication of transverse myelitis, may be either hyperreflexic (upper motor neuron lesion) or areflexic (lower motor neuron lesions). Radiographic voiding cystourethrogram and urodynamic studies are the usual studies

performed for evaluating dysfunction. Another technique, the endorectal sonographic voiding cystourethrogram, developed by Shapeero *et al*. [397], can also evaluate neuromuscular function of the bladder neck and urethra (Fig. 71) and could be applicable to the lupus patient. This technique requires no irradiation or catheterization with its attendant risk of infection. During the procedure, the patient can be monitored continuously, without irradiation, for subtle abnormalities of dyssynergia and for the effects of drugs. This technique can be particularly useful for younger patients who need multiple sequential examinations to evaluate for the efficacy of medical and surgical therapy.

Renal Allografts and Their Complications

William Amend (personal communication, University of California, San Francisco) found that lupus patients comprised 3% of their patients receiving cadaveric allografts and 8% of those waiting for cadaveric allografts. It is more difficult to match the lupus patient with a histocompatible allograft because of the more complex antibody profile in SLE. Improved histocompatibility matching, refined surgical technique, and more effective immunosuppressive therapy (azathioprine, prednisone, and cyclosporine) enhance graft survival [398–400]. However, lupus patients do not appear to do as well as patients with renal allografts with other end-stage renal disease [401]. Several groups of investigators have reported an increased risk of graft failure in lupus patients within the first year and frequently within the first month after transplantation, a prevalence as high as 35–40% [401–410]. The most important cause of early graft loss in the lupus patient appears to be allograft rejection. In addition, thrombosis of renal arteries and veins may lead to graft loss in renal transplant patients because allografts have no collateral vessels [401]. Antiphospholipid antibodies and lupus anticoagulants have been associated with thrombosis of allograft arteries and veins in SLE.

Although there is some overlap, major complications of renal allografts during three major time periods: the first 24 h after transplantation, the first postoperative week, and weeks to months after transplantation. Renal allografts are subject to both renal parenchymal insults ("medical" complications) [398, 400, 411] and mechanical injuries ("surgical" complications) [398–400, 412, 413].

The First 24 Hours after Transplantation

Sudden anuria should alert the clinician to the possibility of hyperacute rejection, renal arterial or venous occlusion, acute compression of the allograft by acute hematoma, or urinoma. When portable scintigraphy (^{99m}Tc DTPA or ^{131}IOH) and/or portable duplex sonography/power Doppler both show no flow, the patient returns to surgery immediately [398].

The First Week after Transplantation

When the transplant patient becomes oligoanuric, the most frequent medical complication is acute tubular necrosis (ATN) that remains stable or slowly improves over several days or even weeks provided that rejection or other insults do not complicate ischemic damage [398, 414, 415]. In previous years, renal scintigraphy was the first test used to document decreased perfusion and/or decreased parenchymal function [414, 415] (Fig. 72) but is nonspecific for differentiating ATN from acute rejection and cycloporine toxicity, which are less common during the first postoperative week [414–416]. Currently, during the first postoperative week, patients are followed with power Doppler/duplex sonography as the baseline study or for excluding accelerated rejection or surgical complications of urinary obstruction and perirenal collections (most commonly hematoma and urinoma). Some investigators empirically biopsy the renal allograft on the seventh day with sonographic guidance (personal communication, William Amend, University of California, San Francisco). Other investigators biopsy the allografts when resistance indices on duplex sonography remain elevated and accelerated rejection is the presumed diagnosis [398]. Obstruction, detected at sonography, is corrected either by direct surgical intervention or by fluoroscopically or sonographically-guided percutaneous nephrostomy or stents depending on the location of the obstruction.

Complications of Renal Allografts Weeks to Months after Surgery

The symptom complex of rejection (fever, oliguria, local tenderness, and hematuria) is diagnostically nonspecific and may also be seen in acute rejection, urinary tract obstruction or extravasation, primary vascular compromise, and infection. Appropriate imaging studies along with the clinical examination will permit the correct differentiation [398].

Medical Complications of Renal Allografts

Power Doppler/duplex sonography are particularly useful for diagnosing rejection. Measurement of the vascular resistance of the renal vascular bed is the most specific imaging technique for evaluating rejection. Maximum systole and minimum diastolic flow velocities are obtained from interlobar, segmental arteries, and arcuate arterioles [398, 417–420]. With rejection, the

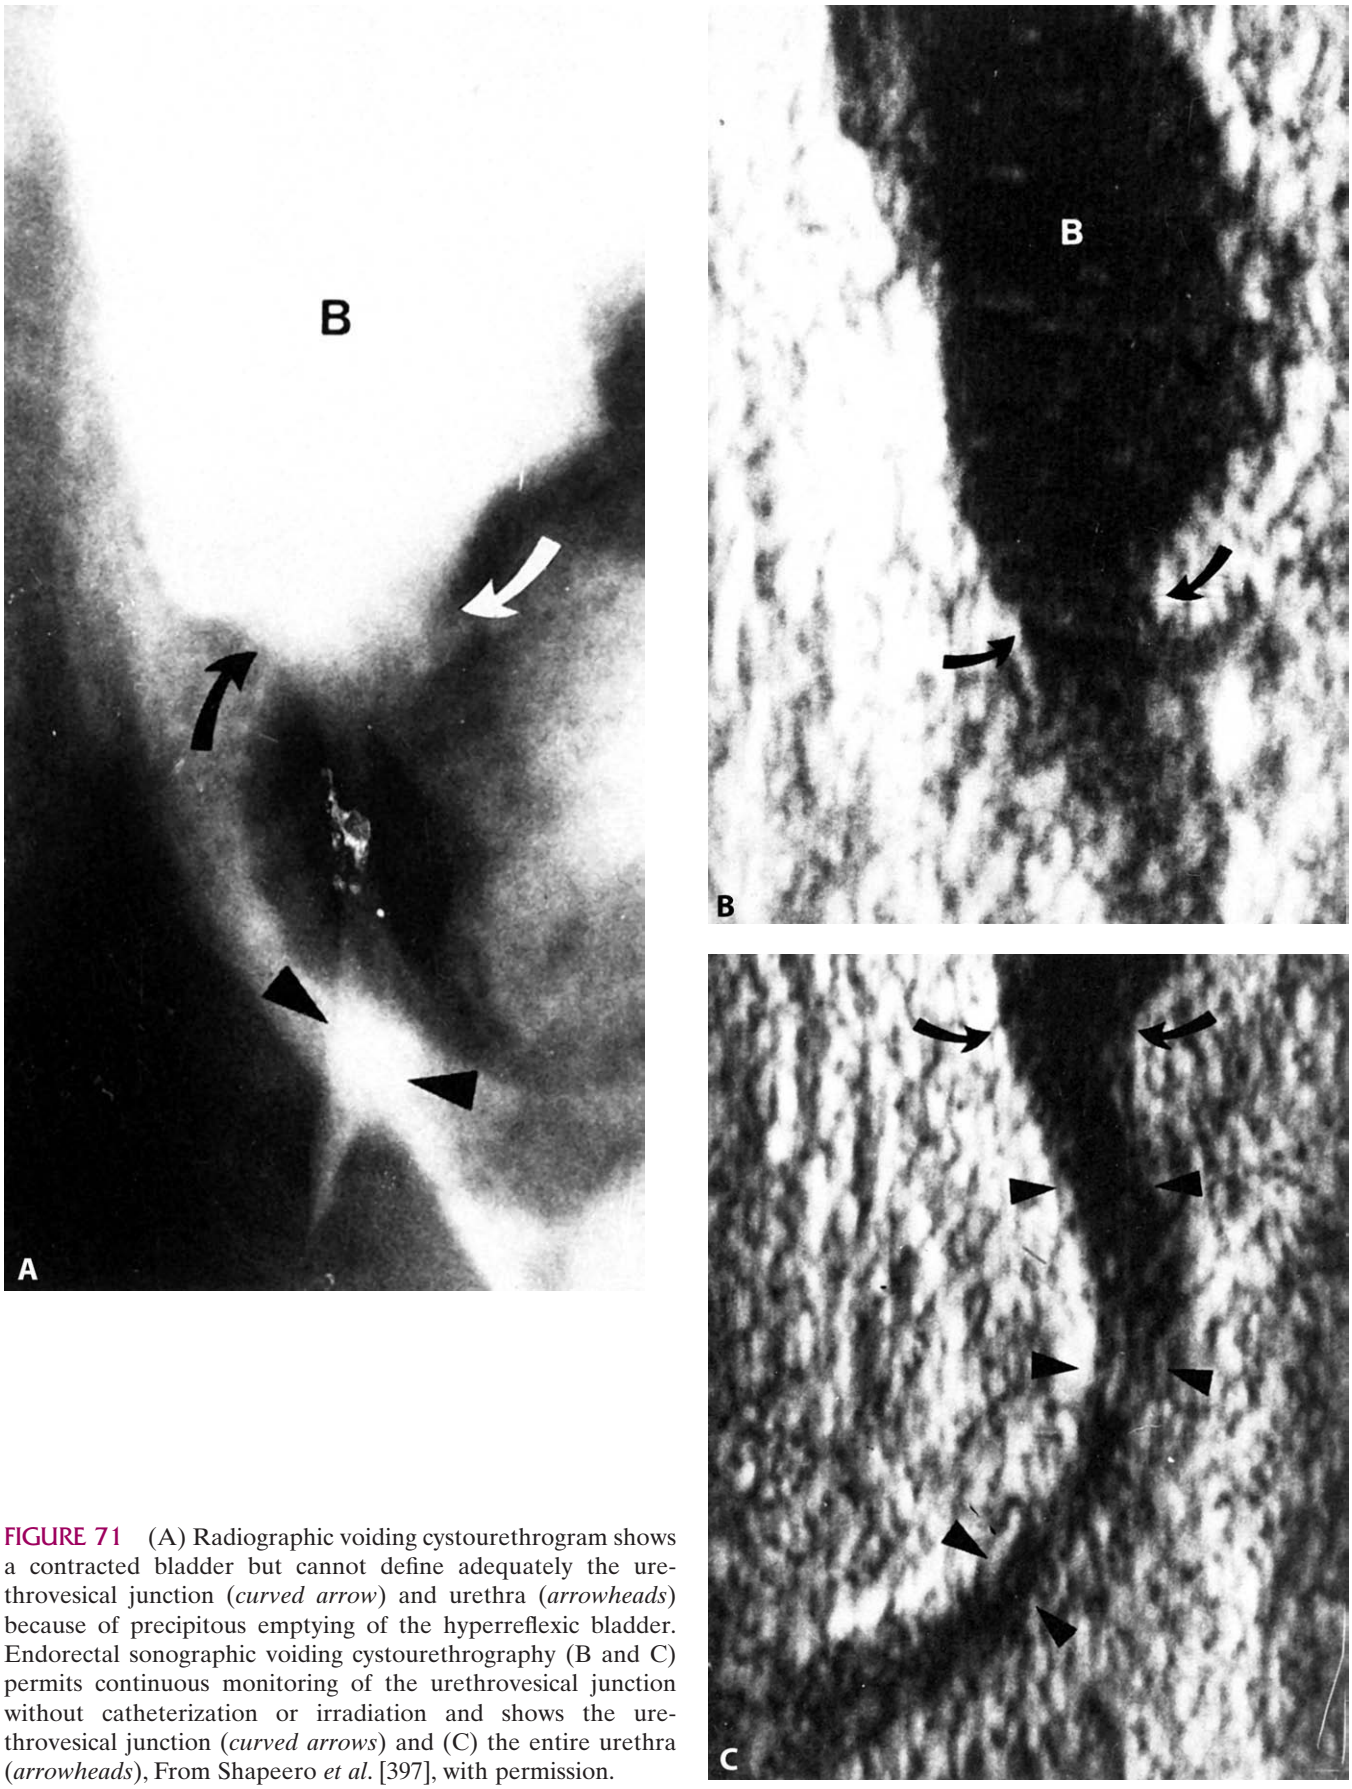

FIGURE 71 (A) Radiographic voiding cystourethrogram shows a contracted bladder but cannot define adequately the urethrovesical junction (*curved arrow*) and urethra (*arrowheads*) because of precipitous emptying of the hyperreflexic bladder. Endorectal sonographic voiding cystourethrography (B and C) permits continuous monitoring of the urethrovesical junction without catheterization or irradiation and shows the urethrovesical junction (*curved arrows*) and (C) the entire urethra (*arrowheads*), From Shapeero *et al*. [397], with permission.

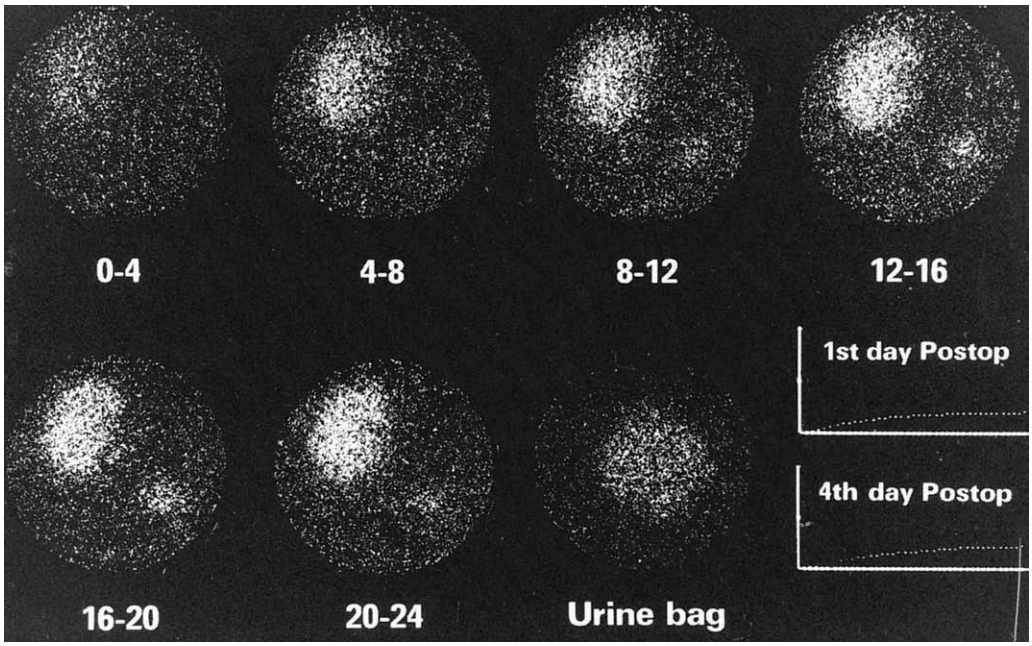

FIGURE 72 ^{131}I scintigraphy and computer-generated renogram (*right*) show delayed perfusion and delayed excretion in a renal allograft from the first to fourth postoperative day suggestive of acute tubular necrosis. From Shapeero [398], with permission.

resistance of the renal vascular bed increases as evidenced by a decrease in, absence of, or even reversal of diastolic flow and is measured by the resistive index (Fig. 73). The sonographic morphologic features of allograft swelling, medullary pyramid enlargement, pelvi-infundibular thickening, increased medullary conspicuity, and diminished renal sinus fat echogenicity are less sensitive than Doppler resistances but may be used in combination with the Doppler spectrum [417, 421–423]. When the clinical and sonographic findings of acute rejection correlate, biopsy is often done for confirmation. Although duplex sonography has a high predictive capability for diagnosing acute rejection, other pathologic processes, such as pyelonephritis, severe ATN, renal vein thrombosis, acute obstruction, and extrarenal compression of the graft secondary to perinephric collections, may occasionally cause elevated vascular resistive indices [419, 424, 425] and should be excluded at sonography [398] and scintigraphy. MRI can be performed when other modalities are equivocal.

Papillary necrosis [426, 427], although uncommon, can develop as early as 2 months after transplantation. Medullary ischemia has been suggested as the final common pathway for this process. Generalized papillary necrosis can result from fulminant acute rejection or may accompany long-term rejection and gradual loss of renal function. It may also be a sequela of acute pyelonephritis, renal vein thrombosis, ATN, or analgesic therapy. IVU is contraindicated in these patients because of deteriorating renal function. Hoffman *et al.* [427] and Shapeero and Vordermark [426] have described the sonographic features of papillary necrosis as multiple round and triangular anechoic spaces and/or echogenic necrosed papillae in the region of the papillae (Fig. 74).

Recurrent lupus nephritis (although relatively rare) [401] or *de novo* lupus nephritis may develop in the allograft and may show the same findings as the native kidney: increased echogenicity at sonography and loss of corticomedullary differentiation at MRI [428–430].

Another complication of renal allografts is segmental infarction. Power flow Doppler/duplex sonography shows decreased perfusion of the infarcted region and a difference in echogenicity between infarcted and normal renal parenchyma. On T2-weighted MR images, the *normal* cortex increases in signal intensity as compared with the cortex on T1-weighted images. However, the infarcted segments of the kidney do not show the signal intensity increase and display loss of corticomedullary differentiation [431].

Because lupus patients with allografts receive immunosuppressive therapy, they are more susceptible to infection. Focal or diffuse pyelonephritis, abscess, and emphysema of the renal allograft show similar sonographic, CT, and MR findings as with the native kidney (see earlier discussion on the native kidney).

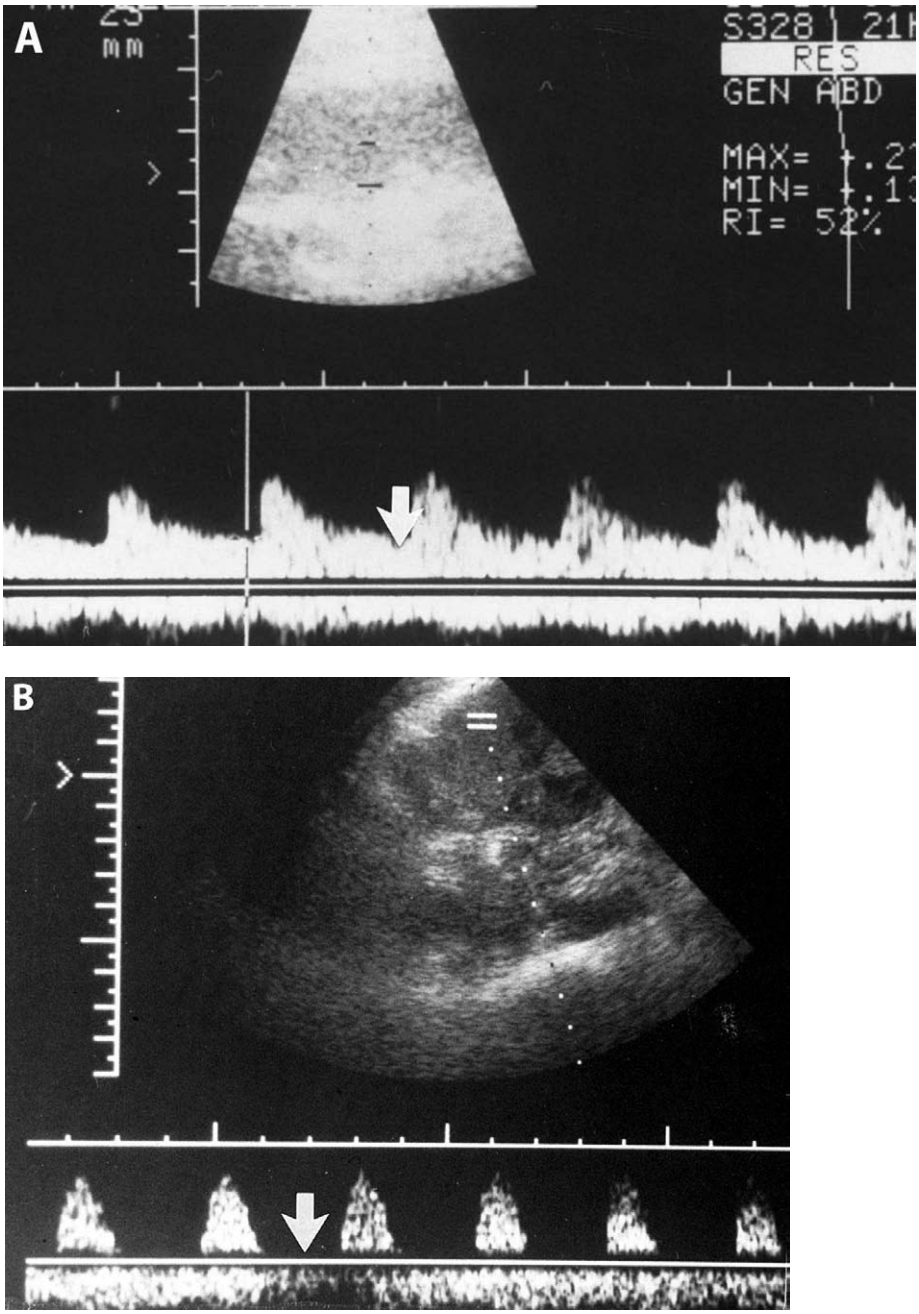

FIGURE 73 (A) Doppler spectrum in a normal renal allograft shows normal diastolic flow (*arrow*). (B) Doppler spectrum in an allograft undergoing rejection shows absent diastolic flow (*arrow*).

Another complication of the renal allograft is the potential development of malignancy. Renal transplant patients, in general, who are on cyclosporine therapy, have 350 times the incidence of lymphoproliferative disorders as the general population [432]. When cyclosporine regimens are compared with those based on azathioprine and cyclophosphamide, lymphomas comprise 20% of neoplasms in the former group and only 11% in the latter group [433]. In the lupus transplant patient, several investigators have found an increased risk of various cancers (Hodgkin's lymphoma, non-Hodgkin's lymphoma, cervical and prostate cancer) [433a, 433b, 433], although the overall risk for malignancy does not appear to be increased [433b, 433c]. Thus, patients with SLE should have careful long-term follow-up with MRI and CT studies when needed.

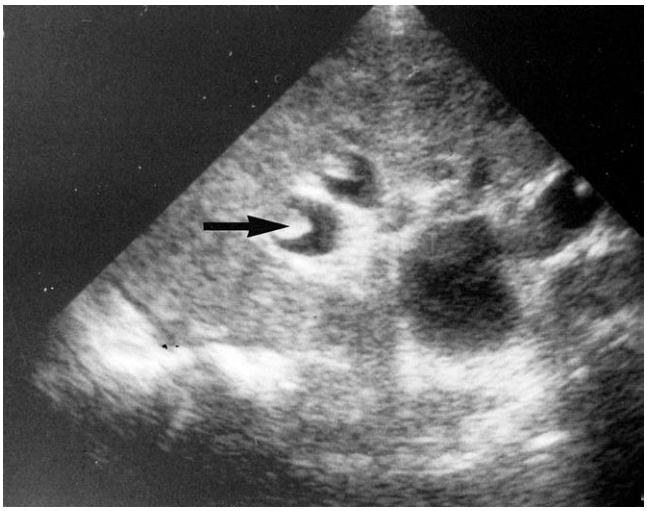

FIGURE 74 Longitudinal sonogram of renal allograft demonstrates necrotic papillae (*arrows*) in papillary necrosis.

Surgical Complications of Renal Allografts

Urinary obstruction is the most common surgical complication of allografts (Fig. 75) and can be divided into three types: (1) intraluminal obstruction from calculus, blood clot, fungus ball, or necrotic papillae; (2) intrinsic ureteral obstruction due to edema, necrosis, stricture secondary to ischemia or kinking; and (3) extrinsic ureteral compression from perinephric collections, retroperitoneal fibrosis, and arterial anastomoses [398–400, 434–439]. Sonography demonstrates hydronephrosis [398] and some of the causes of obstruction: echogenic calculus, fungus ball, blood clot or necrotic papilla, and the perinephric collection. Separation of the pelvocalyceal echoes on sonography, however, does not always signify a urologic complication and can be seen in allograft rejection. When the bladder is overdistended or atonic (the neurogenic bladder in the lupus patient), hydronephrosis can be functional. When sonography demonstrates obstruction and renal function is deteriorating, antegrade pyelography can be performed with Whitaker flow measurements, as needed [400]. Interventional radiographic techniques not only identify the location and type of obstruction but also provide the definitive therapy such as stone or papilla extraction and balloon dilatation and stenting of ureteral strictures by antegrade and retrograde techniques [439, 440].

Extravasation occurs in 1–2% of allografts [436, 440]. Although scintigraphy may suggest extravasation, sonography, CT, and MRI confirm the location of the perirenal collection [398, 411, 440–443], and antegrade or retrograde pyelography and the voiding cystourethrogram show the exact point of leak [443]. The most common locations are the ureteroneocystotomy site or the cystotomy through which the ureterocystotomy was created.

Perinephric collections have been reported in up to 51% of allografts [399, 400, 440–444]. The majority of urinomas and hematomas develop in the first postoperative week, whereas most lymphoceles and abscesses occur after the first week [436]. Both urinomas and lymphoceles conform to the anatomic spaces, whereas abscesses and hematomas may not [399]. Sonography, CT, and MRI can define the extent of the perirenal collections as with the native kidney. Sonography and CT are not specific for characterizing the type of collection. Urinomas and lymphoceles are often cystic masses with or without septations. Hematomas show variable echogenicity depending on their age, changing from echogenic in the acute stage to hypoechoic in the chronic stage. Abscesses may be anechoic or echogenic and show through transmission. As with the native kidney, MRI can help differentiate the lymphocele or urinoma (hypointense on T1-weighted MR images and hyperintense on T2-weighted MR images) from the subacute hematoma or proteinaceous abscess (hyperintense on both T1- and T2-weighted MR images) (Fig. 76). When patients are afebrile and have normal renal function, small collections are usually followed sonographically. When patients are symptomatic (febrile, edematous, or tender over the allograft) or when they have increasing creatinine, fine-needle aspiration should

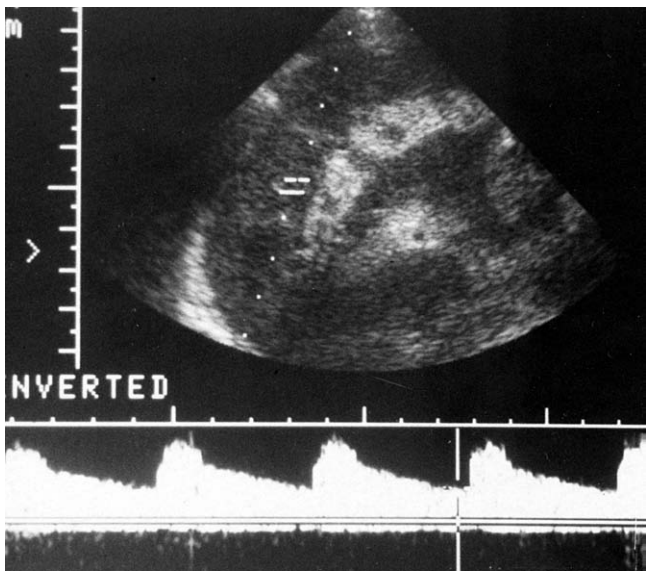

FIGURE 75 Longitudinal sonogram of renal allograft shows separation of the pelvocalyceal echoes and hydroureter consistent with hydronephrosis. The Doppler spectrum demonstrates normal diastolic flow. This 33-year-old lupus patient had decreasing renal function.

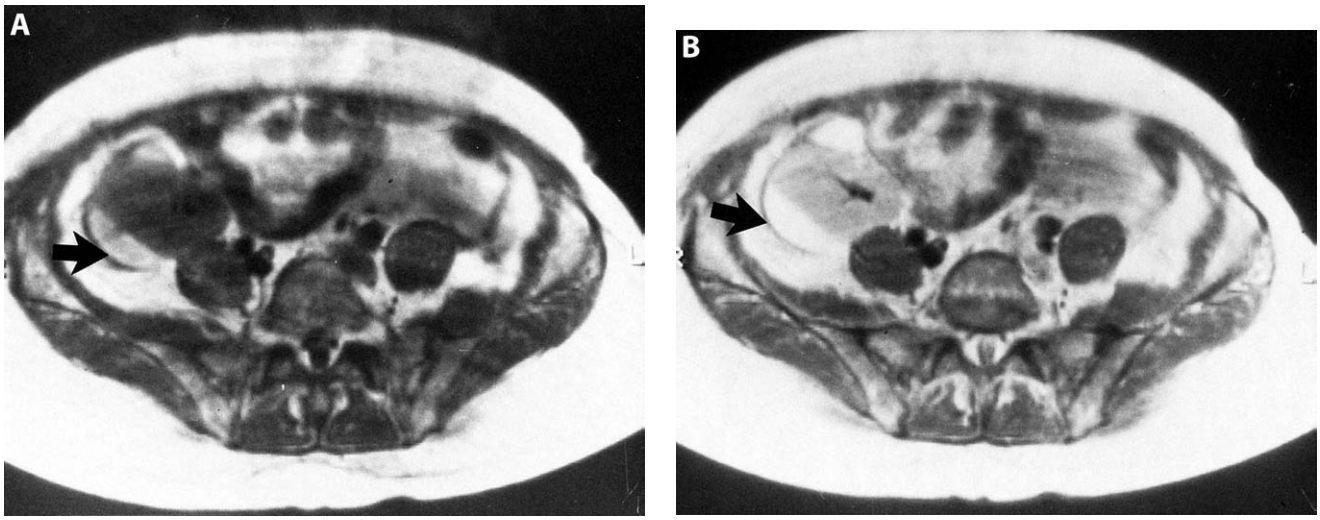

FIGURE 76 (A) Axial T1-weighted MR image (500/30) and (B) T2-weighted MR image (2000/60) show a high-signal-intensity, subacute perirenal hematoma surrounding a renal allograft after biopsy.

be performed with CT or sonographic guidance to determine the etiology. Urinomas and hematomas will require immediate surgical intervention and evacuation. Lymphoceles can be marsupialized internally via a peritoneal window, and abscesses are drained surgically or percutaneously under sonographic or CT guidance.

Vascular Complications of Renal Allografts

Renal artery stenosis is the most frequent surgical vascular complication in renal allografts and occurs in 7–23% of patients [413, 445, 446]. It may be caused by intimal hyperplasia at the anastomotic site, intraoperative trauma to the allograft artery, or arteriosclerosis of the donor vessel. Rarely vascular occlusion can result from torsion of the renal allograft in the intraperitoneal renal allograft [445]. Arterial stenosis should be suspected when patients present with severe and refractory hypertension and/or deterioration of renal function. Previously, conventional angiography or digital subtraction angiography [445a–448] was performed to show the stenotic area. Currently, three-dimensional MRA provides vascular information without ionizing radiation, iodinated contrast medium, or arterial catheterization. MRA improves the accuracy and sensitivity for detecting and grading the severity of the stenosis and provides flow measurements [445]. Eight-one percent of stenoses in renal transplant patients are treated successfully with percutaneous transluminal angioplasty [448]. Other vascular complications identified at angiography, particularly MRA, are intimal dissections, pseudoaneurysms, complete occlusion of the renal artery, renal vein thrombosis, and arteriovenous fistulae resulting from biopsy [398, 399, 445]. Power Doppler/duplex sonography can identify the A-V fistula and renal vein thrombosis [449–453]. MRA can produce excellent images of fistulae and thromboses but, because of expense, may be reserved for equivocal sonographic studies. Interventional radiologic techniques are used for the treatment of fistulae and vascular occlusions. A-V fistulae are occluded with coil placement, and acute vascular thrombi can be dissolved with the infusion of fibrinolytic drugs [454].

IMAGING OF OBSTETRIC SLE

Echocardiography, color flow Doppler, and duplex sonography identify the important fetal and placental abnormalities associated with lupus pregnancies: cardiac-related abnormalities (congenital heart block and other arrhythmias, cardiac dysfunction secondary to myocarditis and rarely pancarditis), intrauterine growth retardation, and placental abnormalities.

Intrauterine Cardiac Abnormalities of Neonatal Lupus

Isolated A-V block occurs in 1 in 20,000 births [455, 456]. Several clinical studies have reported that an isolated congenital A-V heart block develops more frequently in children of mothers with SLE or other connective tissue disease [455–461]. A multicenter evaluation [455] of 7200 pregnant women found that 19 of 55 fetuses with complete AV block had no associated complex cardiac structural defects and were born to mothers who had connective tissue disease or who had tested positive for ANAs, most frequently SS-A/Ro. Autoantibodies, particularly to the SS-A/Ro or SS-B/La

antigens, have been found not only in the serum of mothers, but also in the serum and fetal cardiac tissue of their affected newborns [462–473], suggesting a causal relationship. Although the risk of a patient with SLE having a complete A-V block appears to be low, the risk increases considerably when anti-SS-A antibodies are present [462].

Echocardiography of the fetal heart [455, 460, 471] can depict the anatomic and functional dynamics of the fetal heart: congenital heart block (Fig. 77), other arrhythmias, systolic ejection fractions, chamber enlargement, patent ductus arteriosus, and atrial septal defect. Also, duplex sonography can show associated extracardiac abnormalities associated with cardiovascular disease (hydrops fetalis and effusions).

Investigators comment that mothers with risk factors for neonatal lupus could be prospectively monitored with serial fetal echocardiograms beginning at 16–18 weeks of pregnancy, which is the earliest time for adequate visualization of the fetal heart and fetal bradyarrhythmias [460, 460a]. It was suggested that treatment with dexamethasone might benefit fetuses with incomplete or unstable block or myocarditis by helping prevent permanent fibrosis [460a].

Placental Abnormalities and Intrauterine Growth Retardation in SLE

In SLE, fetal death results from spontaneous abortion, intrauterine prematurity, and intrauterine death [472]. These complications of pregnancy are associated with circulating lupus anticoagulants, thrombocytopenia, and antiphospholipid antibodies and placental abnormalities in the lupus patient [472–475]. Histologic examination

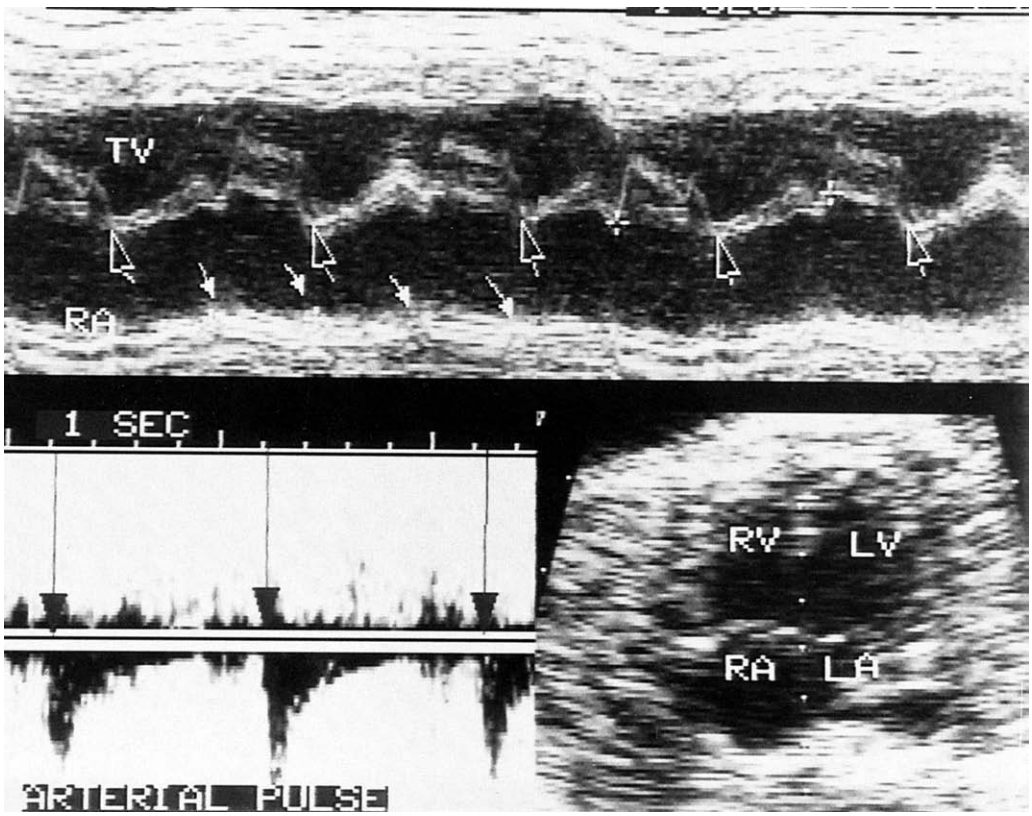

FIGURE 77 M-mode and two-dimensional echocardiography of a 30-week-old fetus of a mother with SLE show complete heart block. The top frame shows the tricuspid valve (TV) moving between the ventricle above and the atrium behind. The point of tricuspid closure is indicated by open arrows and indicates the point of the onset of systole. The ventricular rate is 120 beats/min. Posteriorly, the right atrial wall (RA) is displayed; the onset of contraction is indicated by small arrows; the atrial rate is 60 beats/min. Thus the atrial rate is approximately twice the ventricular rate consistent with a complete heart block. The lower left-hand frame shows a Doppler signal taken from the aortic root at a rate of 60 beats/min that correlates with the echocardiographic findings of a complete heart block. The lower right-hand image shows a normal four-chamber echocardiographic image, suggesting no structural cardiac disease. Courtesy of Dr. N.A. Silverman, University of California, San Francisco.

of the placenta in patients with SLE show extensive changes, including placental infarction, intraplacental hematoma, deposition of immunoglobulin and complement, decreased placental size, thickening of trophoblastic basement membrane, and decidual vasculopathy [467, 468, 472, 476, 478]. Color flow Doppler/duplex sonography also defines placental abnormalities, such as abruptio placenta and placental insufficiency. The sonographic findings of retroplacental hemorrhage, a rounded, thickened placenta, and echogenic blood in the amniotic cavity all suggest the diagnosis of abruptio placenta. At duplex sonography, placental insufficiency is manifested as increased vascular resistance in the fetal umbilical and sometimes uterine arteries [479–482]. When the resistance of these vessels increases, the diastolic flow decreases and the ratio of systolic/diastolic flows increases (Fig. 78A), similar to the increased vascular resistance in the rejecting renal allograft [479–482]. Furthermore, when mothers, particularly those with lupus anticoagulant syndrome, are treated successfully with corticosteroids and aspirin in infant doses, duplex sonography can detect the improvement in vascular resistance, i.e., increased diastolic flow and decreased systolic/diastolic ratio (Fig. 78B) [479]. Placental insufficiency and increased vascular resistance are also associated with intrauterine growth retardation. Duplex sonography provides sequential documentation of the fetal growth and helps determine the need for early delivery [479–482].

IMAGING OF NERVOUS SYSTEM SLE

Nervous system involvement in SLE is both central and peripheral, transient and permanent, and occurs in 30–75% of patients with SLE. It is a major contribu-

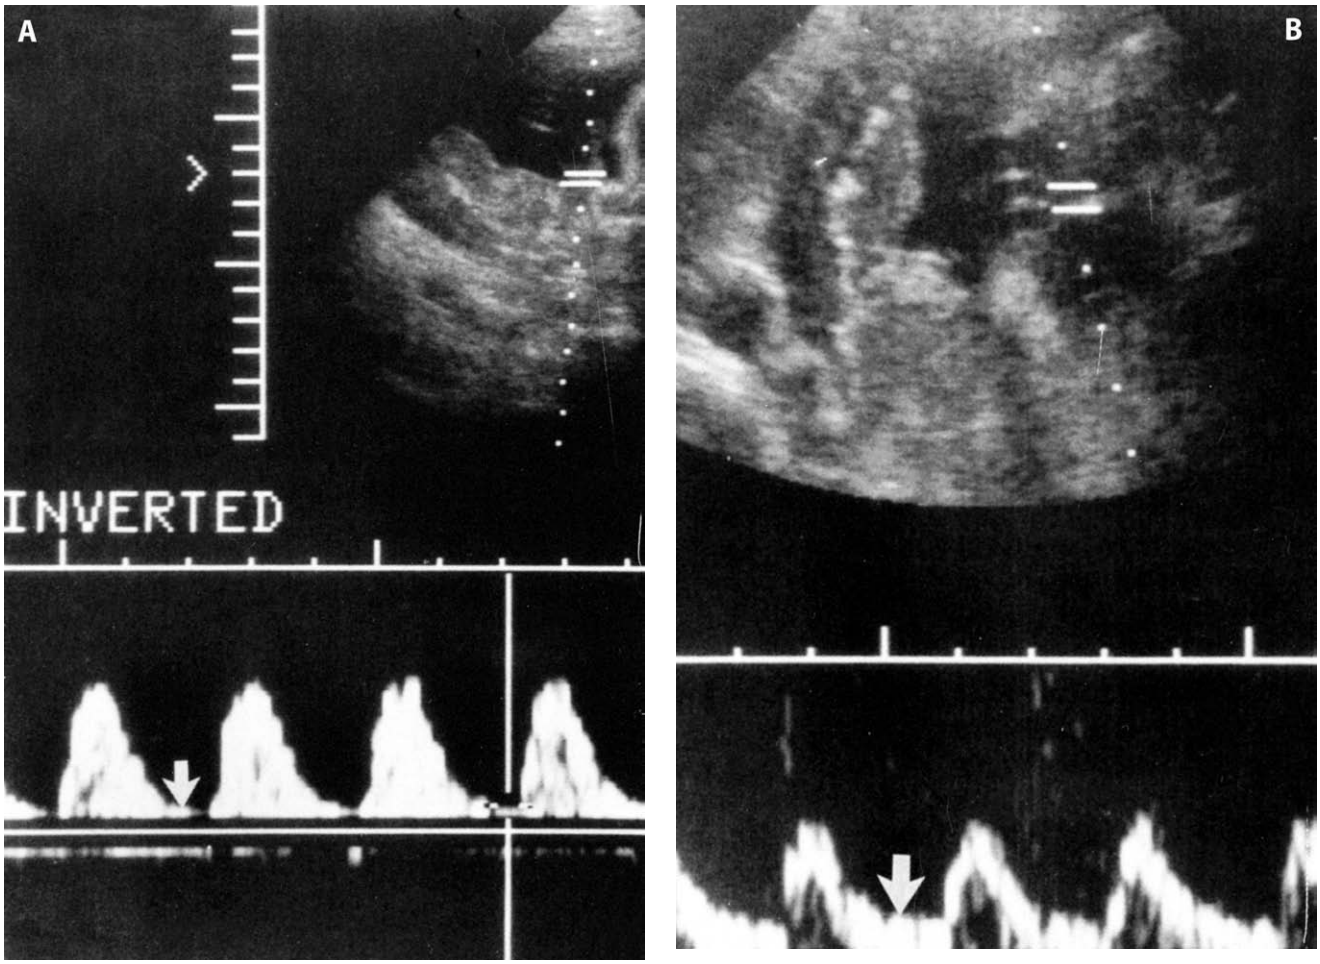

FIGURE 78 (A) Doppler spectrum of a patient with lupus anticoagulant syndrome at 33 weeks gestation demonstrates a markedly decreased end diastolic flow (*arrow*). (B) Twenty-four hours after the initial treatment with high-dose aspirin for infants, the end diastolic flow has improved (*arrow*). From Carroll, [479], with permission.

tor to morbidity and mortality in lupus [483–488]. Nervous system SLE results from a combination of factors related to the autoimmune response: vasculopathy, *in situ* vascular thrombosis, thromboembolism, antiphospholipid antibodies, lupus anticoagulant, circulating inflammatory factors, and antineuronal antibodies [484–501]. In SLE, neurologic impairment may also be associated with uremia, hypertension, infection, and corticosteroid and immunosuppressive therapy.

Central Nervous System Lupus

Cerebral imaging of the lupus patient has changed dramatically since the mid-1990s. MRI, SPECT, and FDG-PET have replaced conventional brain scintigraphy and CT as the primary imaging modalities for evaluating cerebral involvement in SLE [488, 500–512]. MRI, with its contrast resolution, defines focal morphologic lesions and anatomy [500, 502–506], and SPECT provides important information about cerebral blood flow [507–513]. PET [508, 514–524] shows regional blood flow and metabolism. Another diagnostic tool for brain metabolism, MRS, also enhances our understanding of cerebral neuropsychiatric SLE (NPSLE), particularly of inaccessible, deep structures and subclinical disease. MRS quantitates cerebral metabolites and defines brain energetics (ATP, ADP, phosphocreatine). Conventional scintigraphy, the first imaging technique used for lupus encephalopathy, is now considered to be an insensitive test that lacks specificity [483, 529–531]. Prior to the development of MRI, PET, and SPECT, CT was the principal imaging modality for evaluating cerebral lupus [532–539] and is still used for the acutely ill, unstable patient [483] because of its speed and ability to recognize acute hemorrhage (whether intracerebral, subarachnoid, subdural, and epidural hematomas) [483, 540–545], large infarcts and areas of edema [537, 547–549], ventricular dilatation [483, 550], and infectious complications of therapy such as abscesses [483, 551], meningitis [552–556], or mycotic aneurysms [557].

Cerebral and Subdural Hemorrhage in SLE

At CT, acute hemorrhage displays high attenuation because proteinaceous blood highly attenuates the X-ray beam as it passes through the involved region. With age, the protein denatures, and the attenuation characteristics of a clot resemble those of normal brain and may even decrease in attenuation similar to the water attenuation of brain edema [541, 560] (Fig. 79A). As described with other organ systems (see cardiovascular and genitourinary section), MRI is more specific than CT for detecting subacute hemorrhage because subacute clots are high-signal intensity on both T1- and T2-weighted MR images (Figs 79B and 79C).

Cerebral Atrophy in SLE

The most frequent cerebral CT finding [532, 560–562], perisutural atrophy, with or without ventricular dilatation, may be present in 50% of lupus patients [542] and rarely develops rapidly [539]. McCune *et al.* [563] and Sibbitt *et al.* [500] found that MRI, like CT, showed that mild cerebral atrophy occurred frequently in SLE. Atrophy tends to be superficial rather than deep, and ventricular enlargement was uncommon.

There are conflicting opinions as to whether cerebral atrophy is secondary to corticosteroid therapy or to primary lupus cerebritis. Carette *et al.* [535] found no correlation between the presence of cerebral atrophy on CT and lupus cerebritis and suggested that the degree of atrophy was related to the patients' sensitivity to corticosteroid therapy. However, Ostrov *et al.* [564] reported that 10 of 14 patients with primary lupus cerebritis had moderate cerebral atrophy, 4 had minimal atrophy, and none was normal; of 18 lupus patients on corticosteroids who did not have clinical cerebritis, none had moderate atrophy, 6 showed mild atrophy, and 12 had normal scans. In addition, Miguel *et al.* [561] also found that atrophy was related neither to neuropsychiatric manifestations nor to corticosteroid use and suggested that widened sulci could result from subclinical SLE activity. Using MRI computer-generated quantification procedure, Koroza *et al*. [504] found increased mean ventricle-to-brain ratios (VBR) and increased number of hyperintense white matter lesions in 35% of lupus patients who had no history of central nervous system disease. However, no correlation was found between the VBR, total number of hyperintense lesions and cognitive scores. The investigators suggested that MRI is not likely to contribute clinically pertinent information in the evaluation of lupus patients who have cognitive dysfunction but no other overt manifestations of CNS-SLE.

The newest technique for elucidating cerebral metabolism, MRS, combined with MRI, has helped expand our understanding of cerebral atrophy [565]. Using the neuronal marker *N*-acetylaspartic acid (NAA), Sibbitt and associates [546] measured the ratio of NAA-to creatine (C)/phosphocreatine(PC) ratio in 10 lupus patients with cerebral atrophy and 10 lupus patients with no significant atrophy. The NAA-C/PC ratio was decreased with patients with significant atrophy as compared to lupus patients with normal brain volumes. The authors [565] suggested that cerebral atrophy in SLE is caused by neuronal and axonal dropout or damage as manifested by a relative decrease in NAA [565]. Chinn and co-

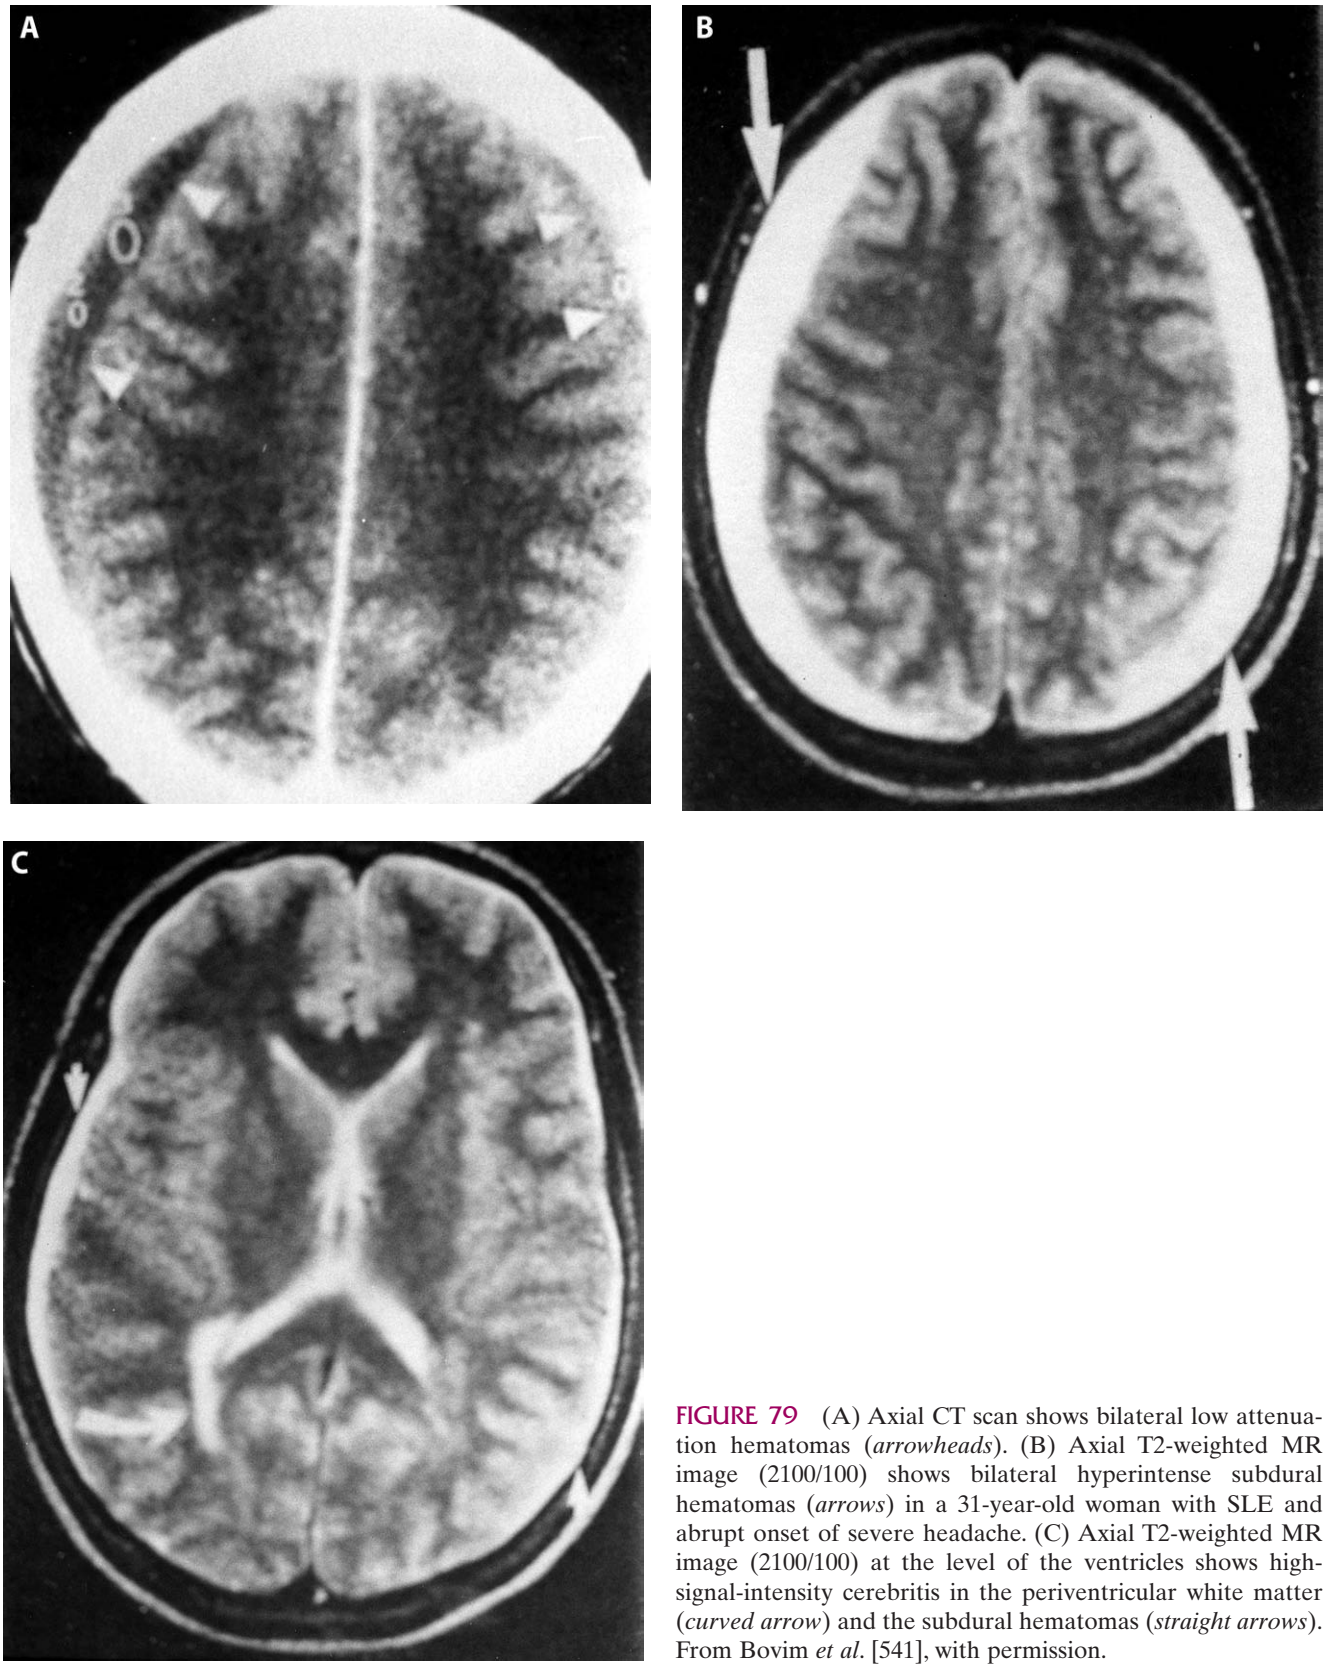

FIGURE 79 (A) Axial CT scan shows bilateral low attenuation hematomas (*arrowheads*). (B) Axial T2-weighted MR image (2100/100) shows bilateral hyperintense subdural hematomas (*arrows*) in a 31-year-old woman with SLE and abrupt onset of severe headache. (C) Axial T2-weighted MR image (2100/100) at the level of the ventricles shows high-signal-intensity cerebritis in the periventricular white matter (*curved arrow*) and the subdural hematomas (*straight arrows*). From Bovim *et al*. [541], with permission.

investigators [566] also found a relative reduction in *N*-acetyl-containing compounds, particularly *N*-acetylaspartate and to a lesser extent *N*-acetyl aspartyl glutamate in lupus patients with cerebral atrophy and showed that the presence of atrophy was not related to current or prior corticosteroid therapy.

Cerebral Calcifications in SLE

CT shows the periventricular, basal ganglia, and cerebellar calcifications in SLE that develop in 1–30% of lupus patients with major or minor neuropsychiatric symptoms (Fig. 80) [561, 567–572]. On a series of 27 patients, one group of researchers showed no correlation between the presence or extent of calcification and age of the patients or duration or type of neurologic presentation. Other investigators found calcifications more frequently in patients with major psychiatric manifestations [561].

Lupus Cerebritis

Compared with contrast-enhanced CT, MRI better defines the presence, number, location, extent, and clarity of noncalcified lesions in lupus cerebritis [483, 500, 573–581] because of its multiplanar imaging and excellent soft tissue contrast (Fig. 81). Unlike CT, MRI does not produce bone-hardening artifacts that obscure parenchymal detail, particularly in the posterior fossa (cerebellum and brainstem) (Fig. 82) [483, 500, 573]. Cerebral lesions in SLE are best detected on T2-weighted MR images as either reversible focal areas of high-signal intensity (ischemia or edema) or fixed areas of high-signal intensity (infarct or residual injury) in white or gray matter or both [483, 500] (Figs 83 and 84). Labile lesions may be superimposed on fixed lesions [499]. Abnormalities that are isolated to gray or white matter are usually not visible on CT [483]. After the acute neurologic event, it is important to obtain an MRI promptly because labile lesions can disappear rapidly with or without corticosteroid therapy. In SLE patients at risk for neuropsychiatric diseases, it can be useful to obtain a baseline MRI to distinguish the chronic lesion from a subsequent acute insult [500].

On MRI studies, quantitative measurement of the T2 of lupus lesions may help distinguish among the different types of cerebral lupus [582]. Tissues that are edematous or infarcted will demonstrate longer T2 (i.e., they appear hyperintense on T2-weighted images). Sibbitt *et al.* [582] found that T2 values were increased in all types of cerebral lesions in SLE and even in normal-appearing brain in patients with SLE as compared with the brains of nonlupus controls. Their SLE patients were subdivided into five subgroups: (1) quiescent minor neuropsychiatric (NP) SLE (such as previous headache, minor cognitive dysfunction), (2) quiescent major (such as previous seizure, coma, psychosis), (3) NPSLE headache without significant focal neurologic finding or major cognitive dysfunction, (4) diffuse NPSLE with acute diffuse neurologic findings and major cognitive deficits (seizures, psychosis, coma), and (5) NPSLE stroke with focal neurologic deficit and positive anticardiolipin antibodies. The increased T2 of gray matter in lupus patients could be mainly attributed to a large increase in T2 of the subgroup of patients who had diffuse NPSLE. These patients showed either a multifocal pattern of T2 increase localized to a few brain segments or a generalized accentuation of T2 affecting cortical segments. The mean age of these patients with diffuse NPSLE was younger than that of other lupus patients. In contrast, the increase in T2 of the white matter was mainly associated with lupus patients with headache, stroke, or prior major NPSLE and not with diffuse findings or quiescent minor NPSLE. Furthermore, T2 values for infarcts were greater than T2 for reversible lesions, which, in turn, were greater than T2 for small nonreversible lesions. It was concluded, therefore, that T2 of reversible and nonreversible focal lesions and infarcts differed significantly, implying that the microenvironments of these lesions differed. The reversible lesions should represent focal edema resulting from the vasculopathy, whereas the focal nonreversible lesions would signify small infarctions with secondary gliosis [582]. Thus, T2 measurements of lupus lesions may be useful in identifying subtle changes that are not evident on conventional MRI.

It was reported that MRI detected abnormalities in 38 of 100 lupus patients with neurologically asymptomatic [503]. SPECT was done on 23 of these patients with positive MRIs and showed areas of hypoperfusion in 14. In addition, the SLE activity index was significantly greater in patients with brain lesions that in those without. This is a preliminary result and further longitudinal prospective studies of asymptomatic lupus patients with cerebral lesions are needed.

In addition to standard T1- and T2-weighted and contrast-enhanced MRI, various investigators have studied magnetization transfer MRI for evaluating neuropsychiatric NPSLE. The contrast created by this technique is different from T1- and T2-weighted MR imaging because of the dipole–dipole interaction between the protons of water and large macromolecules. This transfer of energy from macromolecules to water results in the magnetization transfer effect, i.e., water appears as low-signal intensity. Those tissues that have increased water content will display low-signal intensity on magnetization transfer images. Two studies [505, 506] have

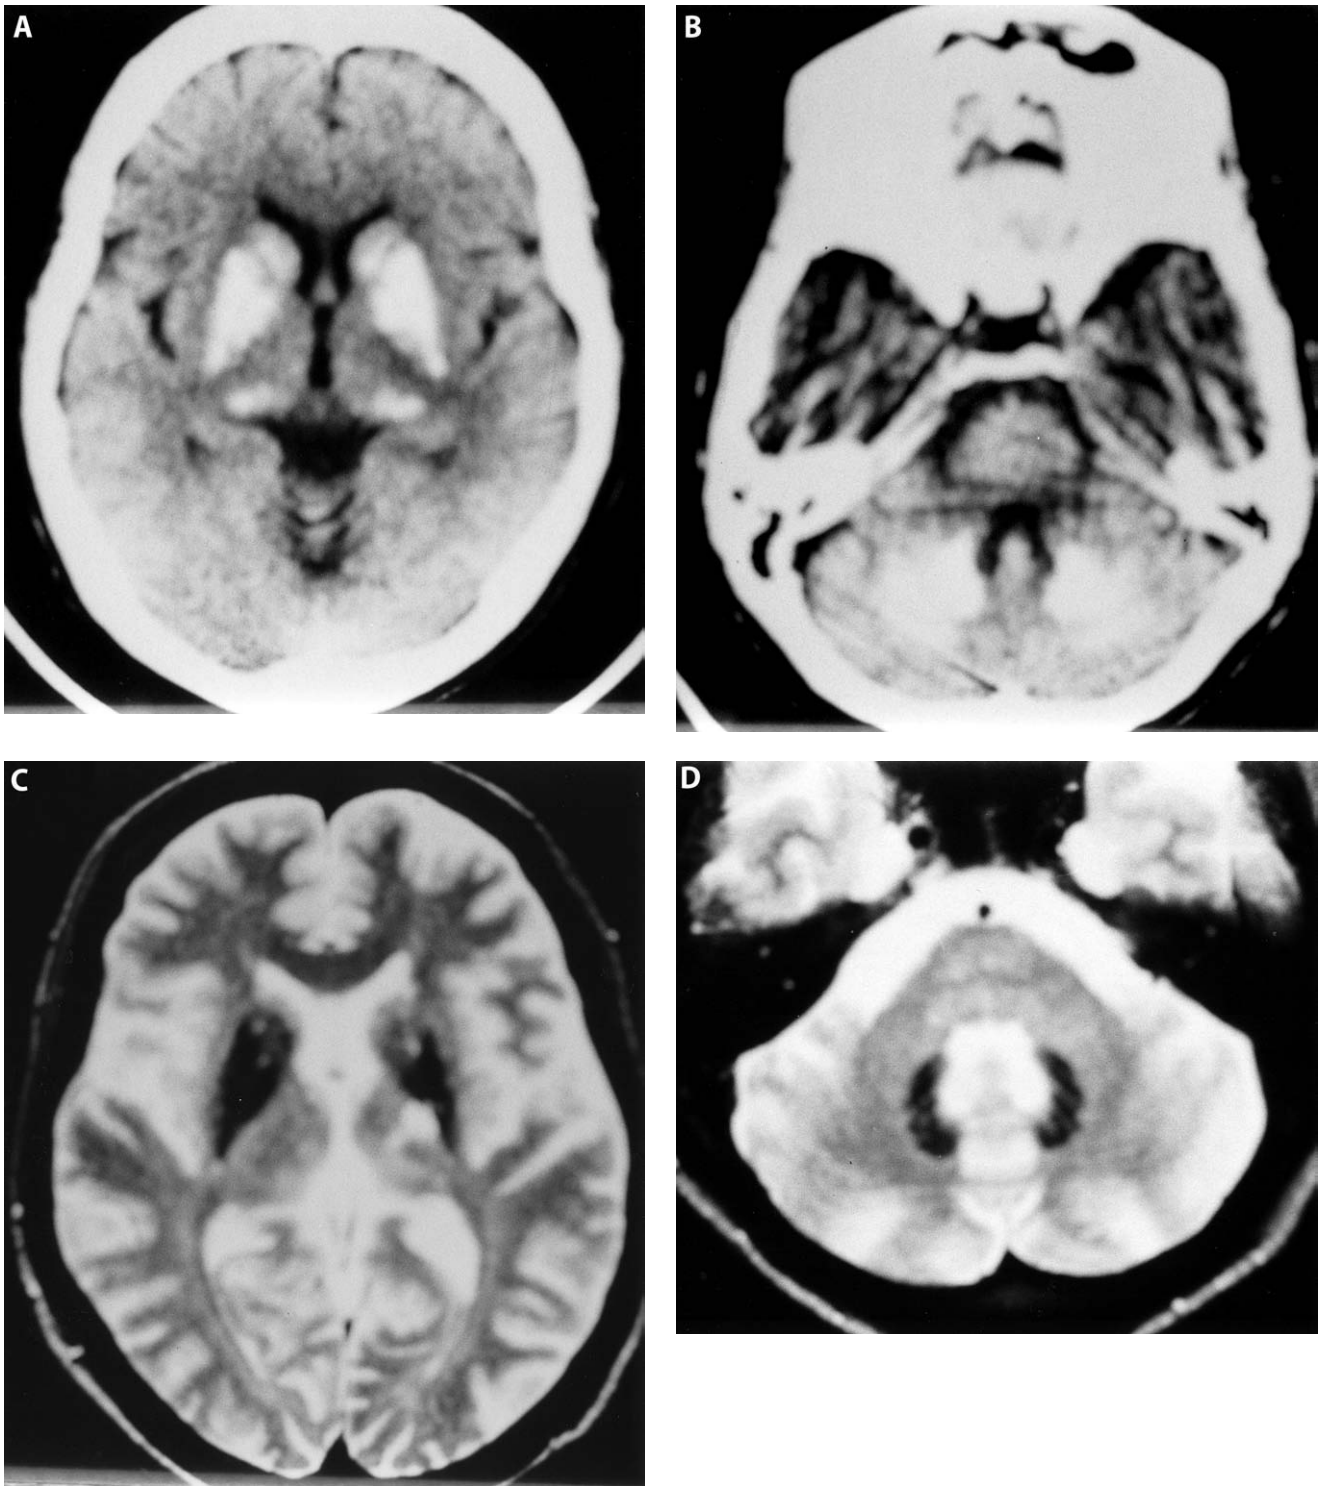

FIGURE 80 (A and B) Axial CT scans of 32-year-old woman with SLE and right hemiparesis and dysarthria show bilateral calcifications in the lentiform nuclei, caudate nuclei, thalamus, dentate nuclei, and the white matter of the cerebellar hemispheres. (C and D) Axial T2-weighted MR scans 19 months later show abnormal low-signal-intensity areas in the basal ganglia and cerebellum in the region of the calcifications. From Yamamoto *et al*. [570], with permission.

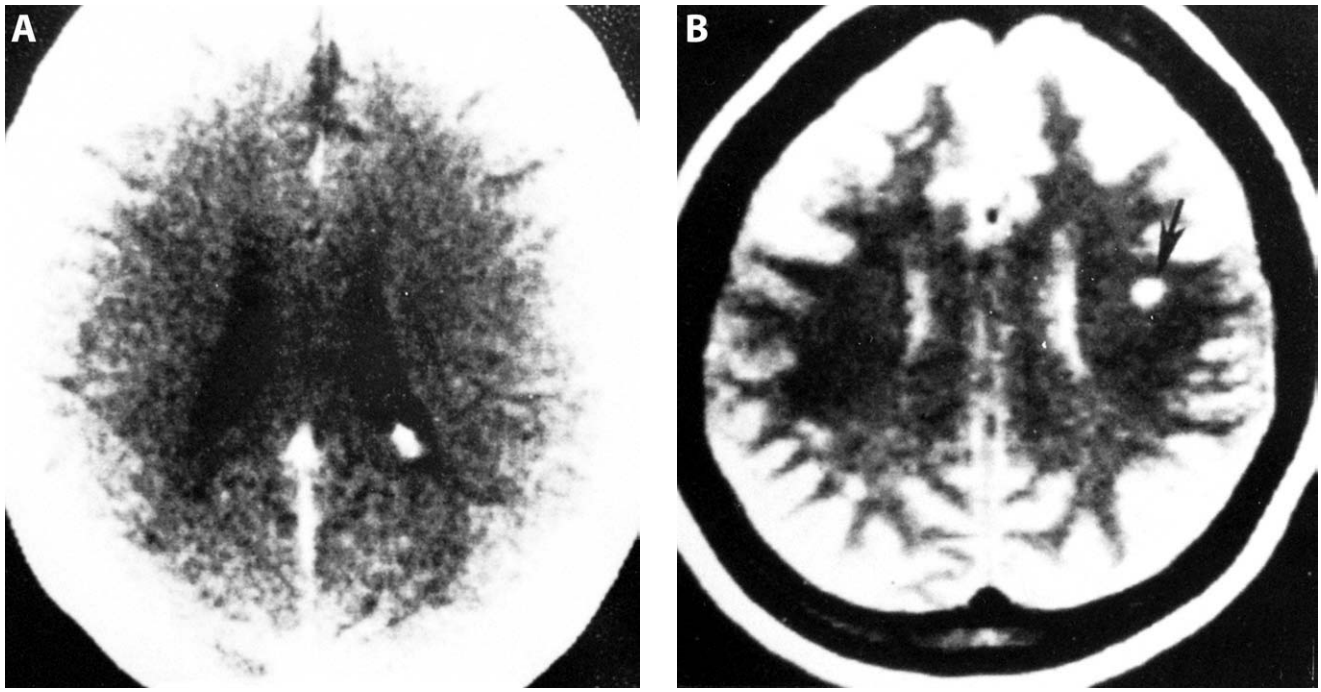

FIGURE 81 (A) Axial contrast-enhanced CT of patient with SLE shows no abnormality. (B) Axial T2-weighted MR image (TR/TE 2000/56) shows a focal area of high signal intensity in the left frontoparietal white matter (*arrow*) in a patient with lupus cerebritis. From Aisen *et al*. [573], with permission.

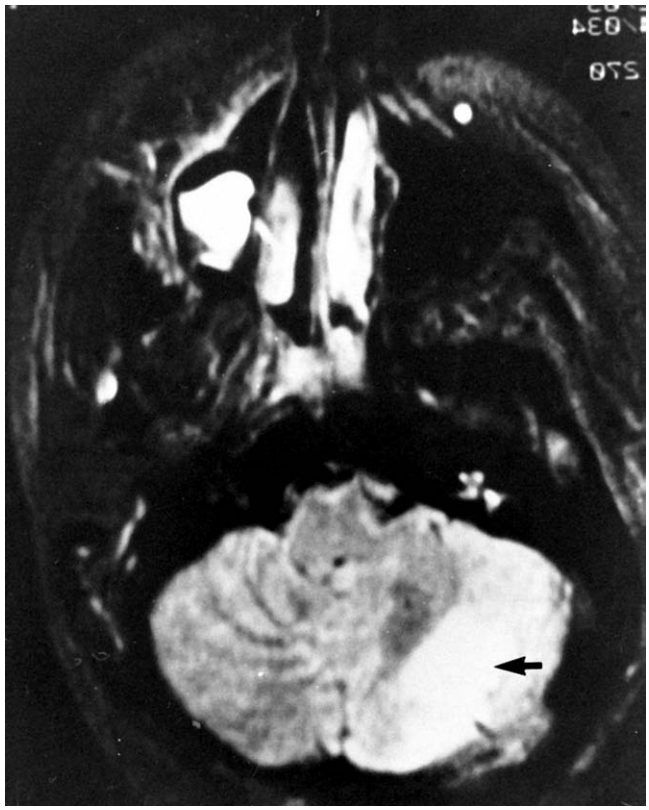

FIGURE 82 Axial proton-density MR image (2000/20) shows a large high-signal-intensity lesion in the cerebellum representing focal edema or ischemia in the cerebellum, but not infarction because it resolved after 8 days of corticosteroid therapy. CT usually misses this type of posterior fossa lesion. From Sibbitt *et al*. [500], with permission.

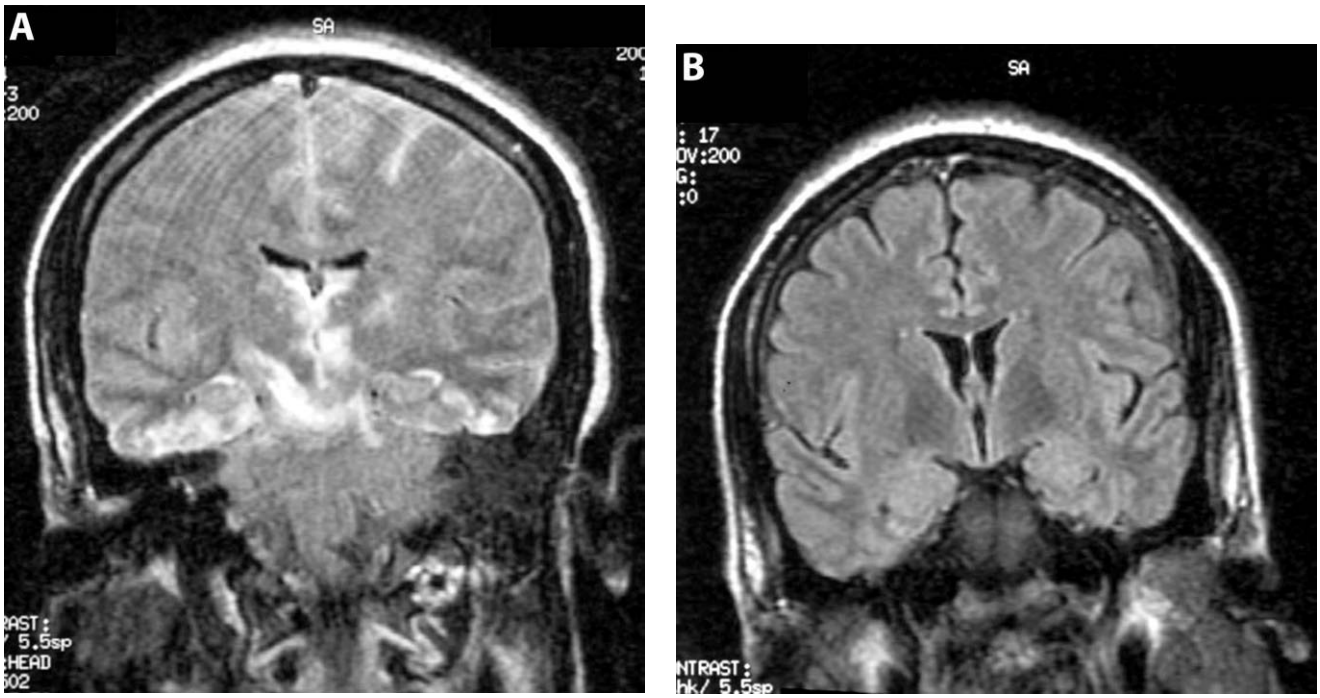

FIGURE 83 Sequential MR images of a 31-year-old woman with acute lupus cerebritis and seizures. (A) Coronal fluid attenuation inversion recovery (FLAIR) MR image (9502/147) shows areas of high signal intensity in the right temporal lobe, basal ganglia, and thalami. (B) After 10 days of corticosteroid therapy, coronal FLAIR MR image (9502/147) shows marked improvement.

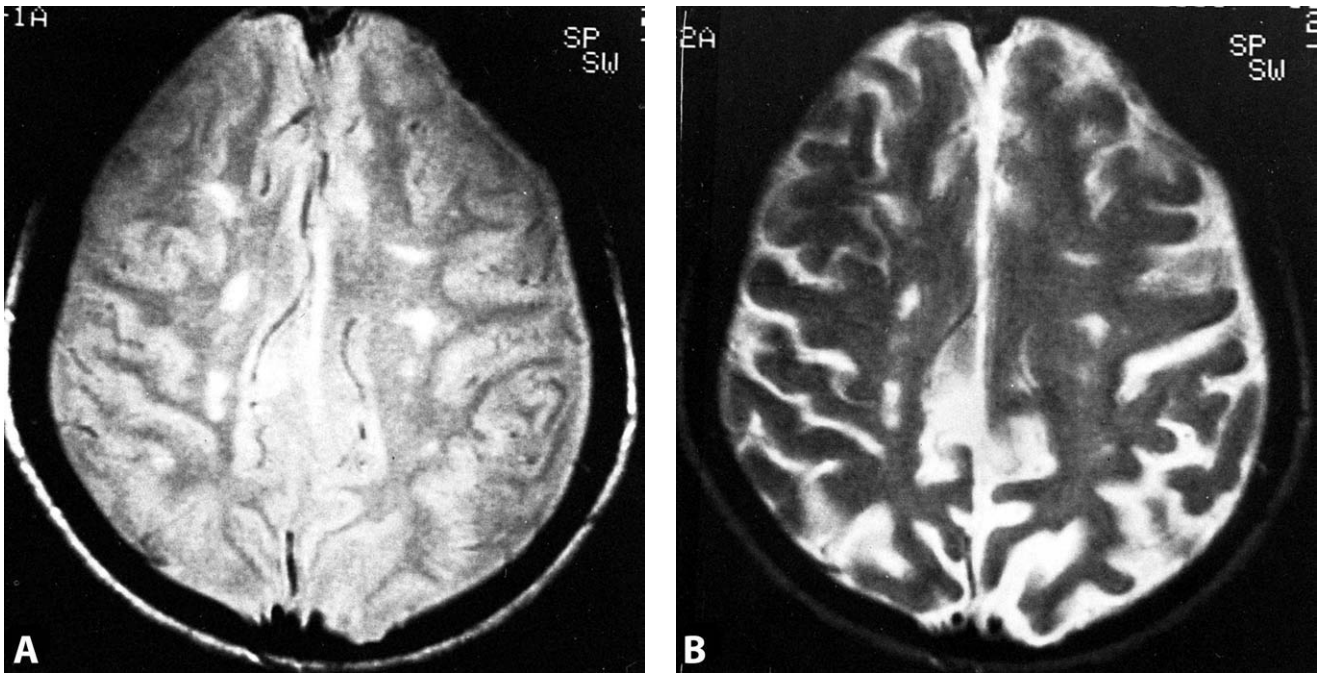

FIGURE 84 (A) Axial proton density MR image (2800/20) and (B) T2-weighted MR image (2800/80) show multiple high-signal-intensity periventricular lesions in a patient with long-standing lupus cerebritis. Courtesy of Dr. M.-F. Kahn, University of Paris.

showed that the magnetization transfer MR imaging detected, with more specificity than standard MRI, microsopic brain tissue damage in NPSLE similar to multiple sclerosis, whereas patients with SLE without NPSLE had findings similar to those of normal patients.

Bell *et al.* [583] found that a combined MRI–serologic approach may have utility in predicting NPSLE responsiveness to corticosteroid therapy. In their study, patients with diffuse clinical disease and symmetrically increased signal intensity in the subcortical white matter on T2-weighted MR images had elevated levels of antineurofilament antibodies and responded to high-dose corticosteroid therapy with resolution of their findings. In contrast, patients with focal central nervous system lupus had hyperintense areas and atrophic changes corresponding to major cerebral vessels and had normal levels of antineurofilament antibodies but elevated levels of anticardiolipin antibodies and lupus anticoagulant and did not respond to corticosteroids.

High-signal-intensity lesions seen in cerebral lupus, when isolated from the clinical history, are nonspecific and may mimic the plaques of multiple sclerosis or the microinfarcts in hypertensive encephalopathy on MRI images [483, 584]. However, when hyperintense lesions are present in both cerebral peduncles and along perivenous channels along the corpus callosum, multiple sclerosis would be the more likely diagnosis.

In recent years, SPECT and FDG-PET have been used to attempt to unravel the complex neuropsychiatric manifestations of SLE and the response to therapy [510, 519, 523]. Both modalities detect lesions not visible on MRI in adults and children [484, 498, 512, 515, 585–590] although MRI will better delineate the focal morphologic changes in a particular area because of its greater spatial resolution [505].

Because FDG-PET was expensive and required rapidly decaying radiopharmaceuticals that were produced by cyclotrons and was not available at most centers, SPECT initially was used more extensively in the evaluation of NPSLE. However, since the late 1990s, the increased proliferation and availability of PET scans have increased the use of FDG-PET [517–522, 524] as well as SPECT [507–513] for evaluating cerebral disease in SLE.

In SPECT studies on patients with SLE, several groups of investigators have reported an increased prevalence of blood flow impairment not only in lupus patients with overt neuropsychiatric symptomatology [507, 512, 588–592], but also in those lupus patients without symptoms [507, 508, 511, 517, 588, 589, 592]. Colamussi *et al.* [507] found that areas of hypoperfusion were more frequent in patients with more extensive NPSLE manifestations. Rubbert *et al.* [592] found that the majority of patients without neuropsychiatric symptoms had normal cerebral perfusion, but patients with minor symptoms (headache, anxiety, cognitive disturbances) frequently had abnormal SPECT studies (73.3%) with two-thirds showing focal areas of hypoperfusion and one-third showing diffuse hypoperfusion. Their patients with predominantly focal uptake defects at SPECT had long-standing disease (>5 years), whereas most patients with normal SPECT or with diffuse hypoperfusion abnormalities had disease of shorter duration. The addition of acetazolamide to SPECT may help test cerebral reserve in the lupus patient. In one report, one lupus patient with no abnormalities at FDG-PET and only minor changes at SPECT showed marked reduction in the cortical perfusion reserve when challenged with acetazolamide [593].

On addition to cerebral perfusion, FDG-PET can evaluate cerebral metabolism. In early ^{15}O-oxygen PET studies, Pinching *et al*. [515] reported that lupus patients with mild cerebral signs, as well as those with severe symptoms, had marked changes on cerebral blood flow and oxygen utilization (Fig. 85). Sequential follow-up scans demonstrated a therapeutic response to corticosteroids. Current FDG-PET show improved resolution as compared with earlier scans (Fig. 86). Pinching *et al.* [515] and Awada *et al*. [516] who used FDG-PET identified a multicentric patchwork during the metabolic phase that correlated with abnormal glucose metabolism. They suggested that cerebrovascular alteration may be more common and widespread than previously thought and may account for the diverse manifestations of cerebral lupus. Volkov *et al*. [594] reported that, in patients with NPSLE, the severity of blood flow and metabolic abnormalities at FDG-PET appeared to correlate with the severity of neuropsychiatric symptomatology. In a longitudinal study of three patients, Carbotte *et al.* [595] showed that FDG-PET abnormalities correlated with focal cognitive deficits; changes in each patient's cognitive profile paralleled changes at FDG-PET. In another FDG-PET study, Weiner *et al.* [524] found hypometabolism in at least one brain region in all patients with severe or mild CNS symptomatology as compared with 40% of patients without symptomatology. The most commonly involved region was the parieto-occipital region (96%) followed by the parietal region (32%). The improvement, stability, or deterioration of symptoms correlated with improvement persistence or worsening of hypometabolism [524].

Another method for evaluating cerebral metabolism in SLE is MRS, which can measure brain metabolites in both chronic and acute NPSLE [525–528, 576]. Sibbitt *et al.* [528] and Griffey *et al.* [525] showed that ATP and PCr were depressed in the white matter in all lupus patients with symptomatic central nervous system disease whether focal (neurologic deficit) or

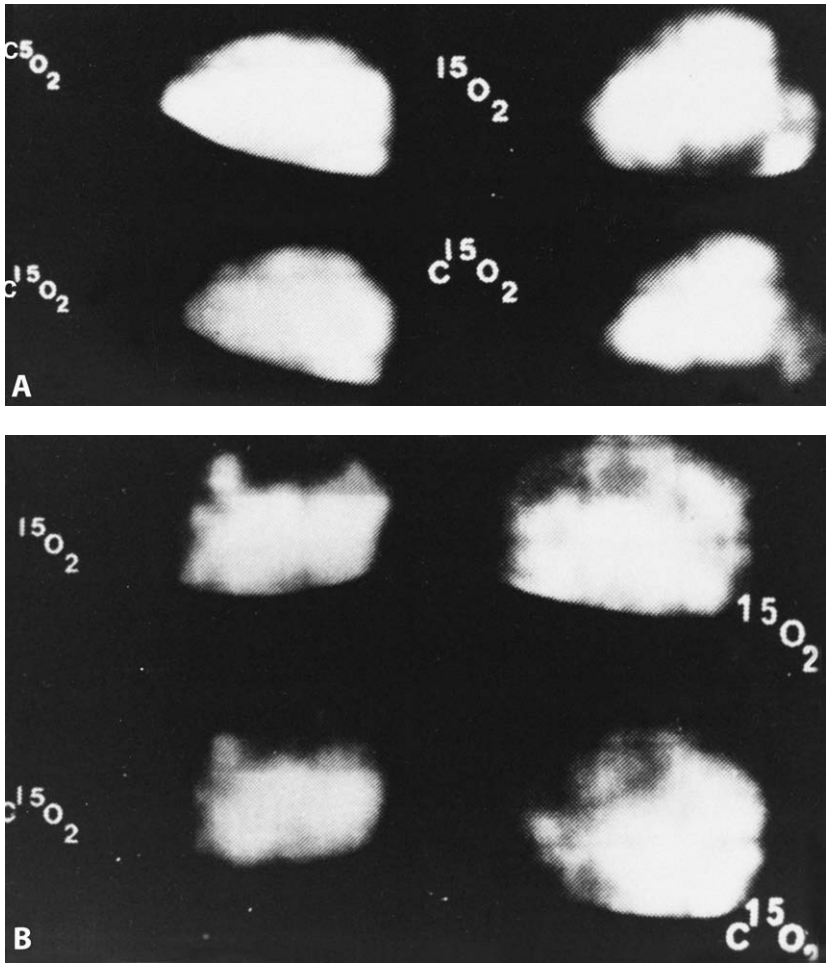

FIGURE 85 (A) Lateral brain PET images with $^{15}O_2$ (metabolism), and $C^{15}O_2$ (blood flow) in a normal patient. (B–D) PET scans of the right hemisphere show several large defects that are more extensive on the metabolism than on the blood flood images in a 52-year-old lupus patient with gross paranoid psychosis. From Pinching *et al*. [515], with permission.

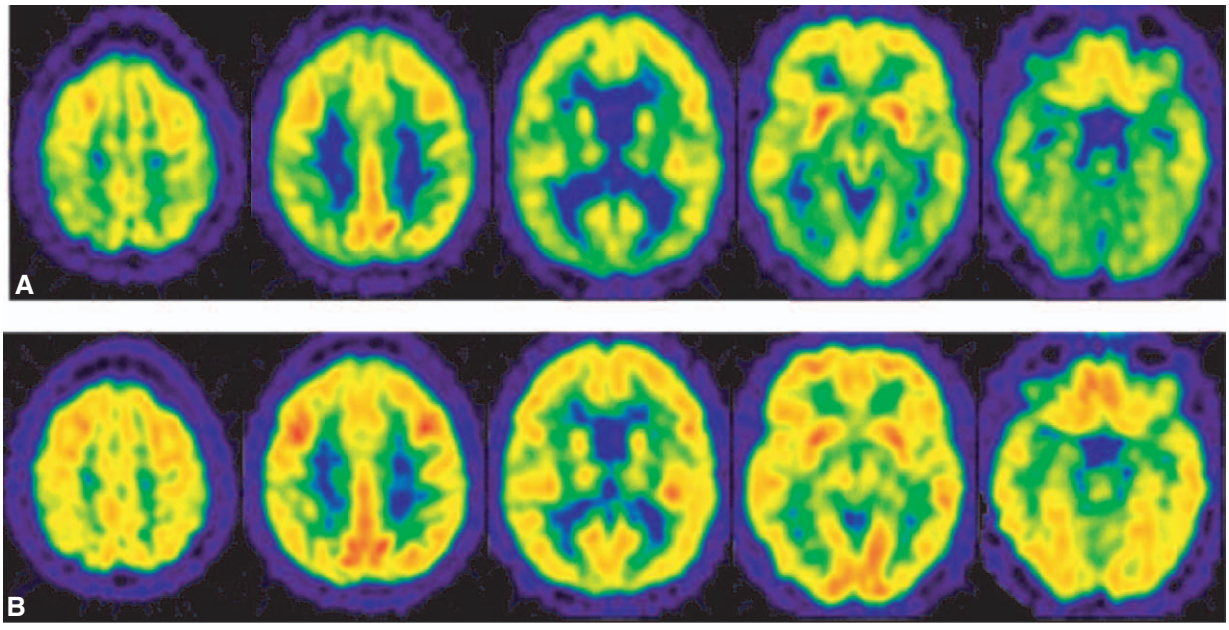

FIGURE 86 (A) Axial FDG-PET scans show multiple defects before treatment in this SLE patient. (B) Therapy with corticosteroids produced improvement on FDG-PET images. Courtesy of Professor E. Nitzsche, Basel, Switzerland.

nonlocalized (headache, confusion) (Fig. 87). The areas of high-energy phosphate depletion did not correlate with the high-signal intensity lesions on MR images. In fact, some patients had normal MR images yet significantly depressed high-energy phosphates that returned to normal with corticosteroid therapy. Thus, depressed high-energy phosphate levels may reflect a more diffuse metabolic process than the focal MR lesion [525]. In addition, lactate and lipid peaks increased in active NPSLE and returned to normal with corticosteroid therapy. Davie *et al.* [526] have also evaluated the application of MRS to SLE, using neuronal marker *N*-acetylaspartic acid markers to cerebral lesions, although its utility is as yet unproved. MRS of these cerebral lesions showed a reduction in the *N*-acetyl aspartate creatine ratio as compared to the normal ratio in lupus patients and control patients with normal-appearing white matter. Twelve of the 13 patients with abnormal MRS had recent or recurrent psychiatric involvement, although there was no correlation between the presence of current neuropsychiatric and/or cognitive dysfunction and the abnormalities. The abnormal NAA/creatine ratio within the cerebral lesions, however, is nonspecific and currently does not allow differentiation of lupus cerebritis from chronic plaques of multiple sclerosis [520].

Thus, for the acutely ill lupus patient, CT allows prompt diagnosis of the bleed or massive infarct. For diagnosis and therapeutic responses in NPSLE, MRI can evaluate the focal infarcted and ischemic brain and the global effects of neuronal damage or loss, and SPECT, FDG-PET, and MRS depict the metabolic and perfusion abnormalities and neuronal loss.

Vasculitis of Cerebral Lupus

When the small- and medium-sized cerebral arteries are affected in SLE, MRA and conventional angiography show a vasculitis with irregular, beaded arteries and areas of narrowing interspersed with zones of aneurys-

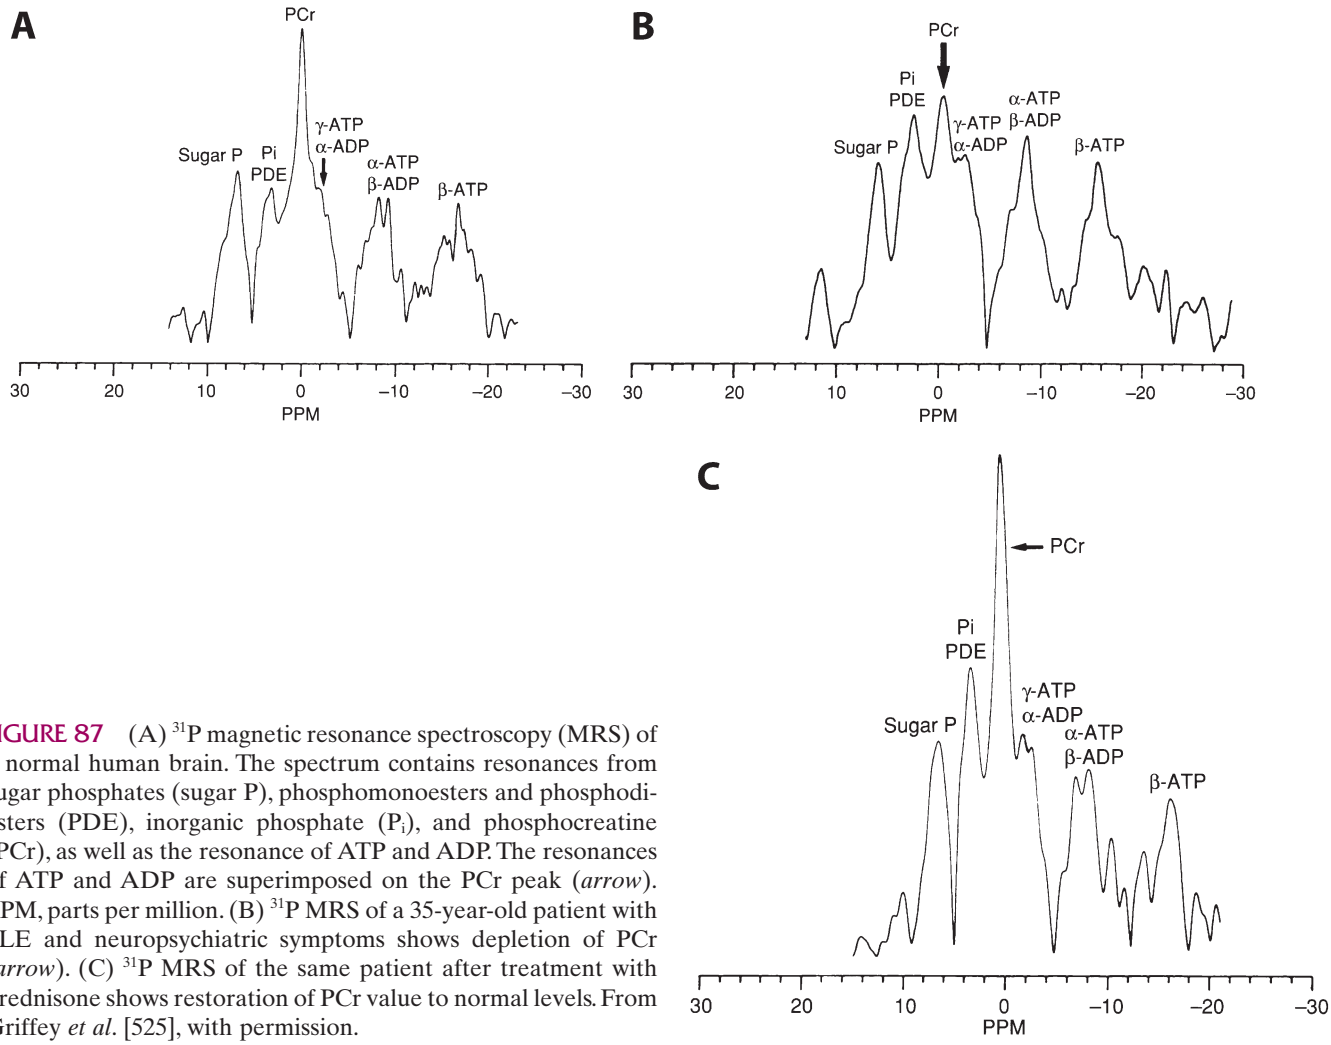

FIGURE 87 (A) ^{31}P magnetic resonance spectroscopy (MRS) of a normal human brain. The spectrum contains resonances from sugar phosphates (sugar P), phosphomonoesters and phosphodiesters (PDE), inorganic phosphate (P_i), and phosphocreatine (PCr), as well as the resonance of ATP and ADP. The resonances of ATP and ADP are superimposed on the PCr peak (*arrow*). PPM, parts per million. (B) ^{31}P MRS of a 35-year-old patient with SLE and neuropsychiatric symptoms shows depletion of PCr (*arrow*). (C) ^{31}P MRS of the same patient after treatment with prednisone shows restoration of PCr value to normal levels. From Griffey *et al.* [525], with permission.

mal dilatation (Fig. 88). Rarely saccular aneurysms develop in the cerebral arteries as in the kidney or liver [596–606]. Major vascular occlusion is less common and may be associated with circulating lupus anticoagulant and more commonly affects the anterior and middle cerebral arteries and, rarely, the vertebrobasilar arteries [607–609]. Venous sinus thrombosis and thrombophlebitis, often manifested by severe, unrelenting headaches, have also been reported in cerebral SLE [537, 589–619]. MRA is currently the primary study used to evaluate the extent of thrombi, nonvisualization of the sinus, and associated cerebral infarcts and edema. Conventional angiography [612–614], is no longer necessary for diagnosing venous thromboses. Occasionally, dural sinus thrombosis clinically presents as patients with increased intracranial pressure and pseudotumor cerebri [614–616].

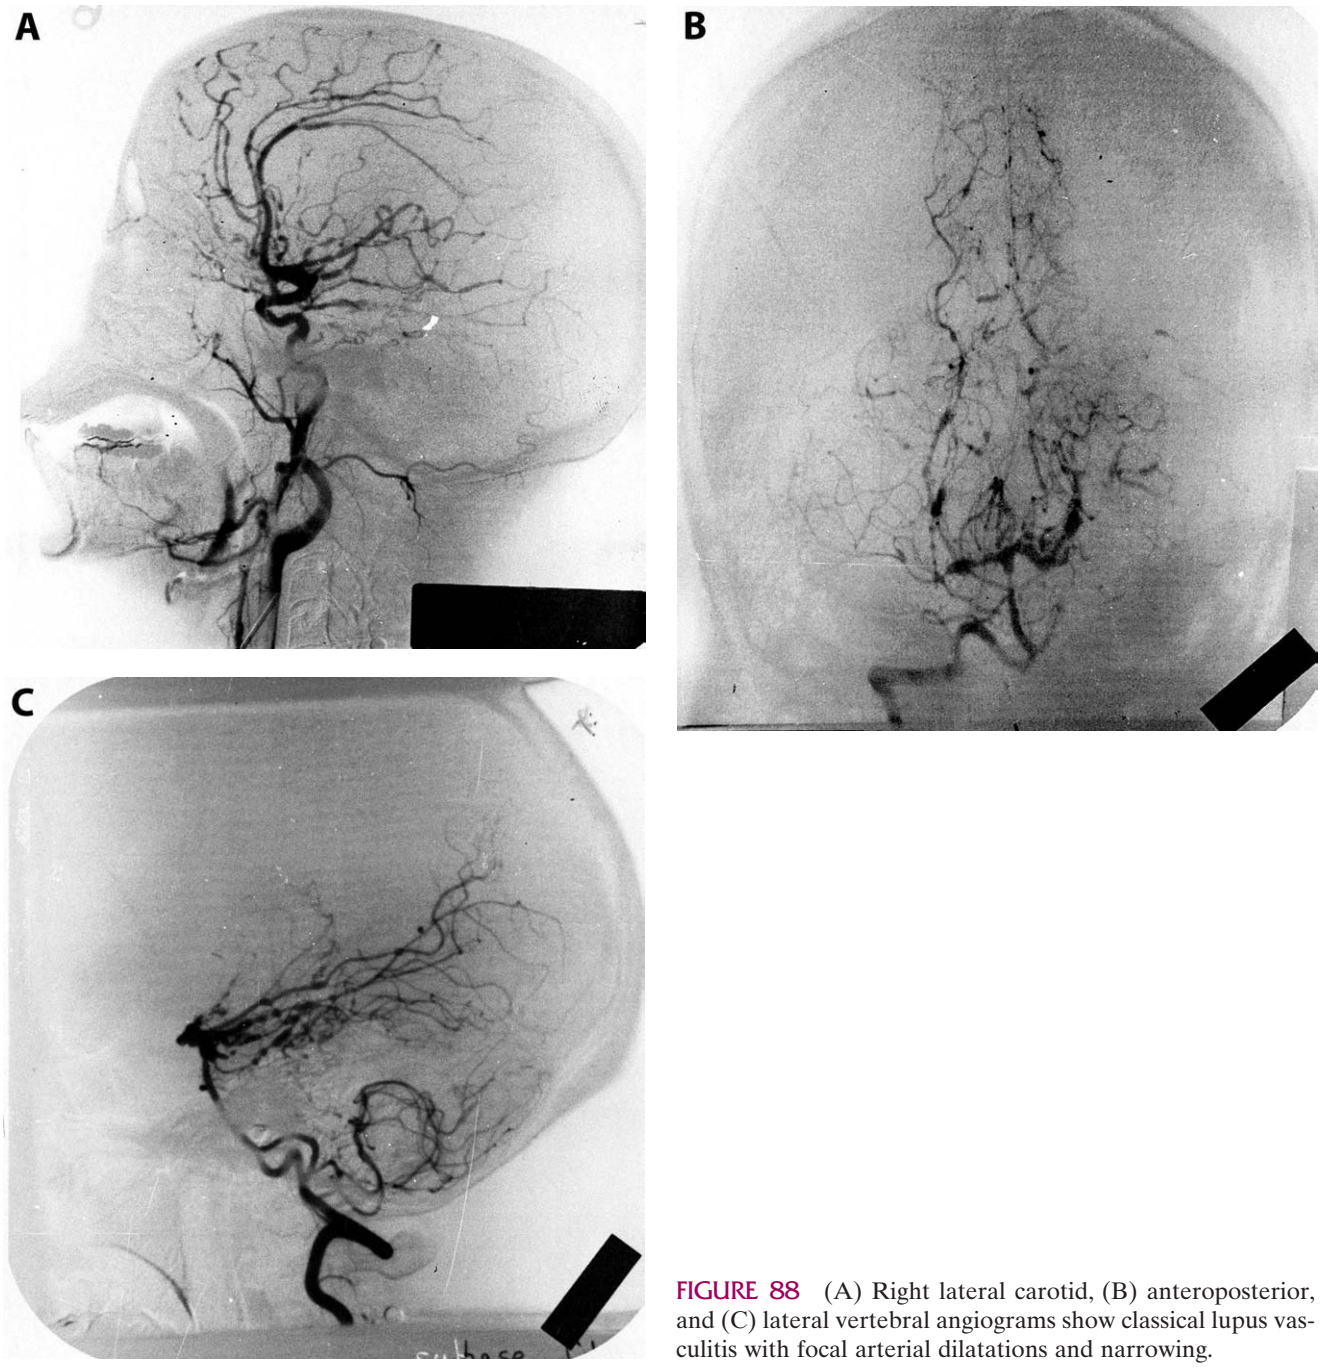

FIGURE 88 (A) Right lateral carotid, (B) anteroposterior, and (C) lateral vertebral angiograms show classical lupus vasculitis with focal arterial dilatations and narrowing.

Parkinsonism in SLE

Parkinsonism, as a manifestation of SLE, is rare and has been reported in nine lupus patients who presented with extrapyramidal symptoms (e.g., bradyphrenia, bradykinesia, hypophonia, rigidity, and abnormal gait). One-third of these patients had MRI studies. T2-weighted MR sequences showed high-signal intensity lesions in the basal ganglia sometimes with associated lesions of the brain stem and cerebral cortex, including the subcortical regions. Contrast-enhanced MRI may show enhancement of the lesions. With corticosteroid therapy, MRI can return to normal, and patients clinically have partial or complete improvement (Fig. 89) [620–622].

Lupus Cerebritis and Progressive Multifocal Leukoencephalopathy

Progressive multifocal leukoencephalopathy (PML) and cerebral involvement in SLE may occasionally occur synchronously [623–625] or lupus cerebritis occasionally may mimic PML both in the clinical course and on CT and MR images [626, 627]. PML is a rare viral infection that may develop in immunosuppressed patients, including the lupus patient. CT and MRI depict PML as areas of patchy or confluent demyelination (low attenuation on CT and high-signal intensity on T2-weighted MR images) in the white matter without mass effect. Histologic examination shows intranuclear viral inclusions and abnormalities of the oligodendrocytes. Electron microscopy and immunohistochemistry demonstrate the JC virus [625, 627].

Lupus cerebritis may rarely display similar MR features as PML. Marsteller *et al.* [626] described a lupus patient with extensive nonenhancing, low-attenuation white matter lesions at CT. Kaye *et al.* [627] reported T2-weighted MR findings in a lupus patient with progressive neurologic and MR findings. Initially MRI demonstrated confluent high-signal intensity areas in the deep white matter (centrum semiovale, corona radiata) consistent with demyelination associated with ventricular dilatation. Rapid progression of the disease ensued over 9 months with extension into the internal capsule, the pons, and cerebral peduncles [627]. In both patients, PML, a nontreatable disease, was considered. Biopsies were performed and revealed no evidence of PML but findings compatible with lupus cerebritis. Thus, in these cases, florid NPSLE, with rapid white matter changes, clinically simulated PML, and a biopsy was required for definitive diagnosis and treatment [627].

Ophthalmic and Orbital Involvement in SLE

Unilateral and bilateral internuclear ophthalmoplegia [628–632] is an unusual manifestation of SLE. MRI can identify the increased signal intensity in the mesencephalon and pons and along the medial longitudinal

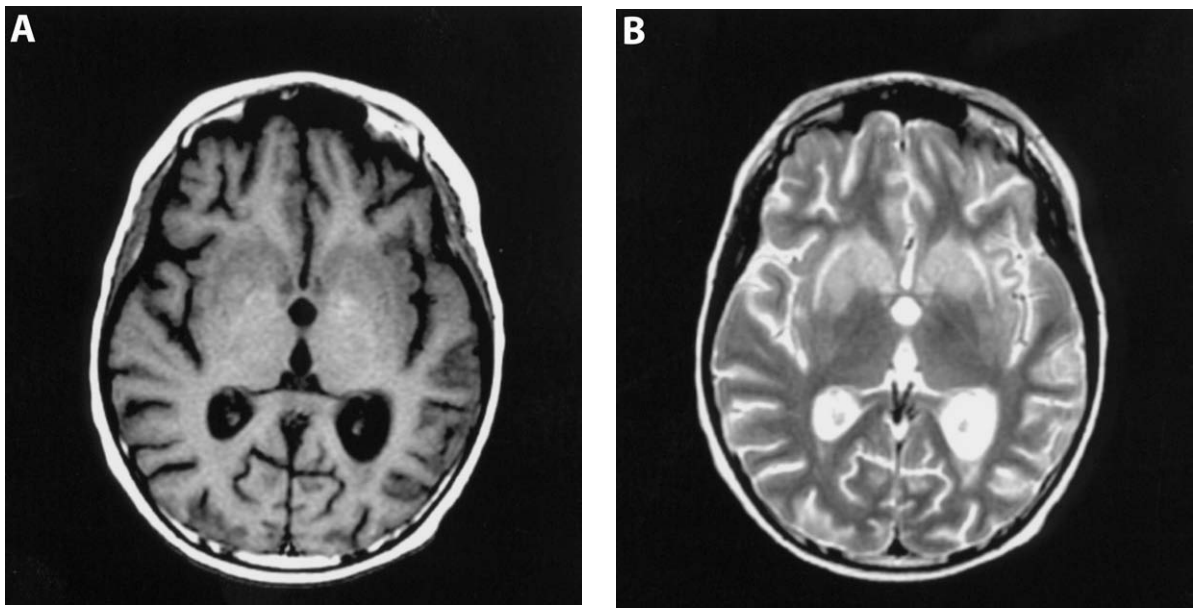

FIGURE 89 (A) Axial T1-weighted MR image shows areas of low signal intensity in bilateral caudate nuclei, putamen, and external capsule that become high signal intensity on T2-weighted MR image (B). This 9-year-old girl had CNS lupus and findings of parkinsonism. (From Kwong *et al*. [621], with permission).

fasciculus (Fig. 90). Postmortem examination reveals pontine infarcts, perivascular adventitial inflammation, intimal proliferation, and thrombosis of the vessels of the midbrain and brain stem and vascular degeneration of the medial longitudinal fasciculus.

Acute optic neuropathy in SLE is characterized by a sudden loss of vision in one or both eyes that may be associated with optic disk swelling [633]. Contrast-enhanced T1-weighted MRI delineates the enhancing, enlarged optic nerves, chiasm, and segment of the anterior visual pathway (Fig. 91).

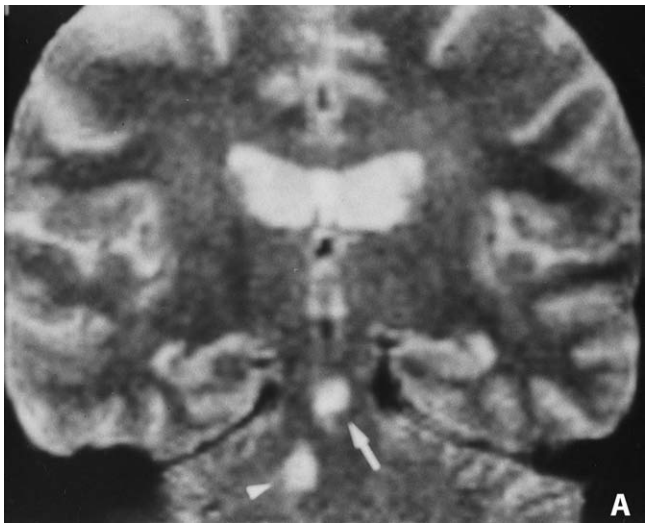
Orbital involvement is uncommon in SLE and may be the presenting manifestation or develop at some time during the course of the disease [634, 635]. On contrast-enhanced MR and CT images, inflamed retroorbital and periorbital tissues enhance as does myositis when present. Both panniculitis and myositis display high-signal intensity on T2-weighted MR images. Microscopic examination of the biopsied inflamed fat reveals fibroadipose tissue infiltrated by inflammatory infiltrate, multinucleated giant cells, and areas of vasculitis; cultures are negative. In all patients on immunosuppressive therapy [634, 635], acute cellulitis should be excluded.

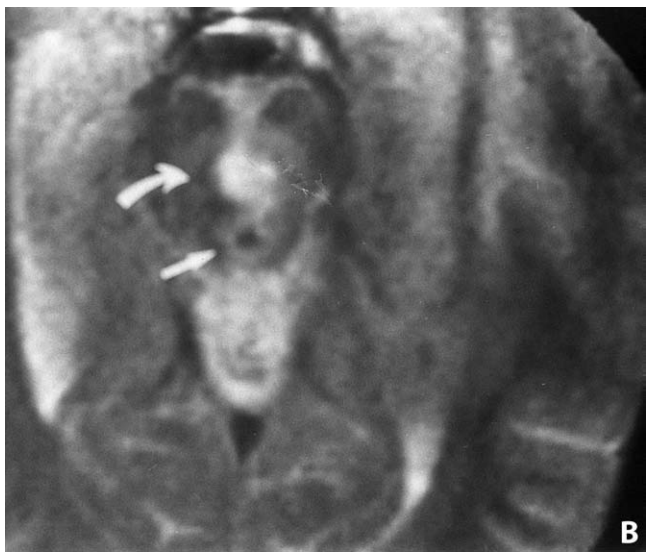
Cerebral Lymphoma in SLE

Cerebral lymphoma has also been reported in systemic lupus [636, 637] but no CT or MRI findings have been described. However, in persons without lupus, primary lymphomas are enhancing masses at CT and hyperintense masses at T2-weighted MRI [638–640].

Complications of Therapy in SLE

Because of their increased susceptibility to infection, lupus patients may develop cerebral or rarely intramedullary abscesses, mycotic aneurysms, and





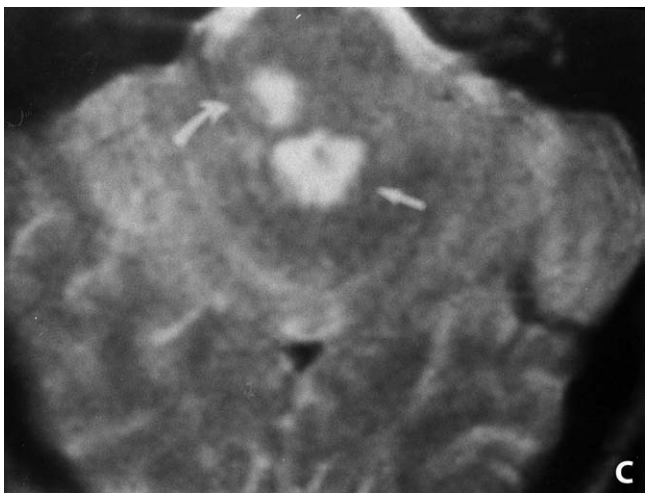


FIGURE 90 (A) Coronal T2-weighted MR image of the brainstem (2000/100) shows a high-signal-intensity lesion in the mesencephalon (*arrow*) and in the pons (*arrowhead*) in a 23-year-old woman with SLE and severe right-sided headaches and diplopia and diagnosis of ophthalmoplegia. (B) Axial T2-weighted MR image (2000/100) at the levels at the mesenephalon shows a high-signal-intensity lesion in the region of the medial longitudinal fasciculi (*curved arrow*). The cerebral aqueduct (*straight arrow*) appears low signal intensity because of cerebrospinal fluid pulsations. (C) Axial T2-weighted MR image of the pons shows a high-signal-intensity lesion (*curved arrow*) in the region of the right medial longitudinal fasciculus, which follows the high signal intensity of cerebrospinal fluid in the fourth ventricle (*straight arrow*). FIGURE 91 This 32-year-old woman with SLE had prior episodes of bilateral visual loss. After treatment with corticosteroids, she returned 4 months later with degradation of her vision to counting fingers in both eyes; her optic discs were atrophic. Clinical diagnosis was vasculitis-induced optic neuropathy. (A) Coronal T1-weighted MR image shows the normally sized intracranial optic nerves. (B) Coronal contrast-enhanced T1-weighted MR image shows enhancement of the intracranial optic nerves (*arrows*). (C) Coronal contrast-enhanced T1-weighted MR image slightly posterior to (A) and (B) shows a mildly enlarged and enhancing optic chiasm (*arrows*). From Sklar *et al*. [633], with permission.

meningitis [483, 554–558]. CT and MRI can identify all three entities. Abscesses appear as low-attenuation masses with well-defined, enhancing walls at contrast-enhanced CT. On T2-weighted MR images, intracerebral abscesses display high signal intensity. On contrast-enhanced T1-weighted MR sequences, abscesses are hypointense centrally with peripheral-enhancing walls [641]. Mycotic aneurysms are rare. When not thrombosed, they present, at contrast-enhanced CT and MRI, as enhancing masses and appear as low-signal intensity masses on T2-weighted MR images because of flowing blood. Conventional angiography and, more recently, MRA confirm the diagnosis (Fig. 92) [559]. With infectious meningitis, contrast-enhanced MRI and CT show intensely enhancing leptomeninges with a gyral pattern. Aseptic meningitis may develop as a complication of immunosuppressive therapy such as ibuprofen or azathioprine and as a manifestation of SLE [642–644] and shows similar features to its infectious counterpart. Rarely subdural fluid col-

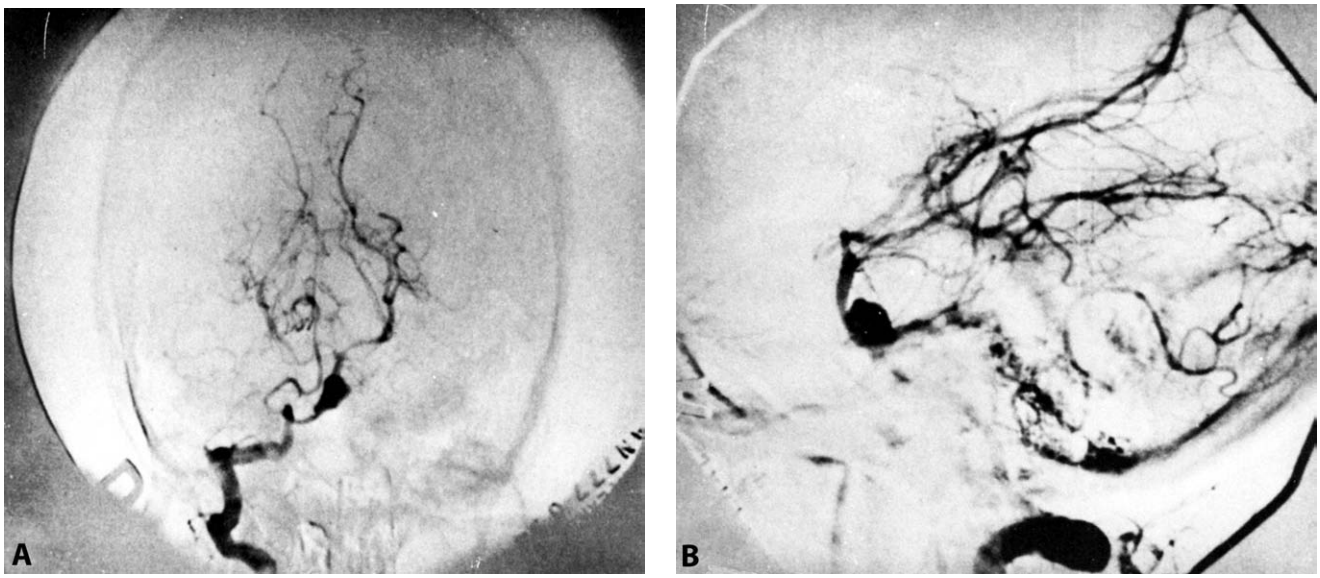

FIGURE 92 (A) Anteroposterior and (B) lateral subtraction vertebral angiograms show a large proximal basilar artery aneurysm. CT shows an enhancing mass anterior to the brain stem compatible with an aneurysm. From Goldman *et al*. [557], with permission.

lections may accompany aseptic meningitis and appear as lenticular hyperintense collections around the brain on T2-weighted MR images [645] and low-attenuation collections at CT.

Spinal Cord and Associated Dura in SLE

Transverse Myelitis in SLE

As compared to the incidence of lupus cerebritis, transverse myelitis is infrequent but may be the presenting manifestation of lupus or may develop at any time during the course of the disease [646–666]. Transverse myelitis sometimes may be associated with lupus anticoagulant and/or antiphospholipid antibodies [646, 648, 654, 655]. Rarely it may manifest as a Brown–Sequard syndrome [667] or anterior spinal artery syndrome [668, 669]. The clinical course can be variable. The onset may be acute, or myelitis gradually may evolve during days to weeks [617, 620]. T2-weighted MRI defines the focal or diffuse (Fig. 93) hyperintense edema of the spinal cord and the cord enlargement [646, 654, 657–659]. These lesions sometimes enhance on contrast-enhanced T1-weighted MR images [646, 663]. With successful therapy (Fig. 94), they resolve. Relapses, however, can occur with similar MR imaging features. Occasionally, well-defined areas of myelomalacia with cavitation or atrophy may result [660–662].

Although multiple sclerosis may also manifest focal hyperintense lesions of the spinal cord, these two disease may differ in location and extent of disease on MRI studies. Although both diseases may produce foci of high-signal intensity, lesions in SLE are fewer in number and extend over several vertebrae, whereas multiple sclerosis shows multiple simultaneous lesions over a shorter length of spinal cord [658, 670, 671].

Meningitis in SLE

As discussed in the section on the complications of central nervous system lupus, meningitis, either infectious or aseptic, is best evaluated on MR images. Rarely, aseptic meninogoencephalitis may be an early manifestation of SLE and disappears with treatment of lupus [672].

Epidural Lipomatosis in SLE

In lupus or other rheumatologic patients [673, 674], epidural lipomatosis, an unusual complication of corticosteroid therapy, is the abnormal deposition of unencapsulated fat around the dura, sometimes causing compression of the thecal sac. Fat accumulation occurs most commonly in the thoracic region but has also been found in the lumbar and sacral regions. The diagnosis should be suspected when a patient, who is receiving corticosteroids, develops signs or symptoms of spinal cord or cauda equina compression. Mild trauma combined with the epidural lipomatosis may further compromise the cord with resultant symptomatology [674].

FIGURE 93 Axial (A) and sagittal (B) T2-weighted (1800/100) MR images of cervical spinal cord show enlargement and focal areas of high signal intensity in a 45-year-old patient with SLE and transverse myelitis. Courtesy of Dr. M.-F. Kahn, University of Paris, and Dr. J.-D. Laredo, University of Paris.

Both MRI and CT show the lipomatosis (hyperintense on T1-weighted MR images and on, T_2-weighted MR images and low attenuation on CT) surrounding the spinal cord. In addition, these modalities exclude other causes of thecal sac compromise, such as a herniated disc or a large epidural hematoma.

Epidural Hematoma in SLE

A rare complication of lupus is the spinal epidural hematoma. Patients may present with transverse myelopathy or develop back pain followed by radicular pain and paresis secondary to spinal cord compression [675, 676]. In lupus patients on immunosuppressive therapy, infection must be excluded. With subacute hemorrhage, MRI demonstrates the medium-to-high-signal intensity epidural collection on the T1-weighted sequence, which becomes high signal intensity on the T2-weighted sequence. Epidural abscesses are hyperintense masses on T2-weighted MR images and show peripheral rim enhancement without central enhancement on contrast-enhanced T1-weighted MR images.

CONCLUSIONS

Conventional radiography continues to be an important modality for the initial evaluation of the lupus patient and, in some instances, for the documentation of response to therapy. For example, radiographic studies are essential for studying and following pleuropulmonary disease (pneumonitis, hemorrhage, pleural effusion), the gastrointestinal tract (acute reversible lupus gastrointestinal ischemia), and the joints (arthritis,

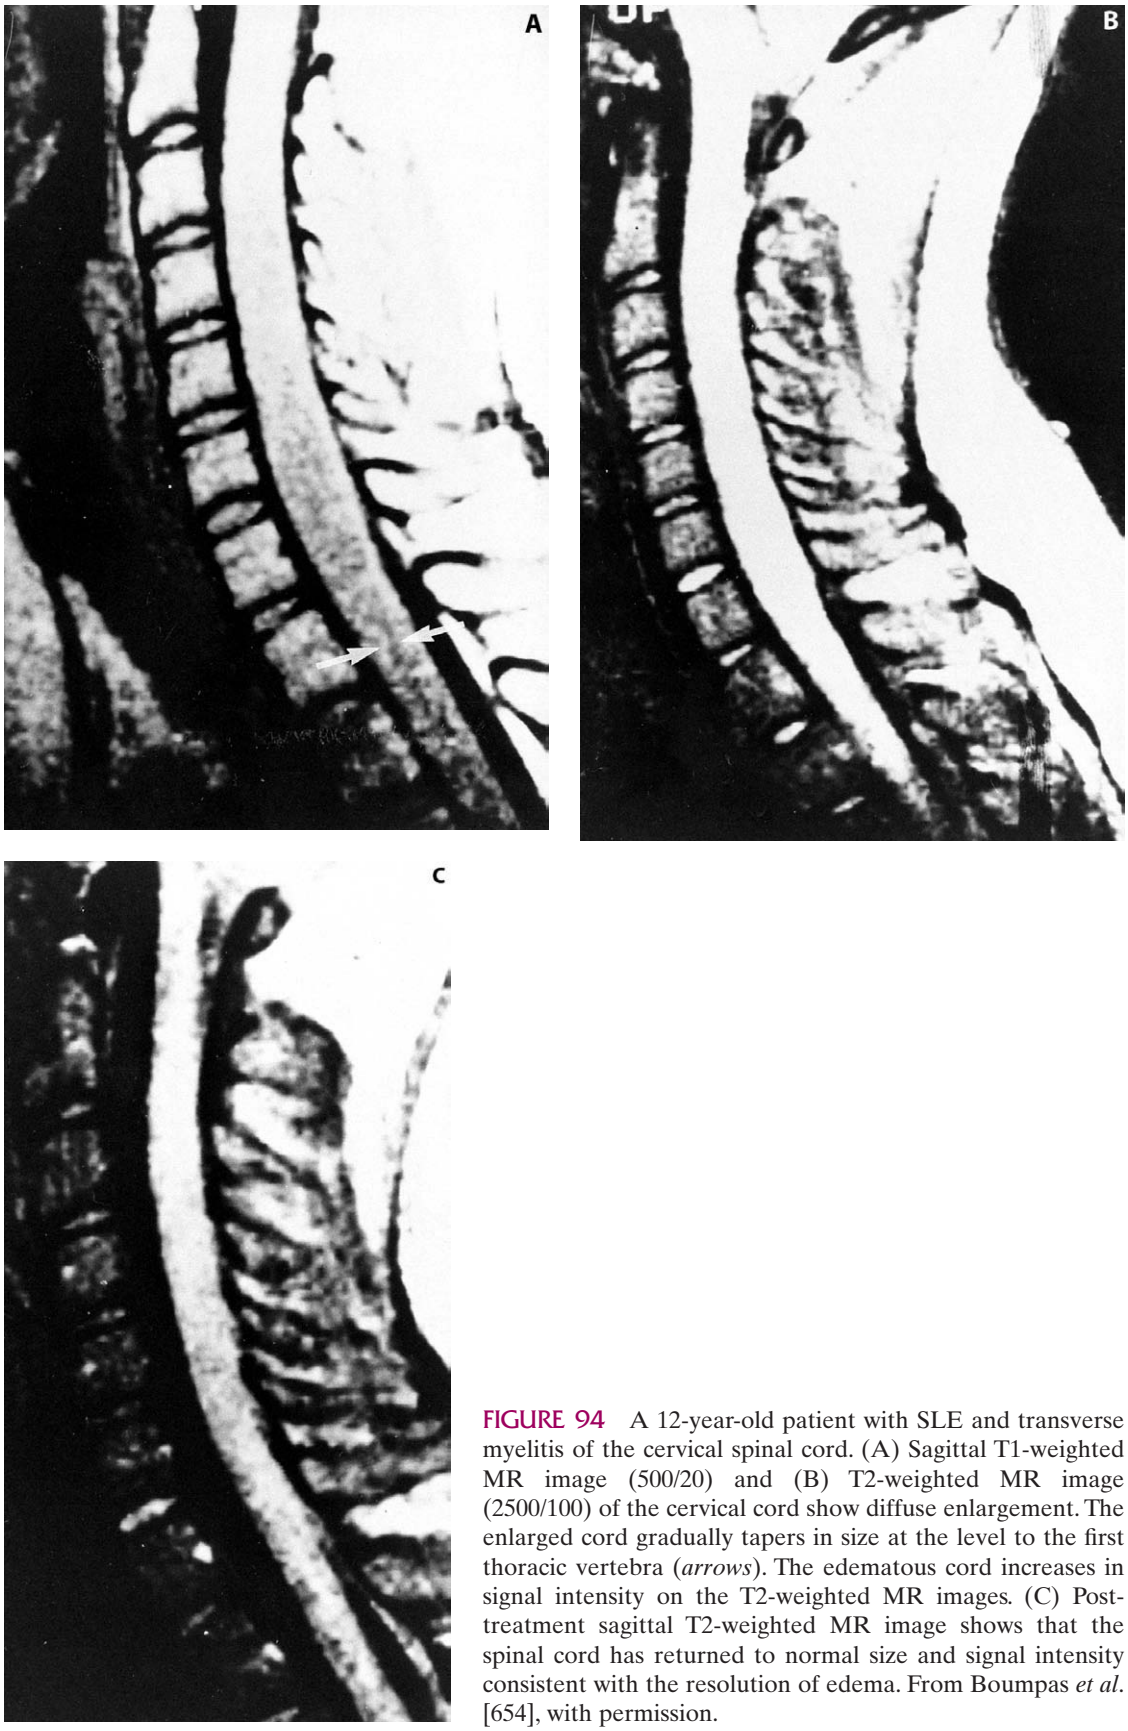

FIGURE 94 A 12-year-old patient with SLE and transverse myelitis of the cervical spinal cord. (A) Sagittal T1-weighted MR image (500/20) and (B) T2-weighted MR image (2500/100) of the cervical cord show diffuse enlargement. The enlarged cord gradually tapers in size at the level to the first thoracic vertebra (*arrows*). The edematous cord increases in signal intensity on the T2-weighted MR images. (C) Post-treatment sagittal T2-weighted MR image shows that the spinal cord has returned to normal size and signal intensity consistent with the resolution of edema. From Boumpas *et al.* [654], with permission.

instability). MRA is the preferred modality for defining lupus vasculitis, arteriosclerosis, and acute thrombosis. The modalities that produce cross-sectional images (ECG power Doppler/duplex sonography, CT, MRI) and the modalities that evaluate metabolism and perfusion (MRS, FDG-PET, SPECT, and MRA/MRI) have advanced dramatically and continue to improve our understanding of patients with SLE by defining their more subtle lesions and radiographically and clinically occult lesions, and their response to therapy and its complications.

MONITORING PATIENTS WITH SYSTEMIC LUPUS ERYTHEMATOSUS

Lisa A. Mandl
Matthew H. Liang

INTRODUCTION

First described over a thousand years ago [1], systemic lupus erythematosus (SLE) frequently manifested as an acute and fatal disease of the young. However, advances in treatment and management since the early 1970s have been so successful that for a large percentage of patients, lupus is now a chronic disease. This has necessitated changes in the approach to monitoring disease. Preventing cumulative organ damage, treating flares early, and minimizing exposure to potentially toxic drugs are now essential tasks in longitudinal management.

Important types of disease assessment include patient reports of signs and symptoms, immunologic markers, organ-specific indices of physiologic function, nonspecific tests of inflammation, and other composite clinical and laboratory indices. None are perfectly reliable, sensitive, or meaningful by themselves. They should be viewed as complementary methods of determining a patient's clinical status in a sometimes confusing clinical presentation.

Each lupus patient has a unique pattern of disease manifestation and laboratory parameters that are useful in assessing disease activity. Ultimately, the clinical relevance of any parameter must be determined by its correlation with physiologic function and with the patient's symptoms. This chapter reviews methods for monitoring patients with lupus.

Once the diagnosis of SLE has been established, the clinician must work out a plan with the patient for ongoing care. The patient must understand that follow-up is required because lupus can be an unpredictable disease. During follow-up, current disease activity, cumulative end organ damage, and ongoing treatment can be assessed. Regular visits also keep the physician up to date with the patient's life circumstances and help maintain a constructive patient–physician relationship. This is particularly important, as recommendations will not be followed if they are not compatible with the patient's lifestyle. The most effective programs occur when patients are active participants in their own care.

The frequency of follow-up for lupus patients can vary. Once a week to once a fortnight may be necessary for an unstable patient who needs close monitoring. Patients who are stable, with minimal or little disease activity on no medications might be seen twice a year. For those on medication, the frequency of visits is also determined by the need to monitor drug toxicity. Studies defining the epidemiology of disease flares are emerging and suggest that on average, patients have a flare every 1 to 2 years [2]. This underscores the need to equip the patient with information so that they can monitor their disease and alert their physician at the earliest sign of a flare. It also shows the need to follow patients regularly and not simply on an as needed basis.

CLINICAL ASSESSMENT

The objective of clinical assessment is to evaluate the various organ systems that can be affected by lupus. Once it is determined that there might be involvement,

other causes of the symptoms must be ruled out and then, most importantly, the physician must determine whether the symptoms represent reversible or irreversible organ damage. The following discussion is organized by organ systems and includes a suggested history, a description of the most common manifestations, and an approach for assessing disease activity and damage.

Constitutional Symptoms

- "Has there been any unintentional change in your weight over the last month?"
- "How is your energy? How does your fatigue affect you?"
- "Have you had any fever in the last month? Did you take your temperature, or have sweats, chills, or shakes?"

Using a variety of definitions, the prevalence of weight loss in case series ranges from 9 to 71% [2, 3]. Significant weight loss (greater than 10% of the body weight, not due to dieting) is probably rare even in patients with active disease, perhaps because these patients often receive steroids, which increase appetite and weight. Therefore, significant weight loss should not be attributed primarily to SLE, but instead alert one to look for other causes, such as hyperthyroidism, malignancy, chronic infection, malabsorption, or poor intake.

Fatigue or decreased stamina is nearly universal in patients with active lupus. It is the limiting problem for one-third to one-half of patients [4]. Fatigue can be the first manifestation of an impending flare and is frequently the first thing that improves as a lupus flare is controlled. Lupus patients often say that their fatigue is like having the flu all the time or that they hit the wall during the day. One can assess fatigue severity by getting the patient to talk about the activities that are made difficult because of the fatigue. Fatigue that prevents one from doing essential or recreational activities is severe fatigue. The precise pathophysiology is unknown but deconditioning likely plays a role, as aerobic training improves the symptoms [5].

When fatigue is an isolated problem (i.e., not in the setting of a flare), the physician should determine whether it might be due to some other disorder. Depression, deconditioning, steroid myopathy, thyroid disease, and sleep disturbance can cause fatigue that is modifiable by addressing the underlying cause. Fatigue out of proportion to disease activity is often due to fibromyalgia [7]. This "dual diagnosis" is frequently ignored and can result in inappropriate therapy for "unresponsive" SLE. In this situation, directed fibromyalgia treatment might be more effective.

In the febrile lupus patient, infection and other causes of fever must be always be excluded. There is no typical fever pattern of lupus. Fever without chills or rigors or positive cultures in patients with leukopenia, a normal C reactive protein, and serologic evidence of lupus activity, such as elevated double-stranded DNA, points to a lupus flare rather than infection, although there is overlap [8].

Mucocutaneous Manifestations

- "Do you have problems with sunlight? Does it make your lupus worse or bring out a rash?"
- "Do your fingers or toes turn dead white?"
- "Have you noticed more hair on your pillow than usual? Do you have bald spots?"
- "Have you had a rash in the last month?"
- "Have you had any sores in your nose or mouth?"

The cutaneous manifestations of lupus are protean, and can involve the epidermal, dermal, and subdermal layers of the skin.

The American College of Rheumatology (ACR) definition of photosensitivity is "an unusual reaction to sunlight by a patient's history or physician observation" [9]. "Unusual reaction" is a vague term and is not explained more specifically. Photosensitivity rashes are usually mild and transient and therefore are only occasionally observed by the physician. Thus, the history is often the only practical way to ascertain the phenomenon. When various objective measures of photosensitivity are compared to the patient's history, there is considerable disagreement [10]. Our criterion for photosensitivity is that sunlight makes the person's lupus symptoms worse or brings out a rash in both the sun-exposed and the unexposed areas within 24 h after sun exposure. Photosensitivity is not well correlated with disease activity [11] and may be associated with decreased mortality [12]. The severity of a photosensitive rash is judged by four features: the extent, the amount of erythema, the thickness, and the scarring or scarring potential (see Table 1).

Raynaud's phenomenon is seen in roughly one-fourth of patients. Clinically, the phenomenon varies during a patient's course and is usually triggered by clear precipitants such as cold or emotional stress. The classic triphasic response is white, blue, and red corresponding to vasospasm, cyanosis, and reperfusion, but this is relatively uncommon. Most studies label patients as having Raynaud's if their fingers are unusually sensitive to cold and turn at least two colors [13].

Raynaud's phenomenon does not necessarily parallel lupus activity or inflammation, but it may herald a flare in otherwise quiescent disease. However, new

onset Raynaud's in a patient over 50 years old may be associated with an occult malignancy and should trigger an age- and sex-appropriate workup [14].

Alopecia in SLE can occur as abnormal patchy or diffuse hair loss with or without scarring. Alopecia may be related to disease activity, but can also be caused by steroid therapy and cytotoxic agents [15]. Alopecia results from disturbed growth of the hair follicles that are actively maturing, not the hair follicles in their quiescent phase. We ask patients if they have observed unusual hair loss on their pillow or if they have any bald spots. When alopecia is apparent by inspection, approximately 50% of the hair is gone and should be rated as severe hair loss. Broken and frayed hairs at the front hairline ("lupus hair") is a pattern of nonscarring alopecia that occurs in SLE and is sometimes apparent on inspection even if the patient denies hair loss.

Oral, nasal, and rarely vaginal mucosa ulcers can be manifestations of active disease. They manifest most commonly as shallow ulcers on the buccal mucosa, hard palate, or in the nose and can be painless or painful. They are usually about 1–2 cm in size, but can be larger and extend into the posterior pharynx [16].

Discoid rash, subacute cutaneous lupus, and acute cutaneous lupus are specific subsets of lupus, and skin inflammation should be used to assess disease activity. However, a myriad of other nonspecific inflammatory skin lesions can occur in SLE, including cutaneous vasculitis, urticaria, livedo reticularis, and hypo/hyperpigmented lesions. Interestingly, the total number of skin lesions, both LE specific and LE nonspecific, appears to correlate with disease activity [17]. Multiple cutaneous lesions may indicate the need for more aggressive systemic therapy.

Ocular Manifestations

- "Have you had problems with your vision?"
- "Have you had any eye pain?"

All structures of the eye can be involved in lupus. Inflammatory lesions of the eye include episcleritis, iritis, retinal vasculitis, cotton wool spots (or cytoid bodies), cranial neuropathies, and optic neuritis (Table 2). Patients with secondary Sjogren's syndrome have keratoconjuctivitis, an inflammatory lesion, secondary to dryness. Classic retinopathy manifests as cotton wool spots and is due either to vasculitis or to accelerated atherosclerosis. Retinopathy can also result from thrombosis due to an associated antiphospholipid syndrome [18]. A baseline fundoscopic examination should be performed on all patients. Retinopathy is related to disease activity, and some believe that it is also correlated with cerebral involvement [19, 20]. Patients without active ocular complaints are unlikely to have an occult sight-threatening disease process [21].

Lymphoreticular Manifestations

- "Have you had swollen glands?"

Lymphadenopathy is a manifestation of immune hyperactivity and can mirror disease activity. Nodes are typically nontender, soft, and range from 0.5 to a few centimeters. Nodes are usually either cervical or axillary, although hilar adenopathy has been described. Generalized lymphadenopathy is rare and usually correlates with disease activity [22]. Splenomegaly is not uncommon.

Cardiopulmonary Manifestations

- "Have you had any problems with breathing or shortness of breath?"
- "Have you had any or chest discomfort or pressure?"

The most common cardiopulmonary manifestations of SLE are caused by inflammation of the serosal surfaces, resulting in pleuritis or pericarditis. Clinical manifestations are classically pain with inspiration and expiration. With a significant effusion, dyspnea may result. As opposed to pleuritis, pericarditis improves with sitting forward and worsens when leaning back. Finding a pleuritic or pericardial rub is not essential, as many patients have symptoms without clear physical findings. Relatively small asymptomatic pleural and

pericardial effusions can be demonstrated by a chest X-ray or by echocardiography. Pericardial effusions can cause tamponade but this is fortunately rare [23]. Inflammation of the myocardium leads to myocarditis (Table 3). Myocarditis is rare and is manifested by decreased ejection fraction or arrhythmia. If the outer surface of the endocardium is involved, then pericardial symptoms may also be present.

Pneumonitis and interstitial lung disease are other manifestations of the lung [24]. Pneumonitis is an inflammatory lesion, and interstitial lung disease can be inflammatory and/or fibrotic. Both are manifested by dyspnea. Acute pneumonitis is usually accompanied by fever, cough, and pleuritic pain and occurs primarily in patients with active multisystem involvement from SLE [25]. Diffuse interstitial lung disease may develop slowly at any time during the disease course and does not necessarily reflect disease activity. Most cases develop in patients with long-standing disease and a history of recurrent pleuritic chest pain. Interstitial lung disease may also follow an episode of acute pneumonitis. In the dyspneic patient, it is important to separate active pneumonitis from chronic interstitial changes, as the treatments are very different. A high-resolution computed tomography scan of the chest, performed prone, is the preferred imaging study to distinguish between these two pathologies. Bronchoalveolar lavage can then be performed to identify active alveolar inflammation. Pulmonary hemorrhage, sometimes massive, occurs in the setting of acute hemorrhagic pneumonitis/capillaritis and the mortality is quite high [26]. The pathology suggests acute immune complex deposition with inflammation. The "shrinking lung syndrome" is characterized by unexplained dyspnea, small lung volumes, and an elevated diaphragm. There is a restrictive pattern on pulmonary function testing. It is unclear if the primary defect is diaphragmatic weakness or a restriction in chest wall expansion; whether it is a manifestation of active disease is also unclear [27].

A rare syndrome of acute reversible hypoxemia is characterized by otherwise unexplained hypoxemia without parenchymal lung disease and responds to corticosterold therapy. It is hypothesized to be related to leukocyte aggregation [28, 29].

Gastrointestinal Manifestations

- "Have you had any belly or stomach pain over the last month?"

Gastrointestinal complaints may be due to the involvement of abdominal structures by SLE or concurrent processes such as infection or side effects of drugs. The abdominal manifestations of lupus are principally vasculitis of the small and large bowel, the peritoneal membrane, and the pancreas. The most common is a sterile peritonitis, the presentation of which can range from painless ascites to an acute abdomen. A painful large abdominal accumulation of fluid must always be evaluated for the possibility of infection or tumor. Mesenteric vasculitis is mostly associated with active multisystem disease and can result in ischemia, infarction, and perforation. Patients usually present with cramping or constant abdominal pain, vomiting, and fever [30]. Pancreatitis is another potentially life-threatening gastrointestinal manifestation of SLE. It can be the first presenting symptom, but is not necessarily associated with active systemic disease [31, 32]. Although controversial, small studies do not suggest that pancreatitis is related to treatment with systemic corticosteroids [32]. However, there has been at least one fatal case of cytomegalovirus-associated pancreatitis, which occurred while the patient was being treated with corticosteroids [33]. Chronic intestinal pseudo-obstruction (CIPO) is an uncommon but well-recognized gastrointestinal manifestation of SLE. It is due to inflammation of smooth muscle in the bowel wall and responds to immunosuppressive treatment [34].

Musculoskeletal Manifestations

- "Have you had any pain or swelling of your joints?"
- "Have you had any unusually sore muscles?"

Joint symptoms (either arthritis or arthralgias) are the most common feature of active disease (Table 4).

Muscle involvement can occur either as a symptomatic myopathy or as an asymptomatic elevation of muscle enzymes. Both joint and muscle symptoms respond to steroid therapy. To be sure that the symptoms are related to lupus activity, one must exclude other causes, such as fibromyalgia, steroid-induced myopathy, or plaquenil-induced myopathy [35].

Neuropsychiatric Manifestations

- "Have you had any problems with coordination, weakness, or numbness?"
- "Have you had loss of consciousness or seizures?
- "Any difficulties with thinking, concentration, or memory?"
- "Any problems with your mood?"

The ACR has developed standardized nomenclature to define neuropsychiatric lupus syndromes [36]. Up to 90% of patients have some type of central nervous system (CNS) disease [37]. Seizures, psychosis, and aseptic meningitis are the most classic associations. Other neurologic and psychiatric conditions also seen in patients with SLE include headaches, demyelinating disorders, chorea, mood disorders, neuropathies cerebrovascular disease, cognitive dysfunction, and transverse myelopathies, among others [37–39] (Table 5). Whenever any of these manifestations occur, one must always look for other causes, such as tumor, infection, metabolic derangements, and medications, as well as looking for evidence of other organ involvement. However, these manifestations do not *a priori* reflect inflammatory disease activity, as they can also be associated with vascular occlusions, especially in the presence of antiphospholipid antibodies. It is vital to evaluate antiphospholipid antibody status in all SLE patients with neurologic signs [40–43].

[a] Infection, malignancy, and drug toxicity must be excluded.
[b] +, useful indicator of disease activity; ±, sometimes useful.

To assess whether the neuropsychiatric symptom is due to active CNS inflammation, a cerebrospinal fluid sample should be obtained and tested for complete blood cell count, protein, glucose, gram stain, IGG index, and oligoclonal banding. Imaging techniques may be useful to define site and extent of the lesions, and magnetic resonance imaging may be able to distinguish damage due to active inflammation from damage due to previous disease [44]. The evaluation of cerebrovascular disease may include standard arteriograms or subtraction angiography or magnetic resonance angiography. Standard electroencephalography (EEG) should be performed in the diagnostic workup of seizures and encephalopathics. SPECT, PET, and related imaging technologies, as well as quantitative EEG, are considered research tools only [45]. Immunochemical tests for CNS lupus such as antibodies to various neuronal constituents such as glial, sphingomyclin, neurofilament, ribosomal P, neuronal, ganglioside, and galactocerebroside and antilymphocytotoxic antibodies are also investigational [46]. Subsets of anti-DNA antibodies may mediate neuronal death via an apoptotic pathway [47].

LABORATORY MONITORING

Hematologic

Leukopenia, lymphocytopenia, and thrombocytopenia are features of active SLE (although one must always ensure other causes, such as drugs or sepsis, have been excluded) (Table 6). Thus, a complete blood count, including a differential, should be performed regularly.

Hemolytic anemia, which can be Coombs' positive, indicates active disease. The Coombs' test, however, is frequently positive without evidence of active hemolysis and is not a good test of disease activity by itself [48]. Neither iron deficiency anemia nor anemia of chronic disease in isolation is indicative of active SLE. Lymphopenia may also predict flares [49]. Marked thrombocytopenia associated with active SLE may need treatment. A reduction in the platelet count has been observed in more than 20% of all SLE patients [4],

usually as a consequence of antiplatelet antibodies, and can be used as a parameter to assess the response to therapy [50]. The combination of thrombocytopenia and hemolytic anemia should always raise the possibility of thrombotic–thrombocytopenic purpura, which can occur in the setting of active and inactive SLE [51].

Renal

Lupus nephritis is often asymptomatic. Signs of inflammatory renal disease and functional impairment should be looked for on a regular basis (Table 7). The urinary sediment is the best tool for assessing active inflammatory renal disease [52].

Semiquantative measurements of hematuria and cellular casts are important tools for monitoring lupus nephritis, especially when done at a dedicated laboratory. Outpatient urine samples should be the second void of the day, collected while the patient is fasting [53]. In patients who are receiving cyclophosphamide, urine microscopy is important in following patients to differentiate hematuria due to glomerular disease from dysmorphic urinary red cells due to cyclophosphamide-induced cystitis or urothelial malignancies.

Proteinuria is an independent risk factor for progressive renal injury in patients with lupus nephritis [54]. However, during flares of lupus nephritis, worsening proteinuria does not predict worse renal outcomes [55]. Quantitative urinary protein may increase with physical activity or decrease because of declining glomerular filtration or treatment with drugs that alter renal blood. Twenty-four-hour urine collections remain the gold standard measurement of urinary protein excretion and should be performed on at least a yearly basis.

Pyuria without hematuria or proteinuria requires that infection be excluded, although it can be a sign of active renal or systemic SLE [56]. Impaired renal function is associated with substantial renal tissue damage from inflammation over time, and therefore spot checks of creatinine and creatinine clearance are not necessarily good gauges of renal disease activity. However, lupus flares associated with a rapid >30% increase in creatinine and an active nephritic urinary sediment have worse outcomes than nephritic flares without changes in creatinine [53]. A sustained doubling of the serum creatinine is a well-accepted outcome measure that reflects at least a 50% fall in the glomerular filtration rate and predicts end stage renal disease in lupus nephritis [53]. In the future, following proinflammatory cytokines such as tumor necrosis factor [57] or urinary excretion of vascular endothelial growth factor [58] may provide more accurate ways of monitoring renal disease over time.

Autoantibodies

The variety of autoantibodies observed in lupus are described elsewhere in this book. Their relationship with disease activity is often difficult to assess: the majority of studies have been retrospective and cross-sectional. Prospective, longitudinal studies, in which immunochemistry is done independent of patient complaints, are limited [59].

Autoantibody testing is often poorly standardized, despite ongoing efforts to establish guidelines and to calibrate measurements by using reference sera [60–63]. These considerations might explain inconsistent findings.

A positive antinuclear antibody is the sine qua non for the diagnosis of SLE. "ANA-negative lupus," a syndrome of clinical lupus without typical autoantibodies, was thought previously to comprise up to 5% of all SLE cases. However, this is now no longer considered a true entity. The phenomenon of "ANA-negative lupus" was based on less sensitive assay techniques and on cross-sectional data, where ANA titers can vary over time and become negative with treatment. Using assays based on human epithelial cells, virtually all patients with clinical SLE have positive extractable nuclear antigens, even if their ANA is negative, and almost all ANA-negative patients will have had a previously positive ANA [64]. However, once documented, following the titers of antinuclear antibody is not helpful in assessing disease activity. Similarly, specific antibodies, such as anti-Ro (anti SSA), anti-La (anti SSB), anti-SM, anti-RMP, and anticardiolipin antibodies, are also useful for diagnosis, but do not help in assessing whether the disease is active [65–69].

The exception to this rule is that antibodies against double-stranded DNA can be useful in assessing disease activity, especially lupus nephritis [70–71]. Several prospective studies demonstrate increasing anti-dsDNA titers preceding clinical flares [71–74]. In a randomized

controlled trial, increasing the prednisone dose in patients with rising anti-dsDNA titers reduced the rate of clinical flares significantly [75]. For quantitative measurements of dsDNA, the Farr assay is superior to the *Crithidia luciliae* test [74].

However, for some patients, the rise and fall of dsDNA do not correlate with clinical events, and persistently high titers are not predictive of flares [60, 76, 77]. Given this degree of individual variability, one should correlate each patient's antibody titers before and after a clinical flare, as that is probably the best way to evaluate whether it can be used legitimately in therapeutic decision making in a given patient.

Immune Complexes

Immune complexes are present in SLE and can be measured using a variety of techniques [78–80]. These tests are not well standardized, and the relationship between immune complexes and disease activity is variable. Immune complex measurement is not part of standard lupus monitoring.

Complement Components

In several studies, clinical lupus exacerbations were preceded or accompanied by falls in complement levels [70, 73, 77]. In some studies, only renal and hematologic flares are associated with decreased complement levels [81]. The total hemolytic complement or CH50 is a functional assay that incorporates the entire complement cascade, but can be normal even when one or more of its components are low. C3 and C4 are not measured by functional assays. CH50 and C4 tend to decrease before clinical signs of disease activity occur, whereas C3 often continues to decline during the height of clinical flare [82]. In patients with active nephritis or vasculitis, C4 levels are often more depressed than C3 levels. However, C3 levels are more predictive of inactive renal disease [77, 82]. Some authors feel that complement levels are more useful in monitoring SLE activity than anti-dsDNA [70, 72], whereas others preferred the latter [74]. As with anti-dsDNA, the association of complement levels and disease activity varies from patient to patient and has to be assessed on an individual basis.

If a patient has a markedly depressed total hemolytic complement, it may be due to an inherited complement deficiency, and therefore following complement is not useful in assessing activity.

Acute-Phase Reactants

The erythrocyte sedimentation rate (ESR) is a sensitive but nonspecific measure of disease activity. It is frequently elevated during flares [59], but does not always mirror the degree of activity and can be elevated in a myriad of other conditions, including infections, malignancies, and paraproteinemias. The role of C-reactive protein (CRP) in monitoring lupus activity has been subject to controversy. In some studies, CRP did not increase during clinical exacerbations [83, 84]. Persistent, mildly elevated levels have been reported in lupus patients with Jaccoud's arthropathy [85]. High CRP levels (>60 mg/liter) are observed in SLE patients with intercurrent infections [86, 87] and in lupus-associated serositis [88]. Mean CRP levels were found to be significantly higher in lupus patients with infections than in those without infections [89], but the range of values overlapped considerably, which means its discriminative value is poor [90]. In newly diagnosed SLE patients, proinflammatory cytokines such as serum interleulan (IL)-1β, IL-6, and tumor necrosis factor-α levels do not correlate with CRP levels, although levels of IL-1ra, another proinflammatory cytokines, do correlate [91]. These data underscore the fact that CRP is not a simple marker of inflammation in lupus. In general, CRP appears to be neither sufficiently sensitive nor specific to be useful in monitoring SLE activity.

DISEASE ACTIVITY INDICES

By the 1980s, there were over 60 different scoring systems for SLE disease activity [59]. A few had been examined for their measurement properties but none of them were widely used. Since then a number of semiquantitative standardized indices, including both clinical and laboratory parameters, have been validated and are used in clinical research [92–95] (see Table 8).

The role of these indices in clinical practice has yet to be determined. Some of these instruments require immunologic testing or specific physical examinations, such as eye examination for cytoid bodies, which are not routine. Nevertheless, they provide an important mnemonic function, may better reflect patients' concerns, and perhaps are more appropriate end points than immunochemical abnormalities [96]. Indeed, studies comparing immunochemical testing to these measures are a way of validating the clinical importance of any immunochemical test. This standardization process should improve the reporting of clinical trials, the ability to compare studies, the conduct of multicenter studies, and the ability to do qualitative and quantitative syntheses of reported trials.

To some degree, these new measures are interchangeable [97]. In addition, with the advent of new biologic agents and the promise of more specific immunologic treatment of lupus, the American Food

TABLE 8 Disease Activity Indices in SLE

Index	Length	Scale	Immunologic testing required[a]	Sensitivity	Notes
BILAG	++++	Categorical	–	+++	Computerized scoring
SLAM	++	Interval	–	++++	Optically scannable
SLEDAI	+	Interval	+	++	
ECLAM	+	Interval	+	?

and Drug Administration and the American College of Rheumatology are developing a priori response criteria, of which one will be an index of disease activity. The measures are discussed in the order of their development.

The **BILAG** instrument was the first of the modem instruments to assess lupus disease activity [98]. The scale, as conceived by its developers, is categorical and reflects an intention to treat eight organ systems separately. It does not easily permit the use of a single numeric value to summarize the overall disease activity. The ratings can be transformed into a continuous scale [99]. The scoring system is complex, varying across organ systems, although a special computer program is available to facilitate scoring. Some of the items, such as lung biopsy, are collected infrequently, leading to relatively high rates of missing data. However, it is a comprehensive instrument, including most signs and symptom that can be seen in lupus. In some studies, BILAG is the most sensitive instrument [95].

The **SLAM** [92] and the current version SLAM-R is being used in the United States, several European countries, Latin America, and Asia. SLAM-R has a more reliable rating of the cardiopulmonary categories and has made laboratory reporting more consistent. SLAM falls between the BILAG and shorter instruments such as SLEDAI and ECLAM in length and is optically scannable with a thorough instruction booklet to guide raters. It can be scored on the spot and does not include expensive immunochemical tests. Each item is graded for severity to quantify changes over time, to better reflect the wide clinical range of SLE. Some investigators believe that the inclusion of milder constitutional symptoms might give undue weight to symptoms that are not specific to lupus. However, like all other instruments, SLAM is administered by expert clinicians who are asked to exclude manifestations not due to lupus. Including constitutional symptoms is useful in covering the entire spectrum of lupus activity, avoiding floor effects, and improving sensitivity to change and to symptoms that matter to patients.

The **SLEDAI** is a short instrument based on multivariate modeling of case scenarios and expert ratings [94]. All variables are assigned organ-specific weights. The instrument includes immunologic tests, and the severity of clinical manifestations is not considered. The advantage of SLEDAI is the comparatively small number of items and the ease of scoring. It may be the most widely used. The lack of severity grading reduces its sensitivity and its usefulness in assessing disease activity over time [92, 95, 100, 101]. The exclusion of mild and moderate clinical symptoms results in a floor effect, in that patients with mild disease cannot be distinguished from patients with an active, organ-threatening disease. In a trial evaluating the safety of hormone replacement therapy and oral contraceptives on SLE, the SLEDAI was insensitive to flares and, as a consequence, was modified to the SELENA-SLEDAI, but it has not yet been extensively validated [2].

ECLAM is a short instrument developed by a multinational group of European rheumatologists [95]. Manifestations are grouped by organ systems and are assigned different weight factors. Disease severity is recorded, but evolving or worsening manifestations are given extra points. The instrument requires complement tests.

ASSESSMENT OF ORGAN DAMAGE

The cumulative inflammatory process of SLE can result in irreversible organ damage, which can be rated with the ACR/SLICC damage index. It has been used primarily for research. The instrument has been shown to be reliable and prognostically important [102]. Early damage as reflected by the initial SLICC/ACR damage index is associated with a higher rate of mortality [103, 104].

MONITORING DRUG TOXICITY

An important task when following a patient with SLE is to monitor the drugs used in treatment for potential toxicity and long-term adverse events. In general, this includes the effects of medications on the

TABLE 9 Recommended Monitoring Strategy for Drugs Used Commonly in Systemic Lupus Erythematosus[a]

Drug	Toxicities requiring monitoring	Baseline evaluations[b]	Monitoring	
			System review	Laboratory
Salicylates, nonsteroidal anti-inflammatory drugs	Gastrointestinal bleeding, hepatic toxicity, renal toxicity, hypertension	CBC, creatinine, urinalysis AST, ALT	Dark/black stool, dyspepsia, nausea/vomiting, abdominal pain, shortness of breath, edema	CBC yearly, creatinine yearly
Glucocorticoids	Hypertension, hyperglycemia, hyperlipidemia, hypokalemia, osteoporosis, avascular necrosis, cataract, weight gain, infections, fluid retention	BP, bone densitometry, glucose, potassium, cholesterol, triglycerides (HDL, LDL)	Polyuria, polydipsia, edema, shortness of breath, BP at each visit, visual changes, bone pain	Urinary dipstick for glucose every 3–6 months, total cholesterol yearly, bone densitometry yearly to assess osteoporosis
Hydroxychloroquine	Macular damage	None unless patient is over 40 years of age or has previous eye disease	Visual changes	Funduscopic and visual fields every 6–12 months
Azathioprine	Myelosuppression, hepatotoxicity, lymphoproliferative disorders	CBC, platelet count, creatinine, AST or ALT	Symptoms of myelosuppression	CBC and platelet count every 1–2 weeks with changes in dose (every 1–3 months thereafter), AST yearly, Pap test at regular intervals
Cyclophosphamide	Myelosuppression, myeloproliferative disorders, malignancy, immunosuppression, hemorrhagic cystitis, secondary infertility	CBC and differential and platelet count, urinalysis	Symptoms of myelosuppression, hematuria, infertility	CBC and urinalysis monthly, urine cytology and Pap test yearly for life
Methotrexate	Myelosuppression, hepatic fibrosis, cirrhosis, pulmonary infiltrates, fibrosis	CBC, chest radiograph within past year, hepatitis B, C serology in high-risk patients, AST, albumin, bilirubin, creatinine	Symptoms of myelosuppression, shortness of breath, nausea/vomiting, oral ulcer	CBC and platelet count every 4–8 weeks, AST or ALT every 4–8 weeks, albumin every 4–8 weeks, serum creatinine, urinalysis

[a] From Rahman *et al*. [104].
[b] CBC, complete blood cell count; AST, aspartate transaminase; ALT, alanine transaminase; BP, blood pressure; HDL, high-density lipoprotein; LDL, low-density lipoprotein.

hematopoetic system, renal function, liver function, and surveillance for malignancies. Establishing the optimal frequency for monitoring patients and selecting the most sensitive tests to use are difficult because many side effects are rare or idiosyncratic. Developing rational monitoring guidelines based completely on evidence is not possible as only a few studies address these issues. In an effort to develop practice guidelines, the ACR has reviewed the pertinent literature and made recommendation for monitoring strategies for drugs used commonly in lupus [105]. One should note that the recommendations reproduced in Table 9 are only guidelines, which must be individualized for specific patients.

LABORATORY EVALUATION OF PATIENTS WITH SYSTEMIC LUPUS ERYTHEMATOSUS

Peter H. Schur

INTRODUCTION

The use of laboratory tests has greatly enhanced our ability to diagnosis systemic lupus erythematosus (SLE) and related disorders. Thus tests such as the antinuclear antibody (ANA) test and tests for antiphospholipid antibodies have in fact been incorporated into the diagnosis of SLE. However, it is important to remember when using these tests, as with any other tests, in a clinical setting to consider their sensitivity, specificity, and predictive value. In addition, laboratory tests are often used to assess the activity of SLE. In this respect, serum complement levels, anti-double-stranded (ds)DNA, and acute-phase reactants have often proved to be useful. Laboratory tests are also used as in any disease to assess organ involvement and function (e.g., renal function). Finally, laboratory tests are often used to evaluate the patient's response to therapy—and again many tests have been useful in this respect (e.g., complement, anti-dsDNA, CBC, renal function).

ANTINUCLEAR ANTIBODIES

Antinuclear antibodies were initially discovered in the 1940s while investigating the immunology of the LE cell test. LE cell tests are rarely performed and have been replaced by the immunofluorescence assay to detect ANAs.

Performance of the ANA Assay

The titer and specificity of antinuclear antibodies vary depending on the antigen substrate used for the assay. Most laboratories currently use HEp2 cells (human epithelial cell tumor line), which provide certain advantages over the frozen sections of murine livers or kidneys [1]. HEp2 cells offer a standardized substrate with larger nucleoli. They also provide better sensitivity for antibodies to nuclear antigens present during cell division, such as the centromere antigens. In addition, ANA titers are almost always higher when measured on HEp2 cells than on frozen sections of murine tissue.

The assay is performed by first incubating acetone-fixed HEp2 cells with patient's serum and then overlaying this combination with fluorescein-tagged antihuman γ globulin [1]. When viewed through a fluorescent microscope, antibodies bound to nuclear antigens produce an apple green nuclear pattern. The pattern of fluorescence and the dilution at which nuclear fluorescence disappears (titer) are subsequently noted. Differences in titer of one tube dilution commonly occur, but are without clinical significance. Certain antibody specificities, such as an anticentromere, can be read directly from the ANA.

In the past, the tremendous interlaboratory variability of ANA results led to a great deal of confusion. However, it is the author's opinion that the ANA is presently reliable and reproducible, as most

laboratories use commercially available tissue culture cell substrates (e.g., HEp2 cells) and participate in proficiency testing.

Enzyme-Linked Immunosorbent Assay

There are ongoing attempts to substitute the enzyme-linked immunosorbent assay (ELISA) for the immunofluorescence ANA assay, the current gold standard [1]. The advantage of an ELISA over the immunofluorescence ANA assay is the ability to automate the procedure. Antigenic substrates for the ELISA have consisted of extracts of nuclei, recombinant antigens, and/or purified antigens.

There are a number of commercial sources of ELISA-ANA testing. Each kit relies on a different method for preparing and coating the nuclear antigens on the microtiter wells, which may account for the variations noted when several kits are compared [2].

Because the ELISA method can be automated and is much less labor-intensive, many commercial laboratories are now screening antinuclear antibody tests by ELISA and then titering only the positive specimens. The reliability of the ELISA assay that employs recombinant nuclear antigens may not be as reliable as other methods, at least when detecting antinuclear antibodies in children [3].

Diseases Associated with a Positive ANA

A positive ANA can be seen with systemic autoimmune diseases, organ-specific autoimmune diseases, and a variety of infections. Their presence does not mandate the presence of illness, as they can also be found in otherwise normal individuals.

Systemic Autoimmune Disease

A positive ANA is an essential component of the definition of some systemic autoimmune disorders, such as systemic lupus erythematosus, but can also be found in association with many autoimmune disorders that are not defined by these antibodies. As a result, the sensitivity of a positive ANA for a particular autoimmune disease can vary widely (see Table 1) [14]:

- SLE: sensitivity, 93%
- Scleroderma: 85%
- Mixed connective tissue disease: 93%
- Polymyositis/dermatomyositis: 61%
- Rheumatoid arthritis (RA): 41%
- Rheumatoid vasculitis: 33%
- Sjogren's syndrome: 48%
- Drug-induced lupus: 100%
- Discoid lupus: 15%
- Pauciarticular juvenile chronic arthritis: 71% [5]
- Raynaud's phenomenon: 36%
- Antiphospholipid syndrome: 50%

Specific Organ Autoimmune Disease

Positive ANAs are occasionally seen in patients with autoimmune diseases that are limited to a specific organ, such as the thyroid gland, liver, or lung. The following sensitivities have been reported in these disorders:

- Hashimoto's thyroiditis: 46% [6]
- Graves' disease: 50% [6]
- Autoimmune hepatitis: 71% [7]
- Primary autoimmune cholangitis: 100% [8]
- Primary pulmonary hypertension: 40% [9]

TABLE 1 Summary of Test Performance Characteristics of the ANA for Major Rheumatic Diseases

		Specificity				Likelihood Ratio	
Disease	Sensitivity Overall	Other CTD	Non-CTD Rheumatic	Healthy	Overall	Positive	Negative
SLE	93%	49%	75%	78%	57%	2.2	0.11
SSc	85%	44%	75%	71%	54%	1.86	0.27
PM/DM	61%	52%	91%	82%	63%	1.67	0.61
Sjogren's	48%	44%	91%	71%	52%	0.99	1.01
Raynaud's	36%	52%	92%	85%	59%	0.88	1.08
JCA	57%	na	na	na	39%	0.95	1.08
With uvetis	80%	na	na	na	53%	1.68	0.39
RA	41%	38%	85%	82%	56%	0.93	1.06

Others

Other well-recognized disorders associated with a positive ANA titer include chronic infectious diseases, such as mononucleosis [10], subacute bacterial endocarditis, and tuberculosis, and some lymphoproliferative diseases [11, 12]. ANAs have also been identified in up to 50% of patients taking certain drugs; however, most of these patients do not develop drug-induced lupus.

False Positives

False-positive ANAs (i.e., ANAs in the absence of autoimmune disease or known antigenic stimuli) are seen more commonly in women and in elderly patients. They are invariably in low titer. Positive ANAs are found commonly in the normal population. When HEp2 cells are used as a substrate, one study of 125 normal individuals found an ANA titer above 1:40 in 32%, above 1:80 in 13%, and above 1:320 in 3% [13]. No patient had anti-dsDNA antibodies. Antibody titers in healthy individuals usually remain relatively constant over time, a finding that can also be seen in patients with known disease.

It is felt that the very low specificity of a positive ANA in the absence of clinical findings of an autoimmune disorder precludes its use as a screening test for disease in the general healthy population.

False Negatives

Certain antinuclear antibodies can be detected at high titer using certain methods and techniques, but are only found at low titer or may even be absent when assayed using other techniques. These confounding findings result from a number of technical and physical nuances, including the method of substrate fixation, the solubility of the antigen (e.g., Ro, La, PCNA, and Ku), and the localization of the antigen outside the nucleus (i.e., Jo-1 and single-stranded DNA). Due to this limitation, a patient with a negative ANA and strong clinical evidence of a systemic autoimmune disorder may require specific antibody assays to accurately diagnosis a rheumatic disease.

In a review of the literature on ANA, including 65 articles that dealt with ANAs and SLE, the sensitivity of a positive ANA was 93%, the specificity vs other connective tissue diseases (CTD) was 49% vs non-CTD rheumatic was 75% vs healthy was 78% (the overall specificity was 57%) [14]. A positive test had a 2.2 likelihood ratio (LR) for the diagnosis of SLE, whereas a negative test had a 0.11 likelihood ratio [14] (see Table 1).

Serial testing of ANAs in patients with SLE has an unknown value [14].

Usefulness of ANA Titer

Unlike nuclear pattern recognition, determination of the titer of antinuclear antibodies still provides clinically relevant information. (1) The presence of very high concentrations of antibody (titer > 1:640) should arouse suspicion of an autoimmune disorder. However, its presence alone is not diagnostic of disease. If no initial diagnosis can be made, it is our practice to watch the patient carefully over time and to exclude ANA-associated diseases. (2) The combination of very low titers of antibody (<1:80) and no signs or symptoms of disease portend a much less ominous prognosis. As a result, these patients need to be reevaluated far less frequently than those with extremely high antibody titers. (3) Little if any data suggest a correlation between ANA titer and the activity of SLE [14].

Types and Usefulness of Staining Pattern

Antinuclear antibodies produce a wide range of different staining patterns, reflecting the presence of antibodies to one or a combination of nuclear antigens. The nuclear staining pattern has been recognized to have a relatively low sensitivity and specificity for different autoimmune disorders, although it was commonly used in the past to detect specific antibody and antigen specificity. At present, specific tests have largely supplanted the use of patterns [15, 16]

- The homogeneous or diffuse pattern represents antibodies to the DNA–histone complex, also called deoxyribonucleoprotein or nucleosome. It is believed that these antibodies are responsible for the LE phenomenon.
- The peripheral or rim pattern is produced by antibodies to DNA.
- Antibodies to Sm, RNP, Ro/SSA, La/SSB, Scl-70, centromere, PCNA, and other antigens produce the speckled pattern.
- The nucleolar pattern is produced by antibodies to RNA polymerase I, fibrillarin, and NOR-90.
- Antibodies to centromeres produce the centromeric pattern.

Despite these general observations, it is increasingly clear that accurate interpretation of different nuclear patterns is confounded by the following difficulties.

- The recognition of specific patterns is operator dependent and does not produce a permanent record. Because the fluorescence fades in 1 to 2 days, one cannot compare a result with other samples without photographing each test result.
- Different serum dilutions can produce varying nuclear patterns.

- One nuclear pattern may obscure and prevent the recognition of another pattern if several antibodies are present simultaneously.
- Certain specificities are visible only on specific substrates. Anti-Ro antibodies and anticentromere antibodies, for example, are not detected with murine organs, but can be found with HEp2 cells.
- Nuclear patterns are neither sensitive nor specific. As a result, no single pattern denotes a single disease and, conversely, several diseases may produce a particular ANA pattern.

Due to these difficulties, specific nuclear pattern recognition is not as useful as previously thought. Pattern recognition has been increasingly supplanted by assays, which detect specific antibodies to an ever-increasing array of nuclear antigens and to antigens not normally found in the nucleus.

Types of Antinuclear Antibodies

Their target antigen defines the different types of ANAs, including single- and double-stranded DNA, nuclear histones, nonhistone nuclear proteins, and RNA–protein complexes. As will be seen, some of these antibodies are relatively specific for a particular disease or for specific clinical manifestations in patients with lupus.

Reflex Testing

Some laboratories have a routine that when an ANA test is ordered they will routinely perform a screening ANA test. Most laboratories, if the screen is positive, will titer the ANA and report patterns. Some laboratories perform what is called "reflex testing." This entails performing tests for anti-dsDNA, Sm, RNP, Ro/SSA, and La/SSB whenever the ANA is positive. This reflexology has the advantage of helping discriminate ANAs associated with SLE (e.g., positive in one of these assays) from nonspecific ANAs immediately instead of waiting for the patient and physician to resort to a second blood specimen and an additional visit to the office/laboratory, making reflex ANA testing cost effective.

Anti-DNA Antibodies

Autoantibodies to DNA were first described in the 1950s. These are the best-recognized specific autoantibodies found in patients with SLE. Antibodies to DNA can be divided primarily into two groups: those reactive with denatured (single-stranded) DNA and those recognizing native (double-stranded) DNA.

Measurement of Anti-dsDNA Antibodies

There are currently three methods commonly used by most clinical laboratories to quantitate anti-dsDNA antibodies. Most of these tests measure both high- and low-avidity antibodies.

The Farr assay is based on the precipitation of radioactively labeled DNA–anti-DNA antibody complexes in 50% saturated ammonium sulfate. This assay primarily detects immune complexes consisting of histone and anti-DNA antibodies [17]. Approximately 50 to 78% of all patients with SLE have elevated titers of anti-DNA antibodies measured by this method; the titers appear to correlate closely with disease activity, especially with active proliferative nephritis [17, 18]. Because this method requires the use of a radioactive antigen, its routine use has been limited.

The *Crithidia luciliae* assay is an indirect immunofluorescent assay that makes use of the fact that the basal body of this unicellular flagellate is very rich in double-stranded DNA in the absence of other nuclear antigens [19]. This method, while of comparable sensitivity to the Farr assay, is more cumbersome to quantitate and the antibodies detected correlate less closely with active nephritis [20, 21].

A third method in routine use utilizes the ELISA technique [22, 23]. Double-stranded DNA adherent to polystyrene microwells, treated to increase their adhesiveness, serves as an antigen to capture antibodies. These antibodies are then quantitated using a second antiserum to human immunoglobulin conjugated to a detector enzyme. This method is positive in approximately 70% of patients with SLE. The IgG antibody titers correlate moderately well with active nephritis and, in the author's experience, there is a good correlation with disease activity in general.

Properties of Anti-dsDNA Antibodies

Anti-dsDNA antibodies can demonstrate different properties based on avidity that affects their usefulness as a diagnostic tool. As an example, high-affinity IgG anti-dsDNA antibodies can be demonstrated in 70 to 80% of patients with SLE when their disease is active [24]. In contrast, some patients with SLE have predominantly IgM or low-avidity IgG antibodies to dsDNA. These antibodies are less useful diagnostically, as they can be found in association with drug-induced lupus, rheumatoid arthritis, Sjogren's syndrome, other connective tissue diseases, chronic infection, chronic liver disease, and normal aging [18]; in these instances, the antibodies have no clinical significance. It is possible that lower avidity antibodies are actually reacting with ssDNA fragments in the DNA preparations used as antigenic substrates.

A number of properties of anti-dsDNA antibodies other than avidity also affect their pathogenicity, including the isoelectric point, isotype, and idiotype. Anti-DNA antibodies that are IgG, cationic, and bind with high affinity correlate best with renal activity.

These antibody properties may vary from individual to individual, over time in the same individual, or with disease activity, even in the face of a stable antibody titer. Thus, there are some patients with SLE who have persistent anti-dsDNA antibody activity despite an improvement in disease activity. Similarly, a small but significant minority of patients have active nephritis without elevations of anti-dsDNA antibody titer. These findings may be related in part to differences in the anti-DNA antibodies over time. Anti-DNA antibodies present in some patients during periods of active nephritis may differ idiotypically from the anti-DNA antibodies present in the same patient during periods of inactive disease [25].

TABLE 2 Anti ds DNA

	Sensitivity	Specificity	Positive LR	Negative LR
SLE vs normals & other diseases	0.573	0.974	16.4	0.49
SLE: active vs inactive	0.66	0.66	4.14	0.51
Lupus nephritis:				
present vs absent	0.65	0.41	1.7	0.76
active vs inactive	0.86	0.45	1.7	0.3

Clinical Relevance of Anti-dsDNA Antibodies

1. They are relatively specific (97%) for SLE, making them very useful for diagnosis (see Table 2) [18, 18a]. They have been found occasionally in autoimmune hepatitis and in a few patients receiving minocycline, etanercept, infliximab, and penicillamine.

2. There is a well-recognized association of high titers of IgG anti-dsDNA titers with active glomerulonephritis [24, 26, 27]; there also appear to be highly enriched amounts of anti-dsDNA antibodies in the glomerular deposits of immune complexes found in patients with lupus nephritis. These observations have led many investigators to believe that anti-dsDNA antibodies are of primary importance in the pathogenesis of lupus nephritis [26, 28].

3. Titers rise when disease is active and usually fall (generally into the normal range) when the flare subsides [26, 29–30]. Early studies reported a tight correlation between high-titer anti-dsDNA antibodies and nephritic activity [18, 26], particularly in the setting of hypocomplementemia [26, 29]. More recent studies, however, have reported exceptions to this correlation of titers and disease activity, e.g., some patients have elevated titers of anti-dsDNA antibodies in the setting of inactive or minimally active lupus [31]. A review of the literature is summarized in Table 2 [18a].

This phenomenon may be attributable to the current sensitive assays that are more likely to detect low-avidity antibodies that previously would have been missed. As mentioned earlier, clinical correlations that hold about high-avidity antibodies appear not to be applicable to those of lower avidity, and current assays are unable to distinguish between high- and low-avidity, i.e., pathogenic and nonpathogenic, antibodies. Thus, while the correlation between antibody titer and disease activity holds for the majority of patients with SLE, there may be some patients for whom this assay has limited clinical utility.

The association between anti-DNA antibodies and other disease manifestations of SLE is far less clear. As an example, there is no relationship between antibody titer and disease activity for lupus cerebritis [32].

Distinguishing active lupus from infectious complications (e.g., secondary to treatment with immunosuppressive agents), from toxic effects of drugs, and from unrelated disease is always a challenge. Anti-DNA antibodies may be helpful in some patients in making this distinction. Although, as noted earlier, there is clear variability among patients, the test becomes very useful once one has demonstrated that a given patient follows the characteristic pattern of rising DNA and falling complement in the setting of a flare. However, once a particular patient shows a disassociation between his or her anti-DNA antibody titer and clinical evidence of nephritis, future changes in anti-DNA antibody activity are unlikely to accurately reflect disease activity. In this setting, therapeutic decisions must be guided by the clinical picture and perhaps by other serological findings such as complement levels.

Anti-ssDNA Antibodies

Antibodies that identify denatured DNA are probably reacting with the purine and pyrimidine bases that are accessible on single-stranded DNA, but are buried within the β helix of double-stranded DNA. Thus, anti-denatured DNA antibodies do not cross-react with native DNA. Antibodies to ssDNA have the following general properties: (1) They have been eluted from the kidneys of patients with proliferative nephritis and may

therefore be of pathogenic significance [33]. (2) They are much less specific for SLE than antibodies to dsDNA. As an example, anti-ssDNA antibodies have been reported in rheumatoid arthritis, drug-related lupus, healthy relatives of patients with SLE [34], and, less commonly, in other rheumatic diseases. Thus, anti-ssDNA has limited usefulness for the diagnosis of SLE. (3) They do not correlate well with disease activity and are therefore not useful for disease management.

Anti-Smith Antibodies and Anti-RNP Antibodies

The anti-Sm and anti-RNP systems are considered together because they coexist in many patients with SLE and bind to related but distinct antigens.

Anti-Sm Antibodies

The Smith antigen is a nuclear nonhistone protein that was characterized in 1966 and was the first nuclear protein auto antigen to be described in SLE [35]. The antigen to which anti-Sm antibodies bind consists of a series of proteins: B; B'; D; E; F; and G, complexed with small nuclear RNAs: U1; U2; U4–6; and U5. These complexes of nuclear proteins and RNAs are called small nuclear ribonucleoprotein particles (snRNPs); they are important in the splicing of precursor messenger RNA [28], an integral step in the processing of RNA transcribed from DNA.

The anti-Sm immune reaction consists of multiple antibodies binding to multiple protein antigens. Thus, although we speak of the anti-Sm antibody, it is actually better described as an antibody system.

Methods of Measurement

While anti-Sm antibodies and anti-RNP antibodies can be detected by immunoprecipitation in agarose gels using radial immunodiffusion or counterimmunoelectrophoresis, these methods are relatively insensitive and difficult to quantitate [35, 36]. Most clinical laboratories now employ either ELISA or hemagglutination to detect these antibodies [37]. Both methods are sensitive, although the ELISA method is quantitated more easily. Because the titer of these antibodies has very limited clinical utility, this methodological difference has little practical significance. In a proficiency survey conducted by the College of American Pathologists, there was greater than 95% agreement in results between the two methods.

Anti-Sm antibodies are insensitive (18 to 30% depending on the assay used) [38, 39], but highly specific for SLE, and generally remain positive when titers of anti-DNA antibodies have fallen into the normal range and the clinical activity of SLE has waned. Thus, the measurement of anti-Sm titers may be useful diagnostically, particularly at a time when DNA antibodies are undetectable.

Anti-RNP Antibodies

The anti-RNP system binds to antigens that are different from but related to Sm antigens. These antibodies bind to proteins containing only U1-RNA. The U1-RNP particle is involved in splicing heterogeneous nuclear RNA into messenger RNA. Anti-RNP antibodies are not specific for SLE, but are a defining feature in the related syndrome, mixed connective tissue disease. The antibody is present in lower titers in several other rheumatic diseases, including scleroderma.

Usefulness

Anti-Sm antibodies occur more frequently in African-Americans and Asians than in Caucasians with SLE. As an example, one series reported a prevalence rate of 25% in African-Americans and 10% in Caucasians (via immunodiffusion) [40]. The prevalence of anti-Sm antibodies in SLE using the ELISA assay varies depending on whether Sm is measured alone or in combination with RNP. Generally accepted rates of anti-Sm antibody positivity in SLE are in the range of 10 to 30% in Caucasians and 30 to 40% in Asians and African-Americans [40].

Antibody titers may fluctuate somewhat over time, although this is a controversial issue. Levels occasionally drift into the negative range when the immunodiffusion technique is used, but this should not occur when more sensitive methods are employed.

Many studies have tried to correlate anti-Sm antibody with disease activity in general and with specific disease manifestations. These investigations have often yielded conflicting results.

- Several authors have reported an association between anti-Sm antibodies and a low frequency of progression to end-stage renal disease (i.e., milder renal disease) [41–43]. However, others have found that the severity of renal disease is similar in patients who do and do not make antibodies to Sm [44].
- One report concluded that the presence of anti-Sm antibodies in the absence of antibodies to DNA was associated with an increased incidence of serositis and a decrease in the incidence of hematologic abnormalities [45].

- Another study found an association between anti-Sm antibodies and the presence of central nervous system (CNS) disease occurring as an isolated clinical finding [31].

These often-contradictory results may be explained by the use of different methods of antibody assay by different investigators, as well as by the application of inappropriate statistical methods.

At this point, there is no evidence that anti-Sm antibodies will be useful for following or predicting disease activity in the way that anti-dsDNA antibodies are used. Antibodies to Sm do function as an important diagnostic marker for SLE. As an example, the presence of antibodies to the Sm antigen system in a patient in whom we suspect the diagnosis of SLE strongly supports the diagnosis. Similarly, in a patient with a less convincing clinical picture, we believe that the presence of these antibodies suggests that even a nonspecific symptom complex is likely to progress to SLE. Given their relatively low prevalence, however, a negative value in no way excludes a presumptive diagnosis of SLE.

Anti-Ro/Anti-SSA Antibodies

Anti-Ro/SSA and anti-La/SSB antibodies are ANAs that have been detected with high frequency in patients with SLE and in patients with Sjogren's syndrome [46].

Immunodiffusion, ELISA, Western blot, and RNA immunoprecipitation detect antibodies to Ro clinically. Most but not all sera react in all three assays. ELISA assays are 10 to 100 more sensitive than immunodiffusion assays; they are also quantitative [47]. The Ro antigen is extracted from human or bovine spleen, Wil-2 cell lines, or represents recombinant fusion proteins [47].

These antinuclear antibodies recognize cellular proteins with molecular masses of approximately 52 and 60 kDa. The 60-kDa protein is complexed with the hy1–5 species of small nuclear RNAs [48].

Relationship between Anti-Ro and Anti-SSA Antibodies

In 1969, Clark *et al.* [49] described the presence of antibodies in the sera of some patients with SLE that reacted with ribonucleoprotein antigens present in saline extracts of rabbit and human spleen. When purified preparations of this antibody were incubated with a human epithelial cell line (HEp2), both the nuclei and the cytoplasm were stained in a speckled pattern. These investigators named the antibody anti-Ro after the original patient in whom the antibodies were identified.

At about the same time, Alspaugh and Tan [50] noted antibody activity in sera from many patients with Sjogren's syndrome that gave the same immunofluorescent staining pattern as that reported for anti-Ro antibodies. These workers referred to this antibody as anti-SSA. It was soon shown that these two antibody systems (Ro and SSA) produced a line of identity on immunodiffusion, indicating that they were reacting with the same nuclear RNA protein [51]. Subsequent research found that anti-Ro antibodies in SLE and anti-SSA antibodies in primary Sjogren's syndrome actually react with different epitopes on the same 60-kDa particle [52].

Anti-Ro/SSA antibodies recognize at least two proteins: a 52 kDa (475 amino acids) and a 60 kDa (525 amino acids). Sera of all patients with anti-Ro/SSA activity detected by immunoprecipitation bind the 60-kD antigen a, whereas sera from only a subset bind the 52-kDa antigen. The additional antigenic reactivity appears to result from a molecular interaction between peptides of the 60- and 52-kDa proteins. No consistent disease association has been noted for any of the fine specificities of these antibodies.

Clinical Significance in SLE

Anti-Ro/SSA antibodies are found by immunodiffusion in approximately 38.6% of patients with SLE; the specificity is 99.986%; and the positive LR is 27571 and the negative LR is 0.4 (47). Anti-Ro/SSA antibodies are found by ELISA in 29.6% of patients with SLE; the specificity is 97.6%; and the positive LR is 12 and the negative LR is 0.7 [47]. Anti-Ro/SSA is found by immunoblotting in 40.6% of SLE patients; specificity 100%; and positive LR is 68 and the negative LR is 0.6 [47] (see Table 3). Anti-Ro/SSA has been associated with photosensitivity, a rash known as subacute cuta-

TABLE 3 Anti-Ro

neous lupus, cutaneous vasculitis (palpable purpura), interstitial lung disease, neonatal lupus, and congenital heart block (CCHB) [46, 53–56]. CCHB occurred in 35 of 278 anti-Ro/SSA-positive (immunodiffusion) SLE mothers and in 1 of 398 anti-Ro-negative mothers (sensitivity 13%; specificity 99.7%; positive LR 43) [47]. There appears to be no predisposition of mothers with anti-52-kDa vs 48-kDa Ro/SSA antibodies to develop CCHB [47] (Table 4). In addition, anti-Ro/SSA did not appear to predict either spontaneous abortions or stillbirths among SLE patients [47].

Association of Anti-Ro Antibodies with Other Disorders

Anti-Ro/SSA antibodies have been noted in 49–69% of patients with Sjogren's syndrome [47] and have occasionally also been noted in patients with rheumatoid arthritis (9.9–20%), progressive systemic sclerosis (7.9–21%), cutaneous vasculitis, dermatomyositis/ polymyositis (23–24%), undifferentiated connective tissue disease, mixed connective tissue disease, juvenile rheumatoid arthritis, chronic active hepatitis, primary biliary cirrhosis, and homozygous C2 or C4 deficiency [47, 48] (Table 3). They are also found in 0.1 to 0.5% of normal subjects; such individuals may have an enhanced sensitivity to ultraviolet light.

Relationship to "ANA-Negative SLE"

In the 1970s, there were several reports of patients who met the American College of Rheumatology criteria for SLE, but were persistently negative for ANA [57]. Although not recognized at the time, this consistently negative finding occurred because sera were tested using mouse and not human tissue as the substrate [48]. By comparison, anti-Ro/SSA antibodies were found in most of these patients when a human cell line extract was used as the substrate for the Ro antigens.

More recently, the substitution of HEp2 cells (a human cell line) for mouse tissue sections in the ANA test has resulted in only a small number of SLE patients who test persistently negative for ANA. Nevertheless, on rare occasions, the anti-Ro/SSA antibody test may be useful in suggesting a diagnosis of systemic autoimmune disease in the face of a negative ANA. In one study of 4025 sera sent for ANA testing, for example, 64 patients were ANA negative by immunofluorescence but anti-Ro positive by ELISA [58]. Of these, 12 and 5 patients were diagnosed with SLE and cutaneous LE, respectively.

Finding anti-60-kDa Ro is somewhat useful in distinguishing SLE from primary Sjogren's syndrome (sensitivity 12%; specificity 97%), whereas detecting anti-52-kDa Ro is more helpful in distinguishing primary Sjogren's syndrome from SLE (sensitivity 44%; specificity 92%) [47] (Table 5).

Anti-La/SSB Antibodies

Approximately 50% of sera from patients with SLE, which have anti-Ro antibody activity, also contain antibody to La, a closely related RNP antigen.

The antigen appears to be a nuclear phosphoprotein with a molecular mass of 48 kDa and is complexed with the Ro particle [59]. In addition to other functions, the La protein serves as a termination factor for RNA polymerase III.

Immunodiffusion, ELISA, Western blot, and RNA immunoprecipitation detect anti-La/SSB antibodies clinically. The La/SSB antigen is derived from rabbit thymus extracts or recombinant fusion proteins. ELISA assays are 10 to 100 more sensitive than immunodiffusion assays; they are also quantitative [47].

TABLE 6 Anti-La

	Sensitivity	Specificity	Positive LR	Negative LR

SS vs normals ID	22	100	>17	0.8
SS vs normals ELISA	71	93	10	0.3
SS vs normals IB	50	100	28	0.5

Clinical Associations of Anti-La

Anti-La/SSB antibodies are found in the following circumstances.

- It is very unusual to encounter sera that contain anti-La/SSB activity without demonstrable antibodies to Ro/SSA in patients with SLE or Sjogren's syndrome.
- Antibodies to the La/SSB by immunodiffusion are present in 13% of patients with SLE (specificity 100% vs normals; positive LR >33; negative LR 0.9). Antibodies to La/SSB by ELISA are found in 24% of SLE patients (specificity 99% vs normals; positive LR 20; negative LR 0.8) [47] (Table 6).
- Anti-La/SSB antibody activity has also been detected in 22% (by immunodiffusion) to 71% (by ELISA) of patients with Sjogren's and has been seen in some patients with scleroderma (2–37%), dermato/polymyositis (3%), rheumatoid arthritis (1%), primary biliary cirrhosis, and autoimmune hepatitis [47] (Table 6).

Indications for Testing for Anti-RO/SSA and Anti-LA/SSB

In the author's opinion, indications for ordering an anti-Ro/SSA antibody test are as follows: women with SLE who have become pregnant; women who have a history of giving birth to a child with heart block or myocarditis; patients with a history of unexplained photosensitive skin eruptions; patients suspected of having a systemic connective tissue disease in whom the screening ANA test is negative; and patients with symptoms of xerostomia, keratoconjunctivitis sicca, and/or salivary and lacrimal gland enlargement.

Once a patient is either Ro/SSA and or La/SSB positive or negative this rarely changes. There is also little if any justification for performing serial determinations of anti-Ro/SSA and/or anti-La/SSB [47].

Nucleosome-Specific Autoantibodies

The first autoantibody described in systemic lupus erythematosus, the "LE factor," was a nucleosome-specific autoantibody. These antibodies are now termed nucleosome-restricted antibodies because they bind to the complex of DNA and histones, but not to the individual components.

Pathogenic Role

An original report suggested that nucleosomes might be critical antigens in the eventual generation of antinuclear antibodies in SLE [60]. Subsequent observations have provided some support for this hypothesis [61, 62]. The appearance of these antibodies may precede the emergence of antibodies to DNA or histones.

Methods of Detection

The detection of antinucleosome-specific antibodies remains problematic because the nucleosomal material used as a substrate also binds anti-dsDNA and antihistone antibodies. The traditional method of circumventing this problem, absorption techniques, is cumbersome and difficult to perform. An epitope recognized only by nucleosome-specific antibodies has not yet been identified.

Incidence and Accuracy

Because of the difficulties in detection, there is a paucity of data concerning the incidence and accuracy of antinucleosome-specific autoantibodies. A prevalence of 48 to over 80% has been noted in patients with SLE [63, 64]. They usually but not always are associated with anti-dsDNA and antihistone antibodies [63]. The specificity of these antibodies remains a source of controversy.

Associated Clinical Manifestations

Nucleosome-specific autoantibodies have been linked with lupus nephritis in murine models of SLE. In humans, however, the results are conflicting. Some series have found a weak but significant association [65, 66], whereas others have not [62, 64]. One study of a large cohort of patients with varied connective tissue disorders and control sera from those with hepatitis C virus infection found that IgG antinucleosomal antibodies were found exclusively in patients with SLE, systemic sclerosis, and MCTD, with prevalences of 72, 46, and 45%, respectively [66]. In addition, antinucleosomal

antibodies of the IgG3 subclass were observed only in patients with SLE and correlated more closely with active disease and particularly with nephritis than anti-DNA antibodies.

Summary

The clinical utility of antinucleosome-specific autoantibodies remains undefined, as their sensitivity, specificity, and association with particular manifestations of SLE remain undefined. Nevertheless, these antibodies are a source of interest because they may have a role in the pathogenesis of autoantibody production in SLE.

Anti-hnRP Antibodies

The spliceosome refers to a complex of nuclear RNA-binding proteins, which processes pre-mRNA into spliced mature mRNA. Among the subunits of the spliceosome are a group of 30 structurally related proteins known as heterogeneous nuclear ribonuclear proteins, which are called hnRNP [67].

Methods of Detection

Autoantibodies specific for the RNA-binding regions of two of the hnRNP proteins, A2 (also called RA33) and A1, produce a finely speckled pattern of staining in the nucleoplasm on indirect immunofluorescence microscopy. Their presence must be confirmed by either immunoblotting or dot blot assays [68].

Incidence and Accuracy

Anti-hnRNP antibodies against the A1 and A2 proteins have been reported with the following frequencies [69, 70]:

- Rheumatoid arthritis: 50% for the A1 protein and 35% for the A2 protein
- SLE: 22 to 38% for A1 and 23% for A2
- Mixed connective tissue disease: 40% for A1 and 38% for A2
- Scleroderma, myositis, Sjogren's syndrome: <5% for A2
- No connective tissue disease: <7% for A1 and A2

The clinical utility of anti-hnRNP antibodies is currently limited because they cross-react with multiple antigens, and antibodies directed against hnRNP antigens other than A1 and A2 may be found in different autoimmune disorders.

Summary

Anti-hnRNP antibodies have limited utility in the diagnosis of connective tissue diseases as they are found at significant levels in multiple disorders and their presence appears to correlate highly with other specific antibodies (such as anti-Sm antibodies).

Anti-PCNA Antibodies

A number of proteins accumulate in the nucleoplasm of cells during the G1/S phase of the cell cycle, which corresponds to the period of DNA synthesis. Approximately 2 to 10% of sera from patients with SLE sera contain antibodies, which react with one such protein: proliferating cell nuclear antigen (PCNA) [71].

Methods of Detection

Anti-PCNA antibodies can be detected by indirect immunofluorescence as a finely granular nuclear staining pattern on rapidly dividing cells. An enzyme-linked immunoassay for the detection of these antibodies has been reported. The dominant epitope of PCNA is an area of 14 contiguous amino acids [72].

Accuracy

Anti-PCNA antibodies appear to be specific (>95%) for SLE; they have not been found in sera from patients with RA or other connective tissue diseases or in normal sera [71]. The incidence of this antibody varies, as its production is rapidly inhibited by the administration of corticosteroids and immunosuppressive drugs.

Clinical Association

The presence of anti-PCNA antibodies in patients with SLE is not associated with any particular clinical manifestation other than arthritis.

Summary

Despite its high specificity, the anti-PCNA antibody test has limited clinical utility because of its very low sensitivity.

Antibodies to Ribosomal P Proteins

Antibodies to ribosomal P proteins are detected by either Western immunoblotting or an ELISA with the latter being the test of choice. The ELISA, which is more sensitive using affinity-purified human P protein rather than bovine P protein, is quantitative and more convenient [73].

The targets of these antibodies were three phosphoproteins (P proteins) located on the 60S subunit of ribosomes [74, 75]. The proteins were designated P0, P1, and P2, with molecular masses of 35, 19, and 17 kDa, respectively. They were thought to be involved in protein synthesis; specifically, in the interaction of EF-1 α and EF-2 with ribosomes.

Clinical Associations

All published studies agree on the specificity of antiribosomal P protein antibodies for SLE [76–78]. These antibodies have not been found using conventional assays in normal controls [77, 79] or in patients with other autoimmune diseases (e.g., rheumatoid arthritis, scleroderma, and myositis) [80].

The antibodies have been detected in 10 to 20% of patients with SLE [76, 77, 81, 82]; however, the incidence may approach 50% in Asian populations and children [80, 83, 84].

Ribosomal P Protein Antibodies and Lupus Cerebritis

The presence of ribosomal P protein antibodies has been strongly associated with lupus manifested by psychosis and/or depression by some [77, 79, 80] but not by others [15, 18]. Similarly, some [77, 79], but not others [82, 85, 86], have found associations between a rise and a fall of antibody titer in association with activity of psychosis.

The aforementioned observations were all based on studies of a relatively small number of patients. Therefore, only the results of a prospective study of large numbers of patients will properly determine whether there is a correlation between active SLE and antiribosomal P antibodies.

Antibodies to Ribosomal P Protein and Non-CNS Lupus

The presence of antiribosomal P protein antibodies has been linked with the involvement of other organ systems in SLE, specifically the liver and the kidney.

1. Liver disease: In a case-control study, liver disease was found in 7 of 20 patients with SLE who had antiribosomal P antibodies, but in only 1 of 20 patients without these antibodies [87]. Antibodies to ribosomal P proteins were not found in sera of patients with chronic active hepatitis, primary biliary cirrhosis, or sclerosing cholangitis; these findings suggest that these autoantibodies were not simply a by-product of immune-related hepatic injury. Others have made similar observations [88].

2. Renal disease: Antiribosomal P antibodies have also been associated with lupus nephritis in some studies [87], including fluctuations of antibodies levels with the activity of renal disease [89]; however, others have noted no such association [77, 82].

3. An association between antiribosomal P protein antibodies and antibodies to cardiolipin has been noted [90]. It is unknown whether the coexistence of such antibodies is associated with a higher risk of neuropsychiatric manifestations.

Variability of Antiribosomal P Protein Antibody Results

Any or all of the following possibilities may distort the results of studies evaluating the frequency of antibodies to ribosomal P proteins and their clinical associations: (1) Differences in methodology for detection of antibody, (2) variable ethnic composition of populations in different studies, (3) small sample sizes, and (4) problem of definition.

Perhaps the biggest confounding factor is the problem of definition. Lupus-related psychosis and depression remain exceedingly difficult to diagnose and still harder to quantify. In addition, authors use different criteria to diagnose these conditions. As examples, one study included in their group of lupus patients with depression only those requiring admission for their psychiatric manifestations [77], whereas another included patients with much less severe disease [85]. Results might therefore not be comparable.

Utility of Antiribosomal P Antibodies in SLE

It is believed that testing for antibodies to ribosomal P proteins may be useful in certain circumstances as they are quite specific, but not sensitive (12 to 16%), for SLE [76, 77, 91]. A positive antiribosomal P antibody might be used diagnostically in a fashion similar to that of antibodies to Sm. As an example, presence of an anti-Sm antibody suggests a diagnosis of SLE even in a patient with otherwise undifferentiated disease. Positive antibodies to ribosomal P proteins may also favor this diagnosis in this setting. In addition, the presence of these antibodies is independent of antibodies to dsDNA [79, 82]. They may therefore remain elevated when other marker antibodies have returned to normal and might again be helpful in diagnosing SLE even with quiescent disease. The utility of these antibodies in these scenarios, as well as their exact role in NPSLE, liver disease, and renal disease, requires further investigation.

Other Autoantibodies

Anti-C1q Antibodies (see Complement Section)

Coombs

Overt autoimmune hemolytic anemia (AIHA), characterized by an elevated reticulocyte count, low haptoglobin levels, an increased indirect bilirubin concentration, and a positive direct Coombs' test, has been noted in approximately 10% of patients with SLE. Even more patients have a positive Coombs' test without evidence of overt hemolysis. The presence of both immunoglobulin and complement on the red cell is usually associated with some degree of hemolysis, whereas the presence of complement alone (e.g., C3 and/or C4) is often not associated with hemolysis. The antibodies are "warm," IgG, and are directed against Rh determinants. IgM-mediated cold agglutinin hemolysis is uncommon. Anemia associated with a positive Coombs may result more from increased splenic sequestration than to direct hemolysis.

Rheumatoid Factors

Rheumatoid factors (RF) represent autoantibodies to the Fc portion of IgG. Most RF are IgM, although RF of all Ig classes have been described. RF, as detected by latex fixation, have been found in 20 to 60% (mean 33%) of patients with SLE [92]. While earlier observations suggested a negative correlation between a positive RF test and lupus nephritis, subsequent studies have failed to confirm this. While RF titers fluctuate little in patients with RA, they tend to both vary in titer and come and go in patients with SLE, to some extent in correlation with the activity of SLE. It is the author's opinion that there is no merit in testing for RF in patients with SLE.

Antiplatelet Antibodies

Antiplatelet antibodies demonstrable as platelet-bound IgG have been shown to be increased in virtually all SLE patients with thrombocytopenia [92]. While the serum antiplatelet antibodies in chronic ITP are IgG3, in SLE sera they are IgG1–4 [93, 94]. Serum antibody assays for antiplatelet antibodies generally, however, do not correlate well with the presence of thrombocytopenia. In contrast, all IgG subclasses are found bound to platelets (in patients with thrombocytopenia) in both SLE and ITP [95]. Testing for platelet-bound IgG may be helpful in evaluating SLE patients with thrombocytopenia. The presence of the antibody suggests an antibody-mediated thrombocytopenia, whereas an absence of the antibody suggests that thrombocytopenia is not due to an ITP antibody-mediated mechanism. The IgG bound to platelets mediates thrombobocytopenia by causing increased phagocytosis of opsonized platelets in the spleen.

Thrombocytopenia in a patient with SLE should also make one suspect the antiphospholipid antibody syndrome (APS) (see later).

Anti-Wbc Antibodies

Anti-white blood cell antibodies, especially antilymphocyte antibodies, have been noted in many SLE patients. This subject is reviewed in Chapter 36. Detection of these antibodies is performed primarily for research.

ANTIPHOSPHOLIPID ANTIBODIES

Antiphospholipid antibodies, such as lupus anticoagulants (LA) and anticardiolipin antibodies (aCL), are recognized causes of thromboembolic phenomenon, thrombocytopenia, and several adverse obstetrical outcomes. This disorder is referred to as the primary antiphospholipid antibody syndrome when these antibodies occur alone. It is called secondary antiphospholipid syndrome when they are found in association with systemic lupus erythematosus, other rheumatic diseases, and certain infections and drugs.

Four types of antiphospholipid antibodies (APA) have been described: (1) Antibodies that give a false-positive serologic test for syphilis (STS), (2) lupus anticoagulants, (3) anticardiolipin antibodies, and anti-β_2-glycoprotein 1 antibodies.

False-Positive Serologic Test for Syphilis

Some patients with SLE have a false-positive serologic test for syphilis. When patient sera contain anticardiolipin antibodies (see later), the false-positive STS occurs because the antigen used in the test is embedded in cardiolipin. As a result, a reaction against this molecule will be interpreted incorrectly as being directed against the treponemal antigen. STS should not be used to screen for APL because it has a low sensitivity and specificity [96].

Lupus Anticoagulants

Lupus anticoagulants are antibodies directed against plasma proteins (such as prothrombin or Beta-2-glycoprotein I) bound to anionic phospholipids [97–99]. The LA blocks *in vitro* assembly of the prothrombinase complex, resulting in a prolongation of *in vitro* clotting assays such as the activated partial thromboplastin time (aPTT), the dilute Russell viper venom time (dRVVT), the kaolin clotting time, and rarely the prothrombin

time. These abnormalities are not reversed when the patient's plasma is diluted 1:1 with normal platelet-free plasma, a procedure that will correct clotting disorders due to deficient clotting factors [97, 100]. Abnormal clotting test results can be largely reversed by incubation with a hexagonal phase phospholipid, which neutralizes the inhibitor [97, 100, 101]. Although these changes suggest impaired coagulation, patients with LA have a paradoxical increase in the frequency of arterial and venous thrombotic events [102, 103].

Anticardiolipin Antibodies

Anticardiolipin antibodies (aCL) react with proteins (e.g., β_2-glycoprotein 1 and annexin V) bound to anionic phospholipids, such as cardiolipin and phosphatidylserine. There is an approximate 85% concordance between the presence of a LA and aCL. In many cases, however, the LA is a separate population of antibodies from aCL [100, 101, 108]. Thus, testing should be performed for both LA and aCL if APS is clinically suspected. LA positivity incurs a somewhat greater risk for thrombosis than aCL.

Different immunoglobulin isotypes and subclasses are associated with aCL, including IgG, IgA, IgM, and IgG subclasses 1 to 4. Elevated levels of IgG aCL (particularly IgG2) incur a greater risk of thrombosis than other immunoglobulin isotypes [104].

IgA aCL is the most prevalent isotype in African-Americans [109]. The predominance of this isotype in combination with the low prevalence of significantly elevated levels of aCL may account for the low frequency of APS in these patients.

Anti-β_2 Glycoprotein I Antibodies

Anti-β2GP1 antibodies directly bind to β2GP1 as opposed to aCL, which frequently bind to a complex of anionic phospholipids and β2GPl. Antibodies to β_2-glycoprotein 1, a phospholipid-binding inhibitor of coagulation, are found in a large percentage of patients with primary or secondary APS [110]. Although antibodies to β_2-glycoprotein 1 are found commonly in those with other antiphospholipid antibodies, they are the sole antiphospholipid antibody found in approximately 11% of patients with APS [110].

Antiprothrombin Antibodies

Antiprothrombin antibodies have been described in association with both clotting and pulmonary hemorrhage [111].

Patients with antiphospholipid antibodies may also have antibodies directed against other proteins, including heparin/heparin sulfate, prothrombin, platelet-activating factor, tissue-type plasminogen activator, protein S, annexin IV and V, thromboplastin, oxidized low-density lipoproteins, thrombomodulin, and kininogen [112–122].

Prevalence of Antiphospholipid Antibodies

Although antiphospholipid antibodies are associated with a propensity for thrombosis and with various autoimmune disorders, they can sometimes be found in normal asymptomatic individuals as illustrated by the following observations.

- Normal individuals occasionally have elevated levels of either IgG or IgM aCL [123, 124]. In one study, for example, the prevalence was 5% on a first test but only 2% on retesting [124].
- Increased levels of IgG or IgM aCL have been observed in 12 to 52% of the elderly [123, 125].
- One study found that 40 of 499 normal blood donors had a positive LA test (frequently young women); however, only 3 had elevated levels of aCL [107].

Associated Disorders

Antiphospholipid antibodies have been noted in increased frequency in patients with SLE: approximately 31% of patients have a LA, 23 to 47% have an aCL, and 20% have antibodies to β_2-glycoprotein 1 [105, 126–128]. However, roughly 50% of patients with a LA have SLE [105, 108]. Antiphospholipid antibodies also occur with increased frequency (5–10%) in women with greater than three spontaneous recurrent abortions [106].

Both LA and aCL have also been found in patients with a variety of autoimmune and rheumatic diseases, including [105]:

- Hemolytic anemia
- Idiopathic thrombocytopenic purpura (up to 30%)
- Juvenile arthritis
- Rheumatoid arthritis (7 to 50%)
- Psoriatic arthritis (28%)
- Scleroderma (25%), especially with severe disease [129]
- Behcet's syndrome (20%)
- Sjogren's syndrome (25 to 42%)
- Mixed connective tissue disease (22%)
- Polymyositis and dermatomyositis
- Polymyalgia rheumatica (20%) [130]
- Osteoarthritis (less than 14%)
- Occasionally in gout and in multiple sclerosis
- Chronic discoid LE [131]

- Eosinophilia myalgia and toxic oil syndrome [132]
- Raynaud's phenomenon [133]

Antiphospholipid antibodies have also been noted in patients with infections and after the administration of certain drugs. These are usually IgM aCL antibodies, which may occasionally result in thrombotic events [105, 134]. Furthermore, the antibodies do not appear to have anti-β_2-glycoprotein 1 antibody activity [135]. The infections that have been associated with these antibodies include hepatitis A and C virus (see next section), mumps, bacterial septicemia, HIV infection, syphilis, HTLV-I, malaria, *Pneumocystis carinii*, infectious mononucleosis, and rubella. Among the drugs that have been implicated are phenothiazines (chlorpromazine), phenytoin, hydralazine, procainamide, quinidine, quinine, dilantin, interferon-α, amoxicillin, and propranolol [134, 136]. A discussion of the clinical manifestations of antiphospholipid antibodies is found in Chapters 39–41.

IMMUNOGLOBULINS

SLE is characterized by a polyclonal gammopathy. In fact, increased levels of Ig have been noted in up to 76% of patients [137]. Elevated levels tend to correlate with active disease. Elevations of IgG (including all four IgG subclasses), IgA, IgM, and IgE have been noted. Two series have suggested an increased frequency (3–4%) of IgA deficiency. Acquired hypogammaglobulinemia, especially of IgG subclasses, has rarely been noted, but should be suspected in patients with recurrent infections. The hypogamma IgG may relate to chronic immunosuppressive therapy.

IMMUNE COMPLEXES

SLE is considered to be the prototype for immune complex-mediated diseases. A number of methods have been developed for the detection of immune complexes in serum based on the (highly) variable biological and physical characteristics of these immune complexes. These methods include complement activation, C1q binding, rheumatoid factor binding, the Raji cell assay, conglutinin assay, assay with C3, and cryoprecipitation. This subject is discussed in depth in Chapter 14. While early results suggested good correlation with clinical activity in patients with SLE, especially lupus nephritis, subsequent studies showed highly variable results. These assays are therefore rarely employed nowadays.

COMPLEMENT

Considerable evidence shows that much of the pathology in patients with systemic lupus erythematosus can be attributed to immune complexes [138, 139] and, thereby, complement activation [138, 140]. These immune complexes may either form in the circulation and later deposit in tissues or form *in situ*. Immune complexes may cause tissue inflammation directly or through activation of the complement system. Complement activation causes the release of various mediators, promotes cell interaction, and ultimately results in inflammation. Evaluation of the complement system, which can serve as an indirect measure of the presence of immune complexes, often correlates with clinical aspects of SLE. Monitoring blood levels of complement may be useful in adjusting therapy for the patient.

Measurement of Complement

The complement system can be assessed by (1) the measurement of total hemolytic complement activity (CH50); (2) the immunochemical or hemolytic measurement of individual components; (3) measurements of complement fragments, activation-dependent neoepitopes, and complexes that arise from complement activation; and (4) the determination of complement metabolism. The total hemolytic complement level (CH50) represents the sum of all components of the system. By adding diluted serum to antibody-sensitized sheep erythrocytes and quantitating the amount of released hemoglobin, one can measure this level in units that represent the reciprocal of that dilution of serum that causes 50% of cells to lyse (i.e., CH50). A CH100 represents that dilution of serum that lyses 100% of sensitized cells; this measurement is not nearly as accurate as a CH50, which reflects actual hemolysis in a more linear fashion than a CH100 [141–145].

Separate complement components generally are measured by immunochemical means: radial immunodiffusion, electroimmunodiffusion, or nephelometry. However, such determinations yield no information about the functional biologic integrity or hemolytic potential of the components being measured. Such functional tests of complement components are rarely employed because of their difficulty in routine clinical assays.

When measuring CH50 or components, it is important to remember that some components are thermolabile. Serum stored at room temperature, even for a few days, is adequate for the immunochemical measurement of individual components as proteins (as, for instance, by immunodiffusion). However, it is essential to store samples (preferably EDTA plasma) as soon as possible

at –70°C when measurement of the hemolytic levels of individual components is desired. The CH50 will remain relatively stable for a few hours at room temperature or overnight at –20°C; however, samples are best stored at –70°C as soon as possible. Heating for 30 min at 56°C is also known to inactivate complement components and decrease/abolish CH50 activity.

These assays give but a glimpse of the dynamic state of the complement system. Serial values may be helpful in assessing this dynamic state: falling values suggest more catabolism (e.g., via immune complex fixation) than synthesis, whereas rising levels suggest more synthesis than catabolism is taking place.

Measurement of both the native components and the activation products of individual components is a way of assessing the catabolic state of the complement system without necessarily doing serial measurements. Activation products in EDTA plasma generally are measured by ELISA using monoclonal antibodies. However, the levels of complement activation factors can also be affected by binding to complement (fragment) receptors, degradation by serum proteases, and renal and hepatic clearance [142].

Complement metabolism is a better way of assessing the dynamic state (i.e., synthesis and catabolism) of individual complement components [146]. However, these studies are rarely performed because of the great difficulty both in isolating hemolytically and biologically active purified components and in maintaining their activity after radiolabeling. The liver is the primary source of synthesis of complement components, with the notable exception of C1q, which is probably produced primarily by macrophages [147]. A more complete discussion of complement abnormalities is found in Chapter 6.

ACUTE-PHASE REACTANTS

The acute-phase response is a major pathophysiologic phenomenon that accompanies inflammation [148, 149]. With this reaction, normal homeostatic mechanisms are replaced by new set points, which presumably contribute to defensive or adaptive capabilities. Focus on this phenomenon first occurred with the discovery of elevated serum concentrations of C-reactive protein (CRP) during the acute phase of pneumococcal pneumonia [150].

Despite its name, the acute phase response accompanies both acute and chronic inflammatory states. It can occur in association with a wide variety of disorders, including infection, trauma, infarction, inflammatory arthritides, and various neoplasms.

Acute-phase proteins are defined as those proteins whose plasma concentrations increase (positive acute-phase proteins) or decrease (negative acute-phase proteins) by at least 25% during inflammatory states [151]. These changes largely reflect their production by hepatocytes.

Increases in acute-phase proteins may vary from approximately 50% with ceruloplasmin and several complement components to 1000-fold for CRP and serum amyloid A. Other positive acute-phase proteins include fibrinogen, α_1-antitrypsin, haptoglobin, and ferritin, whereas negative reactants include albumin, transferrin, and transthyretin.

Clinical Relevance of Acute-Phase Reactants

Despite the lack of diagnostic specificity, the measurement of serum levels of acute-phase proteins is useful because it may reflect the presence and intensity of an inflammatory process. Currently, the most widely used indicators of the acute-phase protein response are the erythrocyte sedimentation rate (ESR) and CRP. The rate at which erythrocytes fall through plasma, the ESR, depends largely on the plasma concentration of fibrinogen [152].

These tests may be useful both diagnostically (1) in helping to differentiate inflammatory from noninflammatory conditions and (2) in patient management because they may generally reflect the response to and need for therapeutic intervention.

Comparison of ESR and CRP

Compared to the measurement of CRP, the ESR has the advantages of familiarity, simplicity, and an abundant literature compiled over the past seven decades. However, the ESR has a number of disadvantages compared to the CRP determination.

1. The ESR is only an indirect measurement of plasma acute-phase protein concentrations; it can be influenced greatly by the size, shape, and number of red cells, as well as by other plasma constituents, such as immunoglobulins. Thus, results may be imprecise and sometimes misleading.
2. As a patient's condition worsens or improves, the ESR changes relatively slowly; by comparison, CRP concentrations change rapidly.
3. The range of abnormal values for CRP is greater than for the ESR, with accompanying clinical implications: as an example, among patients with CRP concentrations greater than 10 mg/dl (100 mg/liter), 80 to 85% have bacterial infections [151].

4. Normal values for the ESR are slightly higher among women than men.

Population studies reveal a skewed, rather than normal, distribution of the plasma CRP concentration. Although most normal subjects have CRP concentrations of 0.2 mg/dl (2 mg/liter) or less, some individuals have concentrations as high as 1.0 mg/dl (10 mg/liter). These higher values have been attributed to a modest stimulation by minimally apparent low-grade processes such as gingivitis or trivial injury. This observation has led to the suggestion that values less than 1.0 mg/dl (10 mg/liter) should be regarded as clinically insignificant [151].

Information drawn from the third national health and nutrition evaluation survey indicates that the upper reference limits in a representative sample of the population vary with age, gender, and race [153]. The following formulas provide values for CRP levels that closely approximate the 95th percentile for subjects without identified inflammatory conditions:

- Females: For those 25 to 70 years of age, the upper limit of reference range = (age/65) + 0.7 mg/dl.
- Males: For those 25 to 70 years of age, the upper limit = (age/65) + 0.1 mg/dl.

For most clinical purposes, CRP values less than 0.1 or 0.2 mg/dl can be regarded as normal and values over 1.0 as indicating clinically significant inflammation. However, although CRP is a sensitive reflector of inflammation, it is not specific. Values between 0.2 and 1.0 mg/dl may reflect minor degrees of inflammation, but may also reflect obesity, cigarette smoking, diabetes mellitus, or other noninflammatory causes of modest elevations in the CRP.

Rationale for Employing Multiple Tests

Although elevations in multiple components of the acute-phase response commonly occur together, not all happen uniformly in all patients. Discordance between concentrations of different acute-phase proteins is common; some may be elevated whereas others are not. These variations may be explained by differences in the production of specific cytokines or their modulators in different diseases [150].

Discrepancies between ESR and CRP are found with some frequency. An elevated ESR observed together with a normal CRP is often a false-positive value for the ESR; this may reflect the effects of blood constituents that are not related to inflammation but that can influence the ESR. However, this conclusion is not always valid. As an example, the ESR may be markedly elevated in patients with active SLE, while the CRP is normal.

As there undoubtedly are a number of other clinical situations in which similar discrepancies occur, there probably is no single best laboratory test to reflect inflammation. Currently, the optimal use of acute-phase protein measurements may be to obtain several measurements rather than a single test, the results of which are interpreted in light of the clinical context and the considerations indicated previously.

ESR can be high with no obvious clinical activity and normal with active disease [154]. SLE represents an exception to the generalization that CRP concentrations correlate with the extent and severity of inflammation in patients with rheumatic disorders. Many patients with active SLE do not have elevated CRP concentrations, although they may have marked increases in CRP concentrations during bacterial infection [155]. This finding can be applied to the differential diagnosis of fever in patients with SLE, but one must remember that CRP concentrations are high in patients with active lupus serositis [156] or chronic synovitis [157].

Serum amyloid A levels also tend to be lower in SLE than in other chronic inflammatory disorders, which may explain why secondary amyloidosis is unusual in this disease [158].

HEMATOLOGICAL ABNORMALITIES

Abnormalities of the formed elements of the blood, and of the clotting, fibrinolytic, and related systems, are very common in SLE. The major clinical manifestations are anemia, leucopoenia, and thrombocytopenia. Thus whenever the author sees a patient with SLE he tends to order a CBC.

Anemia

Anemia is a frequent occurrence in SLE, affecting most patients at some time in the course of their disease. Multiple mechanisms contribute, including inflammation, renal insufficiency, blood loss, dietary insufficiency, medications, and immune hemolysis [159–165].

Chronic Inflammation

The most frequent cause of anemia in SLE is suppressed erythropoiesis from chronic inflammation (anemia of chronic disease) and/or renal insufficiency [162, 163]. The anemia is normocytic and normochromic with a relatively low reticulocyte count. Although serum iron levels may be reduced, bone marrow stores are adequate and the serum ferritin concentration is elevated.

As in other chronic illnesses, serum erythropoietin levels may be inappropriately low for the degree of

anemia. However, some of the apparent reduction in serum erythropoietin may be spurious [166].

Blood Loss

Anemia may reflect acute or chronic blood loss from the gastrointestinal tract, usually secondary to medications (nonsteroidal anti-inflammatory drugs or steroids), or may be due to excessive menstrual bleeding. Iron deficiency anemia is not uncommon, especially among teenagers or young women.

Red Cell Aplasia

Red cell aplasia, probably due to antibodies directed against bone marrow erythroblasts, has been rarely observed [163, 164]. This form of anemia may respond to steroids, although cyclophosphamide and cyclosporine have been employed successfully. Even rarer are isolated case reports of aplastic anemia that is presumably mediated by autoantibodies against bone marrow precursors; immunosuppressive therapy may also be effective in this setting [167–169].

In addition, bone marrow suppression can also be induced by medications, including antimalarials and immunosuppressive drugs.

Autoimmune Hemolytic Anemia

Overt autoimmune hemolytic anemia (AIHA), characterized by an elevated reticulocyte count, low haptoglobin levels, increased indirect bilirubin concentration, and a positive direct Coombs' test, has been noted in approximately 10% of patients with SLE [160–162, 170]. Other patients have a positive Coombs' test without evidence of overt hemolysis. The presence of both immunoglobulin and complement on the red cell is usually associated with some degree of hemolysis, whereas the presence of complement alone (e.g., C3 and/or C4) is often not associated with hemolysis [159–162]. The antibodies are "warm," IgG, and are directed against Rh determinants. IgM-mediated cold agglutinin hemolysis is uncommon.

Lupus has also been associated with a thrombotic microangiopathic hemolytic anemia [171]. Most affected patients also have thrombocytopenia, kidney involvement, fever, and neurologic symptoms, producing a picture of thrombotic thrombocytopenic purpura; some do not have fever or neurologic disease, producing a pattern of hemolytic–uremic syndrome. The pathogenesis of this syndrome is not completely understood. In one report of 4 patients plus 24 others identified from a literature review, antiphospholipid antibodies were searched for in 8 and found in 5 [171].

Leukopenia

Leucopoenia is common in SLE and may reflect disease activity. A white blood cell count of less than 4500/μl has been noted in approximately 50% of patients, especially those with active disease [161, 162], whereas lymphocytopenia occurs in approximately 20% [161]. In comparison, a white blood cell count below 4000/μl (the ARA criteria) occurs in only 15 to 20% of patients [161, 172].

Leucopoenia in patients with SLE can result from immune mechanisms, medications (e.g., cyclophosphamide or azathioprine), bone marrow dysfunction, or hypersplenism [161, 162, 172]. Functional defects of neutrophils have also been noted. They are thought to be induced by immune abnormalities (e.g., immune complexes, inhibition of complement-derived chemotactic factors) and/or medications (e.g., corticosteroids) [173, 174].

Although leucopoenia is more common, leukocytosis (mostly granulocytes) can occur in SLE. It is usually due to infection or to the use of corticosteroids (in high doses) [175], but may be seen during acute exacerbations of SLE. A shift of granulocytes to more immature forms (a "left" shift) suggests infection.

White cell constituents other than neutrophils can also be affected in SLE.

1. Lymphocytopenia (less than 1500 cells/μl), especially involving suppressor T cells, has been observed in 20 to 75% of patients, particularly during active disease [159–161, 176]. This finding is strongly associated with IgM, cold reactive, complement fixing, and presumably cytotoxic antilymphocyte antibodies. In one study, for example, these antibodies were noted in 26 of 29 patients with SLE; the antibody titer correlated directly with the degree of lymphopenia. Another potential mechanism of lymphopenia is increased apoptosis, as reflected by the increased expression of Fas antigen on T cells [177].
2. Steroid therapy may result in low absolute eosinophil and monocyte counts [178].
3. The number of basophils may also be decreased in SLE, particularly during active disease [179]. Basophil degranulation with release of platelet-activating factor and other mediators may play a role in immune complex deposition and vascular permeability.

Thrombocytopenia

Mild thrombocytopenia (platelet counts between 100,000 and 150,000/μl) have been noted in 25 to 50% of patients, whereas counts of less than 50,000/μl occur in only 10% [159, 161, 162, 172]. The major mechanism

is increased platelet destruction by antiplatelet antibodies, leading to phagocytosis via their Fc receptors in the spleen, as in idiopathic thrombocytopenic purpura (ITP) [180]. Other important mechanisms in selected patients include bone marrow suppression by immunosuppressive drugs (other than corticosteroids) and increased consumption due to a thrombotic microangiopathy [171] or the antiphospholipid antibody syndrome.

ITP may be the first sign of SLE, followed by other symptoms as long as many years later. It has been estimated that 3 to 15% of patients with apparently isolated ITP go on to develop SLE [181]. Evan's syndrome, i.e., both autoimmune thrombocytopenia and autoimmune hemolytic anemia, may also precede the onset of SLE.

Splenectomy in ITP was originally thought to predispose to the development of SLE [182]. However, this hypothesis was refuted in subsequent studies [183].

Antibodies to Clotting Factors

Antibodies to a number of clotting factors, including VIII, IX, XI, XII, and XIII, have been noted in patients with SLE [159, 160, 172]. These antibodies may not only cause abnormalities of *in vitro* coagulation tests, but may also cause bleeding. Much more common and more important are antiphospholipid antibodies, the presence of which has been associated with a prolongation of the partial thromboplastin time and an increased risk of arterial and venous thrombosis, thrombocytopenia, and fetal loss.

RENAL FUNCTION

This subject is covered in Chapter 30. The author requests a routine urinanlysis most times when lupus patients are seen. In a patient without a history of renal disease, it should be done at least annually. For those patients with renal disease, routine urinanlysis should be done on a more routine basis, the frequency depending on the severity of the renal disease.

Likewise, a serum creatinine should be done at least on an annual basis. In someone with renal disease, it should be measured more frequently depending on the severity of the disease.

The author tends to do periodic GFR (usually as creatinine clearances) in patients with renal disease to monitor their response to therapy as well as progression.

For patients with proteinuria, especially if they are clinically nephritic, the author monitors periodic 24-h urine for protein, although measuring and monitoring serum albumin is easier to do and is just as useful.

SYNOVIAL FLUID

Joint effusions are generally infrequent and small in volume. The synovial fluid viscosity is generally normal and mucin clots are normal [184]. The white blood cell count is usually under 2000 cells/mm^3 and is infrequently over 10,000. Most of the white blood cells tend to be mononuclear. Total protein tends to be elevated, but complement levels are usually depressed markedly, even more so than in blood, suggesting local activation of the complement system (the same is also found in rheumatoid arthritis). Sugar levels tend to be normal, in contrast to rheumatoid arthritis where they are often low. LE cells can be found, but are not diagnostic. ANAs reflect diffusion from plasma.

PLEURAL FLUID

Pleural effusion in SLE is a mild exudate characterized by an elevation in pleural fluid LDH but not signs of marked inflammation. The findings differ from those in other conditions, particularly rheumatoid arthritis.

- The total white cell count (with a predominance of either lymphocytes or polymorphonuclear cells) is lower in lupus-related effusions [185, 186]. However, because there is substantial overlap, the white count in an individual patient cannot be used to establish the diagnosis.
- Pleural glucose levels in lupus effusions are slightly lower than serum blood levels; by comparison, pleural glucose levels in rheumatoid effusions are reduced significantly [185].
- Low complement levels characterize lupus and rheumatoid arthritis effusions.
- The protein concentration tends to be lower in lupus effusions than in patients with RA, reflecting their transudative as well as slight inflammatory nature.

Although the presence of rheumatoid factor or ANA in pleural fluid suggests RA and SLE, respectively, these findings provide no additional diagnostic information beyond that obtained from the measurement of these autoantibodies in serum and should therefore not be performed. Additional causes of pleural effusions, such as infection, congestive heart failure, and uremia, must also be excluded.

PERICARDIAL FLUID

The pericardial fluid is a fibrinous exudate or transudate that may contain antinuclear antibodies, LE cells,

low complement levels, and immune complexes similar to those seen in lupus pleural effusions [187]. The glucose concentration is normal and the protein concentration is variable, being low with a transudate and elevated with an exudate. The pericardium may reveal foci of inflammatory lesions with immune complexes. There is usually a predominance of mononuclear cells, but scarring may be the primary finding in healed disease.

CEREBROSPINAL FLUID

Routine evaluation of the cerebrospinal fluid (CSF) is usually normal in patients with CNS lupus, except in cases of aseptic meningitis and transverse myelitis. Some reports, however, have noted some pleocytosis (usually mononuclear cells), as well as immunologic abnormalities, including elevated levels of total protein, anti-DNA antibodies, IgG, oligoclonal banding, immune complexes, and interleukin-6, which may roughly correlate with neuropsychiatric disease [188–190]. Other antibrain antibodies have been detected, but these assays should be considered strictly research. While considered useful in one paper, measuring complement levels has been shown not to be of any use clinically. CSF examination is performed primarily to exclude infection and/or bleeding.

LUPUS PREGNANCY

NORMAL AND ABNORMAL PREGNANCY

Definition of Pregnancy

Normal pregnancy differs from nonpregnant normality in signs, symptoms, and hormonal and imaging tests. A woman has *presumptive* pregnancy when she has nausea, disturbances in urination, fatigue, and cessation of menses. Later she will have enlargement of the abdomen, changes in the cervix and uterus, and positive tests for human chorionic gonadotropin (hCG). *Conclusive* signs of pregnancy are the identification of fetal heart action on ultrasound, recognition of the embryo and fetus at any time in pregnancy by ultrasound (vaginal ultrasound in early pregnancy), and perception of fetal movements.

False-positive diagnosis of pregnancy occurs with tumors of the pelvis or uterus (myomas, adenomyosis). A false-positive elevated level of hCG occurs with an hCG-secreting tumor, self-injection of hCG, and systemic lupus erythematosus (SLE) itself [1]. Hyperprolactinemia due to drug induction (e.g., phenothiazines), pituitary tumor, or lymphocytic hypophysitis may simulate pregnancy by causing amenorrhea; hyperprolactinemia also occurs in SLE patients. Amenorrhea with normal hCG and normal prolactin may result from anovulation, emotional disorders, or menopause. Imaginary pregnancy, or pseudocyesis, is usually seen in women nearing menopause or in women with an intense desire to become pregnant. Patients develop typical subjective symptoms, increased abdominal size (due to fat deposition or increased bowel gas), breast changes, and morning sickness. The delusion of pregnancy may persist for years in emotionally distressed women [2].

Special Issues

Ectopic Pregnancy

Ectopic (extrauterine) pregnancy occurs in 1% of all pregnancies; of these, more than 95% are in the oviduct. Mechanical causes of ectopic pregnancy include salpingitis, adhesions, and other anatomic abnormalities. Functional causes include external migration of the ovum, uterine reflux, and altered tube mobility, especially in the setting of progestin-only contraceptives [3] and possibly nonsteroidal anti-inflammatory drugs (NSAID) [4]. Ectopic pregnancy is the second leading cause of maternal morbidity in the United States and the leading cause of maternal morbidity in the first trimester [5]. Signs and symptoms include pelvic pain, amenorrhea with spotting, a hCG value that is lower than expected, and confirmation by abdominal and/or vaginal sonography. Treatment is surgical, often requiring removal of the oviduct [3].

Twin Pregnancy

Dizygotic twin pregnancy results from fertilization of two separate ova; monozygotic twin pregnancy, which occurs one-third as often, is the result of a division of a single fertilized ovum. Diagnosis is almost always based

on ultrasound. With the use of assisted reproductive techniques, rates of twinning have increased. Twin pregnancies have greater than normal rates of fetal malformation, restricted fetal growth, preterm delivery, and spontaneous abortion. Preterm delivery is the major reason for the increased risk of neonatal death and morbidity in twins.

On occasion, one twin succumbs early in pregnancy, but pregnancy continues with one living fetus. At delivery the dead fetus and placenta may be compressed (*fetus compressus*) or flattened (*fetus papyraceous*). Disseminated intravascular coagulation and hypofibrinogenemia may be complications. Incidence of twin resorption after 20 weeks gestation is about 5%, with high likelihood for continuation of the pregnancy and viability of the remaining twin [6, 7].

Pregnancy at the Extremes of Reproductive Life

The mean age of menarche is now 12.8 years [8]. In the older teenage population, obstetrical risks are related to poverty, inadequate nutrition, and poor health before pregnancy. For teenagers 15 years old and less, complications are also related to age. The major risks are preeclampsia, low birth weight infants, and poor neonatal outcome [9].

Maternal complications of women over 35 include chronic and pregnancy-induced hypertension, diabetes, thrombosis, and postpartum pulmonary edema. Late pregnancy bleeding is increased. The risk of Cesarean section doubles after age 35. The maternal mortality rate for this group is increased fourfold because of preexisting medical conditions. The risk of ectopic pregnancy increases with age as well.

Fetal complications of women over 35 include macrosomia, congenital malformations and chromosomal abnormalities, spontaneous abortion, stillbirths, preterm delivery, and restricted fetal growth. Perinatal and infant mortality is also somewhat higher [10].

Other Special Problems

While the dates of conception (the start of pregnancy) may be easily ascertained, the precise point at which a woman is no longer *postpartum* is not at all well defined. The *puerperium* is the period of confinement during and just after birth. By popular use, this term describes the 6 weeks following delivery during which uterine involution occurs and the female reproductive tract returns anatomically to a nonpregnant state. All body systems do not return to the prepregnancy status during this period, however. For example, most women return to their prepregnancy weight 6 months after delivery. Menses may return in 6 to 8 weeks in the nonlactating woman, but ovulation is less frequent in women who breast feed. *Postpartum* depression, felt to be intrinsically related to hormonal shifts of pregnancy, is defined as such if it begins up to 6 months after childbirth [11]. Bone recovery may take up to 2 years. Return of the immune system to its prepregnancy state is not defined.

Physiologic Adaptations in Pregnancy Influencing the Course of Lupus

Gestational changes relevant to lupus fall into four major groups: (1) volume and blood pressure (leading to cardiac, renal, or hypertensive complications), (2) coagulation control mechanisms (thrombocytopenias and circulating anticoagulants), (3) immunologic (complement kinetics, immune complexes, humoral and cellular immunity), and (4) hormonal [12]. These changes may alter the interpretation of phenomena otherwise attributed to SLE or may make an SLE patient unusually susceptible to complications of pregnancy (Table 1).

Volume and Blood Pressure Changes

Lupus patients with renal, vascular, or cardiac compromise may not be able to tolerate the increase in intravascular volume (about 30%) that occurs during normal pregnancy.

TABLE 1 Phenomena of Pregnancy Influencing the Interpretation or Management of Lupus

Normal pregnancy change	Effect on management of lupus
Hematologic	
Hemodilutional anemia	Suggests disease exacerbation
Decreased platelet survival	Worsens disease-induced thrombocytopenia
Increased fibrinogen	Suggests inflammation
Increased factor VIII	Suggests vasculitis
Immunologic	
Immune complexes present	Suggests disease exacerbation
Increased complement	Modifies interpretation of disease-induced hypocomplementemia
Endocrine	
Increased cortisol	?Induces remission, decreased cortisol *postpartum* results in flare
High estrogen	?Worsens SLE
Renal	
Increased clearance	If clearance does not increase, fluid overload occurs; preeclampsia *versus* disease exacerbation may be hard to distinguish
Joints	
Ligamentous loosening	Effusion mimics active arthritis

Thrombocytopenia and Coagulation Factors

In normal pregnancy, platelet survival decreases and plasma levels of fibrinogen and factors V, VIII, and X increase, as does von Willebrand factor, platelet activation inhibitor-1, thrombin–antithrombin complex, prothrombin fragment 1 and 2, d-dimer, and tissue plasminogen activator. Free and total protein S and possibly antithrombin III decrease. Normally, platelet production increases, usually resulting in no net change in the peripheral platelet count, but thrombocytopenia may occur even in uncomplicated pregnancy [13]. In pathologic pregnancy, intravascular coagulation systems may be activated [14]. Thus thrombocytopenia accompanying lupus may be difficult to interpret during pregnancy.

Pregnancy-Induced Immunologic Changes

In pregnancy, cell-mediated immunity is generally depressed, as reflected by abnormal lymphocyte stimulation and other functional tests, decreased T-cell–B-cell ratios, increased suppressor–helper T-cell ratios, and decreased lymphocyte–monocyte ratios [15]. Cutaneous and humoral immune responses, including responses to specific microbial antigens, are selectively depressed, as are cellular measures of inflammation, such as leukocyte chemotaxis and adhesion. Autoantibodies occur in apparently normal young women, particularly in those with complicated gestations, but they do not appear to be specifically induced by pregnancy [16–18]. The number of immunoglobulin-secreting cells increases, inflammatory responses decrease, some plasma proteins increase and others decrease, and circulating immune complexes are often present.

Pregnancy-specific proteins such as α-fetoprotein, β_1-glycoprotein, α_2-macroglobulin, and others suppress lymphocyte function, as do increases in endogenous corticosteroids. Although their roles are not completely understood, interleukins-1 and -3 (IL-1, IL-3), tumor necrosis factor α (TNF-α), interferon-γ (IFN-γ), granulocyte–macrophage colony-stimulating factor (GM-CSF), and other cytokines may be critical in sustaining pregnancy [19]. IL-3, for instance, is diminished in women with repeated pregnancy loss [20]. This is relevant in that the production or metabolism of some cytokines is thought to be abnormal in rheumatic illness.

In SLE, circulating and local levels of cytokines, including IL-1, IL-2, and IFN-γ, may be constitutively or secondarily abnormal [21]. In SLE pregnancy, T-cell function may paradoxically normalize.

In normal pregnancy, total C3, C4, and CH_{50} are usually similar or raised relative to nonpregnant levels. These increments likely reflect an increase in complement synthesis rather than a decrease in activation because the measurement of some classic pathway activation products (C3a, C4a, C5a, but not of the C1s–C1 inhibitor complex) suggests that low-grade classic pathway activation, i.e., increased degradation, occurs in normal pregnancy. Disease-associated decreased complement synthesis may not return to normal during pregnancy [22, 23]. Changes induced by gestation can either falsely normalize (if synthesis does increase) or exaggerate (if synthesis does not increase) disease-related hypocomplementemia. In a mouse model, complement activation *in situ* in the placenta must be inhibited for pregnancy to progress normally [24].

Pregnancy-Induced Hormonal Changes

Estrogen, prolactin, and other hormone levels rise in pregnancy (Fig. 1) [25]. Estrogens upregulate and androgens downregulate T-cell responses and immunoglobulin synthesis [26]. IL-1, IL-2, IL-6, and TNF-α can be regulated by sex hormones. How or if these changes affect lupus in a pregnant woman is unknown.

Non-SLE Pregnancy Complications: Maternal

Hypertensive Disorders: Preeclampsia, Eclampsia, Pregnancy-Induced Hypertension, HELLP Syndrome

Hypertension in pregnancy may have several presentations. The impact of hypertension may be negligible or severe.

Pregnancy-induced hypertension is defined by a blood pressure of 140/90 that develops as a consequence of pregnancy and that regresses *postpartum*. It may include proteinuria, edema, proteinuria, and convulsions.

Coincidental hypertension refers to chronic hypertension that antedates pregnancy or persists *postpartum*. Chronic hypertension is one of the most common medical complications of pregnancy. Risks of coincidental hypertension include preeclampsia, eclampsia, and *abruptio placentae*. The fetus is at risk of growth restriction and death. Underlying hypertension that is worsened by pregnancy, including preeclampsia and/or eclampsia, is termed *pregnancy-aggravated hypertension*. It usually occurs after 24 weeks gestation. Preeclampsia in a chronic hypertensive patient is termed superimposed preeclampsia and is usually severe, developing earlier and often accompanied by fetal growth restriction.

Transient hypertension develops after the middle trimester of pregnancy. It is characterized by mild

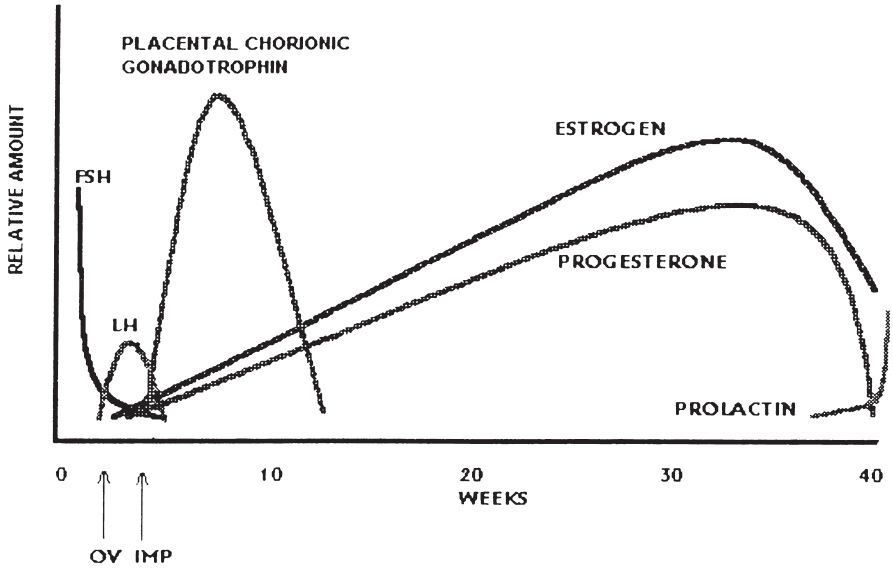

FIGURE 1 Hormonal changes of pregnancy. The pituitary (FSH, LH) controls early pregnancy and lactation (prolactin). Placental hormones (chorionic gonadotropin) are dominant early after implantation, and ovarian hormones (estrogen, progesterone) are dominant in late pregnancy. Ovulation (OV) occurs 2 weeks after the last menstrual period, implantation (IMP) at 3 weeks.

TABLE 2 Common Pregnancy Complications Unrelated to SLE

Complication	Clinical manifestations
Preeclampsia, eclampsia	Proteinuria, hypertension, edema, hyperuricemia, thrombocytopenia, renal insufficiency, abdominal pain, encephalopathy, convulsion
Pregnancy-induced hypertension	Hypertension, proteinuria, edema, renal insufficiency
HELLP syndrome	Hemolysis, elevated liver enzymes, thrombocytopenia (low platelets), abdominal pain, hepatic failure
Thrombocytopenia	Thrombocytopenia
Erythema nodosum gravidarum	Erythema nodosum, leukocytoclastic vasculitis
Chorea gravidarum	Chorea
Herpes gestationis	Pruritic skin rash superficially similar to discoid lupus, IgG and complement at dermal–epidermal junction

elevations of blood pressure that do not compromise the pregnancy. It usually regresses *postpartum* but may return in subsequent gestations. By definition, transient hypertension is diagnosed retrospectively [27, 28].

Preeclampsia, also known as toxemia, is the condition in which an apparently normal woman develops, usually late in pregnancy, hypertension, proteinuria, edema, and hyperuricemia. Untreated, preeclampsia can progress to seizures, in which case the syndrome is named *eclampsia*. Patients with advanced preeclampsia appear systemically ill. They may be vasoconstricted, diaphoretic, and encephalopathic. They may develop other visceral disease, e.g., hepatic infarction or congestive heart failure. Thombocytopenia, often severe, is common. Complement levels may be low. In its eclamptic phase, preeclampsia may be lethal. Antihypertensives, sedatives, and delivery are the cornerstones of treatment.

Preeclampsia can be confused with active SLE. In both preeclampsia and SLE, the patient feels generally ill. Urinary protein rises rapidly a 24-h excretion of 2 to 25 g is common. A patient may go from normal to nephrotic range proteinuria within days. In a preeclamptic lupus patient, proteinuria, abdominal pain, neurologic symptoms, and thrombocytopenia may be interpreted correctly or incorrectly as active lupus.

The acronym of the *HELLP syndrome* stands for *h*emolysis, *e*levated *l*iver enzymes, *l*ow *p*latelets. Experts in this field disagree about the relationship between the HELLP syndrome and preeclampsia. Both occur in late pregnancy and both are associated with hypertension, thrombocytopenia, and liver abnormalities. Patients with this syndrome suffer prominent hepatic enzyme abnormalities (AST and ALT often in the thousands), fever, hepatic pain, and encephalopathy. Often they are very ill. The thrombocytopenia can be life-threatening. As in preeclampsia, fetal and, in severe cases, maternal death may occur. The HELLP syndrome may worsen *postpartum* for several weeks. Some have suggested that

severe preeclampsia and/or the HELLP syndrome is especially frequent in patients with lupus and antiphospholipid syndrome, but detailed epidemiologic studies have not yet been done [29]. (An association of antiphospholipid antibody with thrombotic microangiopathic hemolytic anemia is generally accepted.) Short of ending the pregnancy and providing general supportive care, there is no effective treatment. Cases of HELLP syndrome that continued after delivery have resolved with plasmapheresis [30].

Thrombocytopenia (Anemia, Leukocytosis)

Normal pregnant women become modestly anemic (hematocrit approximately 33) in the third trimester. The apparent lowered blood count is due to hemodilution as the plasma volume increases. Modest leukocytosis may occur, particularly near the normal end of pregnancy and not be meaningful. More problematic is the regular occurrence of thrombocytopenia in late normal pregnancy. This happens in approximately 8% of normal women. Usually of trivial importance, it may reach levels in which hemorrhage is threatened. It self-corrects upon delivery and usually needs no specific treatment. Evaluation for other causes of thrombocytopenia may be necessary.

Hypercoagulability

Pregnancy is associated with increased intravascular coagulation [31]. Pregnancy induces increases in concentrations of the coagulation factors I (fibrinogen), II (prothrombin), VII, VIII, IX, and X. Protein S levels decrease, and the fibrinolytic system is inhibited in the third trimester [32]. As a result, and coupled with increased venous stasis, venous compression by the gravid uterus, and bed rest, the risk of venous thromboembolism is increased five times higher in pregnancy, especially in the third trimester and immediately postpartum. Particularly after a difficult labor, pelvic thrombophlebitis and pulmonary embolization are feared complications. In pelvic thrombophlebitis, clinical indicators in the legs do not occur. Pelvic discomfort and persistent fever within the first few days following delivery are the most reliable symptoms. In contrast, the risks of both cerebral infarction and intracerebral hemorrhage are reported to be increased in the 6 weeks *after* delivery but not during pregnancy itself [33]. "Silent" deficiencies in antithrombin III, protein C, protein S, and the presence of the factor V_{Leiden} mutation all add to the risk of thrombosis in pregnancy [34, 35]. Procoagulant states other than APS also predispose women to recurrent fetal loss, including factor V Leiden, prothrombin 20210 mutation, antithrombin III, and heritable deficiencies of protein C and protein S [36]. Hyperhomocysteinemia due to the C677T MTHFR (homozygous) genotype has resulted in placental thrombosis with stillbirth [37]. Any of these in combination with aPL may increase risk in an additive manner. A recent case report, for example, describes a patient with antiphospholipid and anti-protein S antibodies, factor V Leiden, and recurrent thromboses and abortion [38]. The presence of antiphospholipid antibody may impose an additional risk on pregnant patients.

Increased indicators of platelet activation, prothrombin fragments 1 and 2, and d-dimer all suggest low-grade activation of the coagulation system in normal pregnancy. This seldom is clinically evident, but in cases of amniotic fluid embolization, dead fetus, or retained placenta or fetus, lethal disseminated intravascular coagulation may occur.

Cardiac Disease

Heart disease complicates up to 1% of pregnancies. Previously, rheumatic heart disease was most common but now *congenital heart lesions* constitute at least half of all heart disease encountered in pregnancy [39]. The spectrum of heart disease in lupus pregnancy includes surgically corrected heart disease, valve disease, septal defects, cyanotic heart disease, and pulmonary hypertension. In SLE patients, Libman–Sacks endocarditis is a risk. *Peripartum cardiomyopathy* may occur (during or shortly after labor), often with no apparent etiology. Prognosis is generally poor [40].

Ischemic heart disease is a relatively rare complication of pregnancy, usually associated with classic risk factors but occasionally associated with the antiphospholipid syndrome [41]. Prognosis for a myocardial infarction during the course of pregnancy itself is serious, with 40% mortality in the third trimester. The advisability of undertaking pregnancy after a myocardial infarction is unclear [42].

Diabetes Mellitus

Diabetes during pregnancy may be preexisting or may develop during the course of gestation. A standard classification scheme aids in diagnosis and treatment. *Classes A_1 and A_2* are gestational in onset and are treated with diet alone or diet with insulin, depending on the fasting and 2-h postprandial glucose. *Classes B, C, D, F, R, and H* represent diabetes that predates pregnancy. Classification depends on age of onset, duration of disease, and presence of associated complications. All are treated with insulin and diet [43].

Gestational diabetes is usually a disorder of late pregnancy. Hyperglycemia during the first trimester

reflects overt or preexisting diabetes. Risk factors for a mother to develop gestational diabetes include age over 30 years, history of a prior macrosomic infant, obesity, hypertension, and glucosuria. Screening is with a 1-h (50 g) glucose tolerance test done between 24 and 28 weeks. A plasma value of greater than 140 mg/dl at 1 h indicates the need for a 3-h, 100-g glucose tolerance test [44].

Preexisting, overt diabetes has a more significant impact on pregnancy outcome. The likelihood of successful outcome is related to the degree of underlying maternal cardiovascular or renal disease. Effects on the fetus include spontaneous abortion, malformation, unexplained fetal demise, oligohydramnios, neonatal death and morbidity, respiratory distress, hypoglycemia, hypocalcemia, hyperbilirubinemia, cardiac hypertrophy, long-term cognitive developmental abnormalities, and altered fetal growth. Maternal effects include diabetic nephropathy, retinopathy and neuropathy, preeclampsia, ketoacidosis, and predisposition to infection [45].

Erythema Nodosum Gravidarum, Herpes Gestationis, and Other Rare Complications

Rashes of pregnancy mimic rashes of rheumatic disease and may suggest lupus activation. *Erythema nodosum gravidarum* in clinical appearance, evolution, and histology is identical to erythema nodosum occurring in women who are not pregnant. It is a legitimate question whether this entity is a coincidental appearance of an otherwise common disease. Evidence supporting pregnancy as a specific trigger of erythema nodosum is recurrence in sequential pregnancies. Usually mild, it requires little or no treatment. If treatment is necessary, aspirin or a low-dose steroid for a brief period is sufficient. *Leukocytoclastic vasculitis* in a pregnant woman differs in no important way from leukocytoclastic vasculitis in a woman who is not pregnant; treatment in most cases is optional.

Herpes gestationis is an immunological illness of uncertain cause. It causes a pruritic rash, usually on the proximal extremities. The rash may be extensive. Clinically recognizable by an experienced physician, it resembles discoid lupus erythematosus and may confuse persons who have not seen it before. On biopsy, herpes gestationis demonstrates immunoglobulin deposits at the dermal–epidermal junction, a further point of confusion. These deposits result from antibody directed at the 180-kDa extracellular domain of the bullous pemphigoid antigen of the basement membrane zone. The antibody is strikingly IgG4, which can be identified by a blood or immunofluorescence test. Pathologists unaware of this rare illness may wrongly interpret dermal–epidermal deposits as being indicative of lupus. There is no satisfactory treatment; the condition disappears when pregnancy ends. It recurs with subsequent pregnancies. In one report, a patient had *chronic* herpes gestationis in association with antiphospholipid antibody syndrome. The patient did not respond to corticosteroid, but both conditions responded well to cyclophosphamide administered *postpartum* [46].

Liver Disease in Pregnancy

Many liver conditions induced by pregnancy disappear following delivery. *Intrahepatic cholestasis* of pregnancy, characterized by cholestasis and/or icterus, usually occurs late in pregnancy and is likely stimulated by the high estrogen concentrations in susceptible individuals [47]. *Acute fatty liver of pregnancy* is a rare (1 in 10,000 pregnancies) complication of pregnancy that may be fatal for both mother and fetus [48]. Gross examination of the liver in fatal cases reveals a small soft yellow greasy organ, with swollen hepatocytes filled with microvesicular fat and minimal hepatocellular necrosis. The pathogenesis is unknown. Mean gestational age at onset is 27.5 weeks. It is more common in nulliparous women, women with a male fetus, and women with multifetal gestations. Clinical symptoms include an onset of anorexia, nausea and vomiting, epigastric pain and jaundice, accompanied by hypofibrinogenemia, prolonged clotting, hyperbilirubinemia, and elevation of serum transaminases [49]. Hepatic coma occurs in up to 60% of cases, severe coagulopathy in 55%, and renal failure in 55%. Fetal death is common at this severe stage. Recovery, when it occurs, is almost complete. Management assumes that delivery is essential for cure, in addition to intensive medical support. If hepatic failure does not resolve, liver transplantation is an alternative. The condition does not usually recur in subsequent pregnancies.

Maternal Bone Health; Bone Physiology in Pregnancy and Lactation

Both pregnancy and lactation have a significant impact on bone metabolism. Calcium metabolism is altered as a consequence of a change in the maternal hormonal milieu, the needs of the developing fetus and neonate, weight gain and exercise, and compensatory mechanisms known to affect bone turnover.

The parathyroid hormone remains normal or decreases during pregnancy [50]. Osteocalcin remains in the normal range during the first trimester, declines during the second trimester, and returns to normal during the third trimester [51]. Serum alkaline phosphatase increases gradually in the first and second trimesters and rises rapidly in the third trimester, in part because of the addition of placental alkaline phos-

phatase [52]. Parathyroid hormone-related protein (PTHrP) levels during pregnancy are approximately double those observed during the nonpregnant state [53]. Free 1,25-dihydroxyvitamin D, vitamin D-binding proteins, and bound dihydroxyvitamin D levels all increase during pregnancy [54].

The clinical implications of these changes are controversial. Studies examining bone density during pregnancy have been inconsistent and have demonstrated either a decrease in bone density or no change. Osteoporosis of pregnancy may exist as an uncommon idiopathic entity with resultant fractures [55]. The characteristic risk factors for this group of women, however, are unknown.

Lactation places a significant calcium demand on maternal bone. Approximately 168 to 280 mg/day of calcium are expended during breast feeding. Studies on bone density and fracture risk during lactation, however, have been inconsistent with some studies demonstrating no change [56], others demonstrating a protective effect [57], and yet others demonstrating a significant decrease in bone mass [58].

Placenta and Abruptio Placentae

An understanding of *normal placental physiology and morphology* is critical to understanding the pathological changes that occur in the placenta during pregnancy.

The placenta brings maternal and fetal blood in close relationship. The placenta is partly of fetal origin (the *trophoblast*) and partly of maternal origin (transformation of the uterine mucosa). The fetal trophoblast ensures implantation; it is composed of two layers; the inner cellular layer (*cytotrophoblast*) and the exterior syncytial layer (*syncytiotrophoblast*). The placenta is well defined by the third month. At term it weighs 500 g and is 20 cm in diameter. The human placenta is *villous, hemochorial*, and *chorioallantoic*, meaning that the placental villi are bathed directly in maternal blood and are traversed by vessels coming from the allantoic circulation of the fetus. While maintenance of pregnancy prior to implantation is assured by both ovarian and pituitary hormones, after implantation the placenta assumes an important role in hormone production: chorionic gonadotrophins are discernible several days after nidation, peak at the 60th day, and then fall to low levels until completion of pregnancy [59].

Antepartum bleeding occurs in many otherwise normal pregnancies but puts the patient at increased risk for poor outcome, even though the bleeding may be self-limited [60]. *Abruptio placentae* is premature separation of the normally implanted placenta, usually presenting as a vaginal hemorrhage. However, bleeding may be retained between the placenta and the uterus as a concealed hemorrhage. The frequency of placental abruption is estimated at 1 in 150 deliveries. The perinatal fetal mortality rate is 20%. Etiology is unknown, but incidence increases with maternal age and is higher in women of greater parity. Placental abruption is associated most commonly with pregnancy-induced or chronic hypertension. The risk of recurrent abruption in a subsequent pregnancy is high. Severe abruption may be accompanied by maternal shock, consumption coagulopathy, and renal failure. Management varies with gestational age and status of the mother and the fetus [61].

Placenta previa is a separation of the placenta implanted in the immediate vicinity of the cervical canal. The degree of previa depends largely on cervical dilatation at the time of examination. Digital palpation of the cervix with progressive dilatation may provoke severe hemorrhage. Although serious, the condition is uncommon (0.3%) [62]. As with placental abruption, multiparity and advancing maternal age increase the likelihood of this condition. Clinical symptoms include painless hemorrhage, often at the end of the second trimester and without warning. Associated coagulopathy is rare. Diagnosis is best made with a sonogram. Management depends on gestational age, onset of labor, and severity of hemorrhage. Delivery is always by Cesarean section. The prognosis has improved dramatically in recent years [63].

THE PREGNANT LUPUS PATIENT

Planning for Pregnancy

Communicating with the Obstetrical and Perinatal Team

Except in large centers with special interests, obstetricians, perinatalogists, and rheumatologists generally do not have great experience with lupus pregnancies. It is therefore wise for all interested parties, including the parents, to discuss together predictable complications and outcomes early during the pregnancy, before conception if possible, and to maintain close contact during the pregnancy. In particular, points of conflicting treatment philosophies should be explored and resolved. Common differences between obstetrical and rheumatological opinions include the use of corticosteroids; use of aspirin and heparin; treatment thresholds for proteinuria, hypertension, and thrombocytopenia; frequency and quality of fetal monitoring; and prophylaxis for antiphospholipid antibody. There should be clear prospective agreement about physician aggressiveness in the event of maternal flare near the point of fetal viability. The parents, rheumatologist, obstetrician, and

perinatalogist should also discuss in advance what will be done if there is a choice to deliver a 25-week fetus, with complete maternal safety, or to try to hold to 28 weeks at high risk to the mother. Trying to discuss these points, particularly if there are important differences of opinion, is extremely difficult at the point of crisis.

When Is Pregnancy Best Undertaken?

Advising couples about pregnancy is always difficult and very individualized. Considerations include the mother's current health, the mother's anticipated future health, her physical and emotional ability to care for a child, her desires, her partner's desires, her parents' desires, and many other factors. As a general rule, the longer the patient is in remission, the better her chances for completing a pregnancy without exacerbation. Whether flare rates in pregnant patients are higher, the same as, or lower than flare rates in patients who are not pregnant is still debated (see later).

Patients currently in flare become pregnant. While flare does considerably complicate pregnancy for both mother and child, it is possible for a woman to complete pregnancy even when she is in extreme flare or otherwise seriously ill. The issues to discuss when a woman in flare contemplates or becomes pregnant are her survival, the infant's survival, the doctor's ability to use a full complement of available drugs, fetal damage that may occur with extreme prematurity, and ability of the mother subsequently to care for her (well or ill) child. Included in the latter consideration is the mother's mental and physical state on high-dose prednisone, e.g., the likelihood of her having labile mood or psychosis.

Other than to say that well patients do better than do ill patients, there is no best answer for timing of pregnancy in a lupus patient. Full and very individualized discussion and consensus among all the treating physicians (including obstetricians, nephrologists, hematologists, rheumatologists, perinatalogists, orthopedists, and primary care physicians), both parents, and other concerned relatives is the best way to plan a pregnancy. The discussion should include open statements of known and perceived risks, advantages of proceeding at this or a subsequent point, and the values and priorities of each participant. For instance, if the mother anticipates needing cyclophosphamide within 2 years, is it an advantage to attempt pregnancy now? Do both parents, the obstetrician, and the treating physician agree about the value of attempting to save a 500-g, 24-week infant if the mother is rapidly worsening?

When Is Pregnancy Inadvisable?

Even in full remission, pregnancy "rocks the boat," i.e., introduces a new variable into an already complex situation. Thus pregnancy should always be considered to be adding risk, albeit in many cases the risk is small. Inadvisability is a relative issue. A physician should take a neutral stance, explaining the risks, but not judging a patient's motives, when faced with a patient with bad prognostic indicators who has inflexible convictions regarding her proposed or current pregnancy.

Pregnancy is truly inadvisable only when there is high probability of maternal or fetal death or disability and very little likelihood of a healthy child. Circumstances of this type include severe hypertension, progressive renal failure, patient's current use of teratogenic or abortifacient drugs such as cyclophosphamide or methotrexate, severe central nervous system disease, severe thrombocytopenia, and moderate-to-severe cardiopulmonary disease. Another consideration might be severe thrombosis, usually in women with antiphospholipid antibody, during a previous pregnancy or during use of contraceptive pills.

Initial Assessment

When a patient first announces her wish to consider pregnancy, it is incumbent on her physician to survey expeditiously for pertinent autoantibodies and for dysfunction of relevant organ systems. Table 3 indicates recommended initial and subsequent laboratory investigations.

Clinical evaluation should assure competency or normality of blood pressure, kidneys (by creatinine clearance and 24-h urine protein), cardiac and pulmonary function (by clinical examination), platelet count, and musculoskeletal system, particularly the pelvis and hips. To anticipate and prevent complications, and to advise the patient, the physician should consider the effects on the patient of pregnancy's normal increase in blood volume and cardiac output, diminution of lung volume, and increase in platelet utilization. The clinician should also consider the effect of ligamentous loosening on unstable joints. Testing for anti-Ro/SSA and anti-La/SSB antibodies (predictors of neonatal lupus syndrome) and antiphospholipid antibody and lupus anticoagulant (predictors of pregnancy loss) is also appropriate at this time.

Discontinuing Drugs

There are no absolute rules regarding discontinuation of drugs, even those known to cause fetal harm, prior to pregnancy. Intense bargaining with the patient, weighing the potential danger of recurrent disease in the mother against potential fetal toxicity, is mandatory. Controlled trial data regarding the recurrence rate of symptoms following elective drug withdrawal in

TABLE 3 Monitoring of the Pregnant SLE Patient[a]

Recommended frequency	Monitoring test
First visit	Complete blood count, including platelets Urinalysis Creatinine clearance 24-h urine protein Anticardiolipin antibody Lupus anticoagulant Anti-SSA/Ro and anti-SSB/La antibodies Anti-dsDNA antibody Complement (C3 and C4 or CH_{50})
Monthly	Platelet count[b]
Each trimester	Creatinine clearance[b] 24-h urine protein if screening urinalysis abnormal[b] Anticardiolipin antibody Complement[b] Anti-dsDNA antibody[b]
Weekly (last trimester, mothers with antiphospholipid antibody)	Antenatal fetal heart rate testing ("nonstress test"), periodic biophysical profile
At 18 and 25 weeks (mothers with anti-SSA/Ro and anti-SSB/La antibodies)	Fetal echocardiogram, ?fetal electrocardiogram

[a] The erythrocyte sedimentation rate is often abnormal in uncomplicated pregnancy and is not useful to follow.
[b] More frequently if abnormal.

asymptomatic patients exist only for hydroxychloroquine [64] and for warfarin [65] (Table 4).

In deciding to withdraw a medication, the physician must have knowledge of its persistence in the body. Antimalarial drugs last for months. If the physician *and the patient* agree that a medication is no longer necessary, and that withdrawal is appropriate prior to attempting pregnancy, then an interval between complete withdrawal and pregnancy should be long enough to accomplish the withdrawal and to watch for a possible flare. Thus, ideally, hydroxychloroquine should be discontinued 6 months in advance; 3 months to allow the drug to be fully excreted and 3 months to observe for disease exacerbation. Special care must be taken with drugs such as cyclophosphamide, methotrexate, and warfarin that are teratogenic, as discontinuation after confirmation of pregnancy may be too late. A patient taking warfarin might consider switching to heparin while she is attempting to conceive. As with other aspects of patient care, careful review of all options and individualization of advice is the best plan. General advice regarding common drugs is displayed in Table 5.

Prophylactic Treatment

There is no documented evidence that increasing corticosteroid therapy solely because of pregnancy improves maternal or fetal prognosis. The authors do not employ such prophylactic treatment.

TABLE 4 Risk of Discontinuing Therapy, Two Studied Drugs

Drug	Study interval	Symptom	Recurrence rate after drug withdrawn	Recurrence rate, drug continued
Hydroxychloroquine [64]	6 months	Flare	73%	36%
Warfarin [65]	12 months	Thrombosis	130%	10%

TABLE 5 Advice Regarding Discontinuation of Commonly Used Drugs before and during Pregnancy

Drug	Prior to pregnancy	During pregnancy
Prednisone	Continue at lowest effective dose	Continue at lowest effective dose
Aspirin (anti-inflammatory dose)	Continue at lowest effective dose	Discontinue or use low-dose prednisone
NSAIDs	Continue at lowest effective dose	Discontinue or use low-dose prednisone
Azathioprine	Consider withdrawing	Consider withdrawing
Cyclosporine	Consider withdrawing	Consider withdrawing
Mycophenolate mofetil	Consider withdrawing	Consider withdrawing
Cyclophosphamide	Discontinue	Discontinue
Methotrexate	Discontinue	Discontinue
Hydroxychloroquine	Consider discontinuing 6 months before	Consider discontinuing
Warfarin	Switch to heparin when pregnancy attempted	Switch to heparin

Measurement of Flare in Pregnancy

Global Flare

Identifying the flare of SLE [66] during pregnancy is particularly difficult because pregnancy-induced thrombocytopenia and proteinuria resemble SLE disease activity. A new or increasing rash, lymphadenopathy, arthritis, fever, or anti-dsDNA antibody are the strongest reasons to attribute urinary or hematologic abnormalities to SLE rather than to preeclampsia.

There have been several recent attempts to answer the specific question of whether pregnancy causes SLE to flare, but there is no agreement as yet [67–70]. The most recent study found higher flare rates in pregnant lupus patients compared to nonpregnant controls and to the patients themselves after pregnancy. Flares were most frequent in the second and third trimesters and in the puerperium.

When pregnant patients were prospectively matched with demographically and clinically similar controls, there was no difference of flare frequency between pregnant and nonpregnant SLE patients, either during pregnancy or in the first *postpartum* year; exacerbation occurred in less than 15% of all pregnancies. In another clinic, which prospectively quantifies flare in all patients four times per year, flare was twice as common in pregnant patients as in nonpregnant ones. In a third clinic, in which pregnant patients are stratified according to prepregnant disease status, pregnancy protects against flare. Different populations and entry criteria among these clinics are likely responsible for the different conclusions [71]. Despite the lack of consensus regarding the relationship between SLE flare and pregnancy, it is clear both that many patients do well during pregnancy and that vigilance for flare on the part of the treating physician is always necessary. Modifications have been suggested [72] for measuring SLE flare during pregnancy using the SELENA SLEDAI (SLEPDAI, systemic lupus erythematosus pregnancy disease activity index), the LAI (LAI-P, lupus activity index pregnancy), or the SLAM-R (m-SLAM, modified systemic lupus activity measure) and have been tested [73].

Single Organ Flare

Hematologic

Thrombocytopenia Thrombocytopenia is common in SLE pregnancy, especially in those patients with antiphospholipid antibody. Thrombocytopenia during gestation in patients with SLE occurs in five patterns.

1. Thrombocytopenia occurring early, usually before 15 weeks, usually reaching a nadir of greater than 50×10^9/liter, and remaining constant, occurs in association with antiphospholipid antibody. This type of thrombocytopenia remits after delivery, whether or not treatment is administered, and tends to recur with subsequent pregnancies. It is unaccompanied by signs of SLE activity in other organ systems; fragmented erythrocytes and increased lactic dehydrogenase (LDH) do not occur. Aspirin may reverse the thrombocytopenia [74].
2. A second type of thrombocytopenia, usually occurring after 25 weeks, is most often associated with impending or present preeclampsia. It tends to worsen as pregnancy progresses, is associated with worsening fetal health, and remits after delivery. It is not associated with other signs or symptoms of active SLE. Biochemical and clinical manifestations of preeclampsia or the HELLP syndrome may be present. Treatment directed at early delivery is usually indicated.
3. Severe (often $<10 \times 10^9$/liter) thrombocytopenia of the idiopathic thrombocytopenic purpura type occurs most often with no other signs of active SLE and is not thought to be related to pregnancy. Drug-induced marrow toxicity and hematologic malignancy must usually be excluded by bone marrow examination. It is our experience that this type of thrombocytopenia generally responds to high-dose corticosteroid within 2 to 3 weeks. Intravenous γ globulin has been used successfully as a therapeutic (temporizing) measure. In a minority of patients splenectomy is necessary. Aspirin should not be prescribed to these patients because the risk of hemorrhage, if platelet aggregation is hindered in the face of severe thrombocytopenia, is severe.
4. A moderate ($50–120 \times 10^9$/liter) thrombocytopenia, persistent over long periods of time and responding to prednisone, is accompanied by other manifestations of active SLE: evidence of vascular disease, renal or neurologic worsening, vasculitic skin rashes may be present, erythrocyte fragmentation is common, and serum LDH is often elevated. This thrombocytopenia reflects clinically active SLE.
5. The final type is the common benign thrombocytopenia of late pregnancy, unrelated to SLE.

No specific test clearly differentiates one type of thrombocytopenia from another in pregnant patients with SLE. Tests for platelet-associated immunoglobulin or for antiplatelet antibodies seldom help differentiate among the types of thrombocytopenia. In our experience, approximately one-fourth of all SLE patients experience thrombocytopenia during pregnancy. Antiphospholipid antibody syndrome, active SLE, and preeclampsia are equally distributed causes.

Anemia Anemia is a common complication of SLE. The anemia "of chronic disease" is the most

frequent attributed cause. A true autoimmune hemolytic anemia is uncommon, but does occur, sometimes in association with antiphospholipid antibody [75]. SLE-induced anemia amplifies the normal dilutional anemia of pregnancy and usually indicates a need to use (higher doses of) corticosteroid for protection of the fetus even if the mother tolerates the anemia well. The alternative treatment, maternal transfusion, is only temporarily effective and may carry more risk. Erythropoeitin may be used (see later).

Renal Disease and Preeclampsia

Proteinuria may increase during pregnancy in women with underlying renal disease, the increments being "physiologic" and unrelated to disease activity. It is always prudent to assume that increased proteinuria indicates a problem that requires careful evaluation and perhaps treatment. The differential diagnosis is between renewed or worsened activity of lupus nephritis and superimposed preeclampsia. Increasing urinary protein, clinical signs of active SLE, rising anti-dsDNA antibody, and the appearance of erythrocyte casts favor the diagnosis of lupus glomerulonephritis. Normal serum complement favors preeclampsia (Table 6) [76, 77, 78].

Rapid worsening over days is more common in preeclampsia than in active SLE. Hypertension, thrombocytopenia, hyperuricemia, and, in some cases, hypocomplementemia occur in both lupus nephritis and preeclampsia. Renal biopsy is helpful in distinguishing between lupus nephritis and preeclampsia, but is often not feasible. In women with preexisting renal disease who develop preeclampsia, renal function may not return to its prepregnancy baseline [79].

The interpretation of hypocomplementemic proteinuria in lupus pregnancy is difficult. Low-grade activation of the classic pathway may be attributable to pregnancy alone [80]. Measures of alternative pathway complement activation (Ba and Bb) are abnormal in active lupus nephritis and normal in lupus pregnancies with proteinuria not due to active SLE. Thus evaluation of the alternative complement pathway may be the clearest way to determine whether new proteinuria in the pregnant patient is due to active SLE or to preeclampsia. In the absence of a single definitive test, distinctions between lupus nephritis and superimposed preeclampsia must be made on clinical criteria.

Rash

Normal pregnancy erythemas, particularly of the face and hands, resemble active SLE rashes. Skin areas where there has been prior lupus rash frequently become more erythematous as cutaneous blood flow increases in pregnancy. With experience, distinguishing between active SLE rash and pregnancy-induced change is not difficult. Patients who suddenly discontinue hydroxychloroquine often have an exacerbation of rash and may have exacerbation of other disease manifestations [64, 81, 82].

Arthritis

Joints damaged previously by lupus arthritis often ache and develop noninflammatory effusions during pregnancy, particularly late in gestation as ligamentous loosening occurs. The decision that a given complaint is due to active SLE rather than to physiologic changes of pregnancy depends on the demonstration that the arthritis is inflammatory. Rarely, joint fluid examination is required. If extraarticular manifestations of active SLE are present, it is likely that the effusion represents active SLE.

Neurologic SLE

Neurologic events during the course of pregnancy are rare. There are isolated reports but no cogent evidence that SLE neurologic events, including chorea and transverse myelitis, are induced or exacerbated by pregnancy [83–85]. There are also occasional reports

TABLE 6 Comparison between Preeclampsia and Lupus Nephritis

Clinical measure	Preeclampsia		Lupus nephritis
C3, C4, CH_{50}	May be low		Almost always low
Urinalysis	Red blood cell (RBC) casts rare		RBC casts frequent
Onset of proteinuria	Commonly abrupt		Gradual or abrupt
Hepatic aminotransferases	May be increased		Rarely abnormal
Quantity of proteinuria		Will not differentiate	
Thrombocytopenia		Will not differentiate	
Hyperuricemia		Will not differentiate	
Hypertension		Will not differentiate	

of SLE patients suffering stroke *postpartum*, usually in the setting of coexisting antiphospholipid antibody.

One of the most difficult diagnostic decisions concerns the occurrence of seizures late in pregnancy, when hypertension and renal failure are also present. The circumstances in which the events occur, the presence of other clinical and serologic (rising anti-dsDNA antibody) evidence of active SLE, and response to therapy may all be required to make the distinction between active neurologic SLE and eclampsia. Often, treatment for both is indicated.

Summary of Data: Does Pregnancy Influence the Course of Disease?

Because pregnancy-induced abnormalities resembling lupus flare may occur, the patient's health may worsen, although, in a technical sense, her disease does not. The distinction between disease-induced and pregnancy-induced complications is critical because treatment directed against the primary illness (on the assumption that it has become "active") rather than toward the pregnancy event may be misguided and potentially harmful. Whether pregnancy induces flare remains controversial. Relevant controlled studies are summarized in Table 6. It is likely that referral selection bias, differences in the ways in which different clinics diagnose flare, demographic differences of studied patients, inclusion of patients first diagnosed during pregnancy, and disagreements about the distinctions between preeclamptic and lupus renal and hematologic abnormalities account for the different conclusions reached in different clinics. Regardless of population statistics, every patient should be followed during pregnancy under the assumption that there is a risk of flare.

MANAGEMENT OF PREGNANCY: MOTHER

Monitoring

Women entering pregnancy in full remission should be fully evaluated by their treating medical physician at intervals no less than each trimester. Detailed history and physical examination, looking for signs of lupus activation, are indicated. Laboratory analysis for anti-DNA antibody, complement, 24-h urinary protein excretion, creatinine clearance, and complete blood count including platelets is also indicated, as is repeat tests for antiphospholipid antibody and lupus anticoagulant (if previously negative). Table 3 indicates suggested frequency of monitoring for a patient with an uncomplicated pregnancy. The clinical activity of disease and any pregnancy abnormality mandate more frequent observations.

Treatment of Lupus during Pregnancy

With qualifications, criteria for treatment of the pregnant patient do not differ from criteria for the nonpregnant patient. Clinical flares of skin, joints, blood, kidneys, mucosae, serosae, and nervous systems, *if attributable to SLE activity rather than to pregnancy*, always merit the same increase in corticosteroid therapy that these symptoms would merit if the patient were not pregnant. The choice to use antimalarial, nonsteroidal, and immunosuppressive drugs, however, is restricted by weighing potential fetal injury against control of maternal disease.

Anemia (hemoglobin less than 8.0 g/dl), fever (sustained fever greater than 38.5°C), and hypoalbuminemia (albumin less than 3.0 g/dl) merit more aggressive treatment in the pregnant patient than they might in the nonpregnant patient because these abnormalities threaten the growing fetus. Worsening fetal health, in the absence of clinical exacerbation of SLE, does not justify treatment for SLE.

Pregnancy Complications in Patients Entering Pregnancy with Preexisting Abnormalities

Severe *multisystemic* SLE will seriously complicate pregnancy, primarily through its manifestations of high fever, hypertension, renal failure, and, on occasion, cardiac and respiratory failure, as well as through the treatments administered.

Any *renal* disease, including lupus glomerulonephritis, predisposes patients to preeclampsia. There is some disagreement whether patients with renal SLE do less well than those with other forms of glomerulonephritis. In general, those with preserved renal function and minimal hypertension do well. Even those with severe renal disease often have surprisingly good pregnancy outcomes. Normal urinary protein in pregnancy may be as high as 500 mg/day. Modest increases in urinary protein (particularly in patients with fixed proteinuria), accompanied by proportional increases in glomerular filtration in mid- to late pregnancy and not accompanied by other signs of active lupus, likely do not indicate lupus nephritis and need not be treated. In patients with marked increases in urinary protein, with or without hypertension, it may be impossible to distinguish between preeclampsia and active lupus nephritis, and

may therefore be necessary to treat if delivery is not likely in the immediate future. Hypocomplementemia alone, without renal worsening, is not an indication to treat.

In our experience with 125 completed SLE pregnancies, only 15% of SLE patients entered pregnancy with preexisting renal disease. Of this 15%, two-thirds (10% of the total) developed preeclampsia, a complication that also developed in 14% of the 107 women without preexisting kidney disease. Our experience is similar to that of Nossent and Swaak [86] but differs from the prognoses reported by Petri *et al*. [67]. The latter reported that more than half of women entered pregnancy with preexisting lupus nephritis, and while the authors did not comment on the frequency of preeclampsia, they did report a high frequency of renal flare.

High-dose (60 mg/day) oral corticosteroid therapy is the initial treatment of SLE glomerulonephritis. Corticosteroid therapy may cause hypertension or elevated blood glucose; in the pregnant patient, the risk of hypertension may be greater than in the nonpregnant patient. Thus proactive means to prevent hypertension, and its attendant preeclampsia, are indicated.

Obstetricians frequently use low-dose aspirin (60–100 mg/day) to prevent preeclampsia in women identified as being at high risk [87–90]. Most frequently, preexisting hypertension is the characteristic for which high risk is assigned. Aspirin does not reduce the incidence of preeclampsia in women at low risk for this complication [91]. All forms of renal disease predispose to preeclampsia. Lupus glomerulonephritis is no exception. There is no systematic study of the use of aspirin to prevent preeclampsia in SLE patients. Nonetheless, some physicians, including us, do prescribe this drug.

Both prolonged labor and increased peripartum bleeding may occur when aspirin is used close to term [92, 93]. Premature closure of the *ductus arteriosus* is a risk of use of indomethacin [94]. The aspirin effects are quantitatively minor. Aspirin and other nonsteroidal anti-inflammatory agents may decrease glomerular filtration rates in patients with renal disease.

Patients with severe hypertension, on hemodialysis, or with renal transplants may have successful pregnancies. Management in these situations is very individualized and requires expert multidisciplinary care.

Thrombocytopenia, independent of antiphospholipid antibodies or preeclampsia, is not an independent predictor of fetal death. Women who enter pregnancy with preexisting modest thrombocytopenia may experience a further fall as the pregnancy progresses. While platelet counts must be monitored carefully, a decrease in platelet count from 120 to 80×10^9/ml need not *necessarily* require additional therapy. Treatment of thrombocytopenia in a pregnant lupus patient depends on a clear definition of the cause of the thrombocytopenia. Thrombocytopenia associated with antiphospholipid antibody may respond within several days to 81 mg/day ("baby") aspirin. However, aspirin should not be used in ITP or antiplatelet antibody thrombocytopenia. Prednisone, 30 to 60 mg/day, should be prescribed if the cause of the thrombocytopenia is uncertain. The response to prednisone takes several days to 3 weeks to occur. There is no documented evidence that the treatment of modest thrombocytopenia ($>70 \times 10^9$/liter) improves either maternal or fetal prognosis, but many physicians interpret modest thrombocytopenia as evidence of disease activity and do treat it. When thrombocytopenia is life-threatening ($<30 \times 10^9$/liter) or if delivery is imminent, treatment is indicated.

A temporary remission of thrombocytopenia may be obtained by infusing platelets (response within minutes; duration, hours to 2 days) or intravenous aggregate-free immunoglobulin G (response within days, duration, 2–3 weeks) [95–97]. Neither of these treatments can be used on a long-term basis. Intravenous immunoglobulin adds to the volume load of patients already at risk for hypertension or congestive cardiomyopathy and late in pregnancy could theoretically add a volume load to the fetus, increase fetal blood viscosity, and inhibit fetal immunoglobulin synthesis. However, normal children have been delivered of mothers receiving immunoglobulin therapy. Splenectomy and cyclophosphamide are last resorts in the treatment of thrombocytopenia; both have been used successfully in pregnancy [98]. The potential roles of argatroban or lepirudin in the pregnant lupus patient are unknown; both have FDA pregnancy category B ratings.

Neuropsychiatric disease, so long as it and its treatment do not affect the mother's general health, has little direct influence on pregnancy outcome. Fetal injury from hypoxia during seizures, self-abuse, or neglect during psychosis is possible. Sedation or addiction of the fetus from maternal phenobarbital or other anticonvulsant drugs is also possible, as is drug-related teratology (see later). Corticosteroids, anticonvulsants, and, for stroke, anticoagulation are the primary forms of treatment for neurologic events. These events are rare in pregnancy; they are treated similarly in pregnant and nonpregnant patients, except that warfarin is contraindicated in pregnancy.

Osteonecrosis, with or without total hip replacement, is a common event in SLE. Pregnancy occasionally occurs in a woman suffering this complication. With a few exceptions, neither osteonecrosis nor hip

replacement alters the course of pregnancy or its management. The exceptions are as follows: *protrusio acetabulae* narrows the pelvic inlet, possibly obstructing the passage of a child and thus mandating operative delivery. A markedly restricted range of motion of the hip, especially abduction and abduction in flexion, will interfere with vaginal delivery from the lithotomy position. If the delivery room staff is unaware of the limited motion, they may try to force abduction and risk hip fracture or dislocation. It is wise for the rheumatologist or orthopedist to advise the obstetrical staff well in advance of anticipated delivery of all musculoskeletal disabilities a patient has. Antibiotic coverage is advisable during labor and delivery for women with prosthetic joints. A suitable regimen is cephalosporin or vancomycin plus gentamicin.

Case reports of fatalities due to *pulmonary hypertension* developing or worsening during pregnancy suggest that patients with important lung involvement should avoid conceiving [99, 100]. Because of the growing fetus, diaphragms are high in late pregnancy. Patients with "shrinking lung," or with recurrent pleurisy, may find breathing further compromised. *Arthritis* does not as a rule influence the course of the pregnancy. In nonpregnant patients, full doses of NSAIDs are the first treatment option for arthritis. Although they appear to be generally safe, antiinflammatory doses of aspirin or nonsteroidal antiinflammatory drugs are not recommended in pregnancy because there is little published information concerning safety to the fetus. For treatment of arthralgia or arthritis, low-dose prednisone is preferred [101]. Corticosteroid therapy is the primary treatment for SLE-caused *anemia* (either hemolytic or due to chronic disease), if treatment is necessary, and if anemia is not due to vitamin or iron deficiency, sickle cell disease, glucose-6-phosphatase deficiency, or other Coombs-negative hemolysis. As most patients are minimally symptomatic, the indication for treatment is usually fetal rather than maternal; a hemoglobin concentration of less than 8 g/dl is often used for the decision to treat. Transfusions are occasionally also necessary. Safety and efficacy of human recombinant erythropoietin in pregnancy have been shown, including at least one case of SLE pregnancy with nephritis [102, 103]. There is no transfer of erythropoietin across the placenta [104]. *Rashes* may be treated with topical or systemic corticosteroid or may be left untreated. Some authors comment on the benignity of antimalarial drugs during pregnancy (see later) [105, 106]. Discontinuation of antimalarials in pregnant women or in women contemplating pregnancy is common practice. The only available controlled trial in pregnancy suggests that patients do better taking rather than discontinuing hydroxychloroquine [107].

DRUG TREATMENT IN LUPUS PREGNANCY

Physiology of Drug Metabolism during Pregnancy

Physiologic changes during pregnancy alter maternal pharmacokinetics, which in turn may affect the amount of drug reaching the mother, the placenta, and the fetus [108, 109]. For example, gastrointestinal reflux, with a decrease in gastric emptying, reduces both drug absorption and peak concentration.

Placental drug transfer by diffusion resembles transfer across a lipid bilayer. Transfer is favored by lipid solubility, a large concentration gradient of unbound drug, and maintenance of the drug in a nonionized state in the maternal circulation. Differences in maternal and fetal pH influence the maternal/fetal concentration ratio.

In SLE, hypertension, diabetes mellitus and other conditions, disordered maternal and fetal physiology may produce changes in the placenta that impact drug transfer from mother to fetus. Drug distribution varies significantly during the course of pregnancy through the continuing expansion of maternal blood volume by 30%. In most cases there are no guidelines for adjusting dose. Measurement of blood levels when appropriate and observation for clinical effects and toxicity are necessary.

Common Drugs Used during Pregnancy (Non-SLE)

Non-SLE patients take an average of 3.1 drugs other than vitamins during pregnancy [110]. Commonly used drugs include antiemetics, antacids, antihistamines, antimicrobials, analgesics, and antihypertensives. Issues of teratogenicity are common. Teratogens (agents or factors to which embryo–fetal exposure produces a permanent alteration in the form or function of the child) [111] have different effects at different time periods. Teratogens administered after the vulnerable period usually will not cause structural malformations. Gestational periods are fertilization to implantation (0–2 weeks), embryonic (2–8 weeks, *the most critical period*), and fetal, from 8 weeks to term.

In 1979, the Food and Drug Administration established five categories of possible adverse fetal effects. Category A includes drugs for which controlled studies in human subjects show no fetal risk. Categories B, C, and D have progressively fewer data or greater risk, and category X describes proven fetal risks that clearly outweigh benefits [112].

Penicillins, cephalosporins, and macrolide *antibiotics* (erythromycin and others) are considered fairly safe

(category B). Drugs to avoid include tetracyclines, which cause yellow–brown discoloration of deciduous teeth and of the long bones; aminoglycosides, for which early studies showed associations with fetal eighth nerve damage; and ciprofloxacin, which causes fetal bone malformations. Griseofulvin, an oral antifungal, should be avoided as well.

Antihypertensives may be used in patients with chronic or pregnancy-induced hypertension and are often required in the SLE patient. Methyldopa, hydralazine, and clonidine have a long history of safe use. β-Adrenergic blocking agents do not have the same long record of use but are often recommended in preeclampsia. Calcium channel antagonists are also used, although verapamil (but not nifedipine or diltiazem) may decrease uterine blood flow. Angiotensin-converting enzyme inhibitors (ACE inhibitors) are contraindicated in pregnancy because they are associated with renal anomalies, nephrotoxicity, neonatal anuria, oligohydramnios, and death [113]. Diuretics are commonly used and little studied, with no major problems reported.

Anticonvulsant medications must continue during pregnancy in women with epilepsy or SLE-related seizures, even though the children of epileptic women taking these drugs during the first trimester have an increased frequency of congenital malformations. Hydantoins (including phenytoin) cause fetal hydantoin syndrome (craniofacial and limb malformations accompanied by mental deficiency). Carbamazepine, trimethadione, and valproic acid produce similar syndromes. No reports of malformations exist for phenobarbital or ethosuximide.

Antidepressant drugs used during the first trimester may be associated with some malformations. The newer selective serotonin reuptake inhibitors, however, are category B drugs. Antipsychotic medications, used in pregnancy most commonly for the treatment of hyperemesis, do not show an increased risk of malformation.

Drugs Used for Treating Lupus

Increased drug metabolism in pregnancy may mandate larger than normal doses of all drugs.

Corticosteroids

Prednisone and methylprednisolone have minimal placental transfer and are the drugs of choice for patients requiring corticosteroid therapy. In conventional doses, they are safe for the fetus. Fluorinated corticosteroids (dexamethasone and betamethasone) should not be used unless there is intent to treat the fetus, as these drugs easily cross the placenta [114]. There is no accumulated analyzed experience with "pulse" bolus corticosteroid in pregnancy. High-dose intravenous methylprednisolone does reach the fetus [115–117].

Immunosuppressives

Azathioprine is widely used in renal transplant patients and is thought to be generally safe in pregnancy [118, 119], but fetal cytopenias and malformations have occurred [120, 121]. Cyclophosphamide is contraindicated in early pregnancy because of its teratogenicity and abortifacient properties. There are reports of women given cyclophosphamide before and during pregnancy whose infants appear normal, but experience is small [122]. It may be possible to administer this drug late in pregnancy with less risk. Methotrexate is similarly contraindicated in the first trimester of pregnancy. It is abortifacient; it causes a characteristic fetal syndrome of craniosynostosis and other malformations. Cyclosporine may cause significant maternal toxicity, especially nephrotoxicity, but appears to be safe for the fetus. Mycophenolate mofetil is FDA category C—insufficient information is available.

Nonsteroidal Anti-inflammatory Drugs

Salicylates have no proven association with fetal anomaly [123]. NSAIDs are generally considered nonteratogenic, yet experience with these agents in pregnancy is limited. Aspirin in a therapeutic dose, but not at 80–150 mg/day, has been associated with oligohydramnios, premature closure of the ductus arteriosus, and pulmonary hypertension. Indomethacin, used to treat preterm labor, is also associated with premature ductus closure and fetal pulmonary hypertension. For this reason, anti-inflammatory doses of aspirin or NSAID use should be terminated after 34 weeks.

In general, aspirin is preferred to NSAIDs because of its longer history of use and greater accumulated literature. In many cases of minor arthritis or serositis during SLE pregnancy, low-dose prednisone is preferable to either aspirin or NSAIDs because of its known safety and minimal placental transfer.

Antimalarial Medications

Evidence regarding the teratogenicity of both chloroquine and hydroxychloquine is sparse [124]; the safety of antimalarials is not established. In one publication, 36 infants of 33 mothers had no apparent abnormalities attributable to hydroxychloroquine [125]. No harm to the fetus in treated pregnancies, but maternal flares in untreated pregnancies were shown in a double-

blind, placebo-controlled trial [107]. Concerns with these drugs, based on laboratory animal data, include ototoxicity and ophthalmotoxicity, which have not been reported in humans to date. It seems prudent to avoid use of these agents during pregnancy if possible, although scattered small series report successful pregnancies. Flare after the discontinuation of hydroxychloroquine is a real concern. Flare should be anticipated; the physician and the patient together should weigh the relative risks of continuing the antimalarial against the possibility of having to control an exacerbation with higher dose prednisone.

Intravenous Immunoglobulin (IVIG)

Intravenous immunoglobulin is used for several specific problems during pregnancy. Thrombocytopenia, whether from idiopathic thrombocytopenic purpura, lupus, or antiphospholipid antibody syndrome, generally responds well, although transiently, to this therapy. Several studies have reported successful pregnancy outcomes in patients with aPL treated with IVIG, usually in combination with other therapies. Anticardiolipin antibody titers may decrease with IVIG therapy, possibly related to anti-idiotype antibodies to antiphospholipid antibody present in commercial immunoglobulin preparations and demonstrable in patient plasma after treatment [126, 127].

Apheresis

While plasmapheresis has been used during pregnancy, its efficacy for any single indication is yet to be determined. Reports include case reports of patients carrying a fetus with neonatal lupus and congenital heart block, antiphospholipid antibody-related pregnancy losses, and antiphospholipid antibody-related refractory HELLP syndrome with postpartum renal insufficiency [128].

Drugs Used for Pregnancy

The following drugs are often used by obstetricians for pregnancy or menometrorrhagia management. Their effects on SLE, if any, are unknown.

Hormones

Both androgens (including danazol) and the nonsteroidal synthetic estrogen diethylstilbestrol (DES) may cause congenital anomalies. Oral contraceptives, if taken during pregnancy, do not cause fetal genital malformations [129]. Progesterone suppositories may be prescribed for patients with a presumed luteal phase defect (insufficient progesterone secretion by the corpus luteum or placenta associated with an increased incidence of spontaneous abortion). Progesterone intramuscular injections may also be used in patients undertaking assisted reproduction (see later). This drug is not associated with an increased risk of lupus flare.

Tocolytic Medications

Tocolytic medications are those used to prevent or control preterm labor. These include β-*adrenergic agonists*, *magnesium sulfate*, *prostaglandin inhibitors*, *calcium channel-blocking* drugs, and *nitric oxide donor* drugs.

Before medication, most patients with preterm labor are given a trial of bed rest and hydration. β-agonists decrease contractions but may be accompanied by troublesome cardiovascular effects, including pulmonary edema, palpitations, and glucose intolerance. Traditionally, the β-mimetics most used are *ritodrine* and *terbutaline*. Because of questions of efficacy of oral preparations, only parenteral forms of ritodrine are now available. Terbutaline is used with a subcutaneous pump, but its efficacy is unproven; oral terbutaline therapy is not efficacious [130].

Magnesium sulfate, in high concentration, can alter myometrial contractility, possibly functioning as a calcium antagonist *in vivo*. Its efficacy is controversial. Signs of hypermagnesemia of both mother and fetus must be sought. Prostaglandin inhibitors reduce the frequency of preterm labor, but these agents cause premature closure of the *ductus arteriosus*, necrotizing enterocolitis, and intracranial hemorrhage in the fetus [131].

Calcium channel blockers inhibit contractility of the myometrium but also uterine and systemic blood vessels. Thus there is a risk of decreased uteroplacental perfusion. Other agents include oxytocin inhibitors (atosiban) and nitric oxide donor drugs, as nitric oxide is a potent smooth muscle relaxant. Efficacy and risks of these are not established.

MANAGEMENT: TREATMENT OF FETUS DURING PREGNANCY

Fetal Monitoring

Fetal growth and development in SLE patients may be threatened by disease activity, by abnormality of maternal renal function, by antiphospholipid antibody, and by anti-SSA/Ro and anti-SSB/La antibodies.

Triple Screen False-Positive Tests

Unexplained elevation of maternal α-fetoprotein occurs in patients with systemic lupus erythematosus. The elevation correlates with preterm delivery, high prednisone dosage, and presence of antiphospholipid antibody [132]. Unexplained elevation of α-fetoprotein in patients with antiphospholipid antibody identifies an increased risk of fetal and perinatal death. Presumably, abnormalities in the fetoplacental barrier lead to an increased transport of α-fetoprotein from fetus to mother [133, 134]. It usually does not imply fetal malformation. False-positive elevations in human chorionic gonadotrophin, another component of the "triple screen" for Down's syndrome (α-fetoprotein, hCG, and unconjugated estriol), may also be seen [135].

Antibodies Transmitted

Maternal IgG-mediated thrombocytopenia may be transmitted to the fetus, but most infants born of thrombocytopenic mothers with SLE have normal platelet counts. Occasionally the IgG Coombs' hemolytic antibody may be transmitted to and cause hemolysis in the fetus and newborn. The anti-dsDNA antibody, also transmitted to the infant, has no apparent pathologic effect. The antiphospholipid antibody is associated with placental insufficiency, intrauterine growth restriction and fetal death; it does not usually cause abnormalities in the infant, but fetal thrombosis has occurred (see later). In women with anti-SSA/Ro or anti-SSB/La antibodies, neonatal lupus is a risk. Fetal echocardiography, seeking evidence of heart block or other cardiac dysfunction, is recommended between 15 and 25 weeks [136, 137].

Monitoring

Fetal growth rate and placental volume and appearance may also be monitored by sonography. Weekly antepartum fetal heart rate testing may begin as early as 25 weeks [138, 139]. In the 25- to 30-week period, nonreactive tests are relatively commonly seen. Occurrence of sinus bradycardia is predictive of potential fetal compromise. Later in gestation any nonreactive test is abnormal; sinus bradycardia may indicate a need to deliver, even at early gestational ages. The potential role of umbilical artery waveform determinations is not yet known, but it assists in timing induced delivery [140, 141].

Deciding to Intervene

The decision to end a viable pregnancy requires a yes answer to either of two questions: Is the mother's health likely to deteriorate *irreversibly* if the pregnancy continues? Is the baby likely to grow better delivered than *in utero*? The decision to use a fetotoxic drug requires a yes answer to the first question and an agreement that the risk to the fetus justifies the intervention.

Active lupus, of itself, does not mandate ending a pregnancy, although the decision that cyclophosphamide must be used before the fetus reaches 36 weeks may be reason to terminate or deliver early. Maternal complications that call for urgent termination of a pregnancy, regardless of fetal maturity, are more often pregnancy than lupus related: progressive preeclampsia, in any of its manifestations, progressive hepatic failure from fatty liver, or HELLP syndrome, uncontrollable heart failure, and, sometimes, severe thrombocytopenia. Pregnancies may continue in the face of severe renal failure (including dialysis and transplant), advanced nephrosis, thrombocytopenia, and maternal brain disease. The effects of these specific conditions on an individual child are unknown, but the authors have cared for pregnant patients with each of these conditions who have delivered apparently normal children at or near term. The parents' choice, the length of the pregnancy at the time the complication arises, medications taken by the mother, and individualized predictors of maternal and fetal health all weigh in the final decision.

Obstetrical rules regarding intervention to preserve fetal well-being are reasonably standard. Complete cessation of fetal growth, resorption of amniotic fluid, and poor performance on tests of fetal well-being [antepartum fetal heart rate testing (nonstress test), biophysical profiles, measurements of umbilical artery wave form] all are warning signs that the pregnancy has ceased nurturing the child. Spontaneous fetal sinus bradycardia is a forerunner of fetal death. If there is intent to salvage the child, i.e., if the child is potentially viable (greater than 24 weeks' gestational age), delivery in the face of these findings must be accomplished immediately. Another indication for immediate delivery is the occurrence of cardiac failure or pericarditis, especially in an infant with congenital heart block. Heart block alone, if cardiac function is good, is not an absolute reason to deliver.

Unrelated to lupus, *hydrops fetalis*, incompetent cervix, amnionitis, and other common obstetrical illnesses are reasons to deliver before term.

As a general rule, delivery of a child at 30 weeks or more, or who weighs more than 1500 g, followed by care in an experienced neonatal intensive care unit, gives acceptable levels of risk for complications of prematurity. The frequency of damaged children rises markedly the smaller the child (Table 7) [142, 143].

TABLE 7 Frequency of Major Impairment as a Function of Birth Weight

Birth weight (g)	% with major impairment (range)	% of survivors with major impairment at 75 months
1501–2500	8 (5–20)	—
1001–1500	15 (5–30)	—
≤1000	25 (8–40)	21–29

[a] Data from non-SLE populations [142, 143].

Prematurity, Intrauterine Growth Restriction, and Fetal Death

Fetal death, intrauterine growth restriction, and prematurity (birth before 38 weeks) are common in SLE pregnancies. They result from maternal disease severity, antiphospholipid antibody, or both. SLE activity by itself does not alter the outcome of pregnancy.

Prematurity most commonly results from a decision to deliver because of maternal or fetal distress. Depending on the mix of patients seen and upon variables of diagnostic and obstetrical thresholds, centers differ in the frequency of premature delivery. Rates of 50% are usual. Obstetrical reasons such as placenta previa are rare, but premature rupture of membranes, often associated with corticosteroid therapy, is common.

Congenital Abnormalities

Other than neonatal lupus (see Chapter 17), there are no congenital, genetic, or developmental abnormalities associated with SLE. Brain and other damage resulting from prematurity, placental insufficiency, toxemia, or neonatal lupus are not considered to be congenital abnormalities.

Miscellaneous

Men with SLE may become fathers. Other than the slight increased risk of eventual SLE in the child common to this familial illness, there is no known effect of paternal SLE on the infant, regardless of the clinical condition or serology of the father. Medications may alter male fertility: cyclophosphamide markedly diminishes sperm count and high-dose corticosteroid therapy alters both libido and potency.

Long-Term Outcomes of Lupus Children

There are no large-scale, long-term published follow-ups of offspring of lupus mothers, but data comparing such infants with sex- and gestational age-matched controls suggest that, although intelligence is normal, there may be a high frequency of learning disabilities, particularly in males. It is not clear whether autoantibodies are a cause [144, 145].

TABLE 8 Lupus-Specific Issues That May Force Operative Delivery

- Severe hypertension
- Severe thrombocytopenia
- Severe renal disease
- Immediate need to institute life-saving treatment to the mother that will be harmful to the fetus
- Severe maternal cardiac disease
- Severe pulmonary disease
- Deteriorating heart function in a fetus with congenital heart block
- Orthopedic indication (e.g., protrusio acetabuli blocking the pelvic outlet)

THE PUERPERIUM

Route of Delivery

The decision to deliver vaginally or operatively is an obstetrical one. Criteria that influence this decision are immediacy of the need to deliver (i.e., is there sufficient time for normal labor to proceed?), hemorrhage risk (fetal or maternal thrombocytopenia), placental position, fetal health, position, and size, and maternal pelvic size. Specific lupus issues rarely determine delivery route, although they may upgrade urgency and thus force operative delivery (Table 8). These issues can be generally categorized: severe organ failure, immediate need to institute treatment which may harm the infant, and fetal cardiomyopathy. There is never a need to insist upon operative delivery for the single reason of diagnosis of (uncomplicated) lupus. Other than blood pressure rises during uterine contraction, venous distention during repeated Valsalva maneuvers, and duration of physical activity, there are no characteristics of labor that are necessarily more stressful to the mother than anesthesia and major surgery. The internist may monitor and advise the obstetrician about the patient's organ competencies and stamina but otherwise should not attempt to direct the choice of delivery route.

Treatment in the Peripartum Period

The patient's usual medications continue during the peripartum period as they would during any surgical procedure. In particular, it is advisable to give "stress"

steroid doses beginning with the onset of labor and continuing 24 h after delivery concludes. Anticoagulation, including aspirin, must cease with the onset of labor to resume once the risk of hemorrhage is over *postpartum*. Observation of lochia (bloody uterine discharge after delivery) is a good guide to hemorrhage risk. Reinstituting anticoagulation 1 to 2 days after delivery is usual. Antihypertensive and anticonvulsant medications continue in parenteral forms during the peripartum period. Medications that have been discontinued for pregnancy, such as cyclophosphamide or hydroxychloroquine, may resume as soon as the patient has begun eating again, *unless the mother intends to breast feed and the medication is one that passes to the newborn*.

The authors recommend against, and themselves do not use, routine increases in corticosteroid dose to prevent postpartum flare.

The treating physician should alert the delivering physician and staff to any physical and orthopedic limitations a patient might have. Previously thrombosed femoral or iliac veins in antiphospholipid antibody syndrome patients may develop or release new clots as the pelvic veins become congested and occluded during fetal descent.

It is also useful to alert the neonatalogy staff about the mother's anti-Ro/SSA and anti-La/SSB status. Neonatalogists may be unfamiliar with the rash, thrombocytopenia, and, sometimes, heart block of neonatal lupus. Susceptible infants may first develop the rash when treated with ultraviolet light for hyperbilirubinemia. Alerting the pediatric staff may prevent much unnecessary testing and undue alarming of the parents. (Grave systemic infections, such as cytomegalovirus infection, which threatens mental retardation and blindness, are commonly suggested alternative diagnoses of the rash.)

The treating physician should note that the pregnancy complications of preeclampsia, HELLP syndrome, and fatty liver of pregnancy may continue to progress for several days to weeks *postpartum* before they eventually regress. Treatment decisions should therefore consider the possibility of insufficient hepatic or renal clearance of drugs and the presence of serious confounding illness in immediate *postpartum* patients.

Placentae

Lupus placentas are often small in size. They demonstrate ischemic–hypoxic change, decidual vasculopathy, decidual thrombi, fetal thrombi, chronic villitis, and perivillous fibrin. Antiphospholipid antibody placentae demonstrate decreased weight, ischemic–hypoxic change, decidual vasculopathy, and extensive infarction [146]. It is often difficult to distinguish these changes from those of preeclampsia. A preliminary study suggests that SLE placentas exhibit intense deposits of type IV collagen and laminin, whereas preeclampsia and normal placentas do not [147].

Several processes may determine the extent of placental damage or dysfunction [148]. Occlusive vasculopathy, due to placental intraluminal thrombosis, to endothelial cell proliferation, or to other placental vasculopathy, has been suggested [149–156]. The antiphospholipid antibody competes with the natural placental anticoagulant proteins for phospholipid substrate, possibly interdicting their anticoagulant function and permitting pathologic coagulation to occur in the placenta [157–159]. Antiphospholipid antibody, β_2-glycoprotein-1, and placental anticoagulant protein I are identifiable in the same histologic location in placentas of mothers with fetal death; neither antiphospholipid antibody nor β_2-glycoprotein-1 are present in placentas of women with normal births [160]. Other, putatively immunologic, placental lesions have been described in patients with SLE [161, 162].

Breast Feeding

Definitions

Colostrum is the deep lemon-colored liquid secreted by the breasts for the first several *postpartum* days. Compared with mature milk, colostrum contains more minerals and protein, but less sugar and fat. Antibodies are demonstrable in colostrum; immunoglobulin A may protect the newborn against enteric pathogens. Other host resistance factors, including complement, macrophages, lymphocytes, lactoferrin, lactoperoxidase, and lysozymes, are in human colostrum and milk.

Human *milk* contains α-lactalbumin, β-lactoglobulin, and casein. Most milk proteins are unique [163]. Whey contains large amounts of interleukin-6, with peak levels in colostrum. Prolactin is actively secreted into breast milk [164]. Milk also contains all vitamins, except vitamin K, and little iron. The breast concentrates iodine, gallium, technetium, indium, and sodium. Radioactive scanning materials appear rapidly in breast milk.

Hormonal Status during Lactation

Progesterone, estrogen, and placental lactogen, as well as prolactin, cortisol, and insulin, appear to act in concert to stimulate the milk-secreting apparatus. At delivery an abrupt decrease in the levels of estrogen and progesterone results in unopposed prolactin stimulation of α-lactalbumin production. The intensity and duration of lactation are controlled by the repetitive stimulus of

nursing. Oxytocin, released in pulsatile fashion from the neurohypophysis, stimulates the contraction of myoepithelial cells in the alveoli and ducts, allowing reflex milk ejection.

Drugs in Breast Milk

Drugs in maternal blood cross the capillary endothelium, extracellular space, and hydrophobic barrier created by the alveolar cell membrane cell membrane before entering the milk. Most drug transfer is by passive diffusion.

Compounds with high molecular weights, such as heparin, are unable to pass through the cell membranes into the milk. Because breast milk is mildly acidic, weak bases pass most readily into breast milk, creating a higher concentration in milk than in plasma. Drugs that are weak acids may have lower concentrations in breast milk, and highly lipophilic drugs may partition into milk fat and achieve a high concentration in milk than in plasma [165].

The amount of drug in the milk and *consumed by the infant* depends on the dose, frequency, and duration of exposure, route of administration, and time of administration relative to infant feedings. It is critical to counsel patients not to feed at peak milk levels of the drug but to administer medications after infant feedings or just before the infant's longest sleep period.

The nursing infant is constantly maturing, a fact that also affects its exposure to drugs. The manner in which an infant absorbs, tolerates, and metabolizes drugs can vary within a short period of time due functional readiness of the gastrointestinal tract and development of renal function.

Aspirin and *NSAIDs* are highly protein-bound weak acids that do not pass easily into breast milk. Because infant elimination of such drugs is slow, accumulation can occur if the mother takes high chronic doses. The most reasonable NSAID to use is ibuprofen, 400 mg every 6 h, as this has not been detected in breast milk [166]. Most *antibiotics* appear in breast milk, although concentrations vary. Sulfonamides rarely cause hyperbilirubinemia in the infant. Penicillins and cephalosporins are excreted in low concentrations. Tetracyclines appear in significant concentration, but are usually undetected in the infant's plasma. Nonetheless, because tetracyclines stain teeth in growing children, it is best to avoid their use. Aminoglycosides are surprisingly safe in lactation due to poor gastrointestinal absorption in the infant. Some antibiotics concentrate in breast milk and are contraindicated: these include metronidazole, chloramphenicol, and isoniazid. The major *anticoagulants* are safe during breast feeding. Heparin is too large to pass into breast milk, and warfarin (highly bound to plasma proteins and weakly acidic) is not detectable. Controversy exists regarding the use of *oral contraceptives* during lactation, both with regard to amount of hormone absorbed into the infant's circulation and with effect of the contraceptive steroids on maternal milk composition and yield. Estrogen directly inhibits lactation.

For patients with SLE, the major concern is the safety of *corticosteroid* therapy during lactation. Overall, especially with low doses and appropriate corticosteroid choice (prednisone or prednisolone), very little steroid is transmitted to breast milk. The neonatal effect (plasma level) in a woman taking a maternal dose of prednisolone of 20 mg/day or less is insignificant. Infant corticosteroid exposure is further minimized by feeding just prior to ingestion of the medication.

Complications of Breast Feeding

Breast problems during pregnancy and lactation include infection (mastitis, abscess formation) and galactoceles (noninfected milk-filled cysts that resolve with aspiration). Benign fibroadenomas may enlarge significantly during pregnancy. SLE rash may occur on the breast and around the nipple area and may be initially confused with simple mastitis; it may make breast feeding painful [167].

Suppression of Lactation

The simplest method of lactation suppression is support of the engorged breasts, application of cold packs, and appropriate analgesia if necessary. Symptoms usually disappear within 2 to 3 days.

Medical suppression of lactation is possible with estrogens or bromocriptine. Estrogen therapy, however, may increase thromboembolic risk. Bromocriptine, a dopamine agonist, stimulates the production of prolactin inhibitory factor, leading to a fall in prolactin and cessation of lactation. Adverse effects have been reported with this therapy, including hypertension, seizures, stroke, and myocardial infarction. Although no causative relationship has been established, use of this medication is now uncommon [168]. Oral contraceptives, due to their estrogen content, may inhibit lactation. For women desiring to continue nursing, a progestin-only contraceptive is preferable. There are minimal effects on milk production, neonatal growth, and early development. Smoking reduces breast milk volume and decreases infant growth rate [169]. Corticosteroids have a minimal effect on lactation.

ANTIPHOSPHOLIPID ANTIBODY SYNDROME

Criteria have been established [170] and validated [171] for the antiphospholipid antibody syndrome. Criteria require a clinical event (thrombosis or pregnancy loss) and a laboratory confirmation (moderate or high titer IgG or IgM anticardiolipin antibody or lupus anticoagulant, repeated on two occasions 6 weeks apart). Pregnancy-related criteria include three or more otherwise unexplained embryonic losses before 10 weeks or one or more otherwise unexplained fetal losses after 10 weeks, with or without severe early onset preeclampsia [172], placental infarction, or fetal growth restriction.

Identification of the Patient at Risk

The risk for current pregnancy loss due to antiphospholipid antibody is a function both of prior maternal pregnancy history and of titer of anticardiolipin antibody and/or lupus anticoagulant. Whether a mother is diagnosed as having the antiphospholipid antibody because she has lupus anticoagulant, ELISA-defined antiphospholipid antibody, or both does not alter outcome. A false-positive test for syphilis, in an unselected population of otherwise healthy pregnant women and in the absence of the other antibodies, does not predict outcome [173], but it does have predictive value in SLE patients. Most studies find that a high-titer antiphospholipid antibody is more predictive than a low titer and that the IgG isotype is more predictive of fetal loss than IgM [174–185]. There are few data on IgA antibody in pregnancy. There is some disagreement about absolute risk, probably because patients referred for an evaluation of recurrent fetal loss differ from normal pregnant women and from other women with SLE. The importance of the anti-β2GPI antibody in predicting the risk of APS obstetric complications is controversial. Most but not all studies suggest that while anti-β2GPI antibodies are present in many patients with complications, they do not predict pregnancy outcome with any greater accuracy than do aCL or lupus anticoagulant [186] and do not define a separate set of recurrent aborters [187]. Antiphospholipid antibodies other than anticardiolipin or lupus anticoagulant may occasionally be found [188].

The mechanism by which the antiphospholipid antibody induces fetal loss is not completely clear. Histology of placentas and success of anticoagulant therapy suggest that placental thrombosis is the most likely pathogenesis, possibly induced by neutralization of a protective placental anticoagulant [157, 158]. However, the antiphospholipid antibody may also interrupt trophoblast growth and differentiation or prostacyclin metabolism [189, 190].

Current risk estimates offer no justification for screening apparently normal pregnant women for antiphospholipid antibody [191]. Because low-titer IgM and IgG anticardiolipin antibody are as a rule not associated with poor fetal outcome, there is a legitimate argument for closely monitoring, but not arbitrarily treating, women with low-titer antibodies. Because primiparas and women with prior live-born children and no history of fetal loss, even with a high-titer antiphospholipid antibody, have at least a 50% probability of having a live-born child, an argument can be made for close monitoring, without treatment, of these women, although treatment with low-dose (81 mg/day) aspirin is common. First-trimester miscarriages have many causes, and second-trimester fetal deaths have been considered to be more characteristic of antiphospholipid antibody syndrome [192–196]. Data, however, suggest that a significant number of antiphospholipid antibody-related deaths do occur in the first trimester. There is general agreement that women *both* positive for antiphospholipid antibody *and* having prior fetal losses should be treated.

The antiphospholipid antibody is present in approximately 10% of apparently normal women with recurrent spontaneous abortion. The presence or absence of clinical SLE or of prior thromboses does not influence antiphospholipid antibody-related pregnancy outcome but does, of course, alter the risk for maternal complications and fetal complications related to treatment of the mother. Livedo reticularis, duration or persistence of antibody, hemolysis, and cardiac valve disease have not been examined as predictors of fetal outcome.

Effect of Pregnancy on the Course of Antiphospholipid Antibody Syndrome

There is no evidence that the frequency of thrombosis in antiphospholipid antibody syndrome patients changes in either direction during pregnancy, but anticoagulation of most patients for either fetal or maternal indications may hide a change in rate. Only a few patients not treated with heparin during pregnancy suffer thromboses; comparison rates with normal pregnancies are unavailable [197]. Stroke occurred in two *postpartum* antiphospholipid antibody syndrome patients 8 days after the discontinuation of aspirin therapy, emphasizing the need for *postpartum* as well as antepartum treatment [198]. Ischemic cardiomyopathy and myocardial infarction have also been thought to be *postpartum* complications of the antiphospholipid antibody syndrome [199, 200].

Thrombocytopenia regularly occurs in antiphospholipid antibody syndrome pregnancies and usually remits at the conclusion of a pregnancy. Livedo reticularis does not change during pregnancy. Libman–Sacks endocarditis during pregnancy has resulted in fatal thromboembolism with cerebral infarction [201, 202]. Severe thrombocytopenia may occur requiring IVIG and/or corticosteroid therapy. In one refractory case, laparoscopic splenectomy at 18 weeks gestation was successful [98]. The catastrophic antiphospholipid syndrome (CAPS), with multiorgan involvement, may occur during or immediately following pregnancy [203].

Mechanism of Antiphospholipid Antibody Pregnancy Loss

In pregnancies confirmed by the presence of a fetal heartbeat, the course of events is stylized: mild thrombocytopenia occurs within the first several weeks, but otherwise early pregnancy is uneventful. After 15 weeks fetal growth rate slows. Monitoring studies show, in succession, a nonreactive fetal heart rate pattern, spontaneous bradycardia, diminished fetal motion, decreased amniotic fluid, reduced placental size, and, if delivery is not accomplished, fetal death. During the course of these events, the mother, whether or not she has SLE, generally manifests no evidence of illness other than thrombocytopenia; some authors believe that the likelihood and severity of preeclampsia are greater in women who have antiphospholipid antibody than in those who do not [204]. An association between refractory HELLP syndrome and antiphospholipid antibodies has been proposed. Plasmapheresis was beneficial [205]. Hepatic infarction and renal thrombotic microangiopathy in association with early preeclampsia have occurred in several antiphospholipid antibody patients [206–210]. The probability that fetal death will occur is loosely related to the titer of IgG anticardiolipin antibody and to maternal history of prior fetal death. In carefully selected patients, fetal survival (complicated by prematurity and intrauterine growth restriction) rates of up to 80% are possible.

Lupus anticoagulant is a more specific, but less sensitive, predictor of fetal death than the anticardiolipin antibody. Pregnancy prognosis does not improve if the anticoagulant activity is corrected or if the anticardiolipin antibody titer falls.

Fetal death, prematurity, or intrauterine growth restriction is the effect of antiphospholipid antibody-associated placental insufficiency. Infants usually do not themselves have antiphospholipid antibody syndrome, but transplacental passage, leading to thrombosis, may occur [211]. Eight cases of thrombosis in a fetus carrying antiphospholipid antibody have been described, with varied location of thrombosis, many associated with neonatal death. Following delivery, growth-restricted infants gain weight rapidly. No long-term follow-up studies of infant survivors of antiphospholipid antibody syndrome have been published. Short-term surveys suggest that these children develop normally compared to children of similar prematurity [212].

While widely recognized as a significant factor in fetal distress and fetal loss, the antiphospholipid antibody may have a role in some cases of infertility. Increased levels of autoantibodies in general, and antiphospholipid antibody in particular, occur in patients with failed *in vitro* fertilization or embryo transfer cycles [213, 214]. Impairment of embryonic implantation and abnormal blastocyst development occur in a murine antiphospholipid antibody syndrome model [215].

Monitoring the Mother during Pregnancy

Maternal monitoring consists of measuring platelet count, lupus anticoagulant, and anticardiolipin antibody in early pregnancy. In women with strongly positive antiphospholipid antibody tests, serial testing is unnecessary, as a decrease in titer does not permit relaxation of vigilance. In women with low titer or negative tests, repetition at least once each trimester is useful, as an occasional patient demonstrates an increasingly abnormal test as pregnancy progresses, and the overall prognosis is that of the highest titer seen during the pregnancy. Even when initially normal, the platelet count should be repeated monthly, as thrombocytopenia may occur at any time. The risk of clotting may be increased in the immediate *postpartum* period.

Monitoring the Fetus during Pregnancy and the Puerperium

Monitoring of fetal growth and development, as outlined for patients with SLE, is essential for women with antiphospholipid antibody syndrome. Slowed fetal growth or other monitoring abnormalities indicate a need to intervene and, for viable infants, to deliver if fetal distress is clearly identified. Routine serological monitoring may also be of prognostic importance: several studies have demonstrated unexplained elevations of α-fetoprotein in patients with antiphospholipid antibody and, in these patients, have identified a higher risk of fetal and perinatal death. Presumably, abnormalities in the fetoplacental barrier associated with antiphospholipid antibody lead to an increased transport of α-fetoprotein. False-positive elevation in maternal hCG also occurs. There are no other special fetal risks than those of prematurity and growth restriction.

Premature closure of the *ductus arteriosus* is a theoretical concern in infants of aspirin-treated women but it has not been reported in this group of patients and is thought to be infrequent if it occurs at all. The choice of route of delivery is determined by standard obstetric criteria, including maternal and fetal platelet count.

Treatment

Our treatment recommendations are presented in Table 9. *In women with the secondary antiphospholipid syndrome, in whom SLE mandates the use of prednisone, prednisone should be part of the treatment of pregnancy*. The information provided in Table 9 applies to women with primary antiphospholipid syndrome or in those with the secondary syndrome in whom SLE is in remission.

In the earliest papers, low therapeutic levels of *heparin* (10,000 units BID and higher) were chosen as the optimum regimen. More recent studies suggest that even lower doses (5000 to 7000 units BID) are equally effective [216–218]. There are as yet no controlled clinical trials using low molecular weight heparin. Uncontrolled trials suggest no loss of efficacy but no substantial advantage in side effects or success rates. Most treating physicians also use one "baby" *aspirin* per day in conjunction with heparin.

Physicians offering heparin treatment should be aware of, and review with their patients, the substantial risk of bone loss [219]. No study published to date is definitive, but a loss of bone mineral density of up to 10% has been reported in women receiving heparin for an entire pregnancy [220]. In follow-ups up to 6 months, recovery did not occur. Nonsystematic and conflicting data suggest that recovery may occur by 2 years; breast feeding delays recovery. In one study, 2.2% of women receiving heparin for cardiac reasons suffered symptomatic vertebral fractures [221]. It is unclear whether low molecular weight heparin reduces this risk compared to unfractionated heparin [222, 223]. The risk may be lower for low-dose regimens compared to high dose. Animal data suggest that efficacy may be greater than with unfractionated heparin.

To minimize maternal risk, the safest treatment program for women not taking warfarin is to begin aspirin when the patient plans to conceive and to begin heparin only after pregnancy is confirmed. Heparin then should continue until immediately before delivery. It may be useful to obtain a pretreatment bone mineral density study and to reevaluate after delivery. Low

TABLE 9 Treatment Recommendations for Pregnant Women with Antiphospholipid Antibody

Patient characteristic	Recommendation
Medium or high titer IgG or IgM aPL antibody	
Primipara	Consider aspirin, 81 mg/day, or no therapy initially; if modest (>50 × 10^9/liter) thrombocytopenia occurs, aspirin[a]
Multipara, most recent pregnancy live born without complication	Consider aspirin, 81 mg/day, or no therapy initially; if modest (>50 × 10^9/liter) thrombocytopenia occurs, aspirin[a]
Multipara, most recent pregnancy failure <10 weeks (1 loss)	Aspirin
Multipara, most recent pregnancy failure ≥10 weeks without other explanation, or early or severe preeclampsia or fetal growth restriction	Aspirin while trying to conceive; add heparin, 5000 units BID at confirmation of fetal heartbeat, continue for duration of pregnancy
Low-titer IgG or IgM aPL antibody	
Primipara	No therapy
Multipara, no prior fetal loss	No therapy
Multipara, most recent pregnancy failure <15 weeks (1 loss)	Aspirin
Multipara, most recent pregnancy failure ≥15 weeks without other explanation, or >1 loss	Aspirin while trying to conceive; add heparin, 5000 units BID at confirmation of fetal heartbeat, continue for duration of pregnancy
Multipara, prior preeclampsia, IUGR, hypertension, or renal disease	Aspirin, beginning after first trimester
Normal aPL antibody	
Primipara	No therapy
Multipara, prior preeclampsia, IUGR, hypertension, or renal disease	Aspirin, beginning after first trimester
Multipara, all others	No therapy indicated by antiphospholipid antibody

[a] For thrombocytopenia <50 × 10^9/liter, consider intravenous immunoglobulin and/or prednisone.

molecular weight heparin has been used safely and successfully [224], but anecdotes of potential teratogenicity suggest caution. While evidence-based treatment of patients who fail aspirin and heparin therapy is not clear, almost all practitioners empirically add monthly intravenous immunoglobulin. A large number of small studies and case reports suggest success with the addition of IVIG [225]; however, no large-scale prospective randomized study has yet shown benefit, and a small study failed to show benefit [226]. The usual monthly dosage is a total of 1 to 2 g/kg infused over 1–5 days each month. The mechanism is not understood; it may act *via* an anti-idiotype directed against aCL; IVIG reduces aCL titers *in vivo* [227].

In some published treatment trials, *prednisone*, 40 to 60 mg/day (with low-dose aspirin), has been credited with saving pregnancies of women with lupus anticoagulant and prior fetal deaths [228, 229]. High-dose prednisone in the absence of aspirin is unhelpful. These experiences were small and uncontrolled, they included growth-restricted and premature infants as successes and allowed concomitant aspirin therapy. A controlled trial of pregnant women with at least two prior losses and any titer and isotype of antiphospholipid antibody demonstrated that a regimen consisting of low-dose aspirin (81 mg/day) plus subcutaneous heparin, 10,000 to 12,000 units twice daily, begun after ultrasonographic confirmation of a viable pregnancy (6.5 to 8 weeks) was less toxic and equally effective as prednisone, 40 mg/day, plus aspirin [230]. Prednisone-treated mothers suffered more hypertension, weight gain, diabetes, and premature rupture of membranes. Babies suffered amnionitis and prematurity.

In a group of women more rigorously selected but not randomized to different treatment regimens, prednisone plus aspirin, heparin, and aspirin alone were all effective when current, treated pregnancies were compared with prior pregnancies, but success in one treated pregnancy did not guarantee success with the same treatment in a subsequent pregnancy [231].

Several studies have reported a successful pregnancy outcome in patients treated with *intravenous immunoglobulin*. These studies have been limited to patients who have failed more traditional therapies; immunoglobulin is usually used in conjunction with other therapies rather than alone [232–234].

Warfarin is teratogenic and so is not used in pregnancy; subcutaneous heparin or low molecular weight heparin in full therapeutic doses is the anticoagulant of choice in women with prior thrombotic events. Warfarin may be used *postpartum*, even in women who breast feed. Anecdotes concerning the treatment of antiphospholipid antibody syndrome patients with *immunosuppressive* agents are not definitive and do not justify nonexperimental use of these agents [235].

Apheresis, to remove a pathogenic antibody, has been used in the catastrophic vascular occlusion syndrome and has been considered for *experimental* use in recurrent pregnancy loss, but no published experience on this method has yet appeared. In mouse models of pregnancy loss, interleukin 3, ciprofloxacin (which is thought to increase levels of interleukin 3), and a variety of experimental anticoagulants have all had success [236, 237]. There are no human trials with these agents. Ciprofloxacin damages fetal bone and cartilage and should not be used in pregnant women.

In the absence of clinical SLE, anticoagulation is the primary treatment for recurrent fetal loss due to antiphospholipid antibody. Early studies advocating high-dose prednisone, low-dose prednisone, aspirin, and aspirin plus prednisone have now been superseded by controlled clinical trials from several countries that uniformly support the use of unfractionated heparin (with or without aspirin). Fetal survival rates of more than 80% can be achieved even in women with a high-titer antibody and repeated fetal loss (Table 10), and low-dose regimens are effective.

TABLE 10 Randomized Controlled Trials of Treatment for Recurrent Fetal Loss in Women with Antiphospholipid Antibody

Author	No. A/B	Regimen A	Regimen B	Fetal survival A	Fetal survival B
Cowchock *et al*. [230]	12/8	Heparin 12,000 U BID + ASA 81 mg	Prednisone 40 mg + ASA 81 mg	80	75[a]
Kutteh [216]	25/25	Heparin 13300 U BID + ASA 81 mg	ASA 81 mg	80	44
Rai *et al*. [218]	45/45	Heparin 5000 U BID + ASA 81 mg	ASA 81 mg	70	40
Kutteh and Ermel [217]	25/25	Heparin 8100 U + ASA 81 mg	Heparin 13300 U BID + ASA 81 mg	76	80

[a] Marked increase in fetal and maternal morbidity compared to regimen A.

The rate of later thrombosis in the nonanticoagulated patient with a history only of pregnancy morbidity is high. In one study of patients referred for obstetrical management, 48% developed a new, vaso-occlusive symptom in an average follow-up of 3.2 years [238]. In one retrospective study, more than 59% of women with no prior thrombosis who had fetal loss due to aPL and did not subsequently receive low-dose aspirin suffered a thrombotic event within the next decade, compared to only 10% of similar women who did receive aspirin prophylaxis [239]. It is likely that low-dose aspirin will become standard long-term *postpartum* therapy.

Patients with Prior Thrombotic events; Thrombocytopenic Patients

Patients suffering thrombotic events during pregnancy receive full anticoagulant doses of heparin. Similarly, conventional hematology rules apply for thrombocytopenic patients. In general, it is acceptable to continue anticoagulation if the platelet count is above 100×10^9/ml, and possibly if the platelet count is above 50×10^9/ml.

Treatment for Infertility in Antiphospholipid Antibody Syndrome Patients

There are few studies addressing the issue of fertility in patients with SLE. It is likely that patients with SLE have no decrease in fertility [240, 241].

Over the last decade, an extensive literature has addressed the putative association of antiphospholipid antibodies and infertility. In 1987, El-Roeiy *et al*. [242] reported that 10 of 26 patients undergoing *in vitro* fertilization had aPL antibodies in serum and follicular fluid. Patients with autoantibodies had lower pregnancy rates [242]. One year later the same authors presented evidence of a polyclonal B-cell activation in 26 patients with infertility; half of infertile patients had aPL antibodies and two had lupus anticoagulants [243]. In a different group of 41 infertile women, there was a higher prevalence of antibodies to smooth muscle, nuclear, and phospholipid antigens [244]. Antiphospholipid antibody levels do not change during the course of *in vitro* fertilization; patients undergoing *in vitro* fertilization have a higher prevalence of antiphospholipid antibodies prior to their first procedure [245, 246].

Data implicating the antiphospholipid antibody in infertility and in failure of *in vitro* fertilization and embryo transfer cycles are preliminary. A single clinical study randomized antiphospholipid antibody-positive patients with failed *in vitro* fertilization to aspirin plus heparin or no treatment during the next cycle. Viable pregnancy rates were 49 and 16%, respectively [247].

Patients with the antiphospholipid antibody do not appear to incur serious risks if they undergo ovulation induction and other assisted reproduction techniques. The concern for aPL-positive patients (as opposed to those related to underlying SLE) is an increased risk of thrombosis in the setting of the high estrogen levels achieved. As these levels do not reach those sustained in late pregnancy, risk is likely not increased over that associated with pregnancy itself, the intended outcome of IVF. No thromboses were reported in a series of 10 patients with PAPS who underwent from 1 to 17 cycles of ovarian induction each (a total of 47 cycles). Nine of the 10 patients were treated during their cycles with aspirin and 6 with heparin [248]. The practice of anticoagulant treatment through the early phase of the cycle to reduce thrombosis risk remains unproven but, at least in the case of low-risk aspirin therapy, may be reasonable. Patients with a history of thrombosis and on warfarin prior to IVF should substitute subcutaneous heparin, both before and after time of embryo transfer (holding heparin just before oocyte retrieval).

Postpartum Treatment; Abortion

It is conventional practice to continue aspirin (if used during pregnancy) for at least 1 month *postpartum* to prevent the potential complication of thrombosis. For women who have received heparin up to delivery it is conventional to continue heparin *postpartum* or to change to warfarin and to continue anticoagulation for up to 3 months. If a clotting event has occurred during or following the pregnancy, treatment is continued for a longer period, but absolute points at which anticoagulation might be terminated have not been established.

Patients electing abortion should receive aspirin, 81 to 300 mg/day, for 1 month *postpartum* as a low-risk, low-cost prophylaxis against the theoretical possibility of thromboembolic complications.

Medico-legal Considerations

Physicians treating otherwise well women for recurrent pregnancy loss should keep foremost in their minds the fact that the available treatments engender considerable risk. If pregnancy is not an extremely high priority for the patient, treatment other than aspirin should not be offered, regardless of the number of prior unsuccessful pregnancies or titer of antiphospholipid antibody. Osteoporotic fracture or serious hemorrhage from heparin, osteonecrosis from corticosteroid, or pulmonary edema or hepatitis C from intravenous immunoglobulin are high prices to pay if a child is not intensely desired. If a woman has received such a treat-

ment and has not been forewarned of its complications, and if those complications ensue, her lawyer will certainly remind her that adequate warning is a physician's duty.

Counseling and Other Issues

Because both *oral contraceptive* therapy and antiphospholipid antibody syndrome are associated with a high frequency of vascular occlusive events, it would seem unwise to prescribe oral contraceptives to patients with antiphospholipid antibody. Specific calculations of risks that clearly implicate oral contraceptives in thrombotic events in antiphospholipid antibody syndrome patients have not been defined. Oral contraceptives may increase the risk of venous thromboembolism [249], depending on both the contraceptive "generation" and other patient risk factors. In one large lupus cohort, oral contraceptive use was not associated with venous thromboembolism. An ongoing National Institutes of Health study of oral contraceptives in lupus patients accepts patients with low-to-moderate (<40 GPL units/ml) titer antiphospholipid antibody, suggesting that an answer may be available soon.

Genetic counseling should take cognizance of the fact that the antiphospholipid antibody is often familial [250], including in some cases other family members with SLE, but the degree of penetrance or of disease expression in related family members is not known. In different populations, women with the antiphospholipid antibody have an unusual frequency of HLA-DRw7 [251, 252], HLA-DRw53 [253], HLA-B8, DRw3 [254], or the C4 null allele [255]. There are no known genetic fetal abnormalities associated with the antiphospholipid antibody, and no valid risk calculations regarding the probability that the child will eventually also develop this antibody.

While antiphospholipid antibody is important, many *other causes of recurrent fetal loss* exist [256, 257]. These include abnormalities of chromosomes, sperm, uterus, and cervix, and infection, immune attack on the fetus, and underlying medical illness. Evaluation for recurrent fetal loss generally includes items listed in Table 11 [258].

There are no publications regarding *breast feeding* in women with the antiphospholipid antibody syndrome. Because many live-born infants are premature or growth restricted, breast feeding is often impossible. Those that have been able to breast feed have done so uneventfully. Although maternal antiphospholipid antibody-containing immunoglobulin may be transmitted through breast milk to the newborn, and although low-dose aspirin is also transferred to breast milk, no complications known to be related to breast feeding have been reported. Heparin is not transferred to breast milk and so may be continued if necessary.

TABLE 11 Evaluation for Recurrent Fetal Loss

- General medical and obstetrical history, including chronic illness and diethylstilbesterol exposure
- Complete medical and gynecological examination
- Laboratory evaluation including fasting blood sugar, erythrocyte sedimentation rate, and thyroid function tests
- Blood group, including Rh factor
- Coagulation factors
- VDRL, lupus anticoagulant, anticardiolipin antibodies
- Karyotype of both parents
- Postovulatory progeterone level
- Full endocrine profile
- Pelvic ultrasound
- Hysterosalpingogram
- Laparoscopy

What to Tell Prospective Parents

Most studies associating antiphospholipid antibody with thrombosis or fetal death have begun with the event (thrombosis or prior fetal death) or diagnosis (SLE), identified the antibody, and then either retrospectively or prospectively calculated a frequency of new events in this preselected population. These studies suggest a high risk to all bearers of the antibody. Cross-sectional studies of populations have suggested much lower frequencies of new events in women who have not had a prior adverse event. Therefore, in clinically well women with the antiphospholipid antibody, prophylactic treatment against either thrombosis or fetal death is not indicated, although low-dose aspirin is sometimes used. The occurrence of thrombosis cannot be predicted by changes in antibody titer; the risk of *recurrent* thrombosis in the unanticoagulated patient who is not pregnant is high [259, 260]. In one study of patients referred for obstetrical management, 48% developed a new, vaso-occlusive symptom in an average follow-up of 3.2 years [238]. In another study of women with antiphospholipid antibody and pregnancy loss but no prior thrombosis, 10% of those treated *postpartum* with aspirin and 59% of those untreated had thrombotic events in the subsequent 4.2 years [239]. It is not known whether pregnancy increases the risk for new thrombosis. Discussion of these uncertainties with prospective parents is appropriate.

The likelihood that the patient with primary antiphospholipid antibody syndrome will eventually

develop SLE is low. There are no known risks to the surviving infant beyond those associated with its prematurity.

LUPUS-LIKE DISEASE

Because patients with mixed or undifferentiated connective tissue disease may carry anti-SSA/Ro, anti-SSB/La, or antiphospholipid antibodies, they must be monitored through pregnancy in a manner similar to that appropriate for a patient with SLE or primary antiphospholipid antibody syndrome. Treatment for complications is directed to the organ systems involved, not to the specific diagnosis, and is similar to that used for SLE. Counseling is that relevant to SLE.

Management of pregnancy of patients with secondary Sjögren's syndrome is that of the accompanying connective tissue disease. Treatment of the local manifestations of primary Sjögren's syndrome is not altered by the presence of pregnancy. Most pregnancies in primary Sjögren's syndrome occur before the onset of disease. These patients have an increased risk of fetal loss not attributable to autoantibodies and a risk of neonatal lupus in their offspring as well [261].

It is important to determine whether anti-SSA/Ro or anti-SSB/La antibodies are present in pregnant patients with Sjögren's syndrome and to anticipate the possibility of both cardiac and cutaneous findings of neonatal lupus in infants of those found to be positive (see earlier discussion). There is a possibility that patients with Sjpgren's syndrome are more likely than other anti-SSA/Ro antibody-positive patients to deliver children with neonatal lupus [262]. Counseling should reflect these data.

IN VITRO FERTILIZATION AND RELATED TOPICS

Infertility, Male and Female

The decline of female fertility begins in the middle thirties and becomes marked after age 40. Because the lupus patient has effects of cytotoxic agents, such as cyclophosphamide, and long-term effects of chronic illness, her fertility may decline sooner.

Evaluation for infertility includes consideration of both male and female factors. Testing for the woman includes a day three follicle-stimulating hormone level, thyroid function tests, and cervical cultures. Tests for ovulation include basal body temperature and endometrial biopsy. Low serum progesterone 1 week after ovulation suggests an inadequate luteal phase. A postcoital test gives information regarding quality and quantity of cervical mucus as well as the presence of antisperm antibodies. Tubal function is evaluated with a hysterosalpingogram. Hysteroscopy and laparoscopy may be required [263].

Tests for male factors include semen analysis as well as tests for spermatozoal function, such as the hamster penetration assay and the human zona pellucida assay. Hormone evaluation radiological tests may uncover other causes for infertility [264].

Assisted Reproductive Techniques

A glossary of assisted reproductive techniques is presented in Table 12 [265].

TABLE 12 Glossary of Terms of Assisted Reproduction

Term	Definition
Assisted reproductive technologies (ART)	Infertility treatment procedures involving manipulation of oocytes, spermatozoa, and/or embryos
In vitro fertilization (IVF)	Laboratory culture of aspirated oocytes and spermatozoa followed by transcervical embryo transfer (ET)
Gamete intrafallopian transfer (GIFT)	Direct placement of aspirated oocytes and spermatozoa into fallopian tubes
Controlled ovarian hyperstimulation (COH)	Ovulation induction with monitoring in normal ovulatory women; intent is to induce multiple ovarian follicles
Intrauterine insemination (IUI) Intracervical insemination (ICI) Intratubal insemination (ITI)	Separation of spermatozoa from seminal fluid with suspension in buffer or culture media and insemination into the uterus, cervix, or fallopian tube
Zygote intrafallopian transfer (ZIFT)	Laboratory culture of aspirated oocytes with spermatozoa followed by direct placement of fertilized zygotes or embryos into fallopian tubes
Oocyte donation (OD)	Laboratory culture of aspirated oocytes from a donor woman followed by sperm/oocyte culture and transfer
Intracytoplasmic spermatozoa injection (ICSI)	A micromanipulation technique in which a single sperm is injected into an oocyte. It is used in cases of abnormal spermatazoal function or very low sperm counts

Treatment Regimens Used in Assisted Reproduction

In vitro fertilization, initially developed for patients with tubal disease but now used for a variety of infertility diagnoses, is the most common assisted reproductive technique. The process includes oocyte stimulation, retrieval, *in vitro* fertilization, and embryo placement in the uterus [266].

Preparation of the oocyte donor begins with the administration of gonadotropin-releasing hormone (GnRH) analogues to bring about desensitization of the pituitary gonadotropes to endogenous GnRH. Ovarian stimulation is accomplished by administering human menopausal gonadotropin and ovulation by administering human chorionic gonadotropin (hCG) when many follicles are sufficiently mature. The luteal phase is maintained with low-dose hCG or with exogenous (intramuscular) progesterone. Oocytes are retrieved through transvaginal ultrasound-guided follicular puncture under local anesthesia.

Semen preparation involves separation of motile spermatozoa from seminal fluid, *in vitro* capacitation, addition to cumulus-enclosed oocytes a few hours after their retrieval, and assessment of fertilization. Gamete micromanipulation is used for male factor infertility; the most effective method is intracytoplasmic sperm injection. Fertilized oocytes are reexamined after a further 24-h incubation to confirm that embryonic cleavage has occurred and to assess embryo quality. Embryo placement (usually three per procedure) is accomplished through transcervical transfer to the uterus at the two to four cell stage.

Within 10–12 days of insemination, implantation can be detected by an increase in serum hCG levels. Diagnosis of clinical pregnancy depends on visualization by ultrasound of a gestational sac containing a viable fetus (detectable heart beat) within the uterine cavity.

The pregnancy success rate following *in vitro* fertilization and other assisted reproductive techniques is greater for patients of younger age. For older patients with poor oocyte quality or for patients carrying a maternal genetic defect, oocyte donation is recommended. Use of specific techniques depends on infertility etiology, if identifiable. The description of outcome of assisted reproduction varies. *Biochemical pregnancy* is implantation identified by a transient production of hCG but early loss before sonogram documentation of a fetus. *Clinical pregnancy* progresses to a stage in which a gestational sac and fetal heart motion can be seen. *Ongoing pregnancies* represent currently viable gestations. Success rates may be expressed as pregnancies per transfer or per embryo transferred. There is a greater risk of ectopic pregnancy and of first trimester spontaneous abortions in IVF pregnancies. The most common complication is multiple gestation. Up to 30% of multiple births occur, most being twins [267].

ALTERNATIVES TO ASSISTED REPRODUCTION

Lupus patients sponsor surrogate children, using their own or donated oocytes brought to term in volunteer well women. Lupus patients also adopt children. In the latter case, many patients are severely questioned about their own health. The process varies in different locales. The emotional trauma of enduring such a process may be severe.

Women who have undergone assisted reproduction attempts or who have adopted counsel that the costs are very high and that emotional and physical exhaustion (often including distant travel) is the rule. For women undergoing ovarian hyperstimulation, another burden is added, as the procedure, even in well women, is physiologically exhausting and painful. Lupus exacerbation, however, is rare.

EPIDEMIOLOGY OF SYSTEMIC LUPUS ERYTHEMATOSUS

Dafna D. Gladman

Epidemiology is the study of the frequency, distribution, and determinants of disease in populations. Epidemiological studies of systemic lupus erythematosus (SLE) have focused on the following areas: (1) development and validation of criteria for disease classification; (2) estimation of morbidity and mortality rates in different populations; (3) estimation of prognosis and survivorship of patients with SLE; and (4) determination of etiologic factors, both genetic and environmental. Major findings regarding disease classification, morbidity and mortality rates, prognosis and survivorship, and etiologic factors are reviewed in this chapter.

CLASSIFICATION CRITERIA

A proper case definition for the disease is required for both the conduct and the interpretation of epidemiologic studies [1–4]. In 1971, the American Rheumatism Association (now American College of Rheumatology, ACR) published preliminary criteria for the classification of SLE [5]. Until recently, the 1982 revised criteria were used for case definition [6]; the authors of that revision noted that criteria "should be used mainly for the purpose of classifying patients in reports relating to clinical, serologic, cellular, or pathogenetic studies of SLE." The 1982 dataset has been reanalyzed by Edworthy and colleagues, [7] using the method of recursive partitioning to generate a classification tree in an effort to "identify simpler and more explicit rules to classify patients with SLE." The resultant simple classification tree requires knowledge of only two variables: immunologic disorder and malar rash. Based on the criteria dataset (Table 1), the sensitivity, specificity, and accuracy of the 1982 revised criteria and the classification tree were 96 and 92%, respectively. Criteria were updated by the Diagnostic and Therapeutic Criteria Committee of the American College of Rheumatology in 1997 [8] (Table 2). The updated version of criteria has yet to be tested.

It should be noted that the methods used for classifying patients with SLE were not designed for diagnostic purposes and lack the sensitivity for recognizing milder cases. Although this is a virtue for purposes of analytic epidemiological studies of etiologic features to ensure homogeneity of the case population, it may alternatively be a limitation in descriptive studies of morbidity and observational studies of prognosis, as subjects with a multisystem disease consistent with SLE may not fulfill the criteria [9]. Use of the 1982 revised criteria enabled the recognition of cases with latent lupus [10] and incomplete lupus [11], terms used to describe groups of patients with one or more symptoms or signs of SLE who fail to fulfill the 1982 revised criteria. Although these patients fulfill some criteria for SLE, it is important that they are excluded from epidemiologic studies of SLE because only a fifth to a third of such patients may go on to develop full-blown disease [10, 12]. The inclusion of these patients in studies of prognosis may lead to an erroneous description of better prognosis for patients with SLE.

TABLE 1 1982 Revised Criteria for SLE[a]

	Sensitivity	Specificity	Accuracy
Malar rash	57	98	76
Discoid rash	18	99	57

MORBIDITY DATA

Prevalence

The overall prevalence of SLE has varied from 12 to 50.8 cases per 100,000 persons (Table 3) [13–33]. The individual studies vary over time and place and used different methods of case ascertainment. Thus, while studies conducted in Rochester, Minnesota [16], and San Francisco, California [14], utilized both inpatient and outpatient records for case identification and published criteria for case validation, there were differences in the sampling frame: residents of Rochester and members of Kaiser Foundation Health Plan, respectively, and in the racial composition of the populations, 81 and 99% Caucasian, respectively. The sex- and race-specific prevalence estimates for Caucasian males and Caucasian females, however, are comparable as 95% confidence intervals for these ratios overlap; estimates for the overall prevalence in Caucasians were 44 and 40 per 100,000, respectively. Variability in prevalence rates

TABLE 2 1997 Update of the 1982 American College of Rheumatology Classification Criteria for SLE

Item	Definition
Malar rash	Fixed erythema, flat or raised, over the malar eminences, sparing the nasolabial folds
Discoid rash	Erythematosus-raised patches with adherent keratotic scaling and follicular plugging: atrophic scarring may occur in older lesions
Photosensitivity	Skin rash as a result of unusual reaction to sunlight by patient history of physician observation
Oral ulcers	Oral or nasopharyngeal ulceration, usually painless, observed by a physician
Nonerosive arthritis	Involving two or more peripheral joints, characterized by tenderness, swelling, or effusion
Pleuritis or pericarditis	a. Pleuritis—convincing history of pleuritic pain or rub heard by a physician or evidence of pleural effusion b. Pericarditis—documented by ECG or rub or evidence of pericardial effusion
Renal disorder	a. Persistent proteinuria greater than 0.5 g per day or greater than 3+ if quantitative not performed b. Cellular casts—may be red cell, hemoglobin, granular, tubular, or mixed
Seizures or psychosis	a. Seizures—in the absence of offending drugs or known metabolic derangement, e.g. uremia, ketoacidosis, or electrolyte imbalance b. Psychosis—in the absence of offending drugs or known metabolic derangement, e.g., uremia, ketoacidosis, or electrolyte imbalance
Hematologic disorder	a. Hemolytic anemia with reticulocytosis b. Leukopenia—less than 4000/mm^3 on two occasions c. Lymphopenia—less than 1500/mm^3 on two occasions d. Thrombocytopenia—less than 100,000/mm^3 in the absence of offending drugs
Immunologic disorder	a. Anti-DNA: antibody to native DNA in abnormal titer b. Anti-Sm: presence of antibody to Sm nuclear antigen c. Positive finding of antiphospholipid antibodies based on (1) an abnormal serum level of IgG or IgM anticardiolipin antibodies, (2) a positive test for lupus anticoagulant using a standard method, or (3) a false-positive test for at least 6 months and confirmed by *Treponema pallidum* immobilization or fluorescent treponaml antibody absorption test.
Positive antinuclear antibody	An abnormal titer of antinuclear antibody by immunofluorescence or an equivalent assay at any point in time in the absence of drug

Gourley *et al*. [24]	1993	Northern Ireland	Multiple	25.4
Peschken and Esdaile [31]	1996	Manitoba, Canada	Multiple	22.1

among studies may be due to different methods of case ascertainment, which have utilized general practice diagnostic registries [19], hospital discharge records [15, 17, 20], and outpatient clinic records or combinations thereof [18]. Several studies from the United Kingdom utilized multiple sources to trace patients, including contacting primary care and specialist physicians, a rheumatology database, a renal unit database, immunology and pathology laboratory reports and databases, and hospital activity records (including both inpatients and outpatients and local branches of the Lupus Society [21, 23, 24, 26]).

A study from Denmark used central population registry, outpatient registry, physicians' documentation, and laboratory registry information [32]. In comparing studies using similar methodologies for case identification and validation, the prevalence of SLE is almost identical. Thus Michet *et al*. [16], Nived *et al*. [18], and Nossent [33] used hospital records to ascertain their cases and arrived at a prevalence rate of 40, 39, and 49.5, respectively, whereas three British groups and a Danish group who used several sources to ascertain cases also arrived at similar prevalence rates ranging from 21.7 to 26.1 [21, 23, 24, 26, 32]. The lowest rate at 12/100,000 was determined through use of general practice diagnostic registries [19]. A study based on self-reported, physician-diagnosed SLE suggests that the prevalence of SLE in the United States may have been underestimated and that a more realistic rate is that of 124/100,000 [27]. Indeed the most recent study from Rochester, Minnesota, estimated an age- and sex-adjusted prevalence rate on January 1, 1992, to be 1:1000 [28]. The prevalence in Norwegian women aged more than 30 is 1:1000 [33]. A study from London suggests a similar prevalence rate among Afro-Caribbean and West-African blacks [34].

Incidence

The average annual incidence of SLE in the continental United States has been estimated in several studies; incidence rates vary from 2.0 to 7.6 cases per 100,000 persons per year [13, 14, 16, 18, 22, 28, 29, 32; Table 4]. As noted previously, several reasons may help explain differences between studies. The differences may be attributed to changes in diagnostic classification, as the ACR criteria have been modified from 1971 to 1982, and to the use of different methods for case ascertainment. Of particular interest are differences in incidence reported for the same population utilizing the identical medical record retrieval system in the studies from Rochester, Minnesota; Michet *et al*. [16] attributed the differences to changes in diagnostic classification. The most recent study from the same center, using the 1982 ACR classification criteria, supports that notion [28]. Studies that utilized community-based outpatient medical records [14] documented a high incidence of SLE. In the Swedish study, Nived *et al*. [18] used a system for case identification that employed review of not only inpatient and outpatient computerized

TABLE 4 Incidence Rates in Published Series

Author	Year	Location	Source of patients	Incidence[a]
Siegel and Lee [13]	1965	New York		2.0
Fessel [14]	1973	San Francisco	Community based	7.6
Hochberg [27]	1977	Baltimore, Maryland	Hospital discharge	4.6
Michet *et al*. [16]	1979	Rochester, Minnesota	Rochester epidemiology program project	2.2
Nived *et al*. [18]	1982	Sweden	Hospital/community	4.6
Nossent [22]	1989	Curaçao	Clinic, hospital, death certificate	4.6

Uramato *et al*. [28]	1992	Rochester, Minnesota	Rochester epidemiology program project	5.8
Voss *et al*. [32]	1994	County of Funen, Denmark	Multiple	3.6
Nossent [33]	1996	Arctic region of Norway	Multiple	2.7

[a] Per 100,000.

registers, but also outpatient clinic files. These authors identified 15 cases of SLE for an incidence of 4.8 cases per 100,000 per year, which has remained constant over the 1981–1991 decade [35]. A similar annual incidence rate (2.4 and 2.7) was observed over two consecutive 9-year periods between 1978 and 1996 in the arctic region of Norway [33]. Moreover, some studies may include both definite and probable cases of SLE. McCarty *et al*. [29] demonstrated that while utilizing only one source of data collection may underestimate the true incidence rate (2.4 vs 2.8), the inclusion of probable cases increases the incidence rate from 2.4 to 3.4 per 100,000. The Danish county-based cohort study composed primarily of Caucasians documented an increased incidence from 1/100,000 to 3.6/100,000 during the 1980–1994 period [32].

Thus while it has been pointed out that a single source of case ascertainment may be insufficient to document the true incidence of SLE, care must be taken to achieve true ascertainment of cases so as not to overestimate the rate by including probable cases. As pointed out earlier, probable cases, which may be "latent" or "incomplete" lupus, may not evolve into full-blown SLE.

Effects of Age, Gender, and Race on Morbidity Rates

Another reason to explain the variability in prevalence and incidence rates in the published studies may be the effect of age, gender, and race on these rates. Overall prevalence and incidence rates are higher in females compared to males and are higher in American Blacks, Afro-Caribbeans, Asians, and Native North American Indians than in Caucasian populations. Among Caucasian females, age-specific incidence rates have been estimated in four studies and showed maximum rates per 100,000 per year of 3.8 in the 15- to 44-year age group [13], 6.3 in the 25- to 44-year age group [16], 7.0 in the 35- to 54-year age group [29], and 15.9 in the 45- to 64-year age group. Similar observations for 1-year prevalence rates were made in Leichester, United Kingdom [21], whereas in Nottingham, United Kingdom [22], the peak incidence for Caucasians was in the 50- to 59-year age group. The highest incidence among the Norwegian group was in the 30- to 49-year age group [33]. Median ages at diagnosis for Caucasian females in the first three studies were 39, 39, and 42 years, respectively. Age-specific incidence rates in Caucasian males are difficult to interpret because of small numbers of studied cases, but peak rates of 4.5 and 0.9 per 100,000 per year in the age group 65 years and older have been reported in the New York City [13] and Rochester [16] studies, respectively. In Iceland, the overall age standardized rate was 5.8 for women and 0.8 for males [36]. Almost identical numbers were derived from the study in the arctic region of Norway. Both the Baltimore population study [29] and the Leichester, United Kingdom study [21] noted that SLE develops later in Caucasian males than in Caucasian females.

Age-specific incidence rates in Black females were greatest in the 15- to 44-year age group in New York City [13] and in the 25- to 34-year age group in Baltimore [30], with Birmingham, United Kingdom [26] exceeding 20 per 100,000 per year; age-specific rates in Black males can only be estimated reliably from the

Baltimore study and reached a peak in the 45- to 64-year age group of 5 per 100,000 per year.

Clinical studies have consistently demonstrated a female predominance approaching 90% of SLE cases. This excess is especially noteworthy within the 15- to 64-year age group wherein ratios of age- and sex-specific incidence rates show a 6- to 10-fold female excess in Caucasians and Blacks. No such excess was noted in the age groups 14 years and below and 65 years and above in New York City [13], Rochester [16], or Sweden [18]. A 4-fold excess incidence rate in females aged 65 years and above was found among Baltimore Caucasians but not Blacks [30]. Similar observations were recorded in the Swedish cohort, where the incidence rate was notably higher for women age 65–74 (14.1/100,000) compared to men of the same age (3.2/100,000). These age-related differences in the ratio of sex-specific incidence rates have been thought to be related to hormonal changes occurring during puberty and the child-bearing years. Among the North American Indians of Manitoba the age-adjusted prevalence rate was 42.3/100,000, and the highest rate was noted among the 35- to 54-year age group [31].

Reasons for the excess morbidity from SLE in American Blacks are unknown but may be related to differences in exposure to environmental factors rather than differences in genetic predisposition [30].

Conflicting data exist regarding the excess prevalence of SLE among Asians compared with Caucasians [37]. In Hawaii, the prevalence of SLE was estimated at 41.8/100,000. It was 1.3 times higher in Japanese, 1.5 higher in Filipinos, 2.4 higher in Chinese, but lower in Hawaiians [25]. In Britain, the rate for Chinese was much higher than that of Caucasian or Asians, the latter including individuals from Indian and Pakistan [23, 26]. In the San Francisco study, the prevalence of SLE was not apparently increased among Chinese compared with Caucasians [15]. Data from China, based on population surveys, suggest a prevalence of SLE of 40–70 per 100,000 [38, 39]. A survey in Taiwan identified only one case of SLE among 1836 residents and no cases among 2000 female students [40]. Thus population-based data in three countries fail to support an excess prevalence of SLE among Chinese. Prevalence data from Japan also fail to support the observations in Hawaii of an excess prevalence in Japanese [21]. These discrepancies may also be related to case definitions and to the use of different sets of criteria for the classification of SLE.

An excess incidence and prevalence of SLE among North American Indians compared with Caucasians was suggested in two U.S. studies and one Canadian study [31, 41, 42]. This excess was isolated to only 3 of 75 American Indian tribes and a single Pacific Northwest Indian population, the Nootka, and was also noted among the Manitoba Indians. In the province of Manitoba, Canada, both the crude annual incidence (0–7.4/100,000 vs 0–2.3/100,000) and the prevalence of SLE (33.4/100,000 vs 20.6/100,000) were higher among North American Indians than the rest of the population. These observations could represent chance findings; however, in-breeding and/or environmental factors may explain the clustering. Further studies of Native American Indian populations could identify additional clusters with excess morbidity from SLE in an effort to test hypotheses regarding risk factors for SLE.

TABLE 5 Mortality from SLE by Gender and Race Group in the United States[a]

[a] Rates per 1 million persons per year. WM, white males; WF, white females; BM, black males; BF, black females.

[b] Data include deaths attributed to both discoid and systemic lupus.

MORTALITY DATA

Mortality attributed to SLE in the continental United States has been estimated from community base [13] as well as national [43–46] data (Table 5). Lopez-Acuna and colleagues [46] identified all deaths attributed to both discoid and systemic lupus erythematosus from National Center for Health Statistics (NCHS) data tapes for the period 1968–1978. A total of 11,156 deaths were identified: 2568 (23.0%) were attributed to discoid lupus and 8588 (77.0%) to SLE. There were no differences in this distribution by sex, race, region, or year. There were a total of 6452 deaths in Caucasian females, 2573 in Black females, 1760 in Caucasian males, and 371 in Black males, with average annual age-adjusted mortality rates of 6.0, 17.6, 1.8, and 3.0 per million person-years, respectively (Table 5). Age-specific average annual mortality rates showed a unimodal distribution for all sex and race groups, with maximum rates occurring in the 45- to 54-year age group in Blacks and in the 65- to 74-year age group in Caucasians (Fig. 1).

Kaslow [47] analyzed a subset of these mortality records and examined deaths attributed to SLE alone

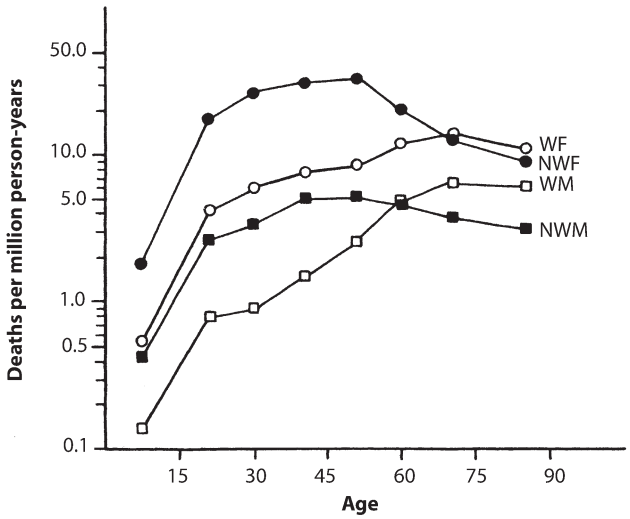

FIGURE 1 Average annual age-specific mortality rates attributed to SLE by sex and race group in the United States, 1968–1989. WM, white males; WF, white females; NWM, nonwhite males; NWF, nonwhite females.

from 1968 through 1976 in 12 states that have 88% of the U.S. residents of Asian descent. Mortality rates were threefold greater among Blacks and twofold greater among Asians compared with Caucasians: 8.4, 6.8, and 2.8 per million person-years, respectively. The age- and sex-adjusted mortality rates for Chinese, Japanese, and Filipinos were 7.5, 6.8, and 5.1 per million persons-years, respectively. Age- and sex-adjusted race-specific mortality rates for Hawaii were greater among Filipinos and the combined Asian group than for the U.S. mainland population, confirming previous observations [48]. A further study from Hawaii demonstrated that mortality were three times higher in non-Caucasians than Caucasians in 1985 to 1989 [25]. It is unclear whether the differences in mortality rates between Asians and Caucasians mirror true differences in incidence rates as is seen with American Blacks (see earlier discussion).

Siegel and Lee [13] noted greater mortality and morbidity from SLE among Puerto Ricans in New York City than among Caucasians. Lopez-Acuna and colleagues [46] analyzed mortality from SLE in Puerto Rico from 1970 through 1977 as well as a subset of the NCHS dataset for five southwestern states: Arizona, California, Colorado, New Mexico, and Texas. A total of 92 deaths from SLE occurred in Puerto Rico; the average annual age-adjusted mortality rates of 7.5 and 2.0 deaths per million person-years in females and males, respectively, were not significantly different from those noted among U.S. Caucasians over the same time period. A correlation between the proportion of Spanish-heritage population and county-specific mortality rates from SLE was noted for females but not males in the five states; the implications of this finding may reflect both ethnic/racial and socioeconomic factors.

Nationwide mortality data regarding SLE have been reported from Finland [15] and from England and Wales [48]; average annual mortality rates were 4.7 and 2.5 per million person-years, respectively. Patterns of age-specific mortality rates in both countries were similar to those in Caucasians; the fourfold greater age-adjusted mortality among English females compared with males is similar to that seen in the United States. Similar results were obtained in a study of the arctic region of Norway, with a crude annual mortality rate of 4.6 per million. A study from Canada comparing the mortality among patients with SLE to the general population demonstrated an overall mortality risk (presented as a standardized mortality ratio, SMR) of 4.9. The SMR was higher for patients under 24 years old than for those 55 or older (14.9 vs 2.83, respectively). A similar SMR (4.6) was described for a Danish multicenter study where the overall mortality rate was 2.9% per year [50]. While the SMR for men and women did not differ, there was an effect of age. The SMR was higher for patients with early onset disease compared to those with late onset disease (57 vs 2.1), supporting the Toronto experience. However, the Norwegian study revealed an overall SMR of 2.2 with rates increasing with age from 1.7 for the 30- to 49-year age group to 3.9 in the over 50 age group [33]. Among the 1000 patients included in the "Euro-lupus project" there was a 4.5% mortality in the first 5 years [51].A multicenter study from Argentina revealed that 12% of 366 patients died over a 6-year study. SMR are not available [52].

Temporal trends in mortality rates have been examined in both the United States [45, 46] and England and Wales [48]. In the United States there was a significant decline in age-adjusted annual mortality rates between 1968 and 1978 for all sex and race groups (Fig. 2). A significant temporal decline in age-adjusted annual SLE mortality rates was also observed among females in England and Wales from 1974 to 1983 but not among males, probably because of small numbers of deaths [48]. A similar decline in mortality rates was observed in the Toronto cohort, where the estimated risk for death was compared for patients entered into the cohort between 1970 and 1977, 1978 and 1986, and 1987 and 1994 [53]. SMRs declined from 10.1 in the first group to 3.3 in the last group. The same decline was observed for the first two groups followed over the next time period. The decline in mortality rates observed in these developed countries is probably due to improved survival in patients with SLE as reflected by (1) a temporal increase in mean age at death from SLE in the United States between 1968 and 1978 (Fig. 3) and (2) 10-year

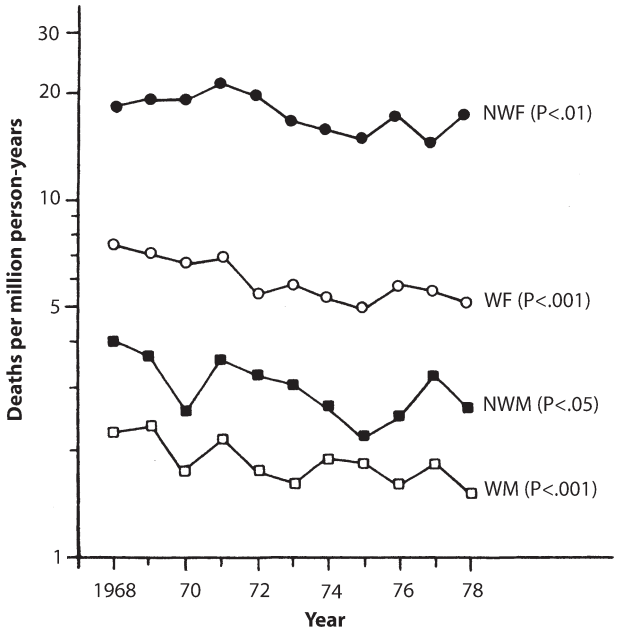

FIGURE 2 Trends in age-adjusted mortality rates from SLE by sex and race group in the United States, 1968–1978. WM, white males; WF, white females; NWM, nonwhite males; NWF, nonwhite females.

cumulative survival rates approaching or exceeding 90% in recent studies [54].

PROGNOSIS AND SURVIVORSHIP

Longitudinal observational studies of patients with SLE to estimate prognosis with respect to survival have been conducted for the past four decades; the first such study, conducted by Merrell and Shulman [55], found a 51% cumulative survival rate at 4 years after diagnosis (Table 6). The survival of patients with SLE has improved remarkably from that study to a 90% 10-year survival in the 1990s, and the 20-year survival figures approach 70% (Table 6) [33, 49–80]. This improved survival is typical of the Western world, whereas in developing countries such as India [71], and among Black Caribbean patients [74], poorer survival has been recorded. Among the Manitoba population, Native Indians fared less well than Caucasians, but they still fared better than patients in the developing countries [31].

Factors Associated with Survival Outcomes

Demographic Factors

A number of features not related to the SLE process itself may be predictive for mortality in patients with SLE, including gender, age at onset, race, and socioeconomic status. Table 7 summarizes the prognostic factors associated with mortality identified in published series. The effect of gender on mortality has been controversial, but the majority of studies suggest that there is no gender effect. However, a Spanish study of 306 patients identified male sex to be associated with worse survival [52]. The role of age at onset of SLE in predicting mortality has also been disputed. Several studies suggested that a higher age at presentation was a risk factor for death [61, 67, 72, 73], but a study comparing adult- and childhood-onset SLE patient populations did not reveal any differences in the 1- to 5-year mortality figures [77]. The latter study, however, did not provide the relationship between the age at onset in the adult-onset patients and mortality. Wallace *et al.* [60] found that an earlier age at onset was detrimental to survival. However, a retrospective study from Taiwan compared survival in patients presenting over age 65, with patients whose SLE started between age 50 and 64 and those in whom disease onset was before age 50 [81]. Survival rates for patients with SLE onset over 65 were 55% at 5 and 10 years compared to 88 and 82%, respectively, for patients with disease onset less than 50. Patients with disease onset between age 50 and 64 demonstrated 5- and 10-year survival rates of 66 and 54%, respectively [81]. Studies that used an age cutoff at 50 or 55 were more likely to find that older age at the diagnosis of SLE was predictive for earlier mortality. Rood *et al.* [82] found than the relative risk of mortality of patients whose onset of SLE occurred between age 17 and 46 was 4.2 times higher than patients with onset of disease before age 14 or after age 50. Similar results were described in a single center study from Hungary [83]. Race also

appears to play a role in both the development of lupus and its prognosis, although it has been difficult to separate off the effects of race from socioeconomic status, particularly with reference to differences between Caucasians and Black patients in the United States. Ginzler and colleagues [61] noted a worse prognosis for Blacks compared with Caucasians in the multicenter lupus survival study. When they entered the study, Blacks also had more severe disease than Caucasians, as reflected in a higher mean number of ARA criteria, mean serum creatinine level, lower mean hematocrit, and greater frequency of central nervous system involvement. Furthermore, Blacks were more likely to be recipients of public rather than private medical insurance. When these possible confounding variables were considered in a multivariate model, Black race was no longer a significant predictor of decreased survival. Studenski and colleagues [63] studied the survival of 411 patients with SLE seen at the Duke University Medical Center between 1969 and 1984. Nonwhite race and public funding of medical insurance were both significantly associated with decreased survival, even after adjustment in a multivariate model. Reveille and colleagues [67] studied survival among 389 patients with SLE seen

at the University of Alabama at Birmingham between 1975 and 1984. They also found that Black patients had a worse prognosis than Caucasians, even after adjustment for the source of funding of medical insurance in multivariate analysis. Of interest was the finding of a higher frequency of renal involvement in the Black compared with Caucasian patients; Black patients are recognized as a group to have more severe disease than Caucasian patients. Poverty was an independent predictor of mortality in the LUMINA study [80].

SLE Factors

Major organ involvement, particularly central nervous system and renal disease, has been associated with poor prognosis. Only three studies have identified central nervous system disease as a risk factor in any of the studies to date [57, 66, 84]. However, the presence of renal involvement carried a poor prognosis for lupus patients in most studies [52, 57, 60, 61, 66–71, 73, 84]. The Mayo cohort of lupus nephritis patients [85] demonstrated lower than expected survival rates at 5, 10, and 20 years, with rates of 80, 69, and 53%, respectively. Moreover, elevated serum creatinine, reduced creatinine clearance, and progressive World Health Organization (WHO) class were associated with decreased survival. Similarly, patients with lupus nephritis from Los Angeles who underwent renal transplantation had a 5-year survival rate of only 85.9%, a rate much lower than the >95% rates reported for lupus cohorts [86]. Thus, patients with severe nephritis clearly have reduced survival.

Lung involvement, including pleuritis, pulmonary infiltrate not related to infection or heart failure, pulmonary hemorrhage, and pulmonary hypertension, emerged as a predictive factor for mortality in the analysis performed by Abu-Shakra *et al*. [73]. Lung damage was also identified as a risk for mortality in a British study, which investigated the validity of a damage index [87]. Mok *et al*. [88] found that the main risk factors of death included heart involvement, hyperlipidemia, and renal damage. They also found that treatment with steroids, antimalarial agents, and cyclophosphamide improved survival. Similar risk factors for mortality were identified in a multicenter cohort from Argentina [52]

Using the Systemic Lupus International Collaborating Clinics/American College of Rheumatology (SLICC/ACR) damage index, they found that damage in the pulmonary system predicted death within 10 years of diagnosis. Early damage as reflected by the initial SLICC/ACR damage index is associated with a higher rate of mortality [89].

Overall Disease Activity as a Predictor for Mortality in SLE

The assessment of disease activity in SLE has become easier with the development and validation of a number of instruments over the past several years [90]. Overall disease activity has been shown to be a prognostic factor for mortality in a number of studies [79, 91–97]. Disease activity, measured by the systemic lupus erythematosus disease activity index (SLEDAI), at the time of presentation to the lupus clinic, was a predictor for mortality in the Toronto cohort [73]. Overall SLEDAI predicted short-term mortality within 6 months of a visit [97]. Disease activity at last visit emerged as a predictive factor for death in a mutlivariate analysis performed by Peschken and Esdaile [31].

SLEDAI-2K, a recent modification of SLEDAI, was also found to be predictive of mortality [98]. Although a high SLEDAI score (>10) was not a predictor among Black Caribbean patients, a high weighted SLEDAI score, depicting disease activity over the course of disease, was associated with decreased survival in both univariate and multivariate analyses [99]. Disease activity over time measured by the average mean SLEDAI (AMS) was a prognostic factor for death in the Toronto cohort [100].

It is of interest that socioeconomic factors, such as higher education and private insurance, were associated with less disease activity at diagnosis in a sample of 99 subjects enrolled in a multicenter study of modifiable risk factors for SLE in the United States [101]. As noted, because the degree of disease activity has been found to predict mortality, these factors may be relevant. Indeed, the question arises as to whether contribution of the socioeconomic status and disease activity to mortality are independent from each other. The LUMINA study suggests that both disease activity (measured by the systemic lupus activity measure—SLAM) and poverty are independent risk factors for mortality [80].

Reasons for Improved Survival

The improved survival in patients with SLE may have resulted from advances in medical therapy in general (e.g., improved antibiotics, antihypertensive agents, and the availability of renal dialysis and transplantation), as well as a more judicious use of lupus-specific therapy. Other explanations proposed for improved survival include earlier diagnosis and inclusion of milder cases in more recent studies. These latter theories are not supported by the pattern of the disease seen over two decades [53, 76]. Moreover, it is clear that the improvement in survival is above and beyond the improvement in survival of the general population [53].

Causes of Death

Despite the improved survival for patients with SLE over the past several decades, patients with SLE are three times more likely to die earlier than the general population. The majority of fatalities among patients with SLE are attributable to active disease, especially renal and central nervous system involvement and infections [32, 49, 56, 58, 61, 71, 74, 75, 79, 102]. The infections may be bacterial and involve multiple organisms, often occurring in the setting of active SLE, or opportunistic, occurring in patients on high-dose steroids and cytotoxic therapy [49, 103]. Comorbid conditions and other complications of therapy account for the remainder of deaths. During the past decade, increasing attention has been directed toward a preventable cause of mortality; steroid-associated coronary artery disease [49, 53, 104, 105]. This has been particularly noticeable among patients who have lived for more than 5 years. Studies suggest that premature atherosclerosis is common among patients with SLE [105–111]. Thus efforts in patient management should be directed toward not only keeping corticosteroid doses as low as possible, with the use of hydroxychloroquine and other steroid-sparing agents, but also preventing and aggressively treating known coronary artery disease risk factors, including hypercholesterolemia, obesity, hypertension, and diabetes, and counseling against smoking and a sedentary lifestyle [110]. Routine preventive medical interventions, including those just mentioned, as well as vaccination for influenza and pneumococcal infection [112], should be promulgated for all patients with SLE to improve survival. Abu-Shakra *et al*. [113] demonstrated that vaccinations do not aggravate disease activity in patients with SLE.

Morbidity Outcome

With improving survival among patients with SLE, attention over the past decade has been directed increasingly toward outcome measures other than survival. Gladman and Urowitz [114] reviewed disease-related morbidity outcomes, including renal failure, atherosclerosis, coronary artery disease, avascular necrosis of bone, and cognitive neuropsychological dysfunction. Petri *et al*. [115] used important renal disease, the number of hospitalizations, and neurologic diseases as morbidity outcomes in their lupus cohort. These outcomes were not related to race or socioeconomic status but were related to noncompliance with medications and to type of medical insurance. Indeed patients were hospitalized not only for active disease, but more commonly for complications of the disease [116]. The Systemic Lupus International Collaborating Clinics developed the SLICC/ACR damage index for clinical epidemiologic studies [117]. This index includes items in 12 organ systems and describes accumulated damage since the onset of SLE without attribution. The index has been proven to be reliable [118] and valid [87, 119]. Similarly, measurement of disease activity using validated quantitative indices has been recommended [120], and representative indices have been developed for use in clinical research [121]. Several of these indices have been shown to be comparable [122–124]. The use of disease activity indices has been shown to be helpful in a clinic setting as well [125]. In addition to the description of disease activity and damage in patients

with SLE, several investigators have studied physical disability and psychosocial adjustment as health status outcomes in patients with SLE [126–129]. Fatigue has been recognized as a major problem for patients with SLE, and it does not appear to be simply related to disease activity [130, 131]. Petri [132] showed that the morbidity of SLE is influenced by race in the Hopkins lupus cohort. It has been suggested that three aspects of the disease are necessary to describe prognosis in SLE, namely disease activity, accumulated damage, and health status/quality of life [133].

ETIOLOGIC FACTORS

Epidemiologic studies of etiologic factors in SLE have focused on three broad areas: (1) endocrine–metabolic factors (2) environmental factors, and (3) genetic factors.

Endocrine–Metabolic Factors

The strongest risk factor for the development of SLE is female gender. In a review of five series of juvenile-onset SLE and seven series of adult-onset SLE totaling 317 and 1177 cases, respectively, Masi and Kaslow [134] showed that the sex ratio at age of onset or diagnosis rises with puberty from 2:1 to approximately 6:1, peaks in young adulthood at 8:1, and then declines with female menopause in the sixth decade. The authors thought that these data indicated that study of sex-related factors offered a clue to the pathogenesis of SLE. Studies in the (NZB × NZW)F_1 hybrid mouse, a murine model of SLE, support a role for female hormones in the modulation of autoantibody production and development of renal disease and death [135]. Indeed, Lahita and colleagues [136–141] and others [142, 143] have reported abnormalities in the metabolism of estrogens and androgens in both males and females with SLE. Data also indicate that increased estrogen levels might initiate autoimmune diseases in many women and men. Estrogen hydroxylation is increased in both men and women with autoimmune diseases such as lupus [144].

Grimes and colleagues [145] studied 109 newly hospital-diagnosed cases and an equal number of controls discharged from Emory University Hospital between 1973 and 1982; cases differed significantly in age distribution and race distribution from controls. The investigators found no association of age at menarche, parity, history of infertility, fetal wastage, or oral contraceptive usage with SLE. Hysterectomy appeared to be protective, with a crude odds ratio of 0.55; however, after adjustment for age, the odds ratio was 0.73, with 95% confidence intervals (CI) of 0.4 and 1.5. Simultaneous adjustment by age and race was not performed. A history of endometriosis was more common in women with SLE, but the odds ratio did not significantly differ from unity. Sanchez-Guerrero *et al*. [146] used a prospective cohort to study the role of the use of oral contraceptives in the development of SLE and found that past use of oral contraceptives was associated with a slightly increased risk of developing SLE [relative risk of 1.9 (95% CI 1.1–3.3)]. The same authors examined the relation between postmenopausal hormone use and development of systemic lupus erythematosus in a prospective cohort study (Nurses' Health Study) [147]. With never users of postmenopausal hormones as the reference group, age-adjusted relative risks for systemic lupus erythematosus ($n = 45$ women) were 2.1 (95% CI, 1.1 to 4.0) for ever users, 2.5 (CI, 1.2 to 5.0) for current users, and 1.8 (CI, 0.8 to 4.1) for past users. A proportional increase in the risk for systemic lupus erythematosus was observed that was related to the duration of use of postmenopausal hormones (test for trend, $P = 0.011$). Thus they concluded that postmenopausal hormone therapy is associated with an increased risk for developing systemic lupus erythematosus. However, hormonal therapy does not have a deleterious effect on existing SLE [148].

Environmental Factors

Historically, SLE has been considered to have a viral etiology [149, 150]; however, despite several decades of investigations, no firm documentation of a definite viral etiology has been identified. More recent studies have focused on human retroviruses, especially human T lymphotropic virus, type I (HTLV-I); however, the majority of studies have failed to demonstrate an association between antibodies to HTLV-I and SLE [151–154]. Nonetheless, investigations employing molecular–biologic techniques to identify viral proteins, including reverse transcriptase, continue. All but 1 of 196 patients with ANA-positive lupus had been exposed to EBV, whereas 22 of 392 controls had not [155]. Moreover, SLE patients had a higher titer of anti-EBV-VCA antibodies compared with unaffected controls.

The presence of a transmissible agent, presumed viral, was hypothesized to explain the concurrence of human and canine SLE in the same household [156]. An epidemiologic study comparing households that included dogs that had lupus to households including healthy dogs, matched by veterinarian, failed to find any excess cases of SLE or asymptomatic, seropositive subjects with anti-DNA antibodies among household contacts of index dogs [157].

The most likely noninfectious environmental factors to have an etiologic role in SLE are chemicals. The syndrome of drug-induced lupus, reported most commonly with hydralazine, procainamide, and isoniazid, provides a model to study the possible effects of other chemicals, especially aromatic amines [158]. In a case–control study of 44 subjects with connective tissue disease, including 23 with SLE, a further 9 with unclassified connective tissue disease, and 88 age-, sex-, and race-matched controls, Freni-Titulaer and colleagues [159] determined exposure to occupational and environmental factors, including medications associated with drug-induced lupus and chemicals with structural similarities to these medications. Results of matched univariate analyses demonstrated significant associations among use of hair dyes, use of hair permanent solutions, and use of hair spray with connective tissue disease; in the multivariate analysis, the association of use of hair dyes with connective tissue disease remained significant, with an odds ratio of 7.1 (95% confidence interval: 1.9, 26.9). Some hair dyes contain aromatic amines, which are absorbed through the scalp and then metabolized through acetylation. However, these results were not confirmed by a large prospective study [160].

Genetic Factors

The application of genetic epidemiology to SLE has generated strong evidence of a hereditary predisposition to this disorder. Familial aggregation of SLE has been demonstrated in two studies [161, 162]. Hochberg [161] studied the occurrence of SLE among first-degree relatives of 77 patients with SLE and age-, sex-, and race-matched controls without a history of rheumatic disease. Eight (10.4%) of the SLE probands had one or more first-degree relatives with SLE compared with only one (1.3%) of the controls [relative risk (RR) = 8, $P = 0.03$]. SLE occurred in 9 (1.67%) of 541 first-degree relatives of SLE probands but in only one (0.18%) of 540 first-degree relatives of controls (RR = 9, $P = 0.01$). Of the 9 affected first-degree relatives of SLE probands, 7 were female and 2 male, whereas the only affected control first-degree relative was female; thus the prevalence of SLE in female first-degree relatives was 2.65% vs 0.40% (RR = 6.8, $P = 0.04$) Lawrence *et al*. [162] studied 41 consecutive patients with SLE, identified from hospital registers, who had 147 available first-degree relatives, aged 15 years and older, of whom 128 were fully evaluated with examinations and serologic studies. Control relatives were selected from family surveys of probands with osteoarthritis, psoriasis, and colitis. Definite SLE was found in 5 (3.9%) of first-degree relatives of SLE probands compared with only 1 (0.8%) of 128 matched first-degree relatives of controls ($P = 0.001$).

Twin studies have demonstrated a greater concordance rate among monozygotic (MZ) than dizygotic (DZ) twin pairs, providing further support for a genetic contribution to the mechanism of familial aggregation of SLE [163–165]. Block *et al*. [163] studied 12 twin pairs and reviewed data on 17 additional published pairs. Concordance of clinical SLE occurred in 4 (57%) of the 7 monozygotic pairs and none of the 3 dizygotic pairs. Of the 12 MZ pairs in the literature, concordance for SLE was documented in 7 (58%); thus concordance for SLE was present in 11 (58%) of 19 total monozygous pairs. The authors interpreted these results as strong evidence for a genetic contribution to SLE; however, they also acknowledged a role for nongenetic factors in the expression of the illness. Arnett and Shulman [164] noted a striking concordance of clinical and laboratory features of SLE in monozygotic twin pairs compared with nontwin sib pairs. These observations also support a genetic influence on disease expression in SLE. A subsequent study based on self-reported diagnoses in persons listed in a nationwide, chronic disease twin registry found a lower rate of concordance in monozygous twin pairs [165]. Of 107 twin pairs meeting the American College of Rheumatology 1982 revised criteria for the diagnosis of SLE, 24% of 45 MZ pairs and 2% of 62 DZ pairs were concordant.

Two separate analyses support a polygenic mode of inheritance of SLE. Using Block's data on concordance of SLE in monozygotic twin pairs, Winchester and Nunez-Roldan [166] calculated that a multigenic hypothesis with either three or four dominant alleles best explained the familial inheritance of SLE. Lawrence *et al*. [162] determined that a pattern of polygenic inheritance with only moderate heritability best fit their family data. Advances in quantitative methods of segregation analysis, however, have allowed the study of single gene effects in other conditions thought to have a polygenic mode of inheritance.

Segregation or pedigree analysis has been applied to SLE to determine the mode of mendelian inheritance in multicase families. Arnett and colleagues [167] studied 19 multicase SLE families with 232 relatives of whom 24 had SLE, 27 had other autoimmune diseases, and 47 others had serologic abnormalities, including high-titer antinuclear antibodies, antibody to single-stranded DNA, or a false-positive test for syphilis. They postulated a single, genetically determined "autoimmune" trait and applied segregation analysis to family data. Results were consistent with a mendelian dominant inheritance pattern with a gene frequency of 0.06 and a 91% penetrance. The expression of autoimmunity

was modified by gender and age at time of study, but not by HLA-DR phenotype. Further studies by this group estimated the population frequency of the "autoimmune" gene as 0.10, with penetrance of 92% in females and 49% in males [168]. Linkage of this autoimmune gene to other genetic markers was also studied by these investigators; they failed to demonstrate linkage with any HLA phenotype, immunoglobulin allotype, or 21 other polymorphic genetic markers [167, 168].

The genetics of SLE is complex. There are likely many genes involved. While the major histocompatibility complex (MHC) likely plays a role, the exact nature of the contribution of the MHC to the etiopathogensis of SLE is unclear. Moreover, a number of other genes may play a role in this disease, including complement genes, genes related to inflammation, hormones, and genes on the X chromosome [169].

Several investigations into familial SLE have demonstrated a 5–10% familial aggregation [170–172]. Half of the multiplex families were of sib-pair type [170]. Familial SLE did not differ from its sporadic form [169, 171]. Genome scans have implicated a number of genes, including genes on chromosome 6, chromosome 1, and chromosome 4, as well as other chromosomal regions [173–178]. Several of these regions were described in more than one genome scan, whereas others were described in a single investigation. Further studies are clearly necessary before the exact nature of the genetic contribution to SLE is identified.

SUMMARY

Descriptive epidemiologic studies of SLE have been conducted worldwide; the most extensive data are available from Scandinavia, especially Sweden, and the United States. In the United States, Blacks have threefold higher incidence, prevalence, and mortality rates than Caucasians; the reasons for this, however, remain unknown. Observational epidemiologic studies have demonstrated an increasingly favorable prognosis for patients with SLE, allowing the identification of potentially preventable causes of death and a better understanding of long-term morbidity and impact on overall health status. Analytic and genetic epidemiologic studies suggest a multifactorial etiology of SLE; results support a polygenic mode of inheritance, including important roles for an autosomal-dominant autoimmune gene and female sex hormones. A viral etiology remains attractive, particularly in view of recent observations regarding the Epstein–Barr virus. Other environmental factors such as chemical exposures may be important as "triggers" of disease in susceptible hosts.

OVERLAP SYNDROMES

Mixed Connective Tissue Disease and Sjögren's Syndrome

Robert W. Hoffman

CONCEPT OF OVERLAP SYNDROME

Over recent decades we have developed increased recognition of the distinctive nature of seemingly similar connective tissue diseases (CTDs). Many distinct entities are now recognized that were first unified under the broad category of "collagen disease" in the seminal work of Klemperer *et al*. [1]. Most recently, important advances in the characterization of autoantibodies and immunogenetics of CTD have helped to substantially increase our understanding of these diseases. Despite these advances, controversy and confusion remain over the classification of many rheumatic diseases. Classification criteria have been proposed for both mixed connective tissue disease (MCTD) [2–4] and Sjögren's syndrome [5–7], but there are no uniformly accepted classification criteria for either. Furthermore, there remain patients with rheumatic diseases who fail to meet any standardized classification criteria. These patients are often designated as having "undifferentiated connective tissue disease" (UCTD). Over time these patients may evolve to meet existing classification criteria for one CTD, such as systemic lupus erythematosus (SLE), MCTD, or Sjögren's syndrome, or they may remain unclassifiable, and therefore remain labeled UCTD. Finally, additional groups of patients meet the classification criteria for more than one disease entity, such as SLE and rheumatoid arthritis (RA) or SLE and systemic sclerosis (SSc). These patients are also considered part of the spectrum of the overlap syndrome.

Immunogenetic markers and autoantibodies have proven to be useful in disease classification. Investigators have combined the use of both with success. As shown in Table 1, many selective immunogenetic associations have been reported with the presence of specific autoantibodies. Population-based immunogenetic studies have shown association of the presence of antinuclear ribonucleoprotein (RNP) antibodies with human leukocyte antigen (HLA)-DR4 [8, 9]. We have demonstrated that the presence of autoantibodies against one specific polypeptide of the RNP complex, U1-70-kDa, is independently associated with select genotypes of HLA-DR4 and HLA-DR2 [10, 11]. Structural analysis of HLA genes demonstrated that this association could be mapped to a shared sequence in the highly polymorphic antigen-binding segment of the HLA-DRB1 gene [11]. This HLA epitope was shared among all of the disease-associated HLA-DRB1 alleles. When the clinical features of these patients (selected based on the presence of the anti-U1-70-kDa antibody) were analyzed, the results come full circle by finding that these patients exhibited clinical features characteristic of MCTD [10].

In Sjögren's syndrome, studies on anti-Ro/SSA and anti-La/SSB autoantibodies have demonstrated strong association between these autoantibodies and the presence of specific HLA genes. The presence of anti-Ro/SSA and anti-La/SSB autoantibodies was associated with both HLA-DR and HLA-DQ alleles [12–15]. The highest anti-Ro/SSA antibody levels occur in patients heterozygous for the presence of two HLA-DQ

TABLE 1 Production of Specific Autoantibodies Is Associated with Distinctive HLA Phenotypes or Genotypes[a]

Disease	Autoantibody specific	Immunogenetic association
MCTD	RNP[b]	HLA-DR4
SLE	DNA	HLA-DR2, DQw1
CTD	RNP	HLA-DR4
CTD	RNP/Sm	HLA-DR4
CTD	U1-70 kDa[c]	HLA-DR4/DRB1*0401, *0404, *0407, *0408 HLA-DR2/DRB1*1501
Sjögren's syndrome	Ro/SSA	HLA-DQw1/DQw2, HLA-DR3, HLA-DR2
SSc	Centromere Scl-70/topoisomerase I	HLA-DR1, DR4(w13), DRw8; HLA-DR5 (w11) HLA-DR5(w11)/DRB1*1104; HLA-DPB1*0201, *0601, *1001, *1301
Polymyositis	Jo-1/transfer RNA synthetase	HLA-DR3

[a] CTD, connective tissue disease; HLA, human leukocyte antigen; MCTD, mixed connective tissue disease; RNP, ribonucleoprotein; SLE, systemic lupus erythematosus; Sm, Smih antigen; SSc, systemic sclerosis. Data from Hoffman and Sharp [120].
[b] Nuclear RNP or U1 RNP.
[c] A polypeptide of the U1 RNP complex.

alleles: HLA-DQw1 and HLA-DQw2 [13]. Similar immunogenetic associations have been reported for a variety of autoantibodies in other rheumatic diseases, as shown in Table 1. These studies, combining characterization of patients by autoantibodies and immunogenetics, provide a valuable new framework for disease classification.

Despite advances in defining new autoantibodies and characterizing the immunogenetics of CTDs, inherent problems remain in classifying such diseases with pleomorphic clinical manifestations and unknown etiology. We have been reminded, with the discovery of Lyme disease, that a disease caused by a single etiologic agent can result in many different clinical manifestations. In the case of Lyme disease, symptoms can range from arthritis to skin rashes to carditis to central nervous system disease. Approaching the problem of disease classification from the opposite point of view can be equally difficult. A single clinical syndrome, such as polyarthritis, can have many different etiologies. The results of disease classification studies are also influenced by additional factors, such as ascertainment bias in data collection and the background genetics of the population being studied. Until the etiology or etiologies of SLE, MCTD, Sjögren's syndrome and the overlap syndromes are proven, classification will remain problematic and open to dispute. Classification does, however, provide a valuable framework for research, treatment, and prognosis. To that end, the fact that MCTD and Sjögren's syndrome can be classified by clinical, serologic, and, more recently, distinctive immunogenetic characteristics supports the concept that such classification serves useful purposes.

MIXED CONNECTIVE TISSUE DISEASE

Historical Overview

The initial observations on MCTD were made by Sharp *et al.* [16] in a rheumatic disease clinic at Stanford University during 1961–1969. In this clinic, a complement fixation test for antinuclear autoantibodies (ANA) was used in monitoring patients' response to therapy. In patients with typical SLE, their ANA titers declined and usually became negative during clinical remission. In contrast, some interesting patients were noted to have extraordinarily high titers of ANA that persisted during periods of both active disease and clinical remission. The clinical characteristics of these patients did not fit any of the traditional rheumatic disease classifications but combined features of SLE, polymyositis, and SSc and therefore were referred to as MCTD.

In order to further elucidate the autoantibody pattern in these MCTD patients, a very sensitive passive hemagglutination (PHA) test was developed that revealed that their sera had extremely high titers (often >1:1,000,000) of antibodies to an extractable nuclear antigen (ENA) described previously by Sharp *et al.* [17]. Using the PHA test, enzyme digestion studies further revealed that these antibodies were directed against an RNase- and trypsin-sensitive component of the crude ENA. Northway and Tan [18] performed fluorescent ANA (FANA) analyses on these MCTD sera and found that they produced speckled patterns at high titers that were eliminated by RNase treatment of the tissue

sections. Thus, the circulating antibody in MCTD appeared to have a specificity for a nuclear RNP (nRNP) antigen. In comparison, PHA testing revealed that 50% of the sera of typical SLE patients in this clinic also contained antibodies to ENA that were usually present at a lower titer and frequently were directed against an RNase-resistant component of ENA [17]. Antibodies to the Smith (Sm) antigen and native DNA, known serologic markers for SLE, were seldom detected in these MCTD patients. Because of the similar clinical and serologic features in this group of patients, it was proposed that MCTD might represent a distinct rheumatic disease syndrome [16].

In the early 1970s, reports from several laboratories indicated that Ouchterlony double immunodiffusion can also be used to detect autoantibodies reacting with ENA by the PHA method [19–21]. Thus it became clear that the crude antigenic complex referred to as ENA contains at least two immunologically distinct components: the RNase- and trypsin-sensitive RNP antigen and the RNase- and trypsin-resistant Sm antigen. The Ouchterlony method showing lines of identity with immunoprecipitation bands produced by well-characterized reference sera provides a very precise identification of the specificity of RNP and Sm antibodies; however, PHA with titers before and after RNase digestion of ENA can be useful because of its great sensitivity (100,000-fold more sensitive that the Ouchterlony and 100- to 1000-fold more sensitive than the FANA) [21]. Thus, the FANA may not be adequate as a screening test very early in the course of MCTD when antibody levels may be lower [22].

Following the initial report of MCTD, studies in several centers agreed that the serologic pattern of high titers of RNP antibodies in the absence of Sm antibodies is usually associated with MCTD and is much less common in SLE, is infrequent in SSc, and is almost never seen in other rheumatic diseases [19, 21, 23, 24]. In contrast, Sm antibodies, usually in association with lower titers of RNP antibodies, are seen most commonly in SLE [21, 23].

Clinical Features

General Features

In recent years, the fact that patients are coming to medical attention earlier and being observed longitudinally has led to a greater appreciation of the gradual evolution of MCTD over time. Early in the course of the disease, patients are likely to have only Raynaud's phenomenon, fatigue, swollen hands, and myalgias and arthralgias, findings that do not fulfill any of the CTD classification criteria (sometimes referred to as UCTD).

TABLE 2 Transitions in MCTD in Longitudinal Study

Disease classification	No. classified at initial medical evaluation	No. classified at latest medical evaluation
MCTD	14	31
UCTD	7	3
SLE	6	0
Adult or juvenile RA	4	0
SSc	2	0
Polymyositis	1	0

This mild syndrome may persist for years in some, but others develop additional manifestations, leading to a diagnosis of MCTD [24–29]. Thus, retrospective reviews of medical records and cross-sectional studies may not provide an accurate assessment of this evolving CTD. In the initial prospective longitudinal study at the University of Missouri–Columbia, 60% of 34 patients with high anti-RNP antibody titers on entering the study had more limited clinical manifestations and were diagnosed by their physicians as UCTD, SLE, RA, SSc, or polymyositis (Table 2) [28]. However, over a period of years, 91% had developed clinical features typical of MCTD, whereas only 9% remained undifferentiated. In another prospective long-term study in Sweden [27], 17 of 23 patients with high titers of RNP antibodies had developed sufficient clinical manifestations to fulfill criteria for MCTD at the end of the study, whereas 17 of 23 had not fulfilled any CTD criteria on initial evaluation. Less frequently MCTD may have an acute onset with high fever, inflammatory myositis, serositis, arthritis, aseptic meningitis, or digital gangrene, and the typical overlapping disease is fully expressed when the patients first come to medical attention [16, 24, 28–30].

In a national epidemiologic survey in Japan, MCTD had a prevalence of 2.7 per 100,000 compared with 20.9 for SLE, 5.7 for scleroderma, and 4.9 for polymyositis-dermatomyositis [31]. The female-to-male ratio of MCTD was 16:1.

In our clinic, which is likely to be biased toward referral of MCTD patients, MCTD occurs less frequently than SLE but occurs as often as SSc and more frequently than polymyositis. MCTD typically presents when patients are between 20 and 30 years of age and the majority of these patients are female [28, 29]. There is a report in the literature of MCTD occurring in siblings but in our experiences it is very uncommon in families (unpublished results) [32].

The most common clinical features of MCTD in our longitudinal studies [28, 29] were Raynaud's phenome-

TABLE 3 Characteristics of Patients with MCTD

Characteristic	Number of patients	(%)
Clinical		
Raynaud's phenomenon	31	91
Polyarthritis	29	85
Swollen hands or sclerodactyly	29	85
Pulmonary disease	29	85
Inflammatory myositis	27	79
Esophageal hypomotility	25	74
Lymphadenopathy	17	50
Alopecia	13	41
Pleuritis	12	35
Malar rash	10	29

Diffuse scleroderma	7	21
Sjögren's syndrome	4	12
Trigeminal neuropathy	2	6
Laboratory		
Positive FANA	34	100
Positive anti-U1 RNP	34	100
Positive rheumatoid agglutinins	20	59
Hypergammaglobulinemia	18	53
Hypocomplementemia	11	32

non, polyarthritis, swollen hands or sclerodactyly, pulmonary disease, inflammatory myositis, and abnormal esophageal motility (Table 3). Less frequent findings included lymphadenopathy, alopecia, malar rash, pleuritis, pulmonary hypertension, cardiac disease, renal disease, anemia, and leukopenia. The very high frequency of pulmonary disease detected in the study by Sullivan *et al*. [28] had not been noted in our initial report of MCTD, perhaps because the fact that significant pulmonary dysfunction can occur even in asymptomatic patients was not appreciated at that time. The occurrence of pulmonary hypertension as the most frequent disease-associated cause for death was documented in a longitudinal study of clinical outcomes in MCTD [29].

At the 1986 International Symposium on MCTD and Antinuclear Antibodies, three sets of diagnostic criteria for classification of MCTD were proposed (Table 4) [2–4]. Major criteria included Raynaud's phenomenon, synovitis, swollen hands or sclerodactyly, myositis, pulmonary disease, and high-titer anti-RNP antibody. Preliminary evaluations of these criteria have shown a very high sensitivity and specificity [33–35]. It should be noted, however, that advances describing more precise autoantibody (anti-U1-RNP-70-kDa polypeptide and anti-U1 RNA) and immunogenetic specificities that are linked extremely closely with MCTD (see later) were not fully elucidated when these diagnostic criteria were proposed. More recently, a strong linkage has been demonstrated among Raynaud's phenomenon, synovitis, swollen hands or sclerodactyly, myositis, and esophageal dysfunction with anti-U1-70-kDa polypeptide serologic reactivity [10, 11, 29].

Occasionally, patients with MCTD transiently develop an illness while maintaining their serum anti-RNP antibodies that resembles typical SLE with the appearance of antibodies to DNA and/or Sm, higher levels of circulating immune complexes, lupus-like skin lesions, and glomerulonephritis. These findings were present in 4 MCTD patients who had defective reticuloendothelial system (RES) clearance of immune complexes but not in 14 MCTD patients with normal RES clearance and lower levels of circulating immune complexes [36]. Possibly normal RES function in most MCTD patients permits effective clearance of immune complexes and precludes serious renal disease. In the follow-up study of the originally reported MCTD patients, only 1 patient had developed membranous glomerulonephritis [37]. In a longitudinal study, only 18% had clinical evidence of renal disease and no patients developed renal failure [28]. In a subsequent study with follow-up as long as 25 years, 11% of MCTD patients had renal disease [29]. In the Swedish prospective study of MCTD, only 1 patient had glomerulonephritis, in association with a rising anti-DNA titer and a falling anti-RNP titer [27].

In contrast to SLE, where renal and central nervous system disease are the most frequent serious disease complications, pulmonary hypertension associated with proliferative vasculopathy is the most frequent cause of disease-related deaths in MCTD [28, 29, 38–40]. In a longitudinal study, 38% of MCTD patients had pulmonary hypertension [29]. It appears that MCTD patients with high anti-RNP titers and patients with limited SSc (or CREST) with anticentromere antibodies are at a greater risk for developing pulmonary hypertension and proliferative vascular lesions with minimal pulmonary fibrosis than patients with classical SLE, SSc, and polymyositis [28, 29, 40–44]. Pulmonary hypertension in diffuse SSc is usually associated with severe interstitial pulmonary fibrosis [43]. In a study of SLE patients who developed pulmonary hypertension [45], anticardiolipin antibodies were present in 68% and anti-RNP antibodies in 21%. It is not clear, however, what percentage of the patients classified as RNP-positive "SLE" would also have met classification criteria for MCTD in this study. Clearly, there appears to be linkage between anti-RNP and anticardiolipin antibodies and an increased risk for developing pulmonary hypertension [29].

TABLE 4 Diagnostic Criteria for MCTD[a]

Criteria defined by Sharp [4]		Criteria defined by Kasukawa *et al*. [3]	Criteria defined by Alarcón-Segovia and Villarreal [2]
A. Major criteria 1. Myositis, severe 2. Pulmonary involvement with one or more of a. DLCO < 70% normal b. Pulmonary hypertension c. Proliferative vascular 3. Raynaud's phenomenon or esophageal hypomotility 4. Swollen hands observed or sclerodactyly 5. Highest observed anti-ENA (PHA) ≥ 1 10,000 and anti-U1 RNP +, anti-Sm –	B. Minor criteria 1. Alopecia 2. Leukopenia 3. Anemia 4. Pleuritis 5. Pericarditis 6. Arthritis 7. Trigeminal neuropathy 8. Malar rash 9. Thrombocytopenia 10. Myositis, mild 11. History of swollen hands	I. Common symptoms A. Raynaud's phenomenon B. Swollen fingers or hands II. Anti-U1 RNP III. Mixed findings A. SLE-like findings 1. Polyarthritis 2. Lymphadenopathy 3. Facial erythema 4. Pericarditis or pleuritis 5. Leukopenia or Thrombocytopenia B. SSc-like findings 1. Sclerodactyly 2. Pulmonary fibrosis, restrictive change of lung, or reduced DLCO 3. Hypomotility or dilation or esophagus C. PM-like findings 1. Muscle weakness 2. Increased serum Creatine kinase 3. Myogenic pattern in EMG	1. Serological + anti-U1 RNP, PHA titer ≥ eq 1:1600 2. Clinical a. Edema of the hands b. Synovitis c. Myositis d. Raynaud's phenomenon e. Acrosclerosis
Requirements for diagnosis of MCTD			
Definite Four major criteria filled Anti-U1 RNP ≥ 1:4000 by PHA	Probable 1. Three major criteria filled 2. Two major criteria from 1, 2, and 3 and two minor criteria with anti-U1 RNP ≥ 1:1000 (PHA)	1. Positive in either one or two common symptoms 2. Positive anti-U1 RNP 3. Positive in one or more findings in two or three disease categories of A, B, and C	1. Serological 2. At least three clinical findings 3. The association of edema of the hand Raynaud's phenomenon, and acrosclerosis requires the addition of at least one of the other two clinical criteria

[a] DLCO, diffusing capacity for carbon monoxide; ENA, extractable nuclear antigen; EMG, electromyogram; PHA, passive hemagglutination; PM, polymyositis; RNP, ribonucleoprotein; SLE, systemic lupus erythematosus; SSc, systemic sclerosis. From Sharp, [4], Kasukawa *et al*. [3], and Alarcón-Segovia and Villareal [2], with permission.

The follow-up report of the original 25 MCTD patients [37] has been cited as showing evidence of a transition of MCTD to classical SSc. In subsequent more recent studies of larger groups of MCTD patients, diffuse sclerosis developed in combination with other disease features in 19% of the MCTD patients [29]. In the prospective longitudinal study of Lundberg and Hedfors [27] of 32 patients with RNP antibodies, none of them fulfilled criteria for SSc. Thus, it appears that MCTD infrequently spontaneously evolves into diffuse SSc. Interestingly, work has suggested that patients with antibodies against the oxidatively modified form of the U1-70-kDa polypeptide are more likely to have Raynaud's phenomenon and scleroderma-spectrum illness, whereas patients with antibodies against the apoptotically cleaved form of the U1-70-kDa polypeptide are more likely to have lupus skin disease and a lupus-like clinical spectrum of disease [46].

MCTD can be distinguished from polymyositis and other polymyositis-scleroderma overlap syndromes by clinical and serologic features. The diagnostic criteria of Bohan and Peter were used to classify myositis patients as idiopathic myositis ($n = 10$), myositis associated with another CTD ($n = 13$), and dematomyositis ($n = 6$) in a longitudinal, 10-year study from Sweden [47]. Seven patients who had anti-RNP antibodies all were in the category of myositis associated with other CTD features and fulfilled criteria for MCTD [33]. In these patients, myositis appeared during the course of the disease and was rarely the initial manifestation. The other six patients with myositis associated with other CTD features all had a myositis-scleroderma overlap and were

negative for anti-RNP antibodies. PM-1 (PM-Scl) and Jo-1 autoantibodies are markers for polymyositis and a polymyositis-scleroderma overlap syndrome that may resemble MCTD [48, 49]. However, these patients are almost always negative for anti-RNP antibodies and do not manifest other SLE-like features of MCTD.

Specific Manifestations

Mucocutaneous Abnormalities

Raynaud's phenomenon is the most frequent finding in MCTD and may precede other disease manifestations by months or years [16, 19, 21, 24, 25, 29, 50]. Swollen hands and fingers leading to sausage-shaped digits (Fig. 1) are seen in over two-thirds of MCTD patients [16, 19, 21, 24, 25, 50]. Ischemic necrosis or ulcerations of the fingertips are much less common than in SSc [16, 27, 29]. Initial observations that early edematous sclerodermatous changes resolve completely in some patients [16] and observations in a more recent longitudinal study that diffuse scleroderma was transient and sclerodactyly fluctuated in its severity in MCTD [27] contrast with the usual progressive course of the disease in SSc.

About one-third of patients have lupus-like malar rashes and chronic discoid lesions [16, 21, 24, 25, 28, 29, 50]. Other findings include "squared" telangiectasia over the hands and face, periungual telangiectasia, calcinosis cutis, erythema over the knuckles, and violaceous discoloration of the eyelids resembling dermatomyositis, nonscarring alopecia, and buccal and orogenital ulceration. Skin biopsies have shown edema and increased dermal collagen [16]. Direct immunofluorescent examinations of skin biopsies in MCTD patients have shown deposits of immunoglobulins (Ig) at the dermal–epidermal junction [16, 25] and speckled intranuclear immunofluorescence of epidermal cells.

FIGURE 1 Hands of a patient with MCTD demonstrating the tapered or sausage appearance of the fingers and discoloration over the metacarpal phalangeal, proximal interphalangeal, and distal interphalangeal joints.

Joints

Most MCTD patients early in their disease experience joint stiffness and polyarthralgias, and three-quarters of them develop objective arthritis [16, 21, 24, 55]. Typically the arthritis is nondeforming, but it may occasionally resemble RA with ulnar deviation, boutonniere, and swan neck deformities [16, 28, 29, 51–55]. In some studies, rheumatoid-like changes were present in 30–35%, but in contrast to RA, joint involvement was usually limited to the hands and wrists. Although erosive disease is not common, radiographs may show small, marginal erosions, and even a more destructive arthritis including rib erosions has been reported [51–55]. Subcutaneous rheumatoid-like nodules are noted infrequently [16]. Hand deformities in MCTD may occur and result from a flexor tenosynovitis [56]. Rheumatoid factor is frequently present in MCTD (see later).

Muscles

Inflammatory myositis with proximal muscle weakness with or without muscle tenderness is sometimes a severe clinical manifestation of MCTD [16, 21, 28, 29, 57]. Elevated serum levels of creatine kinase and aldolase, myopathic electromyograms (EMGs) and biopsy findings of muscle fiber degeneration, and inflammatory infiltrates resembling polymyositis may be seen. Muscle enzyme levels and EMGs may sometimes be abnormal early in the course of the disease when muscle weakness is minimal. In such patients, histochemical and immunofluorescent analyses of muscle biopsies may reveal perifascicular atrophy, type I fiber predominance, and immunoglobulin deposition within normal-appearing muscle fibers, around or on the sarcoplasmic membrane, or within the perimysial connective tissue [57]. A longitudinal study comparing myositis in MCTD patients positive for anti-RNP antibodies with idiopathic polymyositis and dermatomyositis in patients negative for anti-RNP antibodies noted that the MCTD group had less severe histopathologic changes in their muscle biopsies and more rapid improvement of muscle strength on lower doses of corticosteroids [47]. In a longitudinal study, 51% of patients cumulatively had muscle involvement [29].

Gastrointestinal Tract

Any area of the gastrointestinal tract may be affected by MCTD, although the esophagus is by far the most common location. In a study of 61 patients with MCTD, the first 34 being part of a prospective longitudinal study that included systemic and periodic manometric and

radiographic evaluation of the esophagus, lower esophageal sphincter (LES) pressure and amplitude of peristaltic pressures in the distal esophagus were significantly less than in normal controls [58]. Of the MCTD patients undergoing manometry, 17% had aperistalsis and 43% had low-amplitude peristalsis of the distal esophagus. Of particular note, among patients with abnormal peristalsis, 24% had no esophageal symptoms and 33% had normal cine esophagrams. Heartburn and dysphagia were the most common gastrointestinal symptoms in this study. A statistically significant improvement in LES pressure was observed in 10 MCTD patients who received corticosteroid therapy (mean duration 67 weeks, average dose 25 mg/day) for severe multisymptom involvement. Mean upper esophageal sphincter (UES) pressures were also significantly lower in these MCTD than in normal controls; abnormal UES function may be less frequent in SSc and may represent a distinguishing feature of MCTD [58]. In an MCTD patient whose disease exacerbation was characterized solely by marked esophageal dysfunction and recurrent aspiration pneumonia, corticosteroid therapy was associated with improvement in UES and LES function and resolution of aspiration pneumonia episodes [58]. In another study comparing esophageal motility in SLE and MCTD, 91% of 17 patients with MCTD and only 20% of 14 patients with SLE had manometric abnormalities [59]. Use of proton pump inhibitors has shown that these are very effective for esophageal symptoms in MCTD.

Other much less frequent gastrointestinal manifestations in MCTD have included intestinal hypomotility, dilatation, malabsorption, sclerosis, serositis, small bowel and colon perforations due to vasculitis, pseudodiverticula, pneumatosis cystoides intestinalis, secretory diarrhea, mesenteric vasculitis with bowel hemorrhage, chronic active hepatitis, Budd–Chiari syndrome, acute pancreatitis, and pancreatic pseudocyst [24, 28, 29, 53, 60–62].

Lungs

Pulmonary involvement was not appreciated in the initial report on MCTD [16], probably because of the fact that pulmonary dysfunction is usually asymptomatic in the early phases of MCTD and may be initially undetected unless sought by testing, such as by pulmonary function tests (PFTs) [28, 29]. It has now become apparent that pulmonary involvement is common in MCTD and may result in seriously compromised function, leading to exertional dyspnea and, in some cases, pulmonary hypertension, particularly in the later stages of the disease [28, 29 42, 63, 64]. In a prospective longitudinal study of 47 patients with MCTD [29], 66% had evidence of pulmonary disease, whereas in an earlier study of 34 patients [28], 85% had pulmonary disease. The most frequent clinical findings included dyspnea in 58%, bibasilar rales in 42%, and pleuritic chest pain in 40%. However, pulmonary involvement was also detected in 8 of 11 patients (73%) who had no pulmonary symptoms. Pulmonary function tests were the most sensitive indicators of pulmonary disease, particularly the single-breath diffusing capacity for carbon monoxide (DLCO) that was abnormal (22–69% of predicted) in 72%. In addition, small irregular opacities involving predominantly the bases and middle regions of the lungs were noted in 30% of chest roentgenograms. Following treatment of their multisystem disease with corticosteroids and/or cyclophosphamide, over half of those with abnormal PFTs who were serially studied had improvement in their PFTs and 45% had improvement of dyspnea on exertion for a measured distance. Diaphragmatic dysfunction and pulmonary hemorrhage have occasionally been reported in MCTD [65–68].

Right heart catheterization was performed in 15 of 34 patients in one longitudinal study of MCTD from the University of Missouri [28]; 10 had increased pulmonary artery pressure (31/12–88/39, mean 59/26 mm Hg) and elevated pulmonary vascular resistance (2.2–12.2, mean 6.0 units), but pulmonary wedge pressure was abnormal in only 1 patient. The high frequency in our center may reflect a biased referral of more complicated patients. Severe capillary loop changes similar to those seen on nailfold capillaroscopy in SSc and a progressive decline in DLCO may identify MCTD patients who are at a greater risk for developing pulmonary hypertension [28]; only 1 of 10 patients with pulmonary hypertension had a normal DLCO. In contrast to diffuse SSc in which pulmonary hypertension is usually associated with interstitial pulmonary fibrosis, in MCTD pulmonary hypertension is usually associated with proliferative vascular abnormalities with marked narrowing of the lumen of small- and medium-sized pulmonary arteries and arterioles, but without significant interstitial fibrosis [28, 29, 40–44] (Fig. 2). The presence of antiphospholipid or anticardiolipin antibodies has been found to be associated with pulmonary hypertension in some studies [29], although not in others [69]. Death from pulmonary hypertension may have biased the selection against an inclusion of patients who will develop pulmonary hypertension in some studies [69]. Early pulmonary hypertension in MCTD may be treated successfully, and pulmonary hypertension is the most common disease-associated cause of death in MCTD. Thus, it is important to identify and treat early pulmonary disease and pulmonary hypertension in MCTD before major dysfunction develops. It appears that the presence of antiphospholipid or anticardiolipin anti-

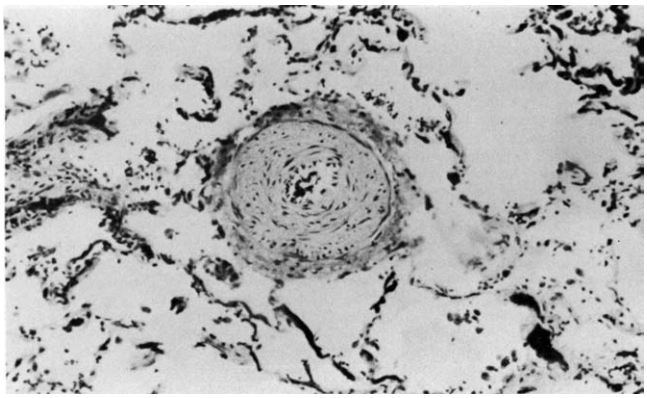

FIGURE 2 Small pulmonary artery in an 18-year-old woman with MCTD showing intimal proliferation and smooth muscle hypertrophy without accompanying inflammation or pulmonary fibrosis, associated with severe pulmonary hypertension. From Alpert *et al.* [145], with permission of the American Heart Association.

bodies may be a marker for increased risk of this complication in MCTD [29].

Heart

Pericarditis, usually responsive to corticosteroid therapy, has been reported to occur in 10–43% of patients with MCTD and may be more frequent in children than in adults [16, 24, 26, 44, 70–72]. Myocarditis has been recognized with increasing frequency and may be due to inflammatory cell infiltrates and/or proliferative vasculopathy of the epicardial and intramural coronary arteries [41, 44, 70–73]. Mitral valve prolapse was detected in 32% of patients with MCTD, 36% of patients with SLE, and 32% of patients with SSc compared with 10% in normal controls in an echocardiographic study [74]. Electrocardiographic abnormalities in MCTD have included conduction disturbances, arrhythmias, and chamber enlargement/hypertrophy [70].

Kidneys

Renal disease occurs in approximately 25% of MCTD patients and may be more frequent in children [24, 27, 28, 29, 39, 75–77]. Often it is asymptomatic. The most prevalent lesion is membranous glomerulonephritis, which can result in the nephrotic syndrome. Of has been reported that renal abnormalities in MCTD respond to treatment with corticosteroids [28, 29]. Focal glomerulonephritis can also occur in MCTD, whereas diffuse proliferative glomerulonephritis is rare [75]. The presence of antibodies against the Sm-D polypeptide and the HLA-DR2 phenotype is, however, a marker of severity for renal disease in MCTD [77, 78]. Proliferative vascular lesions similar to those occurring in the lungs and other tissues may be found in the kidneys. These proliferative vascular lesions have been associated with renovascular hypertension.

Nervous System

About 10% of patients with MCTD have had neurological involvement [21, 24, 27–30, 79], although there was a higher frequency in two reports [27, 79]. The most frequent neurological problem is trigeminal neuropathy [21, 80–82]. Vascular headaches are also relatively common [83]. Aseptic meningitis, which can occur in MCTD [80] must be distinguished from bacterial meningitis, which can occur unexpectedly in patients who appear otherwise healthy and are not on immunosuppressive medications [84]. Organic mental syndromes, encephalopathy, and seizures are less frequent than in SLE [16, 24, 71, 79]. Other neurologic manifestations of MCTD have included peripheral neuropathies, cauda equina syndrome, transverse myelitis, retinal vasculitis, and cerebral hemorrhage or infarction [16, 24, 71–79, 85–88].

Hematologic Findings

About one-third of patients with MCTD have anemia and leukopenia [16, 21, 28, 29]. The anemia is usually consistent with the anemia of chronic inflammation; although the Coombs' test may be positive, a frank hemolytic anemia is rare [16, 89]. Severe thrombocytopenia appears to be more common in children that in adults with MCTD [16, 21, 24, 90]. In one report of 14 children with MCTD, 6 had severe thrombocytopenia with 2 requiring splenectomy, and 1 died of an intracranial hemorrhage [24]. Red cell aplasia and thrombotic thrombocytopenia are rarely seen in MCTD [89, 90–92].

Miscellaneous Features

Sjögren's syndrome may occur in conjunction with MCTD [93, 94]. It has been reported that secondary Sjögren's syndrome occurred in 42% of a well-characterized population of 55 MCTD patients [93]. In contrast to primary Sjögren's syndrome, even massively enlarged lymph nodes in MCTD when biopsied have revealed only lymphoid hyperplasia and not lymphoma [16]. Fever and lymphadenopathy occur in about one-third of MCTD patients [16, 21, 25]. Persistent hoarseness and Hashimoto's thyroiditis are occasionally observed in MCTD. There is limited information on pregnancy in MCTD; one study showed a high risk of fetal loss and disease exacerbation similar to SLE, whereas two studies showed only a slight risk of fetal loss or maternal disease flares [30, 95, 96].

Laboratory Features

Polyclonal hypergammaglobulinemia is present in the majority of patients with MCTD [16, 21, 28, 29]. Rheumatoid agglutinins, often at very high levels, are detected in over 50% of MCTD patients. False-positive Venereal Disease Research Laboratory (VDRL) tests occur in about 10% of patients, with anticardiolipin antibodies also detected in some of these patients [38, 69]. In a comparative study in the author's laboratory, 41% of 59 SLE patients and 15% of 48 MCTD patients had antiphospholipid (anticardiolipin) antibodies; there was an association with 26 clotting events or other features of the antiphospholipid syndrome in the SLE patients, but these clinical complications were not noted in the MCTD patients [69]. Antiphospholipid antibodies may, however, be associated with pulmonary hypertension [29]. In a long-term outcome study, when pulmonary hypertension was present in 38% of the population studied, anticardiolipin antibodies did appear to be linked to pulmonary hypertension [29]. Antilymphocyte antibodies are noted much less frequently in MCTD than in SLE [97]. Circulating immune complexes have been noted in active MCTD [98], but their levels are generally lower and their RES clearance is reported to be less prolonged than in active SLE [36]. Serum complement levels are usually normal in MCTD.

Patients with MCTD characteristically have a high titer (often >1:1,000,000) of antibody to the RNase-sensitive (RNP) component of ENA, and anti-RNP antibodies are detected by Ouchterlony double immunodiffusion or ELISA [16, 21, 28, 29]. Antibodies to single-stranded DNA (ssDNA) can be detected [17], but in contrast to SLE high antidouble-stranded DNA (dsDNA) antibody titers and anti-Sm antibodies are unusual and transient in MCTD [28, 29]. Patients with anti-Sm antibodies by Ouchterlony immunodiffusion or reactivity with the Sm-D polypeptide by immunoblotting, however, are at substantial risk of nephritis and other SLE spectrum clinical manifestations of disease [77, 78]. Rarely, patients who appear clinically to have MCTD have been seen who will initially not have detectable RNP antibodies and then will become positive, typically following treatment with corticosteroids [16, 21, 26, 99]. This serologic pattern of high titers of anti-RNP antibodies usually persists for years during both active and inactive disease, but ultimately antibody levels may fall or become undetectable during sustained clinical remission [28, 29, 100].

Although immunologically distinct, a close physical association of RNP and Sm antigens was shown in early biochemical studies by Tamako *et al*. [101]. Lerner and Steitz [102] and Lerner *et al*. [103] subsequently further elucidated the nature of the small nuclear ribonucleoproteins (snRNPs) reacting with RNP and Sm antibodies. Their studies showed that anti-RNP antibodies immunoprecipitate uridine-rich U1 snRNA–protein complexes whereas anti-Sm antibodies immunoprecipitate snRNA–protein complexes containing U1, U2, and U4–U6 snRNAs [104]. Immunoblotting studies by Pettersson *et al*. [100] revealed that anti-U1 RNP antibodies react with snRNP polypeptides with molecular masses 70 kDa (sometimes designated 70 K and previously referred to as 68 K), 33 kDa (A), and 22 kDa (C), whereas anti-Sm antibodies react predominantly with 28- to 29 kDa (B/B′, now B1/B2) and 16-kDa (D, now D1) polypeptides [100] (Table 5). Subsequently, Takeda *et al*. [78] biochemically purified these snRNPs and developed a very sensitive ELISA permitting quantitative assays for autoantibodies to the individual snRNPs (Fig. 3). More recent studies have revealed that there are at least three Sm-B (B1, B2, and B3) and three distinct Sm-D (Sm-D1, D2, and D3) polypeptides in addition to the newly described Sm-E, F, and G snRNP polypeptides [105–107].

TABLE 5 Relationship of Antibodies to ENA, U1 RNP, Sm, and snRNPs

RNase-sensitive ENA	RNase-resistant ENA
U1 RNP	Sm
70 kDa, A, and C snRNPs	B/B′ and D snRNPs

Longitudinal studies have shown persistence high levels of anti-U1 RNP and anti-U1-70-kDa antibodies for many years in MCTD and their subsequent decline and disappearance in patients during prolonged remission [28, 29, 78, 100] (Fig. 4).

In 1988, Deutscher and Keene [108] reported the identification and characterization of antibodies in the serum of a patient with an SLE overlap syndrome that recognized the naked U1 RNA itself rather than the snRNP polypeptides. A sequence-specific conformational epitope on U1 RNA is recognized by a unique autoantibody. The author's laboratory recently analyzed serum snRNP autoantibody patterns, immunogenetic specificities, and clinical features of patients with autoantibodies to U1 RNP who were positive or negative for anti-U1 RNA antibodies [109]. The very high frequency and high level of anti-U1-70kDa antibodies, HLA-DR4, or HLA-DR2, and clinical features of Raynaud's phenomenon, swollen hands, swelling of three or more joints, and myositis were all significantly more predominant among the anti-U1 RNA-positive

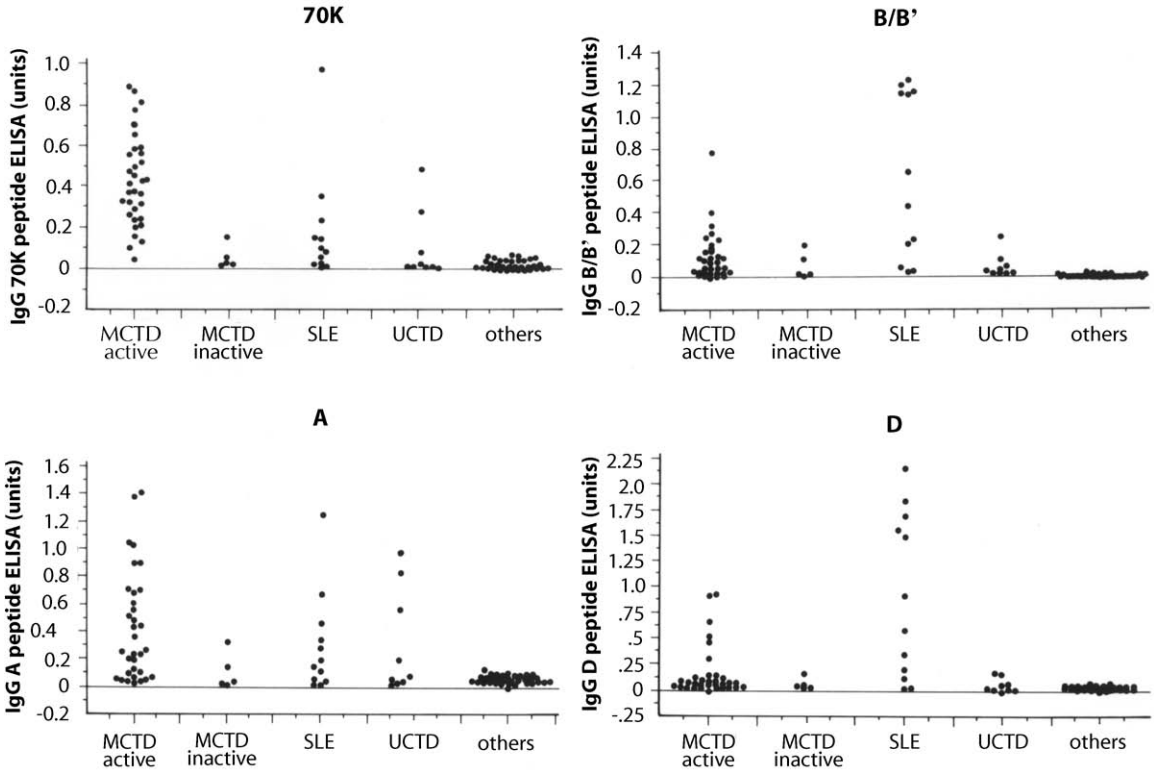

FIGURE 3 Diagnosis in patients whose sera were tested for immunoglobulin G (IgG) reactivity with individual U1 snRNP polypeptides by ELISA. Note that sera of patients with active MCTD showed higher anti-70k (70 kDa) reactivity in the ELISA than sera of patients with inactive MCTD, active SLE, and UCTD. Anti-B/B′ and anti-D reactivity was higher in sera of patients with active SLE than in sera of patients with active MCTD, inactive MCTD, and UCTD. SLE, active SLE, others, 14 patients negative for anti-RNP antibodies but positive for autoantibodies to other cellular components and 20 normal controls. From Takeda *et al*. [78], with permission.

group. In studies from The Netherlands, it was found that increases in anti-U1 RNA antibody levels correlated closely with disease flares, although we have been unable to definitively confirm these results in our patients [29, 110]. Thus, the presence of anti-U1 RNA antibodies may be a specific marker for MCTD and may reflect disease severity and/or activity. Autoantibodies to heterogeneous nuclear RNA, which is associated with nuclear matrix and antibodies to nucleosomes, have also been detected in MCTD [111–113]. These are detected in 20–40% of patients with MCTD, and epitope mapping has shown that there is preferential targeting in MCTD against select parts of the RNA-binding domains.

Histopathology and Immunopathology

The first comprehensive histopathologic investigation of MCTD included observations from three autopsies and five renal biopsies in a study group of 15 children [44]. Although earlier reports had mentioned vascular changes, this report was the first to emphasize the occurrence of widespread proliferative vascular lesions in MCTD. The young age of these patients, short duration of disease, and lack of corticosteroid therapy underscored the likelihood that these vascular changes reflected the natural course of the CTD and were not due to other possible causes that might have complicated the interpretation in an older population. From these autopsies, 31 of 58 organs (53%) had intimal proliferative changes and 9 organs (16%) had medial hypertrophy in blood vessel walls. These obliterative vascular changes were noted in large vessels (e.g., aorta, renal and coronary arteries) and within small arterioles. Particularly striking was the frequency and severity of this vasculopathy in the kidney, lungs, myocardium, intestinal tract, aorta, and coronary vessels, often in the absence of overt clinical manifestations.

Similar obliterative, proliferative vascular lesions have now been described in adults with MCTD, and it has been noted that vascular compromise may lead to organ failure and hemorrhage [28, 29, 41, 42, 64]. In four

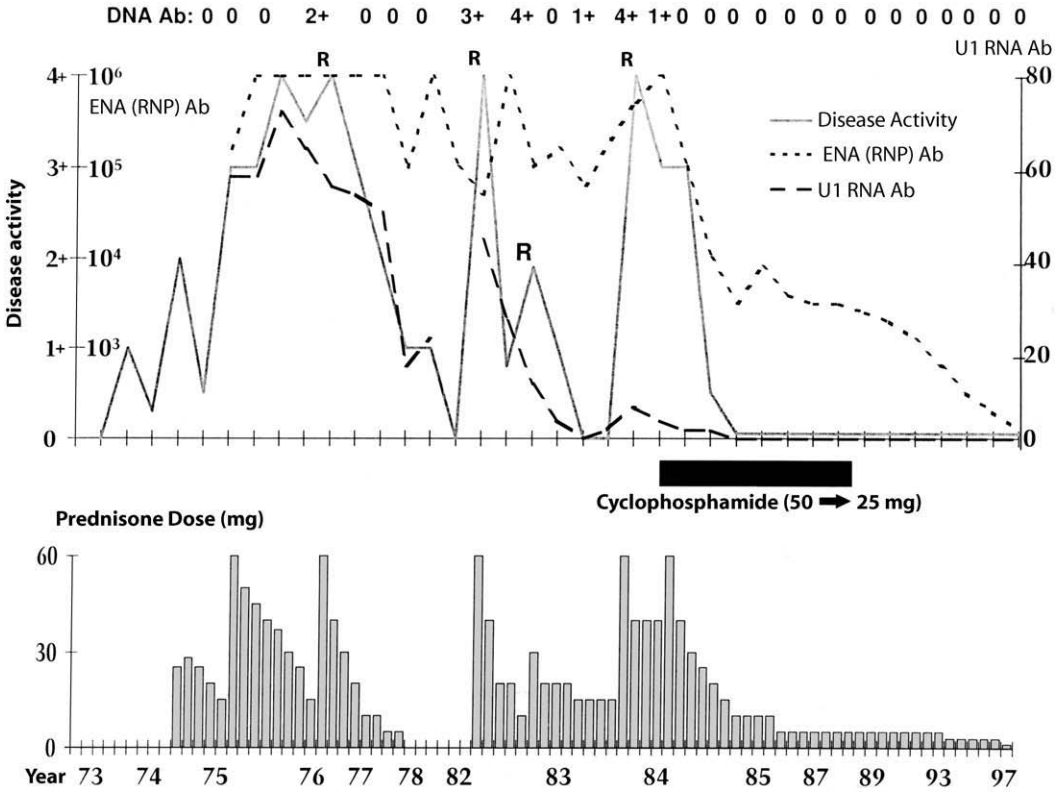

FIGURE 4 Correlation of autoantibodies to native DNA by *Crithidia luciliae*, RNase-sensitive ENA (U1 RNP) by passive hemagglutination, and U1 RNA by radioactive immunoprecipitation with disease activity in a woman with MCTD who was 16 years old in 1973. Note that DNA antibodies were transiently present on four occasions in association with active renal disease (R). Antibodies to U1 RNP remained positive at a very high level over 10 years during periods of both active and inactive disease. The MCTD went into a sustained remission following the addition of cyclophosphamide to the prednisone therapy, and anti-U1 RNP levels finally began to decline in 1985. In contrast to the prolonged high levels of anti-U1 RNP, levels of anti-U1 RNA increased and decreased in close correlation with disease activity and have remained undetectable during her sustained remission.

adult patients with MCTD who had died at the University of Missouri, autopsies revealed this same obliterative vasculopathy with intimal proliferation and medial hypertrophy of arteries in the lungs, kidney, heart, adrenals, and spleen. These proliferative vascular lesions so prominent in MCTD are in distinct contrast to the inflammatory infiltration of blood vessels typically seen in the vasculitis of SLE, RA, and polyarteritis [41].

Characteristic findings in the lungs in MCTD are intimal thickening and medial muscular hypertrophy of the pulmonary arteries and arterioles with little or no interstitial fibrosis (see Fig. 2) [28, 29]. This is in contrast to SSc in which the most characteristic histologic finding is diffuse interstitial fibrosis [43]. Ultrastructural analysis of pulmonary arterial lesions in at least one study in MCTD has shown an abundance of intimal ground substance, increased fibroblast production of collagen, a disordered array of collagen fibers, perforated basal lamina, and hypertrophy of muscle fibers in the media [28, 29]. When analyzed biochemically, these lung specimens showed a selective increase of type III collagen synthesis, resulting in an abnormal type I–type III ratio [28]. This is in contrast to the lungs in SSc where the type I–type III collagen ratio is the same as in normal lungs [114]. Thus, pulmonary hypertension in MCTD is related to proliferative vasculopathy with narrowing of the vessel lumens without significant interstitial fibrosis [41]. Plexiform vascular lesions have also been described in association with pulmonary hypertension in MCTD [41]. Less frequently at autopsy a mixed picture with marked vascular changes and an interstitial fibrosing pneumonitis has been noted [41].

Vascular abnormalities also occur in both limited and diffuse SSc [43]. Obliterative vasculopathy in both MCTD and SSc has also been shown angiographically

in radial, ulnar, and digital arteries [115]. The absence of fibrinoid change, predilection for large vessels, and minimal fibrosis in MCTD seem to distinguish it from SSc [28, 44]. Although medial hypertrophy is the characteristic vascular change in MCTD, there is often a decreased thickness with areas of focal medial atrophy in limited SSc [43]. Replacement of the inner and outer muscle layers of the esophagus, pylorus, and colon with a hyaline material in MCTD also appears to be distinct from the muscle atrophy and fibrosis noted in SSc [44].

The most frequent renal glomerular lesions in MCTD are membranous and mesangioproliferative glomerulonephritis [29, 116, 117], whereas diffuse proliferative glomerulonephritis is seen less frequently than in SLE. Intramembranous, mesangial, and subepithelial electron-dense deposits have been seen on electron microscopy [39, 118, 119]. When diffuse proliferative glomerular changes are mainly inflammatory with minimal chronic changes (crescents, hyaline thrombi, tubular atrophy, and fibrosis), even this more severe renal disease usually responds to corticosteroid therapy in MCTD. Proliferative vascular changes are also seen frequently in the arcuate and interlobular arteries of the kidney as well as in other organs [28] (Figs. 5 and 6).

In a study of skeletal muscle biopsies from 13 patients with MCTD [57], 8 showed a lymphocytic infiltrate either perivascularly or within the perimysium, endomysium, or vessel walls (vasculitis), often in association with focal fiber necrosis. Perifascicular atrophy was seen in 3 cases, and 5 of 11 biopsies that had histochemical determinations showed type I fiber predominance. These findings are similar to the histopathologic changes seen in polymyositis and in the myopathy associated in SLE. Of particular note, however, direct immunofluorescence performed in 10 cases revealed selective deposition of IgG in 7 cases—within normal-appearing vessels, within normal-appearing muscle fibers, around or on the sarcoplasmic membrane, or within the perimysial connective tissue—suggesting that immune mechanisms may be responsible for the myopathy that is so prominent in MCTD. A more recent study of various forms of myositis noted that infiltrating lymphocytes were confined to the endomysium in polymyositis and had a perimysial distribution in MCTD [47].

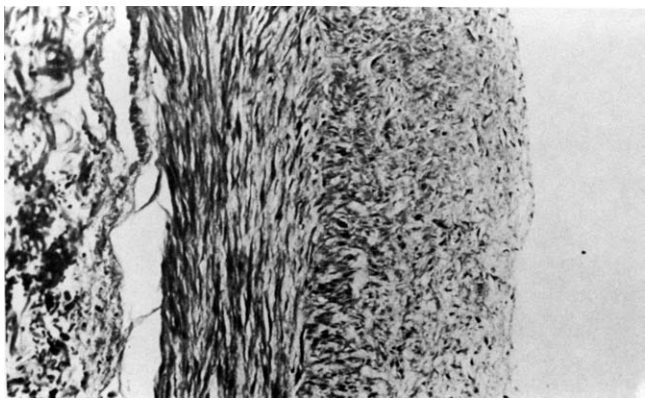

FIGURE 5 Cross section of an intramural coronary artery in an 18-year-old woman with MCTD showing marked intimal hyperplasia and smooth muscle hypertrophy. Cellular elements in the intima are surrounded by a loose fibrillar connective tissue matrix. Acellular elements in the media (presumably mucopolysaccharides) are also increased quantitatively. From Alpert *et al*. [145], with permission of the American Heart Association.

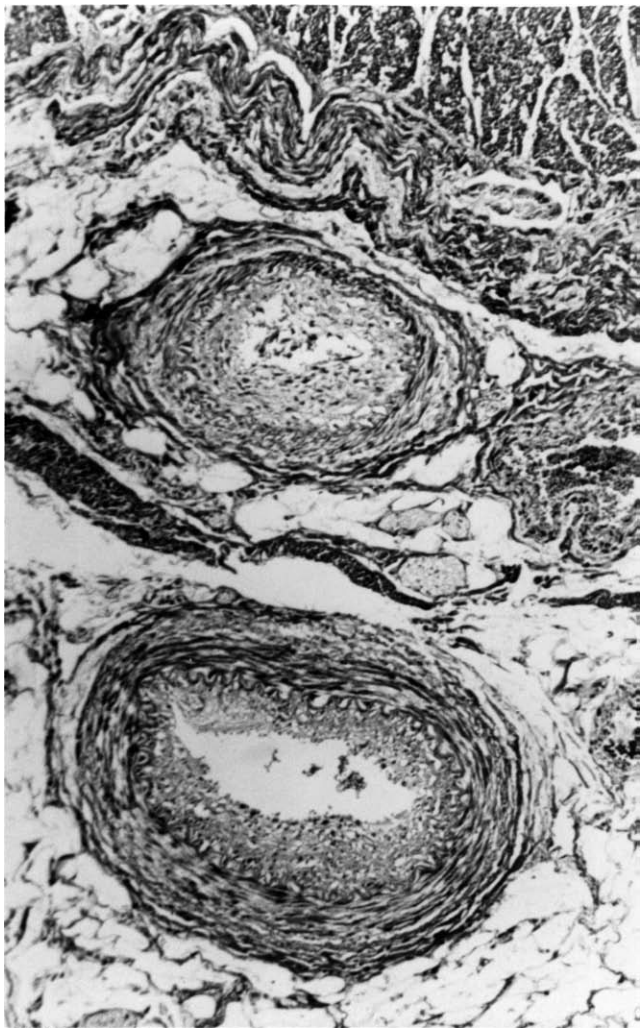

FIGURE 6 Two medium-sized arteries from the ilium of a 15-year-old female with MCTD. These arteries demonstrate intimal proliferation, medial hypertrophy, and luminal narrowing that are characteristic of MCTD. From Sharp and Singsen [119a], with permission.

Immunogenetics

Population immunogenetic studies from Germany, England, Finland, the United States, Japan, and Mexico have shown association between HLA-DR4 and the presence of anti-RNP antibodies or MCTD per se (for review, see Hoffman and Sharp [120] and Sharp and Hoffman [121]). Studies from Japan have also reported association of HLA-DR2 with MCTD [120, 121]. It has been demonstrated that the presence of anti-U1-70kDa autoantibodies is independently associated with select genotypes of HLA-DR4 and HLA-DR2 [11]. Furthermore, a comprehensive analysis of HLA-DR, HLA-DQ, and HLA-DP genes among these anti-U1-70kDa autoantibody-positive CTD patients has been performed [10, 11, 120–122]. It was found that a shared cluster of amino acids, of the sequence FDYFYAQ at positions 26, 28, 30–32, 70, and 73 of the HLA-DRB1, was increased in frequency among patients (Fig. 7). It was concluded that this shared cluster of amino acids, or so-called "shared epitope," might be important in regulating the immune response against the U1-70-kDa autoantigen.

Other genes of the immune system have also been examined in anti-RNP-positive CTD. Polymorphism of genes encoding the heavy and light chains of Ig can be detected by assaying for the distribution of Km and Gm allotypes, respectively, among patients versus healthy controls. Genth *et al*. [9] found that among German patients, the Gm 1,3;5,21 was increased among the anti-RNP-antibody-positive group. Black *et al*. [8] reported the Gm 1,3;5,21 allotype increased among anti-RNP positive patients from the United Kingdom. In a study among anti-U1-70kDa-positive CTD patients from the United States, no Gm or Km allotype associations were found [123].

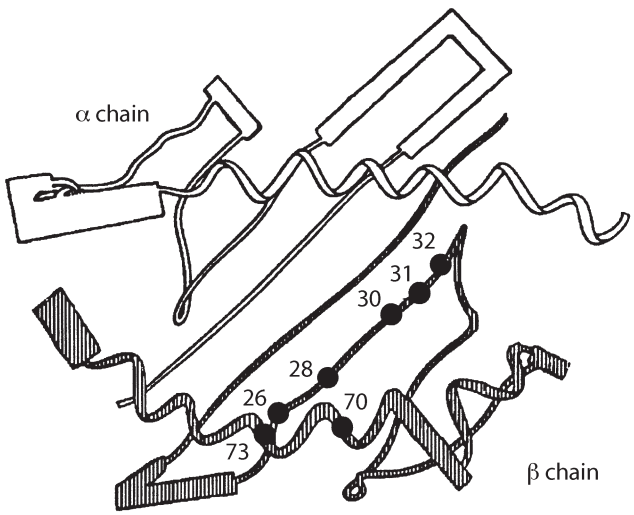

FIGURE 7 Shared epitope of HLA in MCTD. Model of HLA-DR as deduced from X-ray crystallography. Amino acids in positions 26, 28, 30–32, 70, and 73 are shared by HLA-DR4- and HLA-DR2-positive MCTD patients. Amino acid residues in these positions, FDYFYQA (Phe, Asp, Tyr, Phe, Tyr, Gln, Ala), form the shared epitope identified to be common among MCTD patients [11]. From Brown *et al*. [122a], with permission.

Controversy of MCTD as a Distinct Entity

The concept of MCTD has evolved since the original description in 1972 [16]. MCTD is now recognized to occur throughout the United States and the world, with large series of patients described from the United States, Japan, Mexico, Sweden, and France (reviewed in Sharp and Hoffman [121]). Furthermore, controversy over whether MCTD should be considered as a distinct entity has been the subject of several reviews [124–128]. Three major classification schemes have been proposed for MCTD (see Table 4). In recent years, it has been appreciated that there are substantial numbers of patients who manifest Raynaud's phenomenon, arthralgias-arthritis, diffusely swollen hands, and esophageal hypomotility, with high titers of antibodies against the U1-70-kDa polypeptide of RNP. These patients also have distinctive immunogenetics, with population studies demonstrating that they have an increased presence of select genotypes of HLA-DR4 and/or HLA-DR2. It now appears that it is this constellation of clinical manifestations, associated with both anti-U1-70-kDa and anti-U1 RNA autoantibodies and select genotypes of HLA, that most typifies MCTD [120, 121].

Patients with MCTD may also meet classification criteria for other rheumatic diseases, including SLE, RA, polymyositis, or SSc. This appears to be the basis for much of the confusion and controversy surrounding MCTD [121–128]. Thus, based only on clinical manifestations of disease, these patients may be included among patients classified as SLE, RA, or SSc by some authors. Other authors have recognized that a distinct group of patients with features of MCTD exists but have chosen to call them UCTD [129]. Until the etiology of MCTD, SLE, and other CTDs is known, any classification scheme may be flawed and is subject to challenge. We believe, however, that the synthesis of current knowledge on the distinctive features of autoantibody specificity and immunogenetics does support the concept of MCTD as presented here [120, 122, 124–128].

Model for Pathophysiology

A central paradigm of modern immunology is that antigen is processed into small peptide fragments and

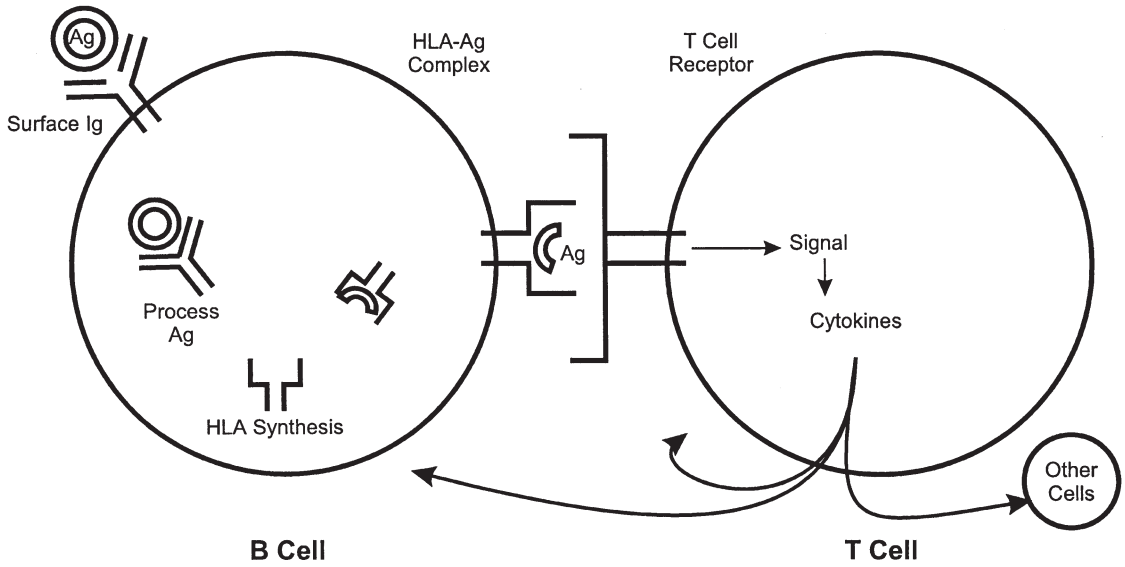

FIGURE 8 Role of T and B cells in MCTD. A central paradigm of modern immunology is that the antigen is processed into small peptide fragments and presented to T cells, bound noncovalently in the antigen-binding cleft of HLA molecules, on the surface of the antigen-presenting cell. This concept is illustrated where surface immunoglobulin (Ig) on B cells binds autoantigens. The antigen is then processed by proteolytic cleavage into small peptide fragments that bind to HLA molecules synthesized recently in the cell. This Ag–HLA complex is presented to autoreactive T cells. T cells that possess the appropriate T-cell receptor are stimulated, which in turn produce and release cytokines. These cytokines can act in both an autocrine and a paracrine manner to expand the autoreactive T cell, as well as to promote proliferation and differentiation of the autoantigen-presenting B cells. B and T cells act in concert to promote autoantibody formation and to promote affinity maturation of autoantibodies of the IgG isotype.

presented to T cells, noncovalently bound in the antigen-binding cleft of HLA molecules, on the surface of the antigen-presenting cell [130]. This is illustrated in Fig. 8. In select instances that may be very germane to autoimmunity, B cells can serve as the antigen-presenting cell. Hypothetically, surface Ig on B cells could be highly efficient in binding autoantigens released from cells undergoing cell death by necrosis or apoptosis. Such free nuclear antigens could then be processed and presented to autoreactive T cells, which in turn produce and release cytokines. The cytokines expand the autoreactive T cell. These cytokines also serve to promote proliferation and differentiation of the autoantigen-presenting B cells, which are in close physical proximity to the responding T cells. In this model, both B and T cells act in concert to promote autoantibody formation and to promote affinity maturation of autoantibodies of the IgG isotype.

T Cells in MCTD

One of the hallmarks of MCTD is the presence of high titers of anti-RNP antibodies of the IgG isotype present in patients' sera. In some cases, these anti-RNP antibodies have been demonstrated to account for one-third of the total serum Ig [131]. The presence of high levels of autoantibodies of the IgG isotype is indirect evidence that T cells are providing help to autoantibody-producing B cells *in vivo*. Furthermore, the association of select HLA alleles with autoantibody production implies a direct role for T cells in autoantibody production.

One hypothesis, for the preferential association of certain HLA-DR4 and HLA-DR2 alleles with the production of anti-RNP and anti-U170-kDa autoantibodies, is that this is an autoantigen-driven immune response. In such a model, the autoantigen (e.g., the U1-70-kDa polypeptide of the RNP complex) binds preferentially to select HLA-DR4 and/or HLA-DR2 alleles and this Ag–HLA complex then stimulates autoreactive T cells to expand and produce cytokines (see Fig. 8). To test this hypothesis, peripheral blood mononuclear cells have been examined for the presence of T cells that react against the U1-70-kDa antigen [132–139]. Fenning *et al.* [134], Hoffman *et al.* [135], and Wolff-Vorbeck *et al.* [136] have reported that human T-cell clones reactive against the U1-70-kDa antigen can be cloned from

peripheral blood mononuclear cells. Holyst *et al.* [137] extended this work and demonstrated that CTD patients have clonable circulating U1-70-kDa-reactive T cells that parallel the specificity of antibodies found in their sera. Furthermore, they have demonstrated that U1-70-kDa-reactive T cells exhibited a T helper cell phenotype and produced cytokines that are important in B-cell help and differentiation. Talken *et al.* [138] examined the T-cell receptor from U1-70-kDa-reactive human T-cell clones and reported that there is nonrandom T-cell receptor usage among T cells reactive against the U1-70-kDa autoantigen, consistent with the selection of T-cell receptors directed against a limited number of antigen epitopes [138, 139]. Taken together, these results suggest that genetic or nongenetic factors determine which T cells are expanded when stimulated with the U1-70-kDa autoantigen. Interestingly, these findings raise the possibility that targeted therapy could be directed effectively against select T cells that are important in the anti-U1-70-kDa response. Such an approach could potentially be effective in suppressing the disease, while leaving T cells with other receptor specificities available to respond to viral and bacterial pathogens.

Distinctive Clinical, Immunologic, and Genetic Features

There are distinctive clinical, immunologic, histopathologic, and genetic features of MCTD that can be identified. These are summarized in Table 6. Clinical features that predominate in MCTD are the constellation of arthritis-arthralgia, swollen hands, sclerodactyly, Raynaud's phenomenon, and abnormal esophageal motility. The development of pulmonary hypertension occurs in a minority of patients, but is often a devastating clinical event. It has also been appreciated that pulmonary disease may frequently be present. Pulmonary hypertension and heart failure are the most frequent disease-associated cause of death in MCTD. Immunologically, B-cell responses are characterized by the presence of high titers of autoantibodies directed against RNP and are particularly distinguished by the presence of high titers of autoantibodies against the U1-70-kDa polypeptide and U1 RNA of the snRNP complex. The presence of antibodies against U1-70-kDa and U1 RNA are useful clinical diagnostic markers in MCTD. Histopathology in MCTD shows that salivary glands, muscle, and other tissues may be massively infiltrated with lymphocytes and plasma cells. There also may be massive lymphoproliferation in MCTD. Histopathology (discussed previously) is characterized by proliferative vascular lesions, including intimal thickening and medial hyperplasia, that may resemble vascular lesions in SSc; however, in the lungs in MCTD there is vasculopathy with virtual absence of interstitial pulmonary fibrosis and selective increase of type III collagen in contrast to SSc [28]. Distinctive genetic (discussed previously) and additional immunologic and histopathologic features are shown in Table 6.

TABLE 6 Distinctive Clinical, Immunologic, and Genetic Features of MCTD

Clinical	Constellation of arthralgia/arthritis, swollen hands, Raynaud's phenomenon, abnormal esophageal motility, sclerodactyly, myositis, pulmonary hypertension
B-cell responses	High-titer U1 RNP antibodies and particularly anti-U1-70-kDa and anti-U1 RNA autoantibodies, typically in the absence of other autoantibodies
Genetic	Association with HLA-DR4 and shared epitope on HLA-DRB1 found on haplotypes bearing HLA-DR4 and HLA-DR2
T-cell responses	snRNP U1-70-kDa and other snRNP-reactive T cells found in the peripheral blood of patients
Immune complexes	Lower levels of immune complexes found in the circulation than in SLE, more rapid RES clearance of immune complexes than from the circulation in SLE
Histopathology	Proliferative vasculopathy in the virtual absence of fibrosis and widespread lymphocytic and plasmacytic infiltrates

Model of Disease: A Synthesis

A working model of disease susceptibility and pathogenesis of MCTD is shown in Fig. 9. It is unclear whether an exogenous agent(s) plays a role in triggering MCTD. Although speculative, it is plausible that an environmental factor(s) may play a role in triggering the disease. It has been proven that genetic factors do contribute to disease [121]. The emerging model, based on work in both human disease and murine models of autoimmunity, would suggest that major histocompatibility complex genes are a major disease-susceptibility factor for disease and that other genes also contribute to disease susceptibility [140–142]. Developing disease might, for example, involve interaction of multiple unlinked susceptibility and resistance genes. Stochastic or random events in immune development, such as those that affect the T-cell repertoire, may also play an important role in whether an individual is prone to development of the disease. The final effector pathway of disease appears to require the interaction of both autoreactive B and T cells. Other immune effector cells

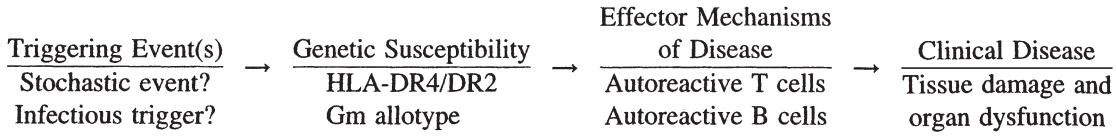

FIGURE 9 A hypothetical model of disease in MCTD. An exogenous agent(s) may play a role in initiating MCTD. An environmental factor(s) may play a role in triggering the disease. It has been proven that genetic factors do contribute to disease. HLA genes and immunoglobulin (Ig) genes have been demonstrated to be disease susceptibility factors, and other yet unidentified genes may also contribute to disease susceptibility. Developing disease might, for example, involve the interaction of multiple unlinked susceptibility and resistance genes. Stochastic or random events in immune development may influence the development of disease. The final effector pathway of disease appears to require the interaction of both autoreactive B and T cells. Other immune effector cells may also then be recruited in the final pathologic response.

TABLE 7 Treatment of MCTD[a]

Type of disease activity	Recommendations
Mild UCTD (Raynaud's phenomenon, arthralgias, myalgias, fatigue, mild synovitis)	NSAIDs, antimalarials, low-dose corticosteroids, avoid cold exposure, calcium channel blockers as tolerated if Raynaud's phenomenon is severe
Disease activity limited to erosive RA-like joint involvement	NSAIDs, antimalarials; low-dose corticosteroids or methotrexate if more severe
Mild to moderate SLE-like involvement (rash, serositis, anemia, leukopenia, fever, lymphadenopathy)	Avoid sun exposure, topical corticosteroids, antimalarials, low to intermediate doses of corticosteroids
SLE-like involvement of major organ systems (pericarditis, myocarditis, thrombocytopenia, glomerulonephritis, aseptic meningitis[b]), myositis, progressive involvement of lug, dysfunction of upper esophageal sphincter with dysphagia and/or aspiration pneumonia	Moderate to high doses of corticosteroids depending on severity, and cyclophosphamide or other cytotoxic drug if steroid dependent
Esophageal reflux without upper sphincter involvement	Raise head of bed, avoid caffeine, discontinue smoking, H2 blockers, H^+ proton pump blockers, metoclopramide, corticosteroids may be used if severe dysphagia related to lower esophageal involvement is not responsive to these conservative measures
Asymptomatic pulmonary hypertension	Right heart catheterization and monitoring pressures in response to therapeutic agents may be a guide to therapy, calcium channel blockers, angiotensin-converting enzyme inhibitors, vasodilators, and possibly cycledophosphamide
Symptomatic pulmonary hypertension	Calcium channel blockers, angiotensin-converting enzyme inhibitors, vasodilators, corticosteroids, cyclophosphamide, or other cytotoxic drugs

[a] NSAIDs, nonsteroidal anti-inflammatory drugs; RA, rheumatoid arthritis; SLE, systemic lupus erythematosus; UCTD, undifferentiated connective tissue disease.

[b] Ibuprofen and Sulindac have been associated with a hypersensitivity aseptic meningitis in MCTD so NSAIDs should be discontinued.

may also then be recruited in the final pathologic response. Some aspects of disease may be mediated solely by antibody, others may be mediated primarily by autoreactive T cell, and others by both B and T cells.

Treatment and Prognosis

Since controlled clinical therapeutic trials have not been performed, the treatment of MCTD is based on information derived from clinical experience. The original report of MCTD suggested that the disease frequently appeared to be responsive to treatment with corticosteroids and/or cyclophosphamide [16]. Subsequently, recognition of severe complications such as pulmonary disease, pulmonary hypertension, and proliferative vascular lesions has led to the appreciation that the outcome is not always favorable [28, 29].

Guidelines for treatment of specific clinical problems in MCTD are presented in Table 7 [128, 143]. A mild UCTD syndrome or arthritis presenting without major organ system involvement can often be treated conservatively with nonsteroidal anti-inflammatory drugs or antimalarials without resorting to corticosteroids; however, if the synovitis is more refractory or bone erosions occur, low doses of corticosteroids and/or methotrexate may be required. Antimalarials and/or

low to intermediate doses of corticosteroids will usually control mild to moderate SLE-like features. Higher doses of corticosteroids (e.g., prednisone 1 mg/kg) may be required for the treatment of more serious systemic involvement (e.g., myositis, myocarditis, pericarditis, glomerulonephritis, or thrombocytopenia).

It has been shown that high titers of anti-U1 RNP with anti-U1-70-kDa antibodies are associated with a high risk of esophageal dysfunction, myositis, pulmonary disease, and pulmonary hypertension, which can be detected by functional tests and biopsies early in the evolution of MCTD when patients are still asymptomatic [28, 29, 58]. Thus, detection of this serologic pattern might guide the clinician to evaluate even asymptomatic patients with studies of esophageal motility, muscle enzymes, EMG, muscle biopsy, pulmonary function (including DLCO), and chest X-ray; depending on the results of these studies, an echocardiogram and possibly a right heart catheterization might be performed.

If abnormalities are detected in these organ systems, early therapeutic intervention may be indicated and may control the disease with more selective or shorter courses of drug therapy than would be required if the disease were more advanced or due to a different CTD. Thus, early pulmonary DLCO abnormalities in MCTD may respond to corticosteroids alone or in combination with cyclophosphamide [28, 29, 58] in contrast to SSc. Early esophageal dysfunction may respond to proton pump blockers. Early treatment of myositis in MCTD may require lower doses of corticosteroids for a shorter duration than in the case of polymyositis [47]. Early pulmonary hypertension in a mildly to moderately symptomatic phase in MCTD may be treated successfully with nifedipine, captopril, or hydralazine in addition to immunosuppressive drugs (the author's experience and uncontrolled trials in the literature appear to favor the use of cyclophosphamide) [28, 29, 143, 144] and potentially avoid more severe disease. When pulmonary hypertension is more advanced and very severe, corticosteroids, cytotoxic drugs, calcium channel blockers, and angiotensin-converting enzyme (ACE) inhibitors have been employed as therapeutic agents, but the responses have not always been favorable [28, 29, 67, 68, 145–148].

The initial report of MCTD suggested a favorable prognosis [16]. Subsequent reports described serious clinical problems due to proliferative vascular lesions, renal disease, cardiac disease, and thrombocytopenia in childhood MCTD. Causes of death were meningococcal or pneumococcal infections in three patients and cerebral hemorrhage associated with severe thrombocytopenia in one patient. A follow-up study of the initially reported MCTD patients related that 8 of the 25 patients had died, although 6 of the 8 deaths were not directly related to their rheumatic disease [37]. Inflammatory tissue manifestations in these patients appeared to have responded to corticosteroid therapy while scleroderma-spectrum features had persisted.

In a initial prospective longitudinal study, almost all of the 34 patients had significant major organ system involvement and were treated with moderate to high doses of corticosteroids and/or cyclophosphamide [28]. Two-thirds responded favorably to treatment, whereas one-third with very severe disease were less responsive to corticosteroids, and four patients died. As in other MCTD reports, inflammatory changes such as rash, pleuritis, pericarditis, and myositis responded to corticosteroids, whereas pulmonary and scleroderma-like features were less likely to respond. A good long-term prognosis for some patients with MCTD is demonstrated by the 38% of these patients studied whose disease became inactive, including 10 in a sustained remission (9 off all therapy) for 7–20 years (mean 16 years).

Subsequent longitudinal studies in MCTD patients in prolonged remission, following intensive corticosteroid and cyclophosphamide therapy, have revealed the eventual disappearance of serum anti-U1 RNP autoantibodies, including the anti-U1-70-kDa snRNP reactivity that had usually persisted for years [29]. Thus, the basic autoimmune process appears to have been altered in these patients. The combined mortality rate from seven long-term studies of MCTD including almost 300 patients was 14%, with a mean duration of disease of over 10 years [27–30, 37, 77, 149]. Of these deaths, 10% were directly related to the disease. Disease-related deaths were associated most frequently with proliferative vascular lesions, pulmonary hypertension, cor pulmonale, pericardial tamponade, and sepsis, with intravascular coagulation, perforated bowel, and renal failure noted less frequently. The prognosis in MCTD appears similar to that of SLE but better than that of SSc.

Relationship of MCTD to SLE

The ultimate conclusion on the relationship of MCTD to SLE awaits the determination of the etiology of these entities. Comparison of the clinical, serologic, and immunogenetic features of MCTD and SLE reveals a number of important differences in addition to several obvious similarities. The contrasting features of MCTD and SLE are summarized in Table 8. Esophageal hypomotility, sclerodactyly, and pulmonary hypertension are common and clinically distinctive features of MCTD, whereas renal disease and serious central nervous system disease are distinctive features of SLE. Serologic

TABLE 8 Relationship of Clinical, Serologic, and Immunogenetic Features of MCTD to SLE

Clinical, serologic, or immunogenetic features of disease	Prevalence in disease[a]	
	MCTD	SLE
Raynaud's phenomenon	++++	++
Esophageal hypomotility	++++	–
Swollen hands	++++	+
Sclerodactyly	++++	–
Myositis	+++	+
Pulmonary hypertension	+++	–
Rheumatoid-like joint changes	++	–
Dermatomyositis-like skin abnormalities	++	–
Renal disease	+	++
Central nervous system disease	–	++
Anti-U1-70-kDa antibodies	++++	–
Anti-RNP antibodies	++++	+
Anti-U1 RNA antibodies	+++	–
Anti-Sm antibodies	–	++
Anti-D polypeptide antibodies	–	++
Anti-B polypeptide antibodies	++	++
Anti-dsDNA antibodies	–	+++
Depressed serum C3 or C4 levels	+	+++
HLA-DR4	++++	–
HLA-DR2	+++	+++
HLA-DR3	–	++++

[a] Ranked on a scale of 4 + (most patients) to – (negative or rarely found).

features unique to MCTD include anti-U1 RNA and anti-U1-70-kDa autoantibodies; anti-Sm and anti-dsDNA antibodies are unique to SLE. When comparing immunogenetic markers, patients with both MCTD and SLE may possess HLA-DR2. The presence of the HLA-DR4 phenotype and the shared epitope on select HLA-DR4 and/or HLA-DR2 genotypes are distinctive immunogenetic features of MCTD [10, 11]. Finally, the HLA-DR3 phenotype is common in SLE and almost always absent in MCTD [10, 120, 121].

SJÖGREN'S SYNDROME

As with MCTD there is no uniformly accepted classification scheme for Sjögren's syndrome. Proposed classification systems for Sjögren's syndrome are as shown in Table 9. Many clinical features of Sjögren's syndrome overlap with those of SLE and other rheumatic diseases. Sjögren's syndrome may coexist in patients who also can be classified as SLE [150]. The incidence of Sjögren's syndrome in SLE has been reported to range from 6 to 90% [150, 151]. It has been reported that 42% of MCTD patients have sicca symptoms compatible with secondary Sjögren's syndrome [93]. Patients with Sjögren's syndrome and a second CTD are said to have "secondary Sjögren's syndrome," whereas those without another identifiable disease are said to have "primary Sjögren's syndrome" [152]. Sjögren's syndrome has been reported to coexist in patients with a number of other diseases, such as SSc, polymyositis, polyarteritis, and primary biliary cirrhosis [152]. Studies on Sjögren's syndrome have reported that it may occur in patients with multiple sclerosis-like demyelinating disease [153, 154], hepatitis C [155–157], human T-cell leukemia virus (HTLV)-I infection, and fibromyalgia [158]. The etiological relationship between Sjögren's syndrome and these entities is controversial, however [159, 160]. The current view favors the concept that hepatitis C and HTLV-I virus can be associated with secondary Sjögren's syndrome. Furthermore, MS-like syndromes and fibromyalgia have been described among patients with SLE [161–163].

Clinical Features

The hallmarks of Sjögren's syndrome are signs and symptoms resulting from a distinctive form of ocular inflammation (keratoconjunctivitis sicca) and salivary gland destruction. Inflammation and destruction of exocrine glands in Sjögren's syndrome result in the sicca complex of ocular dryness (xero-ophthalmia) and oral dryness (xerostomia). Sicca symptoms can also be the result of anticholinergic side effects of many medications, impaired neural innervation of glands, or a defective response to stimuli. In SLE it has been reported that autonomic neuropathy is frequent and may also underlay sicca symptoms in some patients [164]. These observations further complicate the relationship between SLE and Sjögren's syndrome. The term Sjögren's syndrome is reserved by most authors [165] to describe the syndrome caused by the inflammatory destruction of salivary and lacrimal glands.

The ocular symptoms of Sjögren's syndrome that are reported frequently by patients are protean in nature [166, 167]. Common ocular symptoms that have been reported include foreign-body sensation, burning, inability to tear, tiring, soreness, pain, redness, itching, photosensitivity, film over the eyes, change in vision, excess secretions, and difficulty moving the lids [161–168]. Objective ocular findings of keratoconjunctivitis sicca include a positive Schirmer's I test of ≤8 mm of wetting of Schirmer paper in 5 min, abnormal rose

TABLE 9 Proposed Classification Criteria of Sjögren's Syndrome

San Diego criteria[a]

I. Primary Sjögren's syndrome
   A. Symptoms and objective signs of ocular dryness
      1. Schirmer's test less than 8 mm wetting per 5 min
      2. Positive rose bengal or staining of cornea or conjunctiva to demonstrate keratoconjunctivitis sicca
   B. Symptoms and objective signs of dry mouth
      1. Decreased parotid flow rate using Lashley cups or other methods
      2. Abnormal biopsy of minor salivary gland (focus score of ≥2 based on average of four evaluable lobules)
   C. Evidence of a systemic autoimmune disorder
      1. Elevated rheumatoid factor ≥1:320
      2. Elevated ANA ≥1:32
      3. Presence of Anti-SSA (Ro) or anti-SSB (La) antibodies

II. Secondary Sjögren's syndrome
   Characteristic signs and symptoms of Sjögren's syndrome (described earlier) plus clinical features sufficient to allow a diagnosis of RA, SLE, polymyositis, scleroderma, or biliary cirrhosis

III. Exclusions
   Sarcoidosis, preexistent lymphoma, acquired immunodeficiency disease, and other known causes of keratitis sicca or salivary gland enlargement

European Epidemiologic Center criteria

I. Primary Sjögren's syndrome (if at least four items present)
   A. Ocular symptoms (at least one present)
      1. Daily, persistent, troublesome dry eyes for more than 3 months
      2. Recurrent sensation of sand or gravel in the eyes
      3. Use of a tear substitute more than three times a day
   B. Oral symptoms (at least one present)
      1. Daily feeling of dry mouth for at least 3 months
      2. Recurrent feeling of swollen salivary glands as an adult
      3. Drinking liquids to aid in washing down dry foods
   C. Objective evidence of dry eyes (at least one present)
      1. Schirmer I test
      2. Rose bengal
      3. Lacrimal gland biopsy with focus score ≥1
   D. Objective evidence of salivary gland involvement (at least one present)
      1. Salivary gland scintigraphy
      2. Parotid sialography
      3. Unstimulated whole sialometry (≤1.5 ml per 15 min)
   E. Laboratory abnormality (at least one present)
      1. Anti-SSA/Ro or anti-SSB/La antibody
      2. ANA
      3. IgM rheumatoid factor (anti-IgG Fc)

[a] Definite Sjögren's syndrome requires objective evidence of dryness of eyes and/or mouth and a systemic autoimmune process including a characteristic minor salivary gland biopsy (criteria IA, IB, and IC). Probable Sjögren's syndrome does not require a minor salivary gland biopsy but can be diagnosed with demonstration of decreased salivary function (criteria IA, Ib-1, and IC).

bengal or fluorescein staining of the interpalpebral conjunctiva of the eye, and dullness of the conjunctiva and/or dullness of the cornea. Oral symptoms that have been reported commonly by patients include oral dryness, difficulty with mastication or swallowing dry foods such as crackers, oral soreness, dental symptoms, and increased fluid intake, oral fissures, or ulcers of the mouth and lips [167, 169]. Signs of oral dryness may include geographic tongue, lack of salivary pooling under the tongue, poor dentition, angular cheilitis, and oral candidiasis. Otorhinolaryngeal symptoms reported in Sjögren's syndrome include nasal dryness and crusting, epistaxis, decreased smell and taste, persistent hoarseness, chronic cough, crusting serous otitis, and hearing loss due to eustatian tube occlusion. Cutaneous manifestations of Sjögren's syndrome include dry skin, vulvo-vaginal dryness, nonthrombocytopenic purpura, Raynaud's phenomenon, and cutaneous vasculitis. Fatigue is a prominent and often problematic feature of Sjögren's syndrome [170, 171]. Patients may experience arthralgias and myalgias; arthritis and inflammatory myopathy are uncommon except in secondary Sjögren's syndrome associated with RA or polymyositis. Interstitial nephritis and renal tubular defects are frequent in Sjögren's syndrome, although proliferative glomerulonephritis is rare, being seen essentially only in

Sjögren's syndrome with cryoglobulinemia [172]. A range of neurologic manifestations have been reported in patients with Sjögren's syndrome. These include mononeuritis multiplex, symmetric polyneuropathy, trigeminal neuropathy, cerebral vasculitis, progressive myelopathy, transverse myelitis, and myasthenia gravis [173]. A putatively distinctive syndrome of sicca complex presenting as peripheral neuropathy has been reported [174]. Additional uncommon extraglandular manifestations of Sjögren's syndrome that have been described include Hashimoto's thyroiditis, mixed cryoglobulinemia, atrophic gastritis, biliary cirrhosis, sclerosing cholangitis, and lymphocytic infiltration of the lungs. Many of the clinical manifestations described here for Sjögren's syndrome also occur in SLE.

Primary and secondary Sjögren's syndromes have both been associated with an increased risk for developing cancer, especially lymphomas [175]. The risk of developing non-Hodgkin's lymphoma in Sjögren's syndrome is increased substantially over the risk for both the general population and patients with other CTDs [175]. Angioblastic lymphadenopathy, pseudolymphoma to lymphoma in Sjögren's syndrome can be problematic, and a number of publications have addressed this issue [176–182].

Laboratory Features

Hypergammaglobulinemia, a positive FANA antibody test, the presence of rheumatoid factor, often at very high levels, and an elevated erythrocyte sedimentation rate are common in Sjögren's syndrome. Anemia, leukopenia, and eosinophilia occur in approximately one-third of patients. Antibodies to the Ro/SSA antigen, composed of snRNP with molecular masses of 52 and 60 kDa, are found in over three-fourths of patients with primary Sjögren's syndrome [14, 183]. Antibodies to the La/SSB antigen, a 48-kDa phosphoprotein found in association with RNA polymerase III transcripts, are present in over half of patients with primary Sjögren's syndrome [184, 185]. Patients with anti-La/SSB antibodies have been reported to be more likely to have clinical features of Sjögren's syndrome than those with anti-Ro/SSA [183, 184, 186]. The anti-Ro/SSA and anti-La/SSB B-cell responses appear linked, with patients who have anti-La/SSB antibodies present in their sera almost always having detectable anti-Ro/SSA antibodies as well.

Histopathology

The characteristic histopathologic findings in Sjögren's syndrome are focal to diffuse lymphocytic infiltrates with a concomitant destruction of lacrimal and salivary glands. A biopsy of labial minor salivary glands, such as those in labial or conjunctival tissue, has been proposed to be useful in the diagnosis Sjögren's syndrome [187]. Criteria have been published to assist in evaluating and classifying biopsy specimens [188].

Immunogenetics

Susceptibility to Sjögren's syndrome has not yet been mapped to a single allele or locus across all ethnic groups. In Caucasians, alleles associated with Sjögren's syndrome include HLA-B8, DR2, DR3, DRw52, DQw1, DQw2, and the extended haplotype HLA-B8, DR3, DRw52, DQw2 [15]. The presence of high titers of anti-Ro/SSA autoantibody is associated with HLA-DQw1/DQw2 heterozygosity. Molecular genetic studies have mapped disease susceptibility among some ethnic groups to glutamine in position 34 of the HLA-DQ α chain and leucine in position 26 of the HLA-DQ β chain [15, 189]. Furthermore, polymorphisms in the T-cell receptor β chain are independently associated with increased levels of Ro/SSA autoantibodies, and it has been reported that T cells infiltrating the salivary gland in Sjögren's syndrome have similar T-cell receptors (so-called common T-cell clonotypes) [189, 190, 191]. The topics of pathogenesis and treatment in Sjögren's syndrome have been reviewed [192].

Relationship of Sjögren's Syndrome to Lupus

Patients with SLE can have secondary Sjögren's syndrome [193]. In some clinical series, this has been reported to be as high as 90% of SLE patients [12, 194]. Furthermore, many of the clinical features of SLE and Sjögren's syndrome do overlap and therefore classification of the primary disease in such patients can be problematic. In addition, there are overlaps of both autoantibodies and immunogenetics in the two diseases. For example, HLA-DR2- and HLA-DR3-bearing haplotypes are both associated with susceptibility to SLE and Sjögren's syndrome [195], and antibodies to SSA/Ro are associated with the subacute cutaneous lupus subset of SLE, C-2 deficiency-associated lupus syndrome, neonatal lupus syndrome, and Sjögren's syndrome. Provost *et al*. [196] have identified what they believed to be a new subset of patients with late-onset disease who have overlapping features of SLE–Sjögren's syndrome and the presence of anti-SSA/Ro antibodies.

OTHER OVERLAP SYNDROMES

The literature is replete with case descriptions and small clinical series of patients said to have overlapping

features of various CTD. Classification of such patients is subject to the problems already discussed. There are, however, several of these overlap syndromes that deserve specific comment.

Patients with PM-Scl/PM-1 autoantibodies have been identified as having a polymyositis-scleroderma overlap syndrome. Raynaud's phenomenon, muscle weakness, pulmonary disease, tendon involvement, and increased risk of severe renal disease have been reported to characterize this syndrome [48, 196]. Widespread sclerodermatous features are uncommon [48]. The presence of this autoantibody is associated with HLA-DR3 [197].

Patients described with autoantibodies reactive against the Ku antigen were found in the original study to have a polymyositis-scleroderma overlap syndrome [198, 199]. Subsequently, it has been found that anti-Ku antibodies can also be detected in the sera of patients with SLE, MCTD, Sjögren's syndrome, SSc, and polymyositis. The prevalence of anti-Ku reactivity is, however, low in these other groups of patients. The prevalence of the antibodies in clinical studies appears related to the method used for detection [198, 199]. The presence of anti-Ku autoantibodies is associated with HLA-DQw1 [198, 199].

A distinctive group of patients has been recognized by the presence of autoantibodies against various transfer RNA (tRNA) synthetases [200, 201]. The first of these antibodies described was anti-Jo-1, which is directed against histidyl-tRNA synthetases. These anti-aminoacyl tRNA synthetase antibodies are associated with inflammatory myositis, but have overlapping features with other CTDs in the majority of patients. Clinically, patients may have features of MCTD, Sjögren's syndrome, or SLE. Clinical manifestations that may occur in addition to features of muscle inflammation include Raynaud's phenomenon, arthritis, arthralgia, pulmonary fibrosis, dermatomyositis rash, sicca, telangiectasia, and dysphagia. Patients with anti-Jo-1 antibodies have been reported to have an erosive arthritis that may mimic RA and frequently have secondary Sjögren's syndrome. Immunogenetics have shown association of anti-Jo-1 with HLA-DR3 [199].

The presence of anti-RNA polymerase II antibodies, in the absence of scleroderma-specific antibodies to RNA polymerase I and III, has been associated with an SLE-overlap syndrome [202]. These anti-RNA polymerase antibodies are frequently accompanied by the presence of other autoantibodies, including anti-RNP, anti-Ku, and antitopoisomerase I antibodies [203].

Patients initially classified as UCTD may ultimately evolve into diseases that can be classified as SLE or another currently recognized disease category. One large multicenter study is examining the progression of early UCTD. Interim analyses of this patient cohort have been published [204]. It was found that patients with well-established CTD, such as SLE, RA, SSc, or polymyositis-dermatomyositis, at the time of entry into the study had more stable diagnoses than those with early UCTD. They reported that 90–100% of the patients with established diagnoses retained the same diagnosis over 1–5 years, whereas of those with UCTD, only 64% retained the same diagnosis at 1 year and only 47% by 5 years [205].

SYSTEMIC LUPUS ERYTHEMATOSUS AND FIBROMYALGIA

John B. Winfield

ABSTRACT

The fibromyalgia syndrome with its associated chronic pain and multiple painful tender points occurs in more than 25% of patients with systemic lupus erythematosus (SLE). Variables that contribute to pain sensitivity and other symptomatology in fibromyalgia include female gender, poor sleep, deconditioning, a variety of psychological elements, negative beliefs and attributions, and loss of control. Adverse childhood experiences, especially sexual abuse, contribute to vulnerability to chronic, unrelieved stress and psychological distress as adults. Psychological stress in turn leads to dysregulation of the hypothalamic–pituitary–adrenocortical (HPA) axis, the autonomic nervous system, and central nociceptive processing. Proinflammatory cytokines are important mediators, both centrally and peripherally, of fatigue, poor sleep, musculoskeletal pain, and "sickness" in fibromyalgia and SLE. Although the psychological stress and distress that accompanies comorbid fibromyalgia in SLE negatively influences functional impairment and quality of life, and contributes importantly to fatigue and cognitive impairment, the available evidence does not support a role in flares of SLE disease activity or in major organ system injury over time. Optimum clinical assessment and therapy of SLE requires recognition of the contribution of fibromyalgia to overall morbidity in SLE. © 2003, Elsevier Science (USA).

INTRODUCTION

Pain, fatigue, sleep, and quality of life in SLE are strongly influenced by comorbid fibromyalgia and related chronic pain and fatigue syndromes. This chapter reviews the clinical classification of fibromyalgia, its high prevalence in people with SLE, evidence concerning the pathophysiology of pain and fatigue, and the extremely important contribution of psychological stress and distress to overall morbidity in this disorder. While organ system damage in SLE appears to be a consequence of strictly biological disease variables, the possibility that psychological distress contributes to the genesis of autoimmunity and to SLE flares remains an open question.

CLINICAL CLASSIFICATION OF FIBROMYALGIA

Fibromyalgia is a syndrome of chronic widespread pain, fatigue, poor sleep, and multiple somatic complaints. A generalized decrease in the pain perception threshold and in the threshold for pain tolerance is present, which reflect altered central nociceptive processing (see [1] for review). The 1990 American College of Rheumatology (ACR) classification criteria for fibromyalgia specify (1) presence of widespread pain for

>3 months and (2) pain, not just tenderness, that can be elicited by manual pressure of ~4 kg/cm^2 at 11 or more defined tender points [2]. Fibromyalgia is not a discrete entity, however. Because of the strong correlation of the number of painful tender points with psychological distress in fibromyalgia [3], in SLE [4] and other rheumatic disease, and in the general population [5, 6], fibromyalgia as classified by the ACR criteria is the tip of the iceberg. Thus, "fibromyalgia" represents the extreme end of a *continuum* of psychological distress and pain in the population. Clinicians experienced in this area do not slavishly apply the ACR criteria for diagnosis in practice. Most people with fibromyalgia will meet classification criteria for chronic fatigue syndrome and multiple other regional pain syndromes. At our current level of understanding, fibromyalgia is best classified as one of a series of largely overlapping "symptom-based conditions" [7], "functional somatic syndromes" [8], or "unexplained clinical conditions" [8a] that can be grouped together with mood and anxiety disorders.

PREVALENCE OF FIBROMYALGIA IN THE GENERAL POPULATION AND IN SYSTEMIC LUPUS ERYTHEMATOSUS

Chronic pain and fatigue are extremely prevalent in the general population, especially among women, and constitute a huge societal burden: regional pain, 20%; widespread pain, 11%; fibromyalgia by ACR criteria, 3–5% in females, 0.5–1.6% in males; chronic fatigue, ~20% [9–11]. In the United States, fibromyalgia as classified by the ACR criteria appears to be especially common in SLE: prevalence of fibromyalgia in clinic SLE populations is consistently ~20–25% [4, 12–14]. In other countries, for example, India, Spain, and the United Kingdom, fibromyalgia by ACR criteria occurs in 8–10% of SLE patients [15–17]. These may all be underestimates. Thus, in a study of coping responses in 173 patients with SLE in the Hopkins Lupus Cohort, 17% had >11 painful tender points (met ACR criteria) and 45% had 1–10 painful tender points. The latter shared psychological characteristics of the SLE/fibromyalgia patients, but not of the SLE patients without tender points [4]. These findings are similar to an earlier study in which 22% of SLE patients met ACR criteria and another 23% had features of fibromyalgia ("probable fibromyalgia") [12]. Why fibromyalgia should be so common in SLE is less clear. Ascertainment bias undoubtedly contributes in this regard, as does the unrelieved stress and distress associated with a chronic illness like SLE. Additional research in the field of psychoneuroimmunology should provide answers to whether SLE predisposes to fibromyalgia and precisely how and to what extent psychological distress contributes to altered immune system function and autoimmunity (see [18–21] for recent reviews).

PATHOPHYSIOLOGY OF PAIN AND FATIGUE IN FIBROMYALGIA

The hallmarks of fibromyalgia are widespread chronic pain and reduction of pain thresholds. The latter renders peripheral stimuli painful that ordinarily are not painful, such as light touch (*allodynia*). The International Association for Study of Pain defines pain as "an unpleasant sensory and emotional experience associated with actual or potential tissue damage, or described in terms of such damage"[22]. The neurophysiologist views pain as a complex sensation–perception interaction involving simultaneous parallel processing of nociceptive input from the spinal cord that activates a central network encompassing the pain experience in multiple regions of the brain. These regions include sensory-discriminative elements of nociception, afferent input from somatic reflexes, and major contributions from pathways and regions of the brain concerned with emotional/motivational and cognitive aspects of pain, which determine the subjective intensity of pain. The hypothalamic–pituitary–adrenocortical axis and the sympathetic nervous system (principal effectors of the stress response) are activated, as well. Normally adaptive, the stress response may become maladaptive in chronic pain and fatigue syndromes, such as fibromyalgia.

Emotions, cognitive elements (what does the pain mean?), and other psychological factors (coping, self-efficacy for control of pain) represent the psychological correlates of biological systems attempting to restore homeostasis in response to the pain experience. Negative emotions (depression and anxiety), negative beliefs and attributions, and loss of control or unpredictability in one's environment all can function as stressors with actions in these systems. Important biological elements here include cytokines (IL-1 (interleukin-1), IL-6, TNF-α (tumor necrosis factor-α), others), the HPA axis, and the autonomic nervous system which, together with the immune system and the endocrine system, functions as a complex bidirectionally communicating network. Melzak has developed a *neuromatrix* model [23] to explain how the brain functions as a neural network to integrate endocrine, immune, autonomic, afferent, inflammatory, social and behavioral, and pain

inhibitory inputs that influence pain perception and pain behaviors.

In the aggregate, the above psychological elements constitute *psychological stress*, which can downregulate or dysregulate immune responses and contribute to the development of actual flulike "sickness." This sickness is characterized by synthesis of acute phase reactants by the liver and behavioral changes, including increased pain sensitivity, decreased activity, decreased social interaction, reduced cognitive function and vigilance, depressed mood, decreased sexual behavior, and subtle endocrinologic and immunologic correlates. Conversely, peripheral immune stimulation, either by infection or inflammation associated with active SLE, communicates with the brain using the same network to produce a sickness response [24, 25].

BIOPSYCHOSOCIAL MODEL OF CHRONIC PAIN AND FATIGUE

A useful approach to understanding fibromyalgia is based on Engel's biopsychosocial model of chronic illness: health status and outcomes in chronic illness are influenced by the interaction of biological, psychological, and sociological factors [26]. Important biological variables are gender, sleep, physical condition, stress/neuroendocrine and autonomic dysregulation, and central sensitization to pain. Fibromyalgia, like SLE occurs predominately in females, and female gender is associated with increased pain sensitivity generally (see [27] for review). In clinical and experimental studies comparing males and females, females have more pain at all sites and more use of analgesic medications, are more sensitive to pain stimuli, and have central pain modulatory systems that are influenced by phasic alterations in reproductive hormone levels. Of interest with respect to the latter gender characteristic is a recent observation that serum IL-6 levels are significantly increased during the luteal phase of the menstrual cycle [28]. Such observations are of obvious relevance to the oft-noted changes in well-being in healthy women and in disease activity in women with chronic conditions such as SLE and fibromyalgia during this phase of the menstrual cycle. Aversive stimuli and stressful tasks are more likely to evoke sympathetic nervous system and HPA axis responses and greater psychological responses in females than in males. Although data are conflicting [29], it has been observed that woman report essentially all symptoms, including unexplained (somatoform) symptoms, at least 50% more than men [30]. This gender effect, although correlated with anxiety and depressive disorders, remains significant after controlling for psychiatric morbidity.

Poor sleep is almost universal in fibromyalgia and is directly associated with perception of pain during sleep [31, 32]. While not the proximate cause of fibromyalgia, abnormal sleep affects both limbs of the stress response system and contributes to negative mood and cognitive difficulties [33, 34]. As already discussed, a growing body of evidence suggests that in fibromyalgia and related disorders, psychological stress initiates or perpetuates functional alterations of the stress response system, with multiple adverse neuroendocrine, autonomic nervous system, and immunologic effects [18–21, 35–38]. Therefore, it is plausible that neuroendocrine and autonomic dysregulation (sympathetic hyperactivity) contribute to diverse clinical manifestations in fibromyalgia and SLE, including psychological elements, for example, anxiety and depression. As discussed in detail later, however, current knowledge does not permit firm conclusions regarding the impact of psychological variables on more strictly biological aspects of clinical disease expression in SLE.

Cognitive-behavioral variables operant in the chronic pain and fatigue of fibromyalgia include pain beliefs and attributions, hypervigilance (expectancy), active and passive coping strategies, perceived self-efficacy for pain control, mood, depression and anxiety, personality traits and disorders, and pain behaviors. The repertoire of cognitive-behavioral variables in an adult have antecedents in earlier life that determine vulnerability to stress and influence the cognitive, affective, and behavioral aspects of the pain experience. These include poor health in parents, parental pain history, poor family environment, and childhood abuse, particularly sexual abuse [39, 40] (see [41] for review).

Environmental and sociocultural variables are the multiple experiences and forces in the environment and in life and culture that influence the course of chronic pain and fatigue. These include the psychosocial experiences during childhood discussed previously, spousal and family support, work environment/job satisfaction, ethnological factors, focus on definable causes, media hype, and primary and secondary gain. Influences here can be positive and helpful, for example, job satisfaction, or negative, for example, diagnostic "waffling" and inappropriate diagnostic testing. Environmental and cultural variables clearly impel the high prevalence of chronic pain disorders in Western societies.

PSYCHOLOGICAL STRESS IN FIBROMYALGIA

Persons with fibromyalgia often carry a huge psychological burden of stress and distress, and certain data

suggest that psychological distress can precede pain, although this remains an incompletely resolved question. Depression, anxiety, and psychiatric disorders are extremely common. Fibromyalgia patients in tertiary care centers have very high rates of lifetime (81%) and current (48%) psychiatric disorders, and elevations on self-report measures of depression, anxiety, hypochondriasis, and neuroticism [42]. Scores on the Rand 36-item Health Survey (SF-36), a self-report questionnaire measuring functional impairment and well-being, usually are in the severely impaired range in all areas (physical functioning, pain, role limitations, emotional well-being, social functioning, energy/fatigue, general health perception). Depression, maladaptive coping, low self-efficacy, and anxiety contribute to a vicious cycle of negative beliefs, distress, pain and fatigue, somatization, and functional impairment.

DOES PSYCHOLOGICAL STRESS CAUSE OR EXACERBATE SYSTEMIC LUPUS ERYTHEMATOSUS?

The idea that particularly significant psychological stressors, such as death or divorce, might be related causally to onset of SLE or flares in SLE disease activity was raised almost 50 years ago [43]. As reviewed by Herrmann and colleagues [44], stress seems to be one of the factors that can provoke juvenile chronic arthritis, and prospective data support the concept that minor daily stress can aggravate symptomatology and joint inflammation during the course of rheumatoid arthritis. From limited early data, these authors conclude, "[psychological] stress seems to act as an exacerbating factor in SLE, precipitating flares." More extensive information that became available during the past decade argues against this proposition, however, at least with respect to our current methods for assessing SLE disease activity.

In most studies comparing subjects with SLE and fibromyalgia "vs" subjects with SLE and no associated fibromyalgia, no differences between the groups with respect to clinical and laboratory measures of SLE disease activity are observed [12–14, 16]. This is especially apparent in studies using the Systemic Lupus Erythematosus Disease Activity Index (SLEDAI) and/or British Isles Lupus Activity Group (BILAG), which rely on more objective measures of actual inflammation [14, 16]. In a seminal study by Middleton *et al*. [12], Systemic Lupus Activity Measure (SLAM) scores were higher in the SLE/fibromyalgia group, but differences disappeared when the SLAM scores were recalculated after elimination of subjective symptoms that could be attributed to fibromyalgia, such as fatigue. Data regarding levels of anti-double-stranded (ds) DNA in SLE subjects with and without associated fibromyalgia are inconsistent [12, 45]. Associated fibromyalgia appears not to contribute to elevation of the SLICC/ACR damage index [14] or specific organ system involvement, but does make it more difficult for physicians to rate SLE disease activity [13]. Comorbid fibromyalgia in SLE is highly correlated with all domains of the SF-36 indicating worse quality of life (QOL) [14]. Fatigue, which may be the most disabling physical symptom in SLE, is associated with depression and abnormal SF-36 scores, but not with abnormal laboratory values and objective clinical measures of SLE disease activity or damage [14, 46, 47]. Finally, Akkasilpa *et al*. have observed a strong association in SLE of tender points with uncertainty and lack of "hardiness" [4]. In this study, patients with SLE were examined for tender points and assessed by the Health-Related Hardiness Scale (HRHS) and the Mishel Uncertainty in Illness Scale (MUIS). Thirty-eight percent of the subjects had no tender points, 45% had 1–10 tender points, and 17% had > or = 11 TP (tender points), thus meeting one of the ACR criteria for classification as fibromyalgia. Scores on HRHS and MUIS reflecting less hardiness and greater uncertainty correlated highly with increasing numbers of tender points, a measure of psychological distress [3].

The experience of psychosocial stress and attendant psychological distress appear to be more related to *patient perception of illness* in SLE, rather than to the expression of clinically measurable SLE disease activity [46, 48–51]. Adams *et al*. [50] observed that major life events, daily stressors, depression, anxiety, and anger were associated with severity of self-reported symptomatology, such as joint pain and abdominal distress. This was especially true in a subset of subjects, termed stress responders. In a very recent, prospective study, Ward and colleagues [51] directly approached the question of whether changes in depressive symptoms or anxiety led to changes in SLE disease activity. Outcome measures were the SLAM, the SLEDAI, and the European Consensus Lupus Activity Measure (ECLAM). Although as previously noted in an earlier study of the association of comorbid fibromyalgia with SLE disease activity [12], changes in depression and anxiety were positively correlated with SLAM scores, but not when SLAM scores were modified to exclude ratings of depression and fatigue. There was no association with SLEDAI or ECLAM scores or with physician global assessment of disease activity. These investigators found no evidence that psychological distress leads to increased SLE disease activity and concluded that "depression and anxiety scores parallel changes in *patients' assessments* of the activity of their SLE."

From the above, one should not conclude that fatigue and pain sensitivity in SLE or fibromyalgia have no biological basis. A large body of neuroscience research is beginning to clarify the bases for altered central nociceptive processing in chronic pain disorders. Altered cytokine profiles have been identified in fibromyalgia and chronic fatigue syndrome [52–54]. Fatigue certainly can be a symptom associated with systemic inflammation in SLE in the absence of fibromyalgia [16], although it continues to be difficult to precisely define its biological bases [55]. Certain data suggest that prolactin [56] and proinflammatory cytokines, such as TNF-α and IL-6 [52], provide a link between immune stimulation in the periphery, that is, *intrinsic* to SLE, and central nervous system (CNS)-mediated sleep, somnolence, and fatigue. The key concept with respect to symptomatology in SLE, particularly for those persons with SLE who are overly susceptible to psychological stress, is that input to central mechanisms that underlie fatigue and pain sensitivity can be peripheral inflammation, psychological distress, or both. This is especially true for persons with coexistent fibromyalgia. For example, Bruce *et al*. [47] found fatigue severity to be highly correlated with the tender point count (a "sedimentation rate" for distress irrespective of a diagnosis of fibromyalgia [3] in consecutive patients attending an academic Lupus Clinic ($r = 0.46$, $p < 0.001$).

STRESS AND IMMUNE RESPONSES IN SYSTEMIC LUPUS ERYTHEMATOSUS

Only limited data are available concerning the effects of psychological stress on aspects of the immune response in SLE. Attenuated mobilization of leukocytes after acute (10 min of unpleasant environmental noise) or longer-term (administration of a two-h long battery of neuropsychological tests) psychological stress in SLE relative to healthy subjects or non-SLE subjects receiving corticosteroids has been observed [57]; the catecholamine response was normal in this study. Pawlak and colleagues [58] reported that public speaking, an acute psychological stressor, induces similar psychological, cardiovascular, and neuroendocrine responses in patients and controls, but SLE patients exhibit less pronounced increases in natural killer (NK) cell numbers and NK activity than do control subjects, and failure to express increased numbers of β(2)-adrenoreceptors on peripheral blood mononuclear cells. This group also found a stress-induced increase in IL-4-producing cells in SLE patients only, whereas IFN γ^+ cell numbers increased due to stress in SLE subjects and control groups [59]. Consistent with the idea that there is altered sympathetic regulation in SLE, is evidence that baseline and post-hCRH testing in moderately active SLE shows sympathetic hyperactivity as assessed by blood pressure and heart rate measurements [60]. Such data obviously raise the question of whether changes in cytokine patterns might be responsible for stress-induced exacerbation of disease activity in SLE.

In a prospective study of the effect of psychosocial stress carried out over nine time points at 6-week intervals, [48], a clear relationship with laboratory and clinical indices of disease activity in SLE was not evident. The static design of this study has been criticized by Schubert *et al*. [61] as unsuitable for revealing true effects because of the enormous individual variation in the psychosocial, laboratory, and clinical variables and the long intervals between assessments. In an attempt to clarify this issue, this group investigated the dynamic interactions among psychosocial, emotional, and physiological variables in single subject with SLE on a *daily* basis for 63 days according to a time-series analytic approach. Although SLE disease activity remained quiescent throughout this period, an association of psychosocial stressors and urine neopterin levels was observed. A similar study using "integrative single case studies" as a new biopsychosocial approach to the psychoneuroimmunology of SLE found interesting associations of daily psychosocial stressors and associated emotions with urine neopterin and changes in urine cortisol [62]. Urine neopterin appears to be a marker of SLE disease activity [63], raising the possibility, at least, of clinically significant effects of psychological stress. Of interest in this regard is a recent report that urine neopterin is increased in major depression, but not in fibromyalgia without major depression [64].

FIBROMYALGIA AND ITS IMPACT ON HEALTH OUTCOMES AND QUALITY OF LIFE IN SYSTEMIC LUPUS ERYTHEMATOSUS

Overall health outcome and QOL in SLE is strongly influenced by interactions of individual psychosocial variables (socioeconomic status, education, insurance, social network), stressors of daily life and stress inherent in living with a chronic illness like SLE, and societal factors. While there is considerable variation in patient vulnerability in this regard, low self-efficacy for disease management [65], daily stress (hassles) and level of social support [66, 67], and style of coping [68] have been identified as important variables associated with disease activity, physical function, and mental health. It is less clear that such factors contribute to organ system damage over time, however. For example, in a random

sample of SLE patients at five academic medical centers [69], there was evidence of organ system damage measured by the SCLICC/ACR damage index within a mean of 4 years after disease onset. Older age at diagnosis, greater disease activity at diagnosis, and longer disease duration correlated with greater damage in different organ systems, but race and socioeconomic status did not. These findings are consistent with a dominant effect of more strictly clinical variables, rather than social and behavioral variables, on organ system damage in SLE, as discussed previously.

Comorbid fibromyalgia can amplify the negative influence of social and behavioral variables on QOL in SLE. When fibromyalgia is present, patients with SLE have increased pain, fatigue, and insomnia, more impairment in functional status, decreased sense of well-being, poorer perception of health, and increased rates of unemployment, divorce, and welfare/disability payments [12, 14]. Because psychological distress and pain sensitivity exist as a continuum in the population, many persons with SLE, that is, "stress responders" [50] who do not meet the ACR classification criteria as fibromyalgia (some tender points present, but fewer than 11) are subject to the adverse effects of stress on QOL. Stress here includes major stress (life events), minor stress (daily hassles), less than optimum self-efficacy and self-esteem, and maladaptive coping skills. Taking this approach, Da Costa and colleagues [70] studied the association of stress with changes in functional impairment, as assessed by the Stanford Health Assessment Questionnaire (HAQ). More negative life events and depressed mood were correlated with more abnormal HAQ scores. Changes in the HAQ scores were not related to SLE disease duration, activity, or organ system damage. It follows that reduction of stress, enhancement of social support, preservation of the patient's social roles, and improving coping skills and self-efficacy should all be part of the comprehensive management of SLE [16, 66–68, 71]. Similarly, potentially modifiable sociodemographic variables, such as low education, Medicaid or no health insurance, low income, and having a physically demanding job, predict which ~40% of people with SLE who quit work within a few years after diagnosis [72].

Adaptation of self-report questionnaires as a routine element in outpatient clinical care is an efficient and, in the author's experience, exceedingly effective method for assessing QOL and functional impairment and the social and behavioral variables that influence QOL and functional impairment. In addition, longitudinal monitoring of health status and response to therapy is possible. An example of such an instrument is the Multidimensional Health Assessment Questionnaire (MDHAQ) [73] originally developed by Pincus and Callahan. The MDHAQ takes only a few minutes to complete while patients wait to be seen by the physician, and screens for difficulties with activities of daily living, for psychological distress with Likert scales for sleep, stress, anxiety, and depression, and for somatization via a checklist of current symptoms. Ten-centimeter visual analog scales for pain, fatigue, and global self-assessment of overall health provide additional useful information. If the physician reviews the findings from this questionnaire in the examining room with the patient, patient acceptance of this instrument is universally excellent. Patient/physician communication is enhanced by assuring that the physician is aware of what in the patient's life and illness is most distressing to them. The author combines the MDHAQ with pressure algometry (dolorimetry) at four fibromyalgia tender points in the routine assessment of all patients at each clinic visit, an approach that is highly sensitive for detection of comorbid fibromyalgia in SLE and other rheumatologic disorders.

RELEVANCE OF STRESS, DISTRESS, AND FIBROMYALGIA TO NEUROPSYCHIATRIC MANIFESTATIONS OF SYSTEMIC LUPUS ERYTHEMATOSUS

Cognitive impairment is one of the most common and distressing neuropsychiatric problems in both fibromyalgia and SLE. Using the ACR case definitions for neuropsychiatric syndromes in SLE in a prospective Texas cohort study of 128 subjects, 79% exhibited cognitive impairment by standardized neuropsychological testing and in approximately one-third, impairment was rated as moderate or severe [74]. Anxiety and mood disorders also were prevalent: anxiety disorder, 24%; major depressive-like episode, 28%; mood disorder, 23%. In fibromyalgia, there is a general consensus that cognitive dysfunction is related to psychological stress and distress, rather than any irreversible brain injury. In SLE, a variety of pathogenetic variables have been proposed: psychosocial variables, psychiatric disorders independent of SLE [75], intrathecal cytokines [76], extra-CNS immune activation-derived cytokines acting on the brain [77], and autoantibody or immune complex-mediated brain injury [78, 79]. The exact contributions of these putative variables remain to be clarified. Cognitive impairment in SLE is particularly difficult to assess and study, and most studies have not clearly defined the possible contribution of comorbid fibromyalgia and its associated "fibrofog." Hay *et al.* [75] observed a point prevalence of ~20–25% for both psychiatric disorder and cognitive impairment in a prospec-

tive cohort of 49 patients with SLE at two time points. Only 1 of 9 patients with cognitive impairment at first interview was still impaired at second interview, suggesting absence of any irreversible or subclinical brain injury. Rather, change in cognitive function mirrored change in psychiatric status.

Certain data suggest that the high prevalence of cognitive impairment in SLE is independently associated with depression, but not with other clinical variables [80, 81]. Others have not observed a strong association of cognitive impairment with depression [82]. While cognitive impairment, along with anxiety and depression may reflect the psychological impact (stress and distress) of active SLE, with improvement during periods of remission [83], most investigators have found cognitive difficulties to be unassociated with clinically active SLE [82, 84]. The role of proinflammatory cytokines, which have been associated with cognitive impairment and pain sensitivity in both SLE and fibromyalgia [77] and intrathecal anti-phospholipid antibodies are currently under active investigation. The author's bias is that much of the cognitive and emotional difficulties in SLE derive from the same biopsychosocial variables operant in fibromyalgia. In other words, cognitive impairment in SLE reflects fibrofog.

CONCLUSIONS

Fibromyalgia and related chronic pain and fatigue disorders are exceedingly common in SLE. The biopsychosocial variables that underlie chronic pain and fatigue are becoming increasingly well understood, both with respect to their relative contributions and in terms of psychoneuroimmunological mechanisms. The psychological stress and distress that accompanies comorbid fibromyalgia in SLE strongly influences quality of life, functional impairment, rates of unemployment, divorce, and welfare/disability payments. Current evidence does not support the idea that fibromyalgia contributes measurably to clinical and laboratory measures of disease activity in this disorder. Similarly, organ system damage over time appears to be primarily a consequence of more strictly biological disease variables. Fatigue, mood and anxiety disorders, and cognitive impairment are manifestations of comorbid fibromyalgia, not SLE. Optimum clinical assessment and therapy of SLE requires recognition of the contribution of fibromyalgia to overall morbidity in SLE.

NEUROPSYCHIATRIC SYSTEMIC LUPUS ERYTHEMATOSUS

Rogelio Garcia-Cavazos
Robin Brey

INTRODUCTION

Systemic lupus erythematosus (SLE) is an autoimmune disorder affecting multiple organ systems, including the central (CNS) and peripheral nervous systems (PNS). CNS involvement in SLE is a complex diagnostic entity due to its multiple clinical presentations. The American College of Rheumatology ACR [1] established case definitions and diagnostic criteria for 19 CNS and PNS syndromes observed in SLE patients, which collectively are referred to as neuropsychiatric systemic lupus erythematosus (NPSLE) syndromes (Table 1).

The new ACR [1] guidelines for NPSLE eliminate the frequently used term lupus cerebritis. Although cutaneous and visceral vasculitis is not unusual in SLE [2], true cerebral vasculitis is rarely found in SLE despite its popular use as a clinical diagnosis [3–5]. Similarly, because both psychiatric and peripheral nervous system disorders may also be present, a term such as CNS lupus is overly specific and thus should also be avoided in discussions about NPSLE.

Prevalence of NPSLE Syndromes Using the American College of Rheumatology Case Definitions

Systemic lupus erythematosus is a disease with a fluctuating course and NPSLE manifestations can occur as a single or multiple events at any time during the course of the disease, even during periods in which no nonnervous system SLE disease activity is detected [6, 7]. Approximately 40% of the NPSLE manifestations develop before the onset of SLE or at the time of diagnosis and 63% within the first year after diagnosis [7].

Estimates of the prevalence of NPSLE have ranged from 14 to over 80% [1, 8–14], and most are based on research conducted before the introduction of the ACR criteria for NPSLE. The goal of the ACR case definitions, criteria, and nosology guidelines was to increase consistency in the classification of patients and standardize clinical descriptions and reporting requirements in NPSLE research [1]. Encouraging results are beginning to emerge from research efforts conducted in different research centers across geographic regions. At least three studies [12–14] have reported prevalence of NPSLE based on the ACR 1999 criteria. The three detected the presence of 14 to 17 of the 19 syndromes described by the ACR [1] and report identical prevalence of cranial neuropathy (1.5%) and chorea (1%). These studies also report very similar prevalence of five other syndromes: cerebrovascular disease (2%), total spectrum of headache (56–61%), total spectrum of mood disturbances (69–74%), psychosis (5%), and total range of cognitive disorders (75–80%).

It should be noted that agreement on the prevalence of cognitive, mood, and psychotic manifestations was high in these studies and assessment was based on standardized examination instruments. This is a significant methodological improvement, as difficulty in defining psychiatric abnormalities and cognitive dysfunction is likely to be a source of discrepant prevalence rates of NPSLE across studies. Continued, extensive use of the

ACR criteria for NPSLE will help clarify the sources of discrepancies and improve reporting practices in NPSLE research.

Pathogenesis of NPSLE Syndromes

The pathogenic etiology of NPSLE is likely to be multifactorial and may involve autoantibody production, microangiopathy, and intrathecal production of proinflammatory cytokines [15]. Histopathologic studies reveal a wide range of brain abnormalities caused by multifocal microinfarcts, cortical atrophy, gross infarcts, hemorrhage, ischemic demyelination, and patchy multiple-sclerosis-like demyelination [16], but these are not diagnostic for NPSLE [6]. Bland microvasculopathy (characterized by vessel tortuosity, cuffing of small vessels, vascular hyalinization, endothelial proliferation, and perivascular gliosis), formerly attributed to deposition of immune complexes but now suspected to arise from activation of complement, appears to be the most common microscopic finding [16, 17]. However, this too is a nonspecific finding as patients without NPSLE also show these changes [15]. A histologically normal brain with no specific pathognomonic brain lesions is also a common finding in NPSLE [16].

Autoantibody production has been implicated in vasculopathic and autoantibody-mediated neuronal injury mechanisms. Anti-ribosomal P antibodies (anti-P) have been linked to diffuse CNS involvement in NPSLE [18, 19]. Anti-phospholipid (aPL) autoantibodies, detected by immunoreactivity to anticardiolipin (aCL) assays and/or their ability to prolong phospholipid-dependent coagulation assays (lupus anticoagulant, LAC), are implicated in the microvascular thrombo/embolitic and endothelial damage found in the brain of NPSLE patients [6].

Vasculopathy in SLE

Neuropathologic studies in SLE patients have frequently found a small vessel vasculopathy consisting of proliferative changes of the intima, vascular hyalinization, and perivascular lymphocytosis. This small vessel vasculopathy has been seen both in SLE patients with only psychiatric symptoms as well as those with focal NS manifestations [15]. Interestingly, single photon emission computed tomography (SPECT) and MR spectroscopy studies suggest that both cerebral atrophy and cognitive decline in SLE patients may be related to chronic cerebral ischemia [20–22]. It is possible that SPECT and MR spectroscopy studies represent a functional image correlate for cerebral vasculopathic change.

Cytokines

Cytokines appear to have regulatory roles in mediating SLE-disease activity and inflammation in target organs [23, 24]. Work has highlighted the importance of SLE monocytes in the generation of potentially pathogenic cytokines, particularly IL-6 and IL-10 [25]. The balance between proinflammatory and anti-inflammatory cytokines and the degree and extent of inflammation appear to profoundly influence SLE-mediated disease manifestations [23].

Several, largely cross-sectional studies in SLE have suggested that IL-6 is a marker of disease activity [26–28]. There are multiple other mechanisms whereby SLE patients might have higher IL-6 levels. The C5b-9 complex stimulates IL-6 [29]. Diabetes, which is increased in SLE patients taking prednisone, is associated with higher IL-6 levels [30, 31]. Homocysteine, which is elevated in 30% of SLE patients, leads to higher IL-6 levels [32]. Over 33% of SLE patients are morbidly obese, another associate of IL-6 levels [33]. Finally, dehydroepiandrosterone (DHEA) is low in SLE; a low level of DHEA could increase IL-6 secretion [34, 35].

Few studies have investigated the role of cytokine abnormalities in NPSLE patients. Cerebrospinal fluid (CSF) IL-1 and IL-6 levels are increased in SLE patients with CNS involvement compared with non-SLE neurological controls [25, 26]. Both serum and CSF IL-6 levels are elevated in NPSLE patients vs non-NPSLE patients or healthy controls [25, 26]. In one study, however, there was no difference in serum IL-6 levels between NPSLE patients and CNS infection control patients [25]. In another study, CSF IL-6 activity paralleled NPSLE disease activity most consistently [27]. In a study of 15 SLE patients without overt CNS disease (vs rheumatoid and healthy controls), regression analysis showed that serum DHEA-s and IL-6 accounted for unique portions of the variance in measures of learning and attention, after controlling for depression and corticosteroid treatment [28].

While many of these studies suggest that cytokine levels in the CSF may reflect SLE-mediated CNS activity, serum levels also appear to be important in patients with NPSLE manifestations. In addition, cytokine stimulation of peripheral nerves and sensory receptors has been shown to lead to large changes in neural activity and physiological and behavioral responses in the CNS. The synthesis and release of IL-1α, IL-6, and tumor necrosis factor-α (TNF-α) play a prominent role in the mediation of these phenomena [36]. These proinflammatory cytokines do not easily cross the blood–brain barrier, and therefore their effects on neural events are

postulated to occur either by entring into the CNS using specific transport systems or in areas where the blood–brain barrier is more permeable (e.g., circumventricular organs) or by binding to other receptors on endothelial cells of brain vasculature leading to endothelial release of other mediators into brain parenchyma. Another reasonable alternative is that cytokines act by activating afferent neurons in a paracrine action at the site where they are released, leading to neural events within the CNS in the location where these peripheral afferent neurons terminate. Experimental evidence supports this hypothesis, particularly in the case of the vagus nerve [36]. In addition, animal models have demonstrated induction of diverse manifestations of "sickness behavior" such as fever, fatigue/malaise, decreased pain thresholds, and hypocampal-dependent memory impairment by these mechanisms [36].

Adhesion Molecules

Other processes leading to immune-mediated brain dysfunction in SLE probably involve abnormal endothelial–white blood cell interactions that allow proteins or cells access to the CNS. The expression of adhesion proteins on endothelial cells appears to be upregulated in SLE, and facilitates lymphocyte entry in CNS disease [37–46]. Shedding of the active form of these molecules occurs, and soluble levels can be measured in both serum and CSF [45, 46].

Studies of circulating soluble adhesion molecules in SLE have yielded contradictory results [47–49]. In addition, there is disagreement as to whether soluble adhesion molecules are an accurate reflection of membrane bound proteins. Soluble serum levels of intercellular adhesion molecule 1 (ICAM-1) increase with systemic disease activity in patients with SLE [50, 51]. Wellicome and colleagues [52] evaluated soluble serum levels of vascular cell adhesion molecule 1 (VCAM-1) in patients with rheumatoid arthritis and SLE and found elevations in both groups as compared to normal controls. Janssen and colleagues [46] studied soluble serum levels of ICAM-1, VCAM-1, and E-selectin in SLE and found that soluble VCAM-1 levels were elevated during active disease, and normalized with remission in SLE. These findings were replicated by Spronk and colleagues [53] who also described an elevation of soluble VCAM-1 levels with disease activity and a fall with clinical remission in SLE, but no difference in ICAM-1 and E-selectin levels between SLE patients and controls at any time point. Machold *et al*. [54] likewise failed to find a difference in mean ICAM-1 levels between SLE patients, rheumatoid arthritis patients, and normal controls; however, within the patient groups, soluble serum ICAM-1 levels correlated with other markers of disease activity, for example, sedimentation rates and clinical findings. Levels of sICAM-1, but not sE-selectin, may decreased after corticosteroid therapy [55], although this is controversial [56, 57]. In one study, only combined elevation of three adhesion molecules (sCD14, sICAM-1, and sE-selectin) correlated with SLE prognosis [58].

Autoantibodies and NPSLE

Autoantibody production has been implicated in vasculopathic and autoantibody-mediated neuronal injury mechanisms. Anti-ribosomal P antibodies (anti-P) have been linked to diffuse CNS involvement in NPSLE [18, 19].

Anti-phospholipid antibodies (aPL) are a family of antibodies directed against plasma proteins bound to negatively- charged phospholipids that lead to hypercoaguability through effects on the protein C/protein S system, platelets, endothelial cells, and complement activation [59, 60]. APLs, defined as the lupus anticoagulant (LA), anticardiolipin (aCL), and anti-β_2 glycoprotein 1 (anti-β2GP1), are strongly associated with localized NPSLE, including TIA (transient ischemic attack), stroke, seizure, and cerebral vein thrombosis [61].

Multiple studies have also shown an association of aPLs with cognitive dysfunction in SLE [62–65]. Denburg *et al*. [63] found, in a cross-sectional study, that LA-positive patients were two to three times more likely than LA-negative patients to be cognitively impaired, primarily on tasks of verbal memory, cognitive flexibility, and psychomotor speed. In a 5-year prospective study, Hanly *et al*. found that patients who had persistent IgG aCL positivity had a reduction in psychomotor speed, and patients who had persistent IgA positivity had a reduction in conceptual reasoning and executive ability [62]. In a study of 45 SLE patients assessed twice, persistently elevated aCL levels were associated with poorer cognitive function, particularly speed of attention and concentration [64]. High titers of CSF IgG aCL have been detected in SLE patients (vs controls) with lupus headache, acute psychosis, cognitive dysfunction, higher cortical dysfunction, and altered consciousness [65]. Lupus anticoagulant, but not IgG aCL, was associated with reduced regional cerebral blood flow in a SPECT study [66]. However, one comparative study of positron emission tomography (PET), HMPAO-SPECT, and magnetic resonance imaging (MRI) scans did not find any correlation with aCL [67]. Anti-phospholipid (aPL) autoantibodies are also implicated in both microvascular thrombo/embolic episodes and endothelial damage.

Non-Immune-Mediated Mechanisms

Neurological complications of SLE also result from abnormalities either not directly related to the primary disease or as an effect of non-nervous system organ involvement. Many of these processes result in neurological dysfunction, including confusion and seizures, that are indistinguishable from primary immune-mediated damage. The major etiologies in this group are infections, toxins (including medications), and metabolic derangements. Although survival in SLE has improved over the years, infection remains a leading cause of morbidity and mortality in the disease [8]. Meningitis from both bacterial pathogens such as *Neisseria* and opportunistic infections including *Candida* and *Cryptococcus* occur [68]. The spectrum of infections includes bacterial, viral, fungal, and parasitic organisms [69]. Septic emboli continue to be a cause for concern in patients with fever. The high frequency of infections is due to diminished immunocompetence resulting from both medication and the underlying disease. The importance of identifying CNS infections is underscored by studies showing that patients on high-dose corticosteroids for NPSLE have a higher mortality rate than those on lower doses [70].

The toxins most often causing neurological abnormalities in SLE are medications. Corticosteroids and antihypertensive medications can produce neurological and psychiatric symptoms [71–73]. Metabolic abnormalities likely to affect the nervous system include uremia, as well as disorders of calcium, sodium, and magnesium. The rapid reversibility of abnormalities on some neurodiagnostic studies may well reflect transient metabolic abnormalities [74, 75].

Murine Neurobehavioral SLE

A number of animal models exist for various clinical and serological manifestations of SLE. Some of these, such as NZB, (NZB × NZW)F1, MRL/lpr, and BXSB mice represent inbred strains that provide an opportunity to study the evolution of spontaneous SLE disease manifestations [76, 77]. Others, such as MRL/++, another inbred stain that develops mild autoimmune disease manifestations late in life, provide an opportunity to examine agents or environmental manipulations that accelerate selected features of disease expression [76]. Disease manifestations can be induced in "permissive" strains, that is, those that do not ordinarily develop autoimmune disease, using a variety of agents, such as immunization with the 16/6 idiotype anti-DNA antibody (reviewed in Ref, 78), or treatment with human anti-cardiolipin antibody (aCL) [78–80]. Finally, advances in transgenic technology have allowed investigators to study highly selected aspects of the immune response either in disease expression or as therapeutic modalities, for example, by manipulating MHC expression [81], or by inserting "autoimmunity" genes into strains lacking an autoimmune background [82, 83].

None of these models provides us with a perfect reflection of human SLE-related nervous system disease. Nonetheless, important information about immunopathological events leading to brain disease can be gained from studying them. Such information is likely to provide clues about human SLE-related brain disease that can be further evaluated in appropriately designed human studies.

Murine Strains with Spontaneous Disease

All of the inbred autoimmune strains develop a variety of clinical and serological features that are similar to disease manifestations seen in patients with SLE, rheumatoid arthritis, or Sjögren's syndrome [76, 77]. Although the time course and particular expression of disease varies from strain to strain, all have been studied most widely as models for autoimmune renal disease associated with high-serum anti-DNA antibody levels and immune complex formation. Only recently have these strains been investigated more intensively for the development of neurological disease.

In 1973, Lampert and Oldstone described immune complexes in the choroid plexus of (NZB × NZW) F1 mice [84]. Ten years later, Alexander and colleagues described neuropathological changes in MRL-lpr and MRL/++ mice [85] and Rudick and Eskin described similar changes in (NZB × NZW) F1 mice [86]. Although brain inflammation in (NZB × NZW) F1 mice increased steadily with age, it was not consistently present until 14 months. In contrast to a prominent choroid plexus, a meningeal inflammatory response was noted in MRL/lpr mice by 6 months, with widespread brain inflammation sparing the choroid plexus in MRL/++ mice by 12 months of age. Although Alexander and colleagues mentioned apparent weakness in some animals [85], neither study systematically evaluated neurobehavioral dysfunction associated with these neuropathological findings.

During this same time period, it became clear that (NZB × NZW)F1, MRL-lpr, and BXSB mice all develop a variety of autoantibodies, including those that are reactive with brain antigens [87–96]. In addition, learning, behavioral, and sensorimotor abnormalities have been noted in all autoimmune strains. These increase with age and are associated with increases in serum levels of brain-reactive and other antibodies [95, 96] and the magnitude of brain inflammation over time [97]. There are a variety of potential mechanisms

whereby brain inflammation could lead to brain dysfunction: (1) by causing changes in MHC class II expression by cerebrovascular endothelial and other primary brain cells, or (2) by producing proinflammatory cytokines (which could also change neuronal function or lead to disruption of the blood–brain barrier). Many of the less subtle features of neurological dysfunction in all of the autoimmune murine strains appear late in the disease course when many other abnormalities that could affect neurological functioning are present, including renal failure, hemolytic anemia, systemic vasculitis, arthritis, and high levels of many autoantibodies. The careful categorization of this late-onset neurological dysfunction has been important [92, 93] because it can be a useful endpoint in the study of treatment effects. However, the utility of late-onset neurological dysfunction as a model in and of itself is somewhat limited inasmuch as it may fail to identify key features of pathogenic importance occurring early during the onset of neurological dysfunction.

Some groups have found that the appearance of detectable autoantibody levels coincides with the appearance of the first signs of sensorimotor dysfunction between 8 and 10 weeks of age in MRL/lpr mice. In order for autoantibodies to be causally associated with neurological dysfunction, they must first gain access through the blood–brain barrier. Vogelweid and colleagues were able to demonstrate a disrupted barrier using a more sensitive immunohistochemical technique in MRL/lpr mice [98]. They found an age-related increase in the frequency of both CNS inflammation, composed predominantly of $CD4^{+}$ cells, and perivascular leakage IgG around brain vessels of MRL/lpr mice. Brey and colleagues were also able to demonstrate both aCL and brain–reactive antibody-producing monocytes from whole-brain homogenates of individual 18-week-old MRL/lpr mice [99]. Taken together, these data suggest that antibodies reactive to important brain antigens could gain access to the CNS, whether or not they are actually pathogenic. The blood–brain barrier appears to be disrupted early on and thus could play a key role in SLE-related neurological dysfunction in the MRL/lpr model, especially if antibodies or other systemic mediators of inflammation (e.g., cytokines) are causally related to disease manifestations. Antibody-producing cells are present in the brains of MRL/lpr mice late in the disease course and could play a role as well.

Several studies [96, 100–103] raise the possibility that in addition to any deleterious effects of autoantibodies, an even earlier immune-mediated event may be the trigger of some behavioral defects in MRL/lpr mice. These investigators observed that at a young age, before CNS inflammation or even serologic autoantibodies are present, MRL/lpr mice exhibit some signs of behavioral dysfunction in comparison to congenic MRL/++ controls. This antedates other lupus-related manifestations and worsens with age. One interpretation of these results is that the onset of autoimmune disease in MRL/lpr mice is associated with alterations in emotional and motivational aspects of behavior [103, 104]. This hypothesis has also been supported by findings in NZB autoimmune mice [105].

Murine Strains with Accelerated or Induced Disease

One limitation to using autoimmune-prone mouse strains for studying nervous system dysfunction is that often there are other systemic disease manifestations that could effect nervous system function, as is the case in human lupus patients. Another approach has been to induce autoimmune disease in permissive animal strains or to accelerate disease in strains that have mild autoimmune disease that develops later in life. Some of these have been associated with nervous system manifestations.

Both systemic and neurological autoimmune disease manifestations can be seen in mouse and rat strains immunized with human aCL, anti-double-stranded (ds)DNA of the 16/6 idiotype, or antiproteinase 3 antibodies (reviewed in Ref, 72). Immunization with any of these in naïve animals leads first to the production of antiautoantibody (anti-idiotypic antibodies) and later to the production of host autoantibodies with pathogenic potential.

Mice with high anti-phospholipid (aPL) antibody levels develop poor grip strength, trouble with coordination on the rotating bar, and hyperactivity in an open field test [106]. Rats with high levels of aPL had defective special learning in the Morris water maze compared to control rats. Vasculopathy of brain microvessels was demonstrated in immunized animals by immunofluorescence and electron microscopy [106]. This suggests that high levels of aPL in these animals lead to neurological dysfunction at least in part by damaging the blood–brain barrier.

Brey and colleagues demonstrated accelerated neurological, but not systemic, disease manifestations in MRL/++ mice immunized with both apolipoprotein H and neuronal surface proteins extracted from a murine neuroblastoma cell line [107, 108]. Immunization with either antigen resulted in neurological dysfunction that began around 24–26 weeks and slowly progressed until sacrifice at 44–48 weeks.

These studies suggest that antibodies directed against several brain antigens can independently lead to the accelerated development of neurological manifesta-

tions in this mouse model. More work is needed to determine the pathogenic mechanism by which these antibodies interfere with brain function.

CLINICAL FEATURES

An important consideration in the diagnostic approach to a patient with possible NPSLE manifestations is whether the particular clinical syndrome is due to SLE-mediated organ dysfunction, a secondary phenomenon related to infection, medication side-effects or metabolic abnormalities (e.g., uremia), or is due to an unrelated condition. For each NPSLE syndrome, the ACR case definitions give clear guidance regarding the differential diagnosis and evaluation that is required to make a diagnosis of a primary NPSLE syndrome. It cannot be stressed enough that infection is a major cause of central nervous system syndromes in hospitalized SLE patients [8]. Appropriately, the exclusion of infection plays a prominent role in the differential diagnosis of central nervous system NPSLE syndromes in the ACR guidelines. A great deal of thought and effort by a large group of experts made these guidelines possible. The appendix with clear algorithms for the diagnostic approach to each of the 19 recognized NPSLE syndromes can be found on the American College of Rheumatology's website at http://www.rheumatology.org/ar/1999/aprilappendix.html [109]. This is a tremendous resource for all clinicians who care for SLE patients when faced with the possibility of evaluating a patient for an NPSLE syndrome. A summary of these can be found in Table 1.

TABLE 1 Neuropsychiatric Syndromes Associated with SLE[a]

NPSLE Associated with central nervous system
Aseptic meningitis
Cerebrovascular disease
Stroke
Transient ischemic attack
Cerebral venous sinus thrombosis
Cognitive disorders
Delirium (acute confusional state)
Dementia
Mild cognitive disorders
Demyelinating syndrome
Headaches
Tension headaches
Migraine Headaches
Movement disorders (chorea)
Psychiatric disorders
Psychosis
Mood disorders
Anxiety disorder
Seizure disorders
Transverse myelopathy
NPSLE associated with peripheral nervous system
Autonomic neuropathy
Myasthenia gravis
Peripheral neuropathy
Sensorineural hearing loss
Sudden onset
progressive
Cranial neuropathy

[a] Modified from Sibbitt *et al.* [6] and ACR ad hoc committee [1].

Diagnosis and Management of Individual Syndromes

Acute Inflammatory Demyelinating Polyradiculoneuropathy (Guillain-Barré Syndrome)

Polyradiculoneuropathy is a rare and potentially severe manifestation of NPSLE [110]. The ACR nomenclature defines this entity as an acute, inflammatory, and demyelinating syndrome of the spinal roots, peripheral, and occasionally cranial nerves. The onset of the disease may precede, coincide, or follow the diagnosis of SLE [110]. The disease may follow a monophasic course, follow a relapsing–remitting pattern, or in CIDP, the chronic form of the disease, a chronic course with episodic flares [111, 112]. The differential diagnosis of polyradiculoneuropathy includes acute spinal cord disease, botulism, poliomyelitis and other neurotropic infections, and acute myasthenia gravis.

The diagnostic criteria include clinical features of progressive polyradiculoneuropathy that is usually symmetric and ascending and predominantly motor, and may be associated with arreflexia. It usually peaks within 21 days of onset, and may have an acute or insidious onset with an acute, subacute, or chronic course [109].

Other investigations advocated are CSF analysis, which typically shows elevated protein without pleocytosis, and nerve conduction studies (NCS). Electrodiagnostic findings supportive of polyradiculoneuropathy are one or more of the following abnormalities in three or more nerves tested: (a) conduction block with decreasing compound muscle action potential with more proximal testing, (b) absence or prolonged F waves, (c) conduction velocity slowing, and (d) prolonged distal latencies. Since abnormalities may be subtle early in the course of the disease, NCS may need to be repeated.

Aseptic Meningitis

This is a syndrome of acute or subacute onset characterized by headache, fever, and meningeal irritation, with CSF findings of pleocytosis and negative cultures. Typical CSF findings are mild pleocytosis (usually in the 200–300 cells/mm^3, may be much higher in the severely ill) with lymphocytic predominance and mildly elevated protein [113, 114].

Aseptic meningitis is one of the most infrequent manifestations of NPSLE, occurring in up to 1% [113, 115, 116]. Its onset is usually early in the course of SLE and may actually precede the diagnosis [117, 118]. Most cases of aseptic meningitis are associated with NSAID intake, and other drugs like trimethoprim/sulfamethoxazole [113] and recurrent episodes temporally related to azathioprine [117] have been reported.

Alternate diagnostic considerations must include infectious processes (bacterial, mycobacterial, viral, fungal, and parasitic), subarachnoid hemorrhage, malignancy (leukemia, lymphoma, or carcinoma), granulomatous disease (sarcoidosis), and medications like NSAIDs, IVIg, and azathioprine. NPSLE-related aseptic meningitis is responsive to steroid therapy [114]. The clinical course is usually benign [117], but chronic cases have been described [118].

Autonomic Disorder

Autonomic dysfunction is characterized by sympathetic and or parasympathetic impairment with sparing of the somatic sensorimotor function [119]. It is a disorder of the autonomic nervous system with orthostatic hypotension, sphincteric erectile/ejaculatory dysfunction, anhidrosis, heat intolerance, and constipation.

The reported prevalence of autonomic disorders varies from no difference vs. controls, to as high as 88% [120], and no association with anti-cardiolipin (aCL) antibodies was found [121]. Although it can occur in isolation, approximately one-half of the cases reported in the literature were associated with other neurological deficits [119]. There are no studies investigating whether autonomic dysfunction carries prognostic significance in SLE as it does in diabetes mellitus [122, 123].

Noninvasive cardiovascular testing is the mode of choice to investigate for the presence of autonomic disorders [120, 124]. The heart rate response to postural changes and breathing evaluates parasympathetic function, whereas blood pressure response to sustained hand grips is a test of sympathetic efferent function [119, 120]. Accordingly, the ACR diagnostic criteria recommend CV testing, in addition to sweat test [109]. The differential diagnoses include Lambert-Eaton-related autonomic dysfunction, medications (TCAs), organophosphate toxicity, Shy-Drager syndrome, and other neuropathic processes (i.e., elderly, diabetics).

Cerebrovascular Disease

Cerebrovascular disease is defined as neurological deficits due to arterial insufficiency or occlusion, venous occlusive disease, or hemorrhage with usually focal deficits that may be multifocal in recurrent disease.

Cerebral ischemic events may occur early in the course of SLE, or may precede the diagnosis. This may provide a diagnostic clue of underlying SLE in young patients with stroke that would be otherwise unsuspected [125]. The frequency of cerebrovascular disease as a whole has been reported as ranging from 5.3 [113] to 19% [115]. Venous thrombosis specifically is a rare complication of SLE, and may be seen as the presenting manifestation of the disease [126].

The association between anti-phospholipid (aPL) antibodies venous and arterial thrombotic events has been described both in primary anti-phospholipid antibody syndrome and secondary to SLE [127]. The pathogenesis of aPL antibodies is not fully understood, but may include endothelial activation and injury and alteration of the levels and or function of coagulation proteins [128]. There is also an association with Libman-Sacks endocarditis [129], which is a known source of embolic phenomena. Furthermore, in patients with a first stroke and aPL antibodies, the risk of recurrence is high and usually occurs within the first year [129]. This is acknowledged by the Ad Hoc Committee as they advocate routine ascertainment of aPL antibody status.

The evaluation should include obtaining information regarding potential precipitants and stroke risk factors (i.e., cocaine or amphetamine use, atrial fibrillation, septal defects, hypertension, diabetes, cigarette smoking, and lipid status). Imaging studies include CNS imaging (MRI or computed tomography (CT) and angiogram if indicated) and cardiovascular evaluation (EKG, carotid Doppler US, and echocardiogram). Exclusion of space-occupying lesion in the brain (infections, tumor), trauma, vascular malformation, and hypoglycemia are recommended [109].

Cranial and Peripheral Neuropathies

A variety of neuropathic processes of the peripheral nervous system have been described. The ACR nomenclature recognizes cranial, mono, and polyneuropathies, as well as plexopathies [109, 130] which may be sensory or sensorimotor [131], and axonal or demyelinating [109, 130, 132]. Peripheral sensorimotor neuropathy (PN) is the most common, and mononeuritis multiplex

[133], cranial neuropathies, and plexopathies [134] are progressively less frequent [135]. The onset of peripheral neuropathies usually follows the diagnosis of SLE, but it may actually precede it [130, 132]. Peripheral neuropathy has been linked to cutaneous vasculitis, is common among NPSLE patients with renal failure, and may be an important prognostic factor for mortality in SLE [10, 136–139].

Distal PN tends to affect the longer nerves first, hence the earlier involvement of the lower extremities [132]. Neurological exam may reveal hypesthesia to pinprick and light touch hypesthesia testing, impaired temperature, and vibratory perception [140]. Clinical and subclinical cranial and peripheral neuropathies are detected in 12–47% of unselected outpatient SLE referrals by electromyography and nerve conduction velocity studies [10, 136–139]. However, clinical correlation with electrophysiologic testing is equivocal [130–132, 141], and may underestimate the true prevalence [132]. Even different modalities of electrophysiologic testing yield diverse findings [131]. The clinical manifestations of PN are not fixed and the course is not of inexorable progression, instead fluctuating over time [141]. Other causes of neuropathy, including vitamin deficiencies, diabetes mellitus, leprosy, etc., should be excluded.

Histopathology data is scarce [132]. Studies of sural nerve biopsies showed predominantly axonal degeneration with loss of myelinated and unmyelinated fibers with occasional perivascular inflammatory infiltrates [132, 133, 142]. Scheinberg describes the occurrence of vasculopathic changes in the vasa nervorum, and demyelination [143]. Immune complex, complement, IgG, and C1q deposition have been seen in the vasa nervorum and basement membrane of Schwann cells [144].

Cranial neuropathies most commonly involve CN II–VII, with ocular manifestations, either as internuclear ophthalmoplegia or isolated II, IV, or VI palsy [145–150], facial palsy [151], and trigeminal neuralgia [152] being the most common. Even though audiovestibular involvement is considered rare [153], subclinical involvement may be much more common by audiometric studies independently of hydroxychoroquine treatment [154]. Other reported cranial neuropathies include X [155] or its branches [156, 157] and XII [158].

Demyelinating Syndrome

A demyelinating syndrome is defined as an acute or relapsing demyelinating encephalomyelitis with evidence of discrete neurological lesions distributed in place and time [109]. The diagnostic criteria require the occurrence of two or more manifestations or recurrence of at least one manifestation on distinctly separate occasions. The manifestations include (a) multiple areas of damage to white matter within the central nervous system, causing one or more limbs to become weak with sensory loss; (b) transverse myelopathy; (c) optic neuropathy; (d) diplopia due to isolated nerve palsies or internuclear ophthalmoplegia; (e) brain stem disease with vertigo, vomiting, ataxia, dysarthria, or dysphagia; and (f) other cranial nerve palsies [109].

Transverse myelitis, optic neuropathy and cranial neuropathies are also listed as separate case definitions. Guidelines dictate that patients meeting criteria for either of these and for demyelinating syndrome should be classified as having both. Evaluation for the presence of entities with known associations with demyelinating syndrome (i.e., structural lesions, familial disorders like ataxia and leukodystrophies, sarcoidosis, Behçet's, and multiple sclerosis (MS)), and the exclusion of infectious (TB, HIV, syphilis, etc.) and nutritional (vitamin B_{12} deficiency) causes are advocated. Studies recommended in the evaluation of all patients with possible demyelinating syndrome include CSF evaluation for cell count, protein, oligoclonal bands, IgG index, culture and cytology, MRI, and if indicated, evoked potentials [109].

Lupoid Sclerosis

The association of SLE and multiple sclerosis has been described [159–162]. It has been denominated lupoid sclerosis to illustrate the clinical overlap that exists between the two. There is still debate on whether this represents coexistence of two separate illnesses [161]. However, as mentioned previously, the Ad Hoc committee recognizes this as a distinct manifestation of NPSLE.

The onset of demyelinating syndrome may precede the diagnosis of SLE [161, 163] making the distinction from multiple sclerosis in some cases difficult [114, 160, 161]. Adding to the confusion are the high prevalence of positive anti-nuclear antibody (ANA) in MS (about 81%, typically of low titer), the frequent finding of oligoclonal bands in about 50% of cases of NPSLE, and MRI findings that may often be indistinguishable [164]. The presence of other systemic features of SLE like arthritis, rash or alopecia, the presence of extractable nuclear antibodies, an elevated erythrocyte sedimentation rate (ESR) or CSF findings of pleocytosis or elevated protein may be valuable diagnostic clues [164].

Anti-phospholipid antibody syndrome (APS) may sometimes mimic demyelinating syndrome, as they can both present in young females with multifocal relapsing symptoms, visual disturbances, and high T2-weighted signal in CNS MRI. Visual disturbances of retrobulbar neuritis may last days to weeks and may be bilateral

whereas amaurosis fugax is brief and unilateral. Disseminated CNS involvement, relapsing–remitting course, white matter or spinal cord lesions, oligoclonal bands in the CSF, and abnormal evoked potentials all favor demyelinating syndrome. A history of recurrent thrombosis or miscarriages and the presence of abnormal coagulation studies are suggestive of APS [163].

Optic Neuritis

Optic neuritis is one of the major causes of blindness in SLE [165]. It has been associated with aPL [166–168] and with transverse myelitis [166, 168–170]. In fact, out of 51 cases of SLE-related optic neuropathy reported in the literature by 1997, 41% had signs of spinal cord disease [171], and Jabs *et al*. found it to be as high as 54% [172]. The coexistence of optic neuropathy and transverse myelopathy in non-SLE patients is denominated Devic's syndrome [171, 173], and it is considered to be a variant of MS.

Clinical presentation of optic neuritis is acute visual loss that may be painful or painless. Physical examination reveals an afferent pupillary defect evidenced by an escape phenomenon on the swinging light test, known as Marcus-Gunn pupil. Fundoscopic exam often is normal, as the involvement is frequently retrobulbar. As gliosis occurs, central disk pallor, particularly in the temporal side, may later become evident [165, 174, 175].

Optic neuropathy may be the presenting manifestation of SLE in some cases [171, 175]. Since it is most commonly associated with MS [170], this may lead to confusion in previously undiagnosed patients. Findings suggestive of NPSLE are bilateral involvement (sometimes not suspected clinically, but unmasked by visual evoked potentials (VEP) or visual field testing) [165], bilateral, dense, central scotomata (up to 70% of cases) [165, 175], and severe, persistent visual defects after the first attack, rare findings in MS [167]. Other diagnostic clues are the absence of oligoclonal bands in the CSF and typical VEP findings of markedly decreased or absent responses with little or no conduction delay [167].

Transverse Myelitis

Transverse myelitis (TM) is a rare but serious complication of NPSLE that may occur at any point of the disease [113, 176–179]. Thoracic involvement is most common, with associated optic neuritis in almost half [179]. Some postulate the cause of the susceptibility of this region is an anatomical disadvantage in its blood supply taxed by the vasculopathic changes often seen in autopsy [176, 179]. The reported association with aPL could also play a role [179–181]. The evolution is rapid and often complete within a few hours [182]. Prognosis has always been viewed as dismal [113]. However, Kovacs *et al*. reviewed the 105 cases reported in the literature and found favorable outcomes in most, pondering whether the introduction of early, more aggressive treatment may be the cause [179].

The diagnosis of TM is made clinically, which may be supported by serological tests, CSF analysis, and imaging studies [183]. Physical exam typically reveals paraparesis or paraplegia and a sensory level. Sphincter involvement, manifested as urinary retention or fecal incontinence invariably occurs [176, 183, 184], and fever is very often present at the onset [176]. Deep tendon reflexes are most commonly absent, but they may be hyperactive [176, 184]. Other presenting symptoms include low back, mid-scapular or abdominal pain, and lower extremity paresthesia [176].

Cerebrospinal fluid abnormalities are common but nonspecific and often mild [184]. They include elevated protein, pleocytosis, and hypoglycorrhachia [176, 182]. The latter has been described as a finding typical of TM, as it does not occur in idiopathic TM [185] and may be a clue in undiagnosed SLE. MRI is abnormal in about 70% of the cases [179], which may show high T2 signal, spinal cord enlargement, and contrast enhancement. These last two findings have been reported to correlate with the clinical course on serial imaging [186]. An additional and very important role of MRI is to help exclude space-occupying lesions that may have the same clinical manifestations [184].

Headache

The inclusion of headache as a manifestation of NPSLE is a matter of controversy. With a few exceptions [187, 188], most authors agree there is a higher prevalence of headache and its subtypes in SLE vs. controls or population estimates [12, 13, 189–194]. The dispute arises from lack of correlation with clinical, neuropsychiatric, and laboratory features of SLE, as well as imaging and neurochemical abnormalities [187–191, 193–196], raising the question of whether headache or its subtypes even represent active NPSLE. Previous associations with aCL and Raynaud's phenomenon that would seem to make sense pathophysiologically in vascular-type headaches have not been found in a number of studies [187–189, 191, 194, 196].

The definition of headache in SLE is also a matter of controversy. The work of Atkinson and Appenzeller in 1975 [190] and Brandt and Lessell in 1978 [195] described a severe, disabling, persistent headache, not responsive to narcotics that followed disease activity and would subside with corticosteroids that was later named "lupus headache" [187, 197]. This term is part of the Systemic Lupus Erythematosus Disease Activity Index (SLEDAI), but was deemed too non-specific for

the ACR NPSLE nomenclature. They instead describe migraine with and without aura, tension headache, cluster headache, intracranial hypertension-related, including pseudotumor cerebri, and nonspecific intractable headache, with strict inclusion parameters [109].

The evaluation of headache in SLE is difficult and the vast differential diagnosis includes very serious conditions. These include brain abscess, infectious meningitis, NSAID-induced, cerebral venous thrombosis, hypertension, acute or chronic sinusitis and intracranial hemorrhage, tumor, aseptic meningitis, and metabolic reversible causes like carbon monoxide exposure and caffeine withdrawal [109]. The evaluation consists of a very detailed clinical interview supplemented by additional tests like brain imaging and lumbar puncture as necessary.

Movement Disorders

Chorea is an uncommon clinical manifestation of SLE, characterized by random, irregular and jerky movements that may occur in any part of the body. Two-third of the cases have a single episode and over one-half have bilateral symptoms [198]. Prevalence is about 1–4% of SLE [13, 198, 199] and is the only movement disorder included in the ACR nomenclature. It is the most common movement disorder, but reports of tremor mimicking essential tremor exist [200]. Estrogen-containing oral contraceptives and pregnancy have been known to precipitate attacks [198, 201]. Chorea has been associated with aPL and anti-phospholipid antibody syndrome (APS) [198, 199, 202–205].

The diagnosis is clinical, but supplemented by studies aiding in the differential diagnosis, which includes Wilson's disease, drugs (illicit or prescription), hyperthyroidism, as well a Huntington's and Sydenham's chorea. Since chorea may precede the onset of other SLE manifestations and is clinically indistinguishable from Sydenham's and Huntington's [198, 202, 206, 207], clinical suspicion is of utmost importance. Neuropathologic studies have revealed basal ganglia abnormalities in the minority of patients [206, 208], and imaging studies are nonspecific except in aiding in the differential diagnosis.

Myasthenia Gravis

Myasthenia gravis (MG) is an autoimmune disorder characterized by antibodies against acetylcholine receptors inducing muscle weakness and fatigability commonly affecting bulbar and other voluntary muscles. It is a purely motor disorder and tendon reflexes are spared. Clinical manifestations include ptosis, diplopia, masticatory weakness, dysphagia, and weakness of the extremities and less commonly of the trunk and neck musculature. History in undiagnosed patients may reveal symptoms occurring in the evening, reflecting the accentuation of symptoms with repeat use typical of the disorder.

The association of MG with SLE has been reported in more than 50 cases [209–217]. Muscle weakness in SLE is often a diagnostic problem; given this known association, MG should be included in the differential diagnosis [213, 214]. Myasthenia gravis may either precede or follow the diagnosis of SLE [209]. The development of SLE produces variable impact in the severity of MG and vice versa [209, 212]. Thirty percent of patients with MG have a positive ANA, increasing to 50% in those with thymoma [213]. Interestingly, homology in a sequence segment of U1 RNP and the main immunogenic region of the acetylcholine receptor has been reported [214].

Diagnosis is made by compatible clinical history in association to the presence of anti-acetylcholine receptor antibodies and/or fatigability evidenced by electrophysiological testing (EMG). A trial of edrophonium (Tensilon) or neostigmine should reversibly eliminate the patient's symptoms. The differential diagnosis includes Eaton-Lambert syndrome (reported in a few SLE patients, yet not included in the ACR nomenclature), MS, Guillain-Barré syndrome (GBS), and its Miller-Fisher variant, steroid, congenital, and inflammatory myopathies, medications, metabolic causes, and CVA.

Seizures

Seizures are defined as spells of brief, involuntary, paroxysmal alterations of behavior lasting seconds to several minutes and associated with a transient hypersynchronous discharge of cortical neurons. The behavioral alterations may or may not include convulsions. Recovery after a seizure is typically rapid and complete. It is important to differentiate seizures from spells that may mimic them such as breath-holding spells, migraine, convulsive syncope, narcolepsy with cataplexy, and psychogenic spells [218]. Next it is important to distinguish between isolated seizures and epilepsy, a disorder characterized by recurrent, unprovoked seizures. Provoked seizures are seen in SLE patients with systemic or CNS infection, renal failure, electrolyte imbalances, drug toxicity, or hypertension [219]. Two-thirds to three-fourths of the seizures in SLE patients are generalized tonic/clonic seizures. These tend to occur for the first time during a disease flare and often do not recur until another flare. If residual cerebral injury is sustained during the flare, the patient might develop epilepsy.

Seizures account for 9–58% of NPSLE manifestations reported in clinical series (reviewed in Refs 220–223). Seizures in SLE patient tend to appear early in the disease course [221–223], and may be the presenting feature of SLE [221]. The frequency varies widely, however, depending on the specific SLE population studied. For example, in studies that include an unselected, primarily outpatient population, the frequency of seizures ranges from 9–20% [12–14, 219, 221, 222]. When the study population includes only hospitalized SLE patients, the reported frequency is higher, as is the proportion of patients with conditions that could provoke seizures [8].

The clinical approach to the evaluation of seizures in any SLE patient is to look for those conditions that could provoke seizures listed previously. In a hospitalized patient, this must include a thorough evaluation for infection. A brain MRI scan is done to evaluate for focal cerebral lesions, and an electroencephalogram (EEG) is done to evaluate for epileptiform activity. A lumbar puncture should be performed after brain imaging is obtained in any patient in whom encephalitis or meningitis is suspected, but does not need to be performed routinely.

Cognitive Dysfunction

The etiology of cognitive dysfunction in SLE remains an active research question, but it is clear that it cannot be fully accounted for by past or current corticosteroid treatment, disease duration, disease activity (SLEDAI) or its associated psychological/emotional distress, or sociodemographic factors [7, 13, 224]. The detection of cognitive disorders has been regarded as time-consuming and therefore impractical for routine testing [12, 13], and yet mild to severe cognitive dysfunction remains the most common type of NPSLE manifestation with a prevalence of up to 75% [12–14]. It is most reliably detected and monitored through neuropsychological examination, often revealing a subcortical cognitive syndrome with most prominent compromise in the areas of processing efficiency/speed and attention/concentration, memory function, conceptual reasoning, and cognitive flexibility, approaching dementia in 15 to 25% of NPSLE cases [12, 13].

Cognitive impairment in SLE is not consistently related to psychiatric manifestations and can be detected even in the absence of other current or past overt CNS manifestations [12, 224]. It appears to be selectively linked to aCL but not to anti-P antibodies [13]. History of persistently elevated aCL antibodies over a period of 1–5 years has been linked to greater and sustained cognitive impairment and may be responsible for the long-term subtle deterioration in cognitive function in SLE [62, 64]. Specifically, reduced psychomotor speed has been selectively linked to persistent IgG aCL positivity, and reduced conceptual reasoning and executive function to IgA aCL positivity [64]. Cognitive dysfunction in some studies appears to be a relatively stable feature of CNS involvement in SLE [225], although in others impairment waxes and wanes over time [62, 64]. This may be because aCL levels fluctuate in SLE patients, albeit not always with disease activity. Continued observation with serum samples every 3–4 months may help assess risk for cognitive impairment in the SLE patient and give insights into the nature of some of the patient's complaints.

Psychiatric Disorders

The range of mood disorders in SLE is wide (major depressive episode, mood disorder with depressive, manic, or mixed features) and is estimated to affect 69 to 75% of SLE patients, if standardized examination instruments are used [12, 13]. The prevalence of anxiety disorders ranges from 7 to 70% [12, 13]. Psychosis and depression are two specific psychiatric disorders affecting 5% to 40% of SLE cases, not always in the context of exacerbated disease activity [12, 13, 226].

Psychiatric disorders in SLE have been linked to anti-ribosomal P, but not aCL, antibodies [62, 224, 227, 228]. Anti-ribosomal P antibodies are specific to SLE and their prevalence varies across ethnic groups. Serum, but not CSF, anti-ribosomal P antibodies are strongly associated with the development of psychosis and depression in SLE, but are not implicated in coexisting cognitive dysfunction [18, 228].

It can be difficult to distinguish between the presence of acute confusional state, SLE-mediated psychosis, and corticosteroid-induced psychosis in some SLE patients. Acute confusional state is equivalent to "delirium" defined in Diagnostic and Statistical Manual IV (DSM-IV) as an observable state of impaired consciousness, cognition, mood, affect, and behavior [109]. The term organic brain syndrome is not recommended for general use as "acute confusional state" is more precise with a validated definition. Acute confusional states are often accompanied by cognitive deficits, however, if only cognitive deficits are present and not other features described previously, the syndrome should be diagnosed as "cognitive dysfunction."

Psychosis is defined as a severe disturbance in the perception of reality characterized by delusions and/or hallucinations. If psychosis occurs exclusively during times when an impaired level of consciousness is present, the syndrome should be diagnosed as "acute confusional state." If the onset of psychosis is accompanied by the presence of anti-ribosomal P antibodies or

other evidence of systemic SLE-related organ involvement, the syndrome is most likely related to a direct SLE-related CNS effect. If, however, psychosis occurs as corticosteroids are administered, or the corticosteroid dose is escalated for the treatment of SLE-related disease activity, psychosis as a side effect of corticosteroid therapy should be strongly suspected. This is particularly true if anti-ribosomal P antibody levels are also not elevated.

Risk Factors for Development of NPSLE Syndromes

A number of clinical and serologic parameters have been suggested as risk factors for CNS involvement in SLE. The presence of discoid and articular manifestations is thought to associate with a more benign course and less likelihood of NPSLE [20], while their absence at onset or during flares seems to bestow a higher risk of CNS involvement, primarily cerebrovascular disease and seizures, and also psychosis, acute confusional state, and isolated cognitive dysfunction [20]. Other associations with high likelihood of NPSLE are low serum levels of C_3, and especially C_4, high-titer aCL (IgG) antibodies, and cutaneous vasculitic lesions [20].

When age at disease onset is factored in, the predictive clinical value of cutaneous and articular features for NPSLE is less clear. There is a higher prevalence of discoid lesions, malar rash, cutaneous vasculitis, and neurological involvement at SLE onset and during the course of the disease in juvenile-onset SLE relative to adult-, and elderly-onset SLE [229–232]. Furthermore, hypocomplementemia (C_3 and C_4) and higher anti-DNA and aCL (IgG) antibody levels also are more prevalent in early/juvenile-onset SLE [229–231]. Hence, the risk for CNS involvement in SLE may be more related to a particular serologic profile at the onset of SLE and/or during the course of the disease.

A number of studies suggest that race/ethnicity plays a role in the clinical and serologic phenotype, thus the significance of some immunological and clinical markers for CNS involvement may vary depending on the ethnic composition of the SLE samples studied. SLE-related cutaneous symptoms are more common in Caucasians than in African-Americans, but discoid lupus is more common in African-Americans [233]. Similarly, the prevalence of malar rash and discoid rash is higher in Caucasian than Aborigine Australian SLE samples [234]. It remains to be empirically demonstrated that the risk of CNS involvement in these racial groups depends on their relative susceptibility to develop the articular and cutaneous manifestations in question.

The prevalence of aPL antibodies, including aCL and LAC, is lower in African American and Australian Aborigines than in American and Australian Caucasian SLE samples, respectively [234, 235]. This and the predominance of IgA isotype of both aCL and anti-β_2-GPI antibodies are thought to explain the low frequency of APL syndrome manifestations (e.g., cerebral ischemia) in African-Americans [236]. Given its strong association with aPL antibodies, especially aCL, it is not known whether these variations translate into differential racial prevalence of SLE-related cognitive dysfunction [62, 64]. The fact that specific types of cognitive dysfunction (psychomotor speed and executive function) are differentially affected by IgG aCL and IgA aCL [62] further complicates potential racial effects on cognition in SLE.

Similarly, the prevalence of anti-P antibodies appears to vary across different ethnic groups with SLE (Chinese, Mexican-American, Caucasian, African American, and Greek) [228]. Given the strong and specific association between anti-P antibodies and these psychiatric manifestations in SLE [11, 18, 19], the repercussions in differential prevalence of SLE-related psychosis and depression are not known. The fact that anti-P antibodies are strongly clustered with IgG aCL antibodies in lupus sera, even if they are independently elicited [237], just adds to the complexity of identifying risk factors for specific CNS manifestations in SLE.

NEURODIAGNOSTIC NPSLE

Imaging

There is no single diagnostic test sensitive and specific for NPSLE. The assessment of individual patients is based on clinical neurological and rheumatologic evaluation, immunoserologic testing, brain imaging, and psychiatric and neuropsychologic assessment. These examinations are used to support or refute the clinical diagnostic impression and rule out alternative explanations, and form the basis for prospective monitoring of clinical evolution and response to treatment interventions. Neuroimaging techniques have been used to help identify, locate, and hopefully differentiate the pathophysiological mechanisms that give rise to the wide range of clinical NPSLE manifestations.

Focal neurological symptoms of NPSLE correlate with structural (MRI) abnormalities, and in fact MRI is usually normal in NPSLE patients with diffuse psychiatric (depression, psychosis) and no other CNS manifestations [20, 21]. However, when diffuse manifestations are also accompanied by generalized seizures, MRI shows multiple small, high intensity lesions that often resolve with treatment [20, 21]. In general, diffuse

psychiatric manifestations are more easily detected with functional neuroimaging (SPECT, PET).

On structural MRI, the majority (40 to 80%) of abnormalities in NPSLE are small focal lesions concentrating in periventricular and subcortical white matter [21, 22]. Cortical atrophy, ventricular dilation, diffuse white matter, and gross infarctions are also common [21]. MRI reveals multiple discrete white matter lesions in periventricular, cortical/subcortical junction, and frontal lobe more commonly in patients with past NPSLE manifestations, than in SLE patients without history of NPSLE [20–22]. Focal NPSLE manifestations (stroke, chorea, focal seizures, migraine headaches) uniformly reveal large and small high-intensity MRI lesions in white and gray matter, which tend to persist despite treatment and correlate with elevated aPL antibodies (LAC and aCL), peripheral vasculitis, livedo reticularis, and the patients' focal manifestations [20].

More than 60% of subcortical white matter lesions detected by MRI are missed by FDG-PET during active major (stroke, seizure, psychosis) and minor (headache, dizziness, memory complaints) NPSLE episodes [238]. However, MRI has missed 50–100% of the posterior white matter abnormalities detected by FDG-PET during active minor and major NPSLE [239, 240]. When detected by MRI, these lesions are found mostly in patients with a long history of major NPSLE [240]. Nevertheless, functional methods are generally more sensitive, detecting brain abnormalities much earlier than MRI, even when no overt CNS manifestations are noted, in line with the vasculopathic nature of NPSLE pathogenesis [238, 239].

Visually analyzed FDG-PET consistently reveals abnormalities in prefrontal, parietal (inferior and superior), parieto-occipital, posterior temporal, and occipital gray and white matter regions in active and quiescent NPSLE [239, 240]. Prefrontal, anterior cingulate, and inferior parietal white matter abnormalities have been seen during acute NPSLE but not during quiescent NPSLE [241]. The metabolic disturbances in parieto-occipital (peritrigonal) white matter remain an intriguing finding. Approximately 60 to 80% of active minor and major NPSLE patients consistently show bilateral parieto-occipital white matter FDG-PET hypometabolism in the context of normal conventional MRI and no other PET abnormalities [239, 240].

More recently, magnetic resonance spectroscopy (MRS) has revealed neurometabolic abnormalities even in white and gray matter that appears normal on conventional MRI. Such abnormalities are thought to reflect neuronal injury or loss and demyelination and have been found during active as well as quiescent periods of NPSLE manifestations [242].

Electroencephalography

The EEG is commonly abnormal in any patient with a condition known to cause an encephalopathy. The abnormality is characterized by diffuse slowing (frequencies of less than 8 Hz) and can occur in the setting of many of the conditions that lower seizure threshold [218]. No study has specifically correlated focal or generalized EEG abnormalities with seizure type in SLE patients. However, about 75% of EEG's in SLE patients with seizures demonstrate diffuse abnormalities and 25% focal abnormalities [243].

Cerebrospinal Fluid Evaluation

Cerebrospinal fluid analysis is recommended in some cases of NPSLE manifestations. A lumbar puncture cannot be performed in the following situations: (a) anticoagulated patients, (b) patients with fewer than 20,000 platelets/mm^3, (c) patients with a focal mass lesion or edema that would increase risk for herniation. The CSF analysis is essential to the diagnosis of CNS infection, but in the absence of infection may also be helpful in suggesting a CNS SLE flare. When immune-mediated CNS damage is ongoing during an SLE flare, the CSF IgG index or synthesis rate is often elevated and an oligoclonal banding pattern is seen [11]. In many patients these abnormalities normalize when the flare resolves. Findings of pleocytosis, elevated protein, or hypoglycorrhachia are nonspecific and seen in only about one-third of patients [11].

Autoantibody Testing

Autoantibodies with association to NPSLE include anti-phospholipid (aPL), anti-ribosomal P (aP [psychosis, major depression]) [114], and anti-neuronal (aN [more frequent in NPSLE than non-NPSLE, most frequent in diffuse presentations like cognitive dysfunction and organic brain syndrome]) [114]. With the exception of aPL, they are of limited availability and applicability in the general clinical setting, but may help distinguish diffuse vs focal CNS involvement in active NPSLE [11, 114, 224, 244].

Prognosis of Patients with NPSLE Syndromes

As has been discussed, NPSLE syndromes are multiple and varied. The presence of these syndromes often comes and goes, sometimes without any other apparent SLE-related disease activity. The impact of specific NPSLE syndromes on the overall prognosis for a patient with SLE is not clear, except for the case of

TABLE 2 Treatment of Various Manifestations of Neuropsychiatric SLE

Neuropsychiatric Manifestations	Symptomatic treatment*	Immune-modulating treatment
Seizures	Antiepileptic therapy	High-dose corticosteroids or effective treatment of extraneural disease activity
Delirium	No specific symptomatic therapy	Effective treatment of extraneural disease activity
Psychosis	Antipsychotic medications	Effective treatment of extraneural disease activity
Cerebral vasculopathy	Anticoagulation or antiplatelet agents in selected cases	1. High-dose corticosteroids 2. Cytotoxic immunosuppressives 3. Combination of both
Stroke	1. Anticoagulation 2. Antiplatelet agents	Effective treatment of extraneural disease activity
Transverse myelopathy	No specific symptomatic therapy	1. High-dose corticosteroids 2. Cytotoxic immunosuppressives 3. Combination of both
Cognitive dysfunction	No specific symptomatic therapy	Effective treatment of extraneural disease activity
Anxiety and depression	1. Psychotherapy 2. Cognitive-behavior therapy 3. Supportive-type therapy 4. Biofeedback 5. Pain control 6. Antidepressive agents 7. Anxiolytics	Effective treatment of extraneural disease activity
Drug-induced aseptic meningitis	Withdrawal and avoidance of offending drugs	No specific immunomodulating therapy
Headaches	Migraine treatments Antiplatelet agents	Treatment of extraneural disease activity
Movement disorders	Dopamine antagonists	1. High-dose corticosteroids 2. Anticoagulation if related to anti-phospholipid antibodies
Thrombotic thrombocytopenic purpuras	No specific symptomatic therapy	1. High-dose corticosteroids 2. Cytotoxic immunosuppressives 3. Plasmapheresis
Idiopathic pseudotumor cerebri	1. Carbonic anhydrase inhibitors 2. Repeated lumbar punctures 3. Optic nerve decompression	High-dose corticosteroids

* Includes treatment of secondary causes such as drugs, infections, and metabolic problems related to kidney and liver dysfunction, and electrolyte disturbances.

peripheral neuropathy, discussed previously. All of the NPSLE syndromes have a short-term adverse effect on quality of life and disease morbidity. Studies addressing long-term effects reveal that up to 20% of SLE patients continue to show persisting clinical signs and/or exacerbations of NPSLE manifestations such as seizures, psychosis, and migraines, and thus need long-term therapeutic management [11, 245, 246].

The short-term prognosis is usually favorable in most NPSLE syndromes [113]. Exceptions include transverse myelitis and cerebrovascular disease that may result in significant long-term deficits [113]. However, NPSLE has been identified as a predictor of increased mortality both as a group (5 and 10 year survival) [247, 248], and by individual syndromes (organic brain syndrome [RR 2.92] [249], cranial neuropathy [RR 6.83] [249], and seizures [RR 1.77] (250). The impact on survival is only exceeded by infection [250] and renal disease [129].

Treatment of Patients with NPSLE Syndromes

The management of patients with NPSLE includes symptomatic and immunosuppressive therapies, but evidence for the efficacy of the treatment modalities commonly used is largely limited to uncontrolled clinical trials and anecdotal experience (Tables 2 and 3). An excellent review of general treatment issues in SLE can be found in a supplement to *Lupus* entitled "Special Issue: Old Treatment/New Treatment [251]." In addition, a review of treatment for NPSLE syndromes [252] has also been recently published. The key to treatment

TABLE 3 Immune-Modulating Therapy Commonly Used for NPSLE

Therapeutic agent	Indications
High-dose corticosteroids	Seizures in the setting of active SLE[a] Cerebral vasculopathy[a] Any CNS manifestation in the setting of active SLE
Intravenous pulse cyclophosphamide	Cerebral vasculopathy[a] Non-thrombotic focal neurological deficits in SLE[a] Transverse myelitis[a]
Hydroxychloroquine	Long-term control of active SLE Antiplatelet effect Cholesterol lowering effect
Intravenous immunoglobulin	Any CNS manifestation unresponsive to corticosteroid therapy, cytotoxic therapy, or the combination Concomitant thrombocytopenia
Plasmapheresis	Any CNS manifestation unresponsive to corticosteroid therapy, cytotoxic therapy, the combination, or to intravenous immunoglobulin

[a] May require the combination of both high-dose corticosteroid and intravenous cyclophosphamide.

is to first establish the correct diagnosis by carefully following the guidelines set forth for the diagnosis of NPSLE syndromes by the ACR. It is also important to remember that for many NPSLE syndromes, symptomatic treatment may also be needed in addition to immunomodulatory therapy. These are discussed along with suggested immunomodulatory medications in the following sections. As mentioned previously, very few controlled trials specifically addressing any treatment modality for a specific NPSLE syndrome exists.

Low endogenous levels of dehydroepiandrosterone (DHEA) and other androgens are typical for patients with autoimmune diseases such as SLE, and augmentation of androgen levels has been suggested as a treatment [253]. A number of small controlled and uncontrolled clinical trials with SLE patients suggest that DHEA contributes to amelioration of disease activity, decreasing corticosteroid requirements, diminished flares, and improved cognition [254]. A short-term (1 month) course of DHEA under double-blinded placebo-controlled conditions demonstrated significant therapeutic effects on cognitive dysfunction in mild to moderate SLE [255]. Attention/concentration and learning/memory deficits were the most responsive to DHEA and treatment benefits were unrelated to depression or SLE disease activity. There is no approved standardized therapeutic regime of DHEA for SLE, but DHEA is widely used by SLE patients as a food supplement. Unfortunately, the Federal Drug Administration did not approve the use of DHEA to treat active disease in patients with SLE. More double-blinded placebo-controlled clinical trials are needed to assess the long-term benefits of this agent and its potential risks, which include possible lowering of HDL cholesterol and hormonal dysregulation (with potential adverse consequences for coagulation, atherosclerosis, or development of neoplasms) [254].

Cyclophosphamide is a cytotoxic immunosuppressive treatment option with documented therapeutic benefits in the management of severe NPSLE manifestations unresponsive to other treatment modalities (e.g., cerebral vasculopathy), and is an effective adjunctive agent when used with glucocorticoids for the treatment of transverse myelopathy [246]. A randomized controlled clinical trial comparing long-term use of cyclophosphamide and methylprednisolone reported better overall therapeutic control of SLE-related neurological manifestations (refractory seizures, peripheral and cranial neuropathy, and optic neuritis) with monthly intravenous cyclophosphamide [256]. Larger numbers of improved cases (95 vs 63%) and lower longitudinal levels of disease activity were also observed under cyclophosphamide; the two medications showed relatively equal incidence of new infections (52 vs 63%). However, other studies with SLE report an increased dose-dependent risk of infection and sepsis (fatal in 18% of cases) with intravenous cyclophosphamide [257]. Some [258] have pointed out that the question of efficacy and safety of cyclophosphamide as an alternative to methylprednisolone remains largely unanswered, as it has not been thoroughly assessed by randomized controlled clinical trials.

High-dose chemotherapy combined with autologous hematopoietic stem cell transplantation showed remarkable therapeutic benefits in cases of severe, life-threatening SLE with neuropsychiatric manifestations (and other organ involvement) that had been unresponsive to multiple monthly cycles of intravenous cyclophosphamide [259]. Within months, stem cell transplantation resulted in clinical remission of SLE, significant decline in anti-dsDNA antibody titers, normalization of serum complement levels, reduction and even discontinuation of glucocorticoids, and normalization of the T-cell receptor repertoire [259].

Acute Inflammatory Demyelinating Polyradiculoneuropathy (Guillain-Barré Syndrome)

In regards to the treatment options, most data available is in primary GBS and CIDP. Glucocorticoids for acute inflammatory demyelinating polyradiculoneu-

ropathy were once considered a standard of care until a lack of benefit was demonstrated [260]. This is not the case in CIDP, where treatment failure of steroids is the exception, in which case cyclophosphamide, cyclosporine, interferon, total lymphoid irradiation, and mycophenolate mofetil have been proposed [261].

There is good quality data documenting the efficacy of both plasmapheresis and IVIg. These include double-blind, sham-controlled trials and plasmapheresis–IVIg combinations [262]. Despite their effectiveness in the acute setting, chronic cases require serial maintenance treatments that are costly and impractical, making other maintenance immunosupression more desirable. However, treatment should be tailored to individual patient needs.

The use of the previously mentioned modes of treatment in NPSLE-associated polyradiculoneuropathy has also been documented, yet not nearly as extensively as in their primary counterparts. In acute polyradiculoneuropathy, the response to steroids is inconstant, with about 50% failure rate described in the literature [110, 263]. The outcome in these cases of failure was either successful escalation of therapy or death [110]. Again, the opposite is true in the few cases of NPSLE-associated CIDP where all eight clinical episodes of CIDP treated with high-dose steroids or ACTH responded adequately [111, 112].

There is limited data on plasmapheresis and IVIg, and they are only on the acute form of the disorder. Three case reports of treatment with plasmapheresis resulted in two successes and one failure [263]. A single case report of a patient with severe polyradiculoneuropathy and need for ventilatory support was treated with 5 daily IVIg infusions resulted in steady improvement and sustained remission at 1 year with minimal sequelae [110]. There is one additional case report describing treatment with a combination of high-dose steroids, plasmapheresis, and cyclophosphamide that resulted in very slow improvement and significant sequelae.

Aseptic Meningitis

NPSLE-related aseptic meningitis is responsive to steroid therapy [114]. The clinical course is usually benign [117], but chronic cases have been described [118].

Autonomic Disorder

The management of cases of NPSLE-associated autonomic disorders reported in the literature includes symptomatic treatment like secretagogues and mineralocorticoids, with or without the use of corticosteroids, with variable outcomes [119]. The use of other immunosuppressive agents (namely azathioprine) has also been described [119]. It is known that disease activity alters autonomic responses, thus patients with autonomic dysfunction have a higher risk of life-threatening complications during an SLE exacerbation [123]. Although corticosteroids have been known to positively affect the course of autonomic dysfunction [122], their role has been questioned due to frequent treatment failures and evidence suggestive of interference with circadian blood pressure variation through alterations in the adrenal axis [121].

Cerebrovascular Disease

Anatomopathologic studies have shown the presence of multiple small infarcts in approximately 50% of all NPSLE patients. In this resides a clue to the clinical dilemma of therapy for stroke in SLE as the underlying vasculopathy is a chronic process. Treatment for ischemia (with some of the emerging neuroprotectant medications) does not alter the underlying blood vessel abnormality. Appropriate therapy for cerebrovascular SLE must include the prevention of vasculopathies as well as minimizing the ischemic damage when it occurs. Unless there is evidence of active inflammation, corticosteroids and immunosupression are rarely indicated. Anticoagulation in cerebral venous thrombosis is controversial, but at least two studies show potential benefit: a controlled of anticoagulation alone, and a case series with combination of anticoagulation and corticosteroids [126].

Therapy consists of limiting the extent of damage to the ischemic tissue. Acute therapy includes rest, antiplatelet agents, and appropriate blood pressure management avoiding tight blood pressure control that may result in hypoperfusion. Although numerous studies in animals show that antiadhesion molecules, cytokines or their antagonists, and antioxidants all reduce the extent of ischemic damage, their role in humans are less than clear. Some fibrinolytic procedures show promise in patients with atherosclerotic disease and thromboses. It is not known whether strokes in patents with a predisposition to bleed would respond in the same way. Because patients with strokes normally heal well with conservative therapy, the major issue is usually prevention of recurrent disease.

Demyelinating Syndrome

Lupoid Sclerosis

In patients with motor impairments, physical therapy should be considered at any stage of the patient's illness

[160]. No cases of the use of MS immunomodulating therapy (IF-β1 and 2, glatiramer acetate) in NPSLE-related demyelinating syndrome are available in the literature.

Optic Neuritis

Corticosteroids have been used in almost all cases of SLE with optic neuritis found in the literature. In a case series of 12 patients treated with oral prednisone, distinct favorable outcomes occurred in only three, with equivocal improvement in an additional two patients [175]. One criticism of this paper is the use of relatively low doses of prednisone [264]. Corticosteroid pulse therapy has been proposed as a faster, more effective alternative, with several instances of cases treated successfully [168].

The use of monthly pulse-dose intravenous cyclophosphamide in the optic neuritis of NPSLE has been described both in new onset, previously untreated cases [170], as well as in cases refractory to corticosteroids and oral immunosuppression [168]. They both show complete recovery in about 50% and partial response in 30–50% by visual acuity testing. Visual field testing [168] revealed somewhat less favorable numbers (40% complete response, 45% partial response, and no improvement in 15%).

Plasmapheresis may be a useful addition to corticosteroids in cases where cytotoxic agents may be contraindicated. One case of Devic's syndrome in a pregnant patient with SLE was successfully treated with plasmapheresis in combination with high-dose corticosteroids, resulting in a successful response [173].

Transverse Myelitis

The optimal treatment strategy in NPSLE-related TM is unknown, as there are no controlled trials [178]. Factors associated with favorable outcomes are early treatment and higher doses of corticosteroids, often in pulse doses and in combination with cyclophosphamide [176, 179, 181, 185, 265, 266], an approach currently favored by most clinicians. The association with aPL would imply a role for anticoagulation, but it has never been studied [179].

Several treatment approaches have been described in case reports of refractory cases. Plasmapheresis in different combinations resulted in varying but mostly unfavorable outcomes [179, 267]. Intrathecal dexamethasone and methotrexate was successful in a case refractory to 80 mg/day of prednisolone [268]. Autologous stem cell transplant was done in a case of catastrophic, refractory Devic's syndrome with near-resolution and prolonged remission at 18 months. Physical therapy is of utmost importance in the management of residual deficits at any point in the patient's illness. Although most sequelae consist of flaccid paralysis, residual spasticity may be much more disabling. Selective posterior rhizotomy has been described as an effective approach [269].

Headache

Effective therapy often depends on accurate diagnosis. Evaluation for abnormalities in the sinuses, dentition, and neck are important. Musculoskeletal abnormalities may respond well to nonsteroidal anti-inflammatory drugs, physical therapy, and appropriate exercise. The serotonin receptor agonist (such as sumatriptan) must be used with caution in patients with coronary artery or cerebrovascular disease. A study shows acetaminophen, aspirin, and caffeine to be an excellent therapy for migraine and may be appropriate in patients with SLE and migraine. Agents like beta- or calcium channel-blockers and anticonvulsants are useful in migraine prophylaxis and may be of benefit in patients with SLE. Headache from intracranial hypertension often responds to corticosteroids [270], which are undesirable for long-term management. Acetazolamide with or without furosemide, serial lumbar punctures, and lumboperitoneal shunt are escalating modes of treatment in persistently symptomatic patients.

Peripheral and Cranial Neuropathies

As in other manifestations of NPSLE, no controlled studies of the treatment of peripheral neuropathies exist. Mild symptoms are managed symptomatically. Tricyclic antidepressants and gabapentin have been used to manage neuropathic pain. Corticosteroids remain the first line agent whenever treatment is indicated. However, in cases of severe symptoms if an acute vasculitic process is suspected (i.e., mononeuritis multiplex), cyclophosphamide and pulse-dose corticosteroids are recommended by most. In most case reports and case series, varying doses of oral corticosteroid ranging 10 to 80 mg/day resulted in resolution of the symptoms [149, 155–157].

Movement Disorders

As in other NPSLE manifestations, treatment protocols have not been developed due to the lack of controlled trials. Chorea has a good prognosis, and most treatment approaches result in success, illustrated in most of the literature. In a review of 50 cases of chorea in SLE or aPS [198], over 50% received corticosteroids in varying doses. Haloperidol was the next most

common treatment. Anticoagulation and antiplatelet therapy alone or in combination was also successful. Combination therapy and/or cytotoxic agents were successfully used in treatment failures. Other cases resolved spontaneously or on discontinuation of contraceptives. The chosen treatment approach should match the associated features of the disease: active SLE and chorea would preferentially be treated with corticosteroids, whereas haloperidol would be favored in the absence of active disease; aCL/aPS with thrombotic complications would make anticoagulation the better option [198, 201, 202, 206, 271, 272]. Tremor failed usual treatment for essential tremor and resolved with corticosteroids [200].

Myasthenia Gravis

No randomized controlled trials of the treatment of SLE-related MG exist. Treatments used are the same as those for primary MG with an important exception. Treatment options in primary MG include oral anticholinesterase inhibitors, immunosupression with corticosteroids, cytotoxic agents, plasmapheresis or IVIg, and thymectomy [273]. While most of these therapies have been used in SLE-related MG, there are concerns that thymectomy, commonly recommended in MG, may induce the appearance of SLE [210, 217] and may even exacerbate established cases.

It is known that thymectomy is of no benefit in the treatment of SLE and may induce postoperative flares [212, 274]. Animal studies of thymectomy in autoimmune and normal mice have shown enhanced autoimmunity [213, 275]. A prospective case control study looked at the frequency and occurrence of autoimmune phenomena in recent and distant thymectomy and controls. Results showed an increasing tendency to autoimmunity over time, as evidenced by higher frequencies and titers of ANA, anti-DNA, RF, and aCL in distant vs. recent thymectomies and controls that was further enhanced at follow-up 3 years later. Also, SLE and MCTD in one case each were seen at follow-up only in the distant thymectomy group [276].

Seizures

The decision whether to initiate anticonvulsant therapy after a first seizure is controversial in any patient, including those with SLE. If the seizure is known to be due to a condition that lowers seizure threshold, anticonvulsant treatment is not begun. If a generalized seizure occurs in the setting of an SLE flare, acute high dose corticosteroid therapy is usually used. If the diagnosis of epilepsy is made, the anticonvulsant drugs used in SLE patients are the same as those used in epilepsy patients without SLE. Although some of the anticonvulsant drugs are known to cause a drug-induced SLE syndrome, they have not been implicated in worsening the disease course in patients with SLE.

Cognitive Dysfunction

Unfortunately, there is no specific treatment for the cognitive dysfunction that commonly occurs in patients with SLE at this time. It is hoped that with ongoing research efforts into the underlying pathophysiology of SLE-related cognitive dysfunction, a better understanding of this NPSLE manifestation will be available, leading to new therapeutic strategies.

Psychiatric Disease

In the case of SLE-related psychosis that is not due to corticosteroid side effects, the current treatment recommendations are high-dose corticosteroid therapy along with antipsychotic medications needed to control the patient's symptoms. No specific immunomodulatory therapy is currently recommended for other psychiatric manifestations. Symptomatic treatment such as antianxiety and antidepressant medications and group or individual therapy should be considered.

PSYCHIATRIC ASPECTS OF SYSTEMIC LUPUS ERYTHEMATOSUS

Wendy S. Cohen
W. Neal Roberts, Jr.
James L. Levenson

INTRODUCTION

In a disease, systemic lupus erythematosus (SLE), that afflicts children and young adults, flares without warning, and attacks multiple organ systems so indiscriminately, it seems particularly unjust that it also targets the brain—the core of reason, emotion, and the essence of self. Neuropsychiatric symptoms of SLE were first reported in 1872 by Kaposi, who described two lupus patients with delirium [1]. Depending on the diagnostic methodology utilized, neuropsychiatric manifestations have a prevalence of up to 75–90% [2–4]. They encompass a wide variety of conditions, ranging from stroke, seizures, headaches, neuropathy, transverse myelitis, and movement disorders, to cognitive deficits, depression, mania, anxiety, psychosis, and delirium (acute confusional state). Central nervous system (CNS) involvement is a major cause of morbidity in SLE, and is second only to renal failure and accelerated atherosclerosis as a cause of mortality. The pathogenesis of neuropsychiatric syndromes in SLE is multifaceted and complex, including direct CNS involvement, secondary effects of infection (CNS and systemic), uremia, electrolyte disturbances, hypertension, and other systemic diseases, medication side effects, and psychological reactions to chronic illness. While neurologic disorders in SLE are discussed in Chapter 26, and cognitive impairment in Chapter 28, the present chapter focuses on psychiatric manifestations of SLE, including their prevalence, pathogenesis, classification, diagnosis, and treatment.

Neuropsychiatric SLE syndromes that are not attributable to a localized brain lesion are sometimes classified as "diffuse," and include psychosis, "organic" mood and anxiety disorders, delirium, coma, headaches, generalized seizures, and cognitive dysfunction. "Focal" neurologic SLE syndromes include stroke, cerebrovascular hemorrhage, transverse myelitis, motor disorders, neuropathy, and focal seizures. The validity of the diffuse vs focal categorization of neuropsychiatric SLE is still debated. Classifying neuropsychiatric SLE syndromes as reversible vs irreversible may be useful, since it may have greater implications regarding pathogenesis and treatment.

PATHOGENESIS OF PSYCHIATRIC MANIFESTATIONS OF SYSTEMIC LUPUS ERYTHEMATOSUS

Psychiatric syndromes in SLE can be due to (a) direct CNS involvement (primary neuropsychiatric SLE), (b) infection, other systemic illness, or drug-induced side effects (secondary neuropsychiatric SLE), (c) reaction to chronic illness, and (d) comorbid primary psychiatric illness.

Direct Pathophysiologic CNS Effects of SLE (Primary Neuropsychiatric SLE)

Autopsy Studies

Studies of brain pathology at autopsy have provided clues to the pathogenesis of CNS lupus. In a classic study by Johnson and Richardson in 1968 [5], the most prevalent finding was a noninflammatory small vessel vasculopathy with microinfarcts, whereas vasculitis was rare. Subsequently, a larger study [6] corroborated these findings, and revealed a high prevalence of CNS infection associated with corticosteroid use. Nevertheless, autopsy studies have inherent limitations, since they reveal only anatomical changes, and are performed only on patients with fatal disease. Autopsy studies also cannot exclude whether CNS pathology has been affected by confounding factors such as medication, infection, other systemic illness, or elapsed time (i.e., between neuropsychiatric symptoms and autopsy). In addition, the correlation between brain pathology and neuropsychiatric lupus symptoms is poor. Approximately 20% of brains were histologically normal [5], suggesting disturbances in neurophysiology that are either transient, or not associated with structural abnormalities.

Neuropathogenesis

In a review of the pathogenesis of neuropsychiatric SLE, two major mechanisms of CNS injury have been proposed: (1) antibody-mediated neuronal injury, and (2) antibody-mediated microvasculopathy [7]. Autoantibodies may directly damage neurons either by causing cell death, or by transiently and reversibly impairing neuronal function. Increased *apoptosis*, coupled with impaired clearance of apoptotic cells [8, 9], may result in prolonged exposure of the immune system to DNA (and other intracellular fragments), thereby promoting production of anti-DNA and other autoantibodies [7]. *Complement* factors, particularly C1q, are crucial in the phagocyte-mediated clearance of apoptotic cells. Since a third of SLE patients have antibodies to C1q [10], the resultant C1q deficiency may cause decreased apoptotic cell clearance, and thus enhanced autoantibody production [7]. Antibody-mediated microvasculopathy seems to involve two processes: (a) endothelial damage due to anti-cardiolipin or anti-endothelial antibodies binding to the vessel wall [11], and to a lesser extent, immune complex deposition, and (b) coagulation disturbances due to the prothrombotic effects of anti-cardiolipin antibodies [12], both culminating in ischemia or infarction. These two pathogenic mechanisms may be mutually reinforcing, perpetuating the disease process. Microvascular endothelial injury in the CNS may increase the permeability of the blood–brain barrier, leading to influx of autoantibodies, and further CNS damage.

Factors implicated in the pathogenesis of primary CNS SLE include autoimmune antibodies (anti-neuronal, anti-lymphocyte, anti-ribosomal, and anti-phospholipid antibodies), alterations in cytokines (interferon α, interleukins [IL-1, IL-2, IL-6, IL-8, IL-10], and tumor necrosis factor α [TNF-α]), and complement factors C1q and complement-derived anaphylatoxins C3a and C5a [7, 13, 14].

Autoimmune antibodies that cross-react with neuronal membrane antigens, ribosomal proteins, or phospholipids on platelet or endothelial surfaces seem to play a much larger role in direct CNS involvement than does classic immune complex deposition affecting microvasculature [7, 15, 16]. Serum *anti-ribosomal-P antibodies* have been associated with psychosis [17–22] and severe depression [18, 20], albeit not consistently [23, 24]. In a study by Arnett, the presence of anti-ribosomal-P antibodies conferred a markedly increased risk of psychosis (odds ratio 4.4) and depression (odds ratio 10.5) [20]. As psychosis remits, the antiribosomal-P antibody titer declines [18–21], suggesting that this autoantibody may have pathogenic significance (although the effects of corticosteroid treatment could not be excluded). *Anti-neuronal antibodies*, and, perhaps less commonly, circulating cytokine effects directly on neurons [25], have been associated with neuropsychiatric manifestations that involve global impairment of higher integrative functions [26], including psychosis, depression, delirium, coma, and cognitive dysfunction. In contrast, *anti-phospholipid antibodies* (e.g., anti-cardiolipin), causing discrete episodes of inappropriate clotting [27, 28], and vasculitis involving immune complexes, may account for the less common focal neurologic syndromes. In addition to their association with stroke [29–31], anti-cardiolipin antibodies are also strongly associated with cognitive dysfunction [26, 32, 33]. Accordingly, anti-phospholipid antibodies of different precise specificities may be acting via two different mechanisms to produce focal stroke in a few cases and cognitive impairment in a larger number. *In vitro* evidence suggests that anti-phospholipid antibodies may directly depolarize synaptic terminals. This mechanism may account for some neuropsychiatric symptoms of the antiphospholipid syndrome not attributable to ischemia [34].

Cytokines appear to be involved in the pathogenesis of neuropsychiatric SLE. Although their role remains unclear, they may modulate the autoimmune response, indirectly enhance autoantibody production [35], exacerbate vasculopathy [7, 36], or cause CNS neurotoxicity via increased nitric oxide production [14]. In

neuropsychiatric SLE, interleukins IL-6, IL-8, and IL-10 are markedly elevated in the cerebrospinal fluid (CSF), without concomitant increase in the serum IL-6 and IL-8, suggesting intrathecal synthesis of these cytokines. Resolution of symptoms with cytotoxic therapy is accompanied by a decline in CSF IL-6 levels, although this covariance may be attributable to the treatment itself [37]. The association between neuropsychiatric lupus and elevated interleukin-6 in the CSF has been corroborated in several other studies [27, 38, 39], and psychosis has been linked to increased CSF interferon α [25]. Interestingly, when interferon α is administered therapeutically (e.g., for malignancies, hepatitis C. or amyotrophic lateral sclerosis), it produces neuropsychiatric side effects, including depression, suicidal ideation, delirium, cognitive impairment, and psychosis [40–42]. The neuropsychiatric morbidity associated with interferon α and other cytokines [40] is consistent with, but not proof of, the involvement of cytokine dysregulation in the pathogenesis of CNS lupus. Increased systemic production of TNF-α, a proinflammatory cytokine, correlates with CSF metabolites of nitric oxide, an inflammatory mediator, as well as with the severity of neuropsychiatric SLE symptoms [14]. In patients with neuropsychiatric lupus, kinin levels are increased in plasma and CSF, with disproportionate elevation of tissue kallikrein activity in the CSF relative to plasma, suggesting intrathecal synthesis. Kinin-mediated induction of proinflammatory cytokines, such as IL-1 β, IL-6, and TNF-α, suggests a possible pathogenic role for kinins and cytokines in neuropsychiatric SLE [43]. Nevertheless, since alterations in cytokine levels occur in infection and other inflammatory processes, these fluctuations are not specific to CNS lupus. (See Chapter 26 for an in-depth discussion of the pathogenesis of CNS SLE.)

Reversible vs Irreversible Neuropsychiatric SLE Syndromes: Implications Regarding Pathogenesis

With the possible exception of cognitive dysfunction, all the major psychiatric manifestations of SLE, namely psychosis, depression, mania, anxiety, and delirium, exhibit a degree of reversibility, as does coma. Even the cognitive deficits are sometimes corticosteroid-responsive when cognition is assessed formally [44, 45]. Since psychiatric syndromes tend to resolve within 2 to 3 weeks with corticosteroid treatment [44], they are probably due to reversible or transient mechanisms rather than irreversible neuronal death. Such mechanisms include transient permeability defects in endothelium that permit autoantibodies to traverse the blood–brain barrier. Other potentially reversible mechanisms are antigen–antibody binding, antibody production by B cells, cytokine–receptor binding, and increased cytokine levels.

The reversibility of psychiatric dysfunction stands in contrast to most focal neurologic events, which often have no more reversibility than atherosclerotic stroke, and are associated with fixed lesions on neuroimaging. Similarly, in a subset of patients, the progressive nature of cognitive impairment [33, 45], often with cerebral atrophy, suggests cumulative irreversible CNS damage. This irreversibility, both clinically and neuroanatomically, implies neuronal death, as would be expected from ischemia. Ischemia may be attributable to anticardiolipin antibodies, causing focal clotting, with resultant micro- or macroinfarcts. Less common causes of ischemia include emboli or vasculitis, which involves immune-complex deposition (culminating in thrombosis, sometimes with hemorrhage) immune-complex deposition (causing microinfarcts), or emboli. Yet neuronal cell death at a slow pace may be more common than what may be surmised by the low frequency of overt stroke, and may be at least partly attributable to excitotoxicity-induced apoptosis. Newly described anti-NMDA (*N*-methyl-D-aspartate) receptor antibodies, a subset of anti-DNA antibodies that cross react with NR2 glutamate receptor, can cause cell death by accelerated apoptosis [46]. Because the NR2 glutamate receptor is widespread on neuronal membranes, autoantibodies to it could constitute a possible mechanism leading to generalized cerebral atrophy [47]. Table 1 pairs autoantibodies and cytokines with the putatively associated primary neuropsychiatric SLE syndrome.

Risk factors for direct CNS involvement in SLE include cutaneous vasculitis (odds ratio 33) and antiphospholipid syndrome and its manifestations, especially arterial thromboses (odds ratio 13), as well as recurrent fetal demise, livedo reticularis, and high titers of IgG anti-cardiolipin antibodies [48]. Patients with mainly articular manifestations or discoid rash have a much lower risk of overt neuropsychiatric lupus, as do those few who are ANA-negative, and those with drug-induced SLE. Anti-phospholipid antibodies (anticardiolipin antibodies and lupus anticoagulant) may be the single strongest marker of CNS risk in SLE, given their association with stroke [29–31], cognitive dysfunction [26, 28, 33], and epilepsy [29, 49–51]. A history of previous neuropsychiatric episodes predicts future CNS involvement; each event confers a greater than threefold increased risk of new or recurrent CNS episodes [52]. Preliminary genetic research suggests a possible linkage between locus SLEB3 and lupus with neuropsychiatric manifestations [53]. Hypoandrogenism may also increase the risk of neuropsychiatric SLE [54].

TABLE 1 Autoantibodies and Cytokines Associated with Neuropsychiatric SLE Syndromes

Autoantibody or cytokine	Most likely neuropsychiatric presentation	Other associated neuropsychiatric features	Putative mechanism or neuropathology
Anti-neuronal and anti-lymphocyte antibodies (cross-react with neuronal membrane) [22, 47a, 85, 86]	Cognitive deficits Psychosis		Reversible neuronal dysfunction, but not cell death
Anti-neurofilament antibodies (serum) [47b, 156]	Delirium Cognitive deficits	Seizures	
Anti-ribosomal P protein antibodies (serum) [17, 18, 20, 21]	Psychosis	Severe depression	?Autoreactive T cells
Anti-NMDA receptor antibodies [46]	Impaired learning Other cognitive deficits	Psychosis	Apoptotic cell death accelerated by overstimulation of neuronal NMDA receptors Cerebral atrophy
Anti-phospholipid (including anti-cardiolipin) antibodies (serum) [28–33, 49–51]	Cognitive deficits	Stroke Seizures (common)	Microinfarcts (3 mm size) Noninflammatory (bland) vasculopathy Macroinfarcts (rare)
Interleukin 6 [27]	?Depression	?Psychosis (rare)	
Interferon-alpha (serum, CSF) [25]	Psychosis		
Immune complexes	Stroke		Vasculitis Thrombosis, hemorrhage

Secondary Causes of Neuropsychiatric Symptoms in SLE: Infection, Other CNS or Systemic Illness, or Drug-Induced Side Effects

Although neuropsychiatric symptoms can be attributable to CNS lupus, they are often secondary to complications of SLE or its treatment—especially infection. Since lupus patients have underlying immune dysregulation, and are often immunosuppressed due to corticosteroid or cytotoxic therapy, they are predisposed to CNS and systemic infections, including opportunistic infections, which can simulate neuropsychiatric lupus [2, 55]. Such CNS infections include cryptococcal, tubercular, meningococcal, and Listeria meningitis, herpes encephalitis, neurosyphilis, CNS nocardiosis, toxoplasmosis, brain abscesses, and progressive multifocal leukoencephalopathy. Other etiologies of neuropsychiatric manifestations in SLE include uremia, hypertensive encephalopathy, cerebral lymphoma, and medication side effects, particularly corticosteroids and hydroxychloroquine. See Tables 2, 5, and 6 (latter two tables are on medication side effects).

TABLE 2 Secondary Medical and Psychiatric Causes of Neuropsychiatric Symptoms in SLE

- Secondary medical causes not attributable to CNS lupus
  - CNS infections
    - Meningitis/encephalitis
    - CNS abscess
    - Leukoencephalopathy
  - Systemic infections
  - Renal failure (due to lupus nephritis)
  - Fluid/electrolyte disturbance
  - Hypertensive encephalopathy
  - Hypoxemia (due to lupus pneumonitis, congestive heart failure (secondary to lupus-induced myocarditis, endocarditis, coronary artery disease, or pulmonary hypertension))
  - Fever
  - CNS tumor (e.g., cerebral lymphoma due to immunosuppression, cytotoxic therapy)
  - Medication side effects (especially corticosteroids, hydroxychloroquine)
  - Comorbid medical illness not directly due to SLE or its treatment
    - Hypothyroidism or hyperthyroidism
    - Thrombotic thrombocytopenic purpura
    - Fibromyalgia
- Psychiatric symptoms in reaction to chronic illness
- Comorbid psychiatric illness

PSYCHOLOGICAL IMPACT OF ILLNESS

Stressful Aspects of SLE

Although coping with any debilitating illness is difficult, certain aspects of SLE make it particularly stressful. SLE is a multisystem disease that can be severe, chronic, and unpredictable. It requires major adjustments by the patient and family, and can lead to adaptive or maladaptive responses.

Multisystem Involvement

Since SLE can present in a myriad of ways involving almost any organ system, or with vague systemic symptoms, the diagnosis is often elusive. Patients typically go from one specialist to another over the course of several years, and undergo extensive diagnostic workups before being diagnosed with lupus. One patient commented, "I knew I was ill, but I could get no one [to listen]. . . . It [my constellation of symptoms] was never anybody's department" [56]. The inability of physicians to make a diagnosis may erode the patient's confidence in the medical system. Furthermore, when no etiology can be found for the symptoms, the physician may deem the illness psychogenic, and recommend psychotherapy. Such referrals can engender resentment, since they invalidate the patient's conviction that she is physically ill. The patient may become alienated from the mental health field, and may not be amenable to psychiatric treatment when it may truly be needed in the future [56].

After being diagnosed with SLE, the patient initially may feel relieved that there is a defined illness causing her bewildering array of symptoms. This relief, or "honeymoon period," may abruptly terminate when the symptoms persist or recur despite treatment, or the treatment itself causes serious side effects.

Since SLE can affect many organ systems, the patient may worry that the illness pervades her entire body, even when the disease is limited. The diffuse nature of SLE distinguishes it from most other chronic, recurrent diseases, such as asthma or inflammatory bowel disease, which are primarily limited to one organ. In SLE, the sick portion cannot be cordoned off, for it encompasses the entire self [57].

Because of the multisystem involvement in SLE, and the increasing specialization in medicine, SLE patients are often under the care of an entourage of specialists. Accordingly, the role of the primary care physician may be subordinated, or lost entirely [57]. The patient may then feel there is a specialist for every organ system, but no one taking care of her as a whole.

Severity and Chronicity

The severity and chronicity of SLE result in multiple losses. Patients lose their sense of physical well-being, and may become debilitated or incapacitated. Fatigue alone can be very disabling. As the illness worsens, there is increased dependence on caregivers, and loss of autonomy. Patients also lose the pleasure of participating in certain activities, either because of physical limitations or medical restrictions. Some patients, especially young women, lament having to forgo sunbathing and engaging in outdoor sports. The risk of miscarriage or provocation of a lupus flare may result in giving up childbearing. Patients may at times experience a "loss of self" (or loss of mind) due to the neuropsychiatric manifestations of SLE, especially psychosis, delirium, and cognitive impairment. The CNS involvement and physical debility may result in loss of employment or career. Marital relationships are often strained by the stress of coping with SLE. If a patient feels God has punished her by making her ill, or forsaken her by not healing her, her faith may be shaken. Finally, though less frequently than in past decades, SLE results in premature loss of life.

Unpredictability

One of the most stressful aspects of SLE is its unpredictable course, with sudden exacerbations, remissions, and variable prognosis. The unpredictability of SLE results in a profound loss of control, as well as a loss of ability to plan for the future. One patient commented,

"When I had even a few good days in a row, my hopes would begin to rise, and I would think of remission. Then I would feel worse, and those hopes would be crushed. I felt as if I were trapped on a wild seesaw; I was helplessly fixed on one end, the disease on the other. The illness was in complete control, and all I could do was try to hold on. My family and close friends rode the seesaw with me, equally powerless to stop the mad ride" [58].

Psychological Reactions to Having SLE

In response to the stresses and losses associated with SLE, patients may experience a variety of reactions, which become maladaptive only if they impair functioning or interfere with treatment. Perhaps the most common reactions are grief and depression. Grieving over losses, both actual and anticipated, associated with lupus is a normal reaction to chronic illness. In contrast to depression, grief is an intense but nonsustained sadness, and is generally not accompanied by significant functional impairment. It is also not associated with psy-

chomotor retardation, guilty rumination, worthlessness, hopelessness, preoccupation with death, or suicidal ideation. Depression is characterized by a more sustained, pervasive dysphoria, and/or anhedonia, that is, the loss of interest or pleasure in previously enjoyable activities. (See Classification of Psychiatric Disorders in Systemic Lupus Erythematosus for an in-depth discussion.) When confronted with the unpredictability and chronicity of SLE, some patients feel utterly powerless, and stop making any effort to impact their situation. This resignation, termed learned helplessness [59], is often a sign of depression, and may present as apathy.

Lupus patients may regress into the "sick role," and become increasingly dependent on others for their care. Spouses or other family members may aggravate this tendency by being overly protective of the patient [56]. Regression may also be exacerbated by the disparity between appearing well, yet feeling ill, and having to demonstrate that one is ill to elicit support. Alternatively, to achieve a semblance of normalcy, at times patients minimize their symptoms, which ironically then reduces the support they receive from others, and intensifies their sense of aloneness. This feeling of aloneness is also reinforced by public ignorance and lack of understanding of lupus. Consequently, in addition to having to divulge their illness, patients also may have to explain it to others. SLE patients may become socially withdrawn, especially if they are self-conscious about their appearance. Women with a malar rash or discoid lesions may feel branded as if by the "scarlet letter" [57]. Patients, particularly adolescents, may avoid socializing because of self-consciousness about corticosteroid-induced side effects such as weight gain, "moon facies," increased facial hair, and easy bruising [56].

Anxiety is also an exceedingly common reaction to having SLE, and is often associated with depression and insomnia. In a study by Liang, the most prevalent fears of SLE patients were worsening disease, disability, and death [59]. In particular, patients may worry about developing cognitive impairment, or becoming paralyzed or unable to speak due to strokes. Such neurologic deficits may be especially frightening to contemplate since they may result in debilitation, loss of autonomy, and inability to care for oneself. Similarly, patients may worry about developing worsening renal failure necessitating dialysis. A major concern is the fear of becoming a burden to their families physically, emotionally, and also financially. Some patients with SLE may become incessantly preoccupied with their own mortality [60].

In response to having SLE, some patients feel victimized, and express their anger and frustration. They may become irritable, short-tempered, or hostile, especially toward their spouse and other family members. Other patients react to having SLE by denying their illness. Believing they are well, they are poorly adherent to medical treatment and follow-up.

The unpredictable nature of SLE may cause patients to scale down their own activities and aspirations, and thus avoid being devastated by setbacks. When expectations are set low enough, the vicissitudes of the illness may become more tolerable. Endeavoring to make sense out of their illness, patients may retrospectively misattribute the cause of their SLE flares. Consequently, patients may progressively curtail their activities, social encounters, or even their thought patterns to minimize the risk of relapse. They may also engage in superstitious or ritualistic behavior to prevent recurrence. Patients may blame themselves for having SLE. Such self-blame may be reinforced by the concept of SLE as an autoimmune disease—and the perception that the body is literally waging war against itself [57].

Although depression, denial, and other negative reactions to having SLE are common, at least 50% of patients experience positive reactions at some point during their illness [60]. Patients may sometimes perceive their illness as "a gift." Having such a serious illness can lead patients to reorient their priorities toward spirituality and relationships with family and friends. Patients may also develop a greater appreciation of their remaining abilities, the simple pleasures of life, and the value of time. A primary goal of psychotherapy with SLE patients is to help them reframe their illness in a more positive light, and thereby come to terms with its impact on their lives. Well-adjusted patients are able to find a balance between conflicting needs: the need for empathy and understanding, which requires that patients acknowledge being ill, and the need to appear healthy and move on with their lives, despite being ill [56].

PSYCHOLOGICAL FACTORS AFFECTING ONSET AND COURSE OF SYSTEMIC LUPUS ERYTHEMATOSUS, AND ADHERENCE TO TREATMENT

Stress: Its Role in the Onset and Exacerbations of SLE

Although many patients and clinicians believe lupus may be precipitated or exacerbated by stress, studying this issue is complex, and fraught with methodological difficulties. First, stress is difficult to define, let alone quantify. Events that might be perceived as exceedingly stressful to one patient may leave another unfazed.

Second, negative stressful events, such as divorce, job termination, or death of a child, differ from positive ones, such as marriage or a promotion. Third, most studies of stress-induced illness are retrospective, and therefore vulnerable to biased recall. Patients may be more likely to remember flares and stressful events that are temporally associated with each other, than stresses not associated with flares, or flares occurring in the absence of apparent stress. Fourth, it is important to distinguish between stress intensifying the perception of symptoms, vs etiologically inducing symptoms. In addition, confounding factors must be excluded that could be misdiagnosed as a stress-related lupus flare. For example, stress can predispose to infection, and can exacerbate joint pain from fibromyalgia, a comorbid condition in many SLE patients. Corticosteroid withdrawal can cause arthralgias and mood lability, mimicking a stress-induced flare [61]. Finally, in studying stress-induced illness, it is difficult to distinguish cause and effect. While stress may cause a lupus flare, it is also likely, if not inevitable, that lupus flares cause stress.

Stress-Induced Immune Dysregulation in SLE

If stress precipitates SLE flares, the pathogenesis probably involves immune dysregulation rather than immunosuppression, since theoretically, the latter would decrease disease activity. Several studies have provided support for stress-induced immune dysregulation in SLE. Hinrichsen has shown that in response to acoustic, psychological, and exercise-induced stress, the normal increase in B- and T-supppressor/cytotoxic lymphocytes, and decrease in T-helper lymphocytes are blunted in SLE patients, relative to healthy controls, patients with sarcoidosis, and others receiving corticosteroids [62, 63]. In a study by Jacobs, stress (due to public speaking) was associated with a transient increase in interleukin (IL)-4 producing cells in SLE patients, but not in healthy controls [64]. Since IL-4 producing cells cause proliferation and expansion of activated B cells, and consequently, increased autoantibody production, the stress-induced increased IL-4 levels could precipitate a lupus flare. Furthermore, unlike controls, SLE patients under stress did not develop increased natural killer cell activity or increased levels of interleukin-10, an immunosuppressive cytokine. (Note: Although SLE patients were not receiving major immunosuppressive agents, some patients were on hydroxychloroquine or low-dose methotrexate [64].) In a 6-month prospective study of 41 patients with SLE, daily stress correlated positively with anti-nuclear and anti-double-stranded DNA antibodies [65].

Stress and the Onset of SLE

In a literature review by Herrmann [66], only two studies [67, 68] investigated stress as an etiologic factor in the onset of SLE, and only one was controlled. Otto and Mackay reported that 20 patients hospitalized for SLE had significantly greater stress prior to the onset of their illness than did the seriously ill hospitalized controls [67].

Stress and Exacerbations of SLE

Several studies have supported the contention that stress can exacerbate SLE. Ropes reported that in his cohort of SLE patients, 41 of 45 lupus flares occurred after physical or emotional stress [69]. In another retrospective study, 12 of 19 patients reported experiencing flares of SLE after stressful periods, including the Christmas holiday [70]. A longitudinal study by Wekking revealed that relative to patients with rheumatoid arthritis, those with SLE had a stronger correlation between daily stressors and anxiety, depression, and physical symptoms, although these did not necessarily parallel immunologic parameters [71]. Accordingly, stress, psychiatric symptoms, and the patient's perception of the severity of her lupus are intricately linked [72].

Nevertheless, there is some conflicting evidence regarding whether stress impacts the course of SLE. In a naturalistic study after a severe earthquake in Los Angeles, none of the rheumatology patients studied (10 with SLE and 13 with rheumatoid arthritis) residing near the epicenter developed a significant flare of illness [73]. Among lupus patients followed prospectively, depression and anxiety scores correlated directly with the patients' perception, but not with objective measures, of SLE activity [74].

Individuals vary in their vulnerability to stress-induced lupus symptoms. While some patients seem to have symptoms precipitated by stress, others seem relatively impervious. However, even among stress-responders, the worsening symptoms were associated with distress, but not always with increased disease activity [75].

Premorbid Personality Styles and Response to Having SLE

An astute physician once observed that "it is more important what kind of patient has the illness, than what kind of illness the patient has." Underlying personality traits are often accentuated during times of stress, including illness. Since personality style influences how a patient copes with a chronic, relapsing disease such as

SLE, optimizing the outcome requires that the physician tailor the treatment approach to that individual. In a classic article, Kahana and Bibring delineated several personality styles and the corresponding medical approach that is most therapeutic [76]. Patients with *obsessive* personality traits tend to be rigid, rational, and detail-oriented, and use their intellect to bring order and gain a sense of mastery in stressful situations. For such patients, illness represents a loss of control, and lupus can be particularly frightening since it can affect that which they value most, their minds. To regain control, such patients become even more compulsive, extensively documenting their own symptoms and researching their illness. These patients respond best to a detailed explanation of SLE and its treatment. Patients with *dependent* traits appear needy, clingy, and helpless; their pleas for care seem insatiable. In response to illness, they regress even further, but are terrified of abandonment. The staff should provide them with consistent, nurturing care, while being nonjudgmental in curtailing unreasonable expectations. Patients who are *self-sacrificing* have often experienced many adversities in life, and subordinate their own needs to those of others. For such patients, illness is a means of receiving love and care via increased suffering. Giving reassurance to such patients is counterproductive; it tends to intensify their distress and physical complaints. These patients respond best when the physician acknowledges their suffering, and presents treatment as another hardship they must endure for the sake of those they love. *Histrionic* patients tend to be melodramatic, emotional, and attention-seeking, and are easily overwhelmed. Such patients may perceive illness as a blemish or flaw that makes them unappealing. While focusing on changes in their appearance, they may seem oblivious to more serious manifestations of SLE, yet tend to catastrophize (i.e., imagine the worst). Their focus on more superficial, less dangerous aspects of SLE, (e.g., facial rash) may be a way of defending against more frightening possibilities. The physician should employ a gentle supportive approach with histrionic patients to decrease their apprehensiveness. It is best to provide them with necessary information about SLE and its treatment, but in less detail than for a patient with obsessive traits. Patients with *narcissistic* traits are arrogant and condescending, and have a sense of entitlement, often demanding to be treated by the premier specialist and expecting unlimited access. Nevertheless, their haughtiness is a veneer for fragile self-esteem and feelings of inadequacy. In such patients, illness violates their sense of superiority and invincibility. They respond best when the physician validates them for their achievements, without devaluing his own skills and expertise, for example, "I am impressed that you have been able to be so productive in your work despite your illness; many other patients have been unable to do so." Patients who have *paranoid* traits are suspicious and wary that others might take advantage of them, and tend to harbor resentment. For such patients, illness is perceived as harm inflicted by others, and it exacerbates their suspiciousness and hostility. These patients, who often develop adversarial relationships with their physicians, should be informed as early as possible of any planned diagnostic workup or treatment. In interacting with such patients, physical and emotional closeness should be avoided. Finally, *aloof* patients tend to be reclusive and emotionally withdrawn, and prefer solitary activities. To such patients, illness signifies a threat to their inner sanctum. In working with them, the physician should have minimal expectations regarding their interaction and participation, while not allowing them to become too isolated. [76]

CLASSIFICATION OF PSYCHIATRIC DISORDERS IN SYSTEMIC LUPUS ERYTHEMATOSUS

> Nomenclature's shifting, semantically drifting,
> A term's definition gets muddled.
> Each author will bend it to what he intended,
> And leave the poor reader befuddled. [77]

The literature on neuropsychiatric SLE has been plagued by problems with nomenclature, particularly the lack of standardized terminology. Many investigators have defined terms idiosyncratically or not at all, confounding interpretation. At times, immersing oneself in the literature on neuropsychiatric SLE is utterly bewildering—the language seems to make sense but the meaning is elusive. The terminology has also varied depending on the specialty of the examiner. In a patient with disorientation and a fluctuating level of consciousness, a neurologist may diagnose "encephalopathy," a psychiatrist, "delirium," and a rheumatologist, "acute confusional state." Furthermore, the terminology has been inconsistent over the years, thereby making it difficult to compare studies retrospectively. Terms such as lupoid sclerosis have become obsolete, only to be supplanted by new terms that overlap but are not quite synonymous. More importantly, since there is no gold standard for the diagnosis of neuropsychiatric SLE, ascertaining which conditions are direct CNS manifestations of SLE, vs a reaction to illness, has been controversial. Debate has ensued regarding whether or not headache, depression, anxiety, and other "minor" conditions should be conceptualized as neuropsychiatric manifestations of lupus (see later). Interestingly, in

the 1982 American Rheumatism Association/American College of Rheumatology (ARA/ACR) revised criteria for SLE, neuropsychiatric involvement was defined narrowly, including only seizures and psychosis [78]. Finally, terms such as lupus cerebritis have obfuscated our understanding, since they imply a pathogenesis (inflammation) that remains unproven and is probably incorrect.

To rectify these problems, the American College of Rheumatology (ACR) convened a committee to devise standardized nomenclature for neuropsychiatric SLE, and published guidelines in 1999 [79]. The committee eschewed any terminology that suggested an underlying pathogenesis unless the latter had been well-established (e.g., stroke). It defined neuropsychiatric lupus as "the neurologic syndromes of the central, peripheral, and autonomic nervous system, and the psychiatric syndromes observed in patients with SLE in which other causes have been excluded." The committee proposed "case definitions" for 19 neuropsychiatric syndromes by specifying diagnostic and exclusionary criteria, and "methods of ascertainment" (laboratory workup, neuropsychiatric testing, and neuroimaging). Psychiatric disorders included psychosis, acute confusional state, cognitive dysfunction, anxiety disorder, and mood disorders. Mood disorders were subdivided into (a) major depressive-like episode, (b) mood disorder with depressive features not meeting criteria for major depressive episode, (c) mood disorder with manic features, and (d) mood disorder with mixed features—that is, major depression, minor depression, mania, and mixed episode, respectively. When feasible, terminology from the Diagnostic and Statistical Manual IV (DSM IV) was utilized. A reactive psychological disturbance must be excluded in diagnosing psychosis, anxiety, and mood disorders. If the psychiatric disorder is felt to be a direct CNS manifestation of lupus but occurred in the context of significant psychosocial stress, the latter was to be listed as an association. According to the ACR committee report, the nomenclature was developed to classify neuropsychiatric syndromes and promote research, not to diagnose individual patients. Overall, the ACR criteria significantly broadened the spectrum of syndromes that can be considered neuropsychiatric SLE [79].

Some investigators have criticized the ACR nomenclature for neuropsychiatric SLE for its low specificity. In a cross-sectional population-based study, Ainaila assessed the validity of the ACR nomenclature by comparing the prevalence of neuropsychiatric symptoms in SLE patients and healthy controls. Using the ACR criteria, the sensitivity was 91%; however, the specificity was only 46%. The ACR criteria could not distinguish SLE patients from either neuropsychiatric SLE patients or healthy controls. To enhance the specificity and clinical utility of the criteria, the authors excluded conditions such as headache, anxiety, mild cognitive dysfunction, and mild depression that are not known to be associated with underlying neurologic injury. Accordingly, psychiatric SLE was limited to acute confusional state, psychosis, moderate or severe cognitive dysfunction, and severe depression. Relative to the ACR criteria, their revised criteria had a much higher specificity, 93%, and a slightly higher correlation with the neuropsychiatric SLICC damage index, but a lower sensitivity—46% [80]. Given the reciprocal relationship between sensitivity and specificity, the ACR criteria may be better suited for identifying all possible cases of neuropsychiatric SLE. In contrast, Ainiala's revised diagnostic criteria may be preferable in selecting SLE patients most likely to have direct CNS involvement, thereby minimizing the risk of administering potentially toxic medication unnecessarily [81].

A more fundamental problem with the ACR classification system is that it is difficult to apply clinically. To diagnose neuropsychiatric SLE as the cause of the psychiatric symptoms, one must exclude a primary psychiatric disorder (as well as substance use or a reaction to illness). In contrast, in DSM IV, a primary psychiatric disorder cannot be diagnosed unless medical disorders and substance use are ruled out as etiologies. An inherent problem with the ACR approach is that whereas medical disorders and substance use can be easily excluded, there are no clinical criteria or laboratory tests for excluding primary psychiatric disorders. For example, if a patient with SLE becomes depressed, it is unclear how to rule out primary depression as the cause.

Cognitive Dysfunction

Cognitive dysfunction is the most common neuropsychiatric disorder in patients with SLE, occurring in up to 80% of patients [3, 4]. Cognitive deficits include decreased attention and concentration, impaired memory, difficulty word-finding and problem-solving, and decreased psychomotor speed. On detailed neuropsychological testing, even patients who have never had overt neuropsychiatric symptoms are often found to have cognitive impairment. The cognitive dysfunction cannot be explained by corticosteroids, depression, emotional distress, or systemic disease activity [82–84]. Patients with anti-cardiolipin antibodies are at significantly increased risk of stroke [29–31], and have a three- to fourfold increased risk of cognitive impairment, which is often progressive [28, 33, 45]. Cognitive impairment may be associated with serum lymphocytotoxic antibodies [85], CSF anti-neuronal antibodies [86], and pathological findings such as microinfarcts and cor-

tical atrophy. While cognitive dysfunction often fluctuates and is reversible [45, 87], presumably when attributable to edema and inflammation, it tends to be irreversible when secondary to multiple infarcts, and may culminate in dementia [88].

Perhaps with the exception of schizophrenia and severe depression ("pseudodementia"), primary psychiatric disorders do not typically cause cognitive dysfunction. Accordingly, *in SLE patients with psychiatric symptoms, the presence of cognitive dysfunction, particularly delirium, should prompt a thorough workup for medical etiologies*. Hypothyroidism should also be considered as a possible contributing factor in patients with cognitive impairment. (See Chapter 26 for a detailed discussion of cognitive dysfunction in SLE.)

Depression

Depression is characterized by sad or dysphoric mood, and/or anhedonia (loss of interest or pleasure in formerly enjoyable activities). "Neurovegetative symptoms" of depression include decreased or increased sleep, appetite, and weight, often with decreased libido, decreased energy, and psychomotor agitation or retardation. In addition to neurovegetative symptoms, depression is also characterized by poor concentration, indecisiveness, guilty rumination, feelings of helplessness, worthlessness, or hopelessness, preoccupation with death, and suicidal ideation. Typically, depressed patients appear sad or tearful and have a negative or pessimistic view of themselves, the world, and the future [89]. When depression is severe, it is sometimes accompanied by psychotic symptoms.

Depression seems to be second only to cognitive dysfunction as the most common neuropsychiatric disorder in SLE. The reported prevalence of depression has varied widely, depending on the diagnostic criteria utilized, the patient population (inpatient vs outpatient), and prospective vs retrospective analysis. In research using structured interviews, the prevalence of depression in SLE has been approximately 50% [90]. Since depression is very common in the general population, especially in women, a portion of the depression in lupus patients reflects background prevalence rates.

In SLE, the pathogenesis of depression is multifactorial. Depression may be a preexisting primary psychiatric disorder, an iatrogenically induced illness, particularly from corticosteroids, a reaction to having a chronic disease, and possibly, a direct CNS manifestation of lupus.

The question of whether depression is a direct manifestation of CNS SLE, or a reaction to the stress and multiple losses associated with a chronic debilitating illness, remains unresolved. Evidence that depression is a primary CNS manifestation of SLE includes the possible association of severe depression with antiribosomal P antibodies [18, 20], although others [23, 24, 91] have not corroborated this finding. Utset reported a strong correlation between depression and CNS lupus (defined as stroke, seizures, psychosis, aseptic meningitis, or organic brain syndrome), but not with systemic organ involvement. Depression in SLE patients was also strongly associated with secondary Sjögren's syndrome, a condition that can affect the CNS [92]. In contrast, many investigators have contended that depression in SLE is a reaction to chronic illness. Supporting evidence includes several studies [60, 93], but not all [90], showing a comparable incidence of depression in SLE and rheumatoid arthritis, a disease that is often treated with corticosteroids but does not appear to involve the CNS. Also, there is a lack of association between depression and neurologic symptoms [94] or systemic disease activity [95, 96]. Finally, many studies have found a significant correlation between psychosocial stressors and depression in SLE [72, 95–98].

The ACR classification system for neuropsychiatric SLE divides depression into two subtypes. The first, "major depressive-like episode," is virtually identical to the DSM IV entity, major depression. The second subtype, "mood disorder with depressive features," is a milder depression, most analogous to the DSM IV entity, "depressive disorder not otherwise specified." To diagnose depression as a neuropsychiatric manifestation of SLE, one must exclude depression due to (a) the stress of the illness (adjustment disorder), (b) substance use, or (c) a primary psychiatric disorder. Unfortunately, as previously mentioned, there are no clinical criteria or laboratory tests for excluding a primary depression. Also, in contrast to DSM IV, in the ACR classification system, a depression that is severe enough to meet criteria for major depression, but that occurs in reaction to stress, is not considered a major depressive-like episode, and is excluded as a neuropsychiatric manifestation of SLE.

Diagnosing depression in SLE is confounded by the overlap between depressive symptoms and those of SLE or its treatment. In particular, neurovegetative symptoms and poor concentration are difficult to interpret since they are often attributable to SLE itself and/or medication. Reliable indicators of severe depression in the medically ill include crying, indecisiveness, suicidal ideation, sense of failure, feelings of punishment, and loss of interest in people [99]. If the patient does not feel depressed and is still able to enjoy herself, the likelihood of depression is exceedingly low. Screening questionnaires such as the Beck Depression Inventory can be used to diagnose depression, quantitate its severity, and monitor response to treatment [89]. Such

questionnaires may overdiagnose depression somewhat since they do not distinguish between neurovegetative and cognitive symptoms due to SLE or its treatment, vs those due to depression. Depression must also be distinguished from grief, which is a normal response to the losses associated with chronic illness (see Psychological Reactions to Having SLE).

In SLE patients who present with depressive symptoms, certain medical conditions should be considered in the differential diagnosis. *Hypothyroidism* should be ruled out, since it can mimic depression, and is more common in SLE than in the general population [100]. *Fatigue* due to SLE can be incapacitating and may simulate, as well as precipitate depression. Interestingly, fatigue in SLE patients does not appear to be associated with changes in serum cytokine levels, anti-phospholipid antibodies, or other markers of disease activity, routine lab parameters, or medication treatment, although abnormal CNS cytokine levels could not be excluded [101]. Fatigue due to deconditioning appears to account for as much as half of the persisting fatigue reported by patients with low or suppressed SLE activity. In patients who have become sedentary and thus physically deconditioned after multiple lupus flares, exercise may be beneficial in alleviating both fatigue [102] and depression.

Mild reactive depression is generally treated with psychotherapy alone. In more severe depression, patients respond best to psychotherapy, particularly cognitive behavioral therapy, in combination with antidepressant medication (or occasionally ECT).

Anxiety

Anxiety is quite common in SLE patients, often as a reaction to chronic illness (see Maladaptive Reactions). It may be constant and free-floating (generalized anxiety), intensifying in response to life stressors. Anxiety may also occur suddenly in discrete episodes (panic attacks) with physical symptoms (such as tachycardia, dyspnea, dizziness, lightheadness, nausea, diaphoretic palms), and the urge to flee or a sense of impending doom. SLE patients may also present with social phobia (avoiding interacting with people due to self-consciousness, feelings of inadequacy, or fear of being judged or scrutinized), or specific phobias (including needle phobia, a common cause of noncompliance in medically ill patients). Although the ACR criteria for anxiety exclude anxiety reactions to the stress of having SLE, patients may nevertheless experience hospitalization, medical procedures, interventions, or other aspects of their illness as traumatic, and may have posttraumatic stress-like symptoms that impact on their compliance with treatment and follow-up. Such symptoms include reexperiencing the trauma (in flashbacks, nightmares, and intrusive memories), avoidance of feelings (detachment, emotional numbing) or situations reminiscent of the trauma, and hyperarousal (insomnia, hypervigilance, increased startle response). Anxiety may also manifest as obsessions (recurrent, intrusive, senseless thoughts that engender anxiety) and compulsions (repetitive, senseless acts to alleviate anxiety or prevent a certain event from occurring). In response to the unpredictability of SLE, some patients become superstitious, and develop idiosyncratic beliefs or engage in odd rituals to prevent relapse.

The question of whether anxiety is attributable to direct CNS involvement in SLE, or simply a reaction to chronic illness, remains controversial. Arguments for and against anxiety as a direct CNS manifestation of lupus are analogous to those detailed previously for depression.

The ACR criteria for anxiety exclude not only anxiety induced by the stress of having SLE, but also anxiety occurring during the course of delirium, psychosis, mood disorders, and substance use. Substance withdrawal, particularly alcohol and benzodiazepines, and excessive caffeine use should be considered in any patient complaining of anxiety. Corticosteroids, usually at doses greater than 20 mg/day of prednisone, may cause anxiety. Hyperthyroidism also can cause significant anxiety, usually of the generalized type.

Anxiety is treated with psychotherapy, often in conjunction with antidepressants (such as selective serotonin reuptake inhibitors (SSRIs)), and benzodiazepines. Patient education regarding SLE and its treatment can significantly ameliorate anxiety.

Mania

Mania is characterized by euphoria, irritability, or even dysphoria, with mood lability, grandiosity or inflated self-esteem, and speeding up of thoughts (racing thoughts, flight of ideas), speech (rapid, pressured), and activity level (increased goal-directed activity and decreased need for sleep). Hypomania, a milder form of mania, has the same symptoms but does not impair the patient's overall functioning. Manic patients feel they don't require much sleep, in contrast to patients with insomnia, who complain of lack of sleep. During manic episodes, patients often engage in spending sprees, promiscuity, and other risky or thrill-seeking behavior. When severe, mania may be accompanied by psychotic symptoms, such as paranoia and delusions of grandeur. Since manic episodes can closely resemble cocaine, amphetamine, or alcohol intoxication, substance abuse must be ruled out. Antidepressants can precipitate mania in patients with a bipolar diathesis or

undiagnosed bipolar disorder (manic-depression). Nevertheless, in patients with SLE, the most common cause of mania is corticosteroid therapy. Like depression and anxiety, mania is a clinical diagnosis. Treatment includes discontinuing offending drugs, such as antidepressants, and if possible, tapering corticosteroids. Mood stabilizers (e.g., lithium, divalproex, and carbamazepine), benzodiazepines, antipsychotic drugs, and occasionally ECT are used in treating acute mania. Mood stabilizers are also employed in the prophylaxis of recurrent manic and depressive episodes.

Psychosis

Psychosis is defined as an impairment in reality testing, manifested by delusions (fixed false beliefs) or hallucinations (auditory, visual, olfactory, gustatory, or tactile sensations in the absence of a stimulus). In psychosis due to primary CNS lupus, hallucinations are more commonly visual than auditory, in contrast to schizophrenia. Thought disorder (i.e., tangential or disorganized thinking), and disorganized behavior are included in the DSM description of some psychotic disorders, but not in the ACR criteria. Psychosis in SLE patients can be a manifestation of direct CNS involvement, and in some [17–22] but not all [23, 24] studies, has been linked to serum anti-ribosomal P antibodies. Interestingly, corticosteroids appear to be an uncommon cause of psychosis in SLE patients. Nevertheless, distinguishing psychosis due to CNS lupus from corticosteroid-induced psychosis presents a major diagnostic challenge (see later). Psychosis secondary to substance abuse, particularly cocaine, amphetamines, phencyclidine, and hallucinogens, or alcohol abuse or withdrawal, must also be considered. Psychosis is diagnosed clinically, and treated with antipsychotic drugs, such as haloperidol, risperidone, olanzapine, quetiapine, and ziprasidone.

Acute Confusional State (Delirium)

Acute confusional state, or delirium, was formerly termed organic brain syndrome. It is defined as an impairment of consciousness with impaired ability to focus, sustain, or shift attention. Typically, it has an abrupt onset, and is marked by fluctuations in level of consciousness throughout the day. The degree of disorientation also varies, and may be interspersed with periods of relative lucidity. Sleep–wake cycle is disrupted. Patients sometimes have mood lability and may experience visual illusions or hallucinations and paranoia. There are two subtypes of delirium, a hyperactive and a hypoactive form. *Hyperactive delirium* is characterized by agitation, hypervigilance, and hyperarousal. The patient may be thrashing around in bed and pulling out IV lines. Because of the marked agitation, hyperactive delirium is often misdiagnosed as psychosis or personality disorder ("acting out"). In contrast, *hypoactive delirium* is characterized by amotivation, apathy, somnolence, and quiet confusion. It frequently goes undetected, or is misdiagnosed as depression [103]. The ACR criteria for acute confusional state excludes that due to metabolic disturbances, cerebral infections, substance abuse or withdrawal, or primary neuropsychiatric disorders not related to SLE. Patients presenting with an acute confusional state require a diagnostic workup to rule out underlying medical etiologies, particularly infection, CNS disease (including seizures), metabolic disturbances, and medication-induced effects. Where possible, treatment is based on the underlying etiology. Antipsychotic drugs, sometimes in conjunction with low-dose benzodiazepines, are helpful in alleviating agitation and psychotic symptoms (see Table 9).

Personality Change

Although not included in the ACR classification of neuropsychiatric SLE, personality change is important to recognize since it may signify underlying brain involvement. Personality changes have been reported in SLE patients whose disease has damaged the frontal or temporal lobes. Presentations are typical of those due to any process, such as stroke or traumatic brain injury, affecting that region of the brain. Frontal lobe syndrome has two general patterns: dorsolateral and orbitofrontal [104]. The dorsolateral type is characterized by apathy, abulia (lack of will), and amotivation, and may mimic depression or hypoactive delirium. In contrast, the orbitofrontal type is manifested by impulsivity, disinhibition, promiscuity, mood lability, and impaired judgment, and may resemble mania. Some patients with complex partial seizures have interictal traits such as profound emotions, religious, ethical, and philosophical preoccupation, humorlessness, loquaciousness, hypergraphia, viscosity (social clinginess), hyposexuality, and aggression [105].

PREVALENCE

Estimates of the prevalence of neuropsychiatric disorders in SLE have been exceedingly variable, ranging from 17 to 91% [2–4, 72, 106–108]. This variation is due to multiple factors: (a) lack of standardized terminology, (b) changing terminology over time, (c) differences in diagnostic methods, (d) variations in which disease entities are considered direct manifestations of CNS SLE vs a reaction to a chronic unpredictable illness, (e) differences in study population (inpatient vs outpatient, active neuropsychiatric SLE vs history of neuropsychiatric SLE, (f) differences in specialty of investigator

(rheumatologist, neurologist, psychiatrist, or psychologist), (g) inclusion or exclusion of mild psychiatric symptoms, and (h) inclusion or exclusion of particular CNS neurologic disorders, and the arbitrariness of separating them from psychiatric disorders.

Using the American College of Rheumatology nomenclature, two studies, a cross-sectional Finnish population-based study [3] and a cohort study of predominantly Mexican-Americans [4], examined the prevalence of neuropsychiatric syndromes in outpatients with SLE. Overall, 80–91% of patients had at least one neuropsychiatric disorder, and the prevalence rates in the two studies were similar for individual neuropsychiatric syndromes. Cognitive dysfunction was the most common neuropsychiatric condition, occurring in 79–80%; however, less than a third of those patients had moderate to severe impairment. Major depression occurred in 28–39%, mania or mixed episodes in 3–4%, anxiety in 13–24%, and psychosis in 0–5%. Acute confusional state occurred in 7% of the Finnish patients with SLE, and was not reported in the Mexican-American cohort. Although comparable prevalence studies have not been reported for acutely ill inpatients with neuropsychiatric SLE, the incidence of stroke, seizures, psychosis, and particularly acute confusional state, is likely to be substantially higher.

CORTICOSTEROID-INDUCED PSYCHIATRIC SYMPTOMS

Corticosteroids have been shown to cause a variety of psychiatric syndromes, including mania, depression, mixed states, psychosis, anxiety, insomnia, and delirium. Evidence for an etiologic relationship has come from several studies. In a study by Cade, 55 patients with lupus nephritis were randomized to four treatment groups: prednisone alone, azathioprine alone, prednisone and azathioprine, or heparin and azathioprine [109]. The dosage of prednisone was 60–100 mg/day. The incidence of "psychosis" was 9/28 (32%) in the two groups treated with prednisone, and 0/27 (0%) in the two groups not receiving prednisone [109]. The Boston Collaborative Drug Surveillance Program study demonstrated that in various disorders treated with corticosteroids, the incidence of psychiatric symptoms was dose-related. Psychiatric symptoms occurred in 1.3% of patients receiving ≤40 mg/day of prednisone, 4.6% of patients receiving 41–80 mg/day, and 18.4% of patients receiving >80 mg/day. The mean prednisone dosage in patients who developed psychiatric reactions was 60 mg/day [110]. This dose-relationship has been confirmed in subsequent studies [111]. In a study of asthma patients receiving prednisone, elevations in mood were not correlated with alleviation of asthma symptoms [112], again supporting a causal relationship between corticosteroids and mood changes.

Females are at greater risk for corticosteroid-induced psychiatric symptoms [111, 113]. In addition, a history of mental illness may not increase the risk for corticosteroid-induced psychiatric symptoms [113].

In a majority of patients, the onset of psychiatric symptoms is within the first 2 weeks of corticosteroid treatment [113]. A review of the literature revealed that approximately 90% of corticosteroid-induced psychiatric symptoms occurred within the first 6 weeks of treatment [111]. The dosage of corticosteroids does not appear to affect the time of onset [114]. Nevertheless, rapid onset of psychiatric symptoms has been reported with intravenous pulse methylprednisolone [115].

The incidence of various types of corticosteroid-induced psychiatric reactions in medically ill patients has been reviewed by Lewis and Smith (Table 3) [111, table adapted to include their data].

Mild psychiatric side effects from corticosteroids include insomnia, hyperexcitability, mood lability, mild euphoria, irritability, anxiety, agitation, and racing thoughts. These symptoms may occur in isolation, or as a prodrome to more serious psychiatric reactions. Mood disorders are the most common type of psychiatric reaction to corticosteroids [111, 113]. In most studies, mania, hypomania (mild mania), and mixed states, occur slightly more frequently than depression [112, 113, 116]. Mood lability may be marked, and patients may experience both mania and depression during a single course of corticosteroid therapy [117].

Alternate-day corticosteroid therapy has precipitated mania on treatment days and depression on nontreatment days, simulating rapid-cycling bipolar disorder [118]. Mania and depression are often accompanied by psychotic symptoms such as hallucinations or delusions. In general, the psychiatric symptoms induced by corticosteroids closely resemble those of bipolar disorder [119]. Delirium and psychosis (without mood

TABLE 3 Corticosteroid-Induced Psychiatric Syndromes

	Psychotic features		
	Yes	**No**	**Total**
Depression	19	14	33 (35%)
Mania	21	8	29 (31%)
Mixed (manic/depressed)	6	0	6 (7%)
Psychosis	13	—	13 (14%)
Delirium	6	6	12 (13%)
Total (%)	65 (70%)	28 (30%)	93 (100%)

TABLE 4 Differentiating CNS Lupus Flare from Corticosteroid-Induced Psychiatric Reactions

	Active primary CNS lupus	**Corticosteroid-induced psychiatric reaction**
Onset	After ↓ corticosteroid dosage or ongoing low-dose Rx	Generally ≤2 wks after ↑ corticosteroid dosage (~ 90% within 6 weeks)
Corticosteroid dosage (mg/day of prednisone)	variable	Rare if <40 mg/day Common if ≥60 mg/day
Psychiatric symptoms	*Psychosis, delirium* Mood disorders Cognitive impairment (new onset)	*Mania, mixed states, or depression* (often with psychotic features) Delirium, psychosis
Systemic SLE symptoms	Often present *May coincide with onset of psychiatric symptoms*	Often present, but *precede onset of psychiatric symptoms* (prompting ↑ corticosteroid dose)
Labs	↑ Indices of inflammation (support dx if present but neither sensitive nor specific):	No specific lab findings
Quantitative brain MRI	White matter changes, microinfarcts, cortical atrophy	No specific findings (however, abnormalities may be present from previous episodes of primary CNS lupus)
Response to corticosteroid trial (or ↑ dose)	*Improvement*	*Exacerbation or persistence of symptoms*
Response to ↓ corticosteroid dose	Exacerbation	Improvement

symptoms) are less common, each occurring in approximately 13–14% of patients. Overall, 70% of patients with significant corticosteroid-induced psychiatric reactions have psychotic symptoms [111].

Corticosteroids cause cortical atrophy and loss of hippocampal neurons. Supporting evidence comes from brain magnetic resonance imaging [MRI] studies in patients with Cushing's disease, who have excess endogenous production of cortisol. In a more recent study, Zanardi compared the prevalence and severity of cerebral atrophy using head computed tomography (CT) in SLE patients, non-SLE patients receiving chronic steroids, and healthy controls [47]. Cerebral atrophy occurred at an equivalently higher frequency in SLE and non-SLE patients treated with corticosteroids, relative to controls. The degree of atrophy was more severe in SLE patients, and was not associated with steroid dose, or duration of disease. In SLE patients, the presence of cerebral atrophy was not associated with disease activity or the presence of neuropsychiatric manifestations [47]. In healthy controls, corticosteroids have been demonstrated to cause cognitive impairment, particularly errors of commission [120]. In medically ill patients, corticosteroids have been associated with reversible dementia [121]. Nevertheless, Denburg has reported that low-dose corticosteroids lead to cognitive improvement in some SLE patients [44], presumably because of subclinical CNS lupus.

Although corticosteroids can cause a variety of psychiatric symptoms, evidence summarized by Baker suggests that such symptoms in SLE patients are usually not attributable to corticosteroids [122]. First, severe psychiatric syndromes were reported historically in SLE prior to the introduction of corticosteroids, and occur in SLE patients who have not received corticosteroids. Second, psychiatric symptoms in SLE are more frequent and severe than in other disorders treated with comparable doses of corticosteroids. Third, psychiatric symptoms in SLE are often ameliorated, not worsened, by an increase in corticosteroid dosage or maintenance of high-dose corticosteroids. In contrast, a reduction in steroid dosage often does not alleviate psychiatric symptoms, and may exacerbate them. Finally, in SLE patients who have had a previous psychotic episode while on corticosteroids, retreatment with steroids usually does not precipitate a recurrence of the psychosis [122, 123].

Distinguishing corticosteroid-induced psychiatric reactions from a flare of CNS lupus is one of the most challenging aspects of treating SLE. This clinical dilemma is also difficult to study due to the lack of a gold standard in diagnosing neuropsychiatric SLE. Helpful distinguishing features are summarized in Table 4 [124]. Given the risk of untreated CNS lupus, and the likelihood that corticosteroids will alleviate such flares and only prolong or temporarily exacerbate

TABLE 5 Psychiatric Side Effects of Medications Used in Treating SLE

Medication	Psychiatric side effects
Corticosteroids	**Mood lability**, **euphoria, irritability**, **anxiety, insomnia**, **mania, depression, psychosis, delirium**,[a] cognitive disturbance
Immunosuppressants/immunomodulators	
Azathioprine	Delirium
Mycophenolate mofetil	(Rare) anxiety, depression, sedation
Cyclophosphamide	(Rare) delirium (at high doses)
Methotrexate	(Rare) delirium (at high doses)
Cyclosporine	Anxiety, delirium, visual hallucinations
Tacrolimus	Anxiety, delirium, insomnia, restlessness
Immunoglobulin (intravenous)	Delirium, agitation
LJP-394 (B-cell toleragen–anti-'anti-ds-DNA')	(None reported)
NSAIDS	Depression, anxiety, paranoia, hallucinations, hostility, confusion, delirium, ↓ concentration
Hydroxychloroquine	**Confusion, psychosis, mania, depression, nightmares, anxiety, aggression, delirium**

[a] Common reactions are in boldface type.

corticosteroid-induced psychiatric reactions, an empiric trial of corticosteroids is often the most prudent intervention. Denburg has endorsed a 2-week empiric corticosteroid trial [44]. In a slight variation, McClune has suggested that pending diagnostic test results, the dose of corticosteroids be doubled for 3 days [125]. If the psychiatric symptoms improve, then a CNS lupus flare is the probable diagnosis, warranting ongoing treatment with the higher dose. However, if the patient has an exacerbation of psychiatric symptoms, a diagnosis of CNS lupus becomes somewhat less tenable than a corticosteroid-induced psychiatric reaction. Accordingly, corticosteroids should be tapered to half of the original dosage [125].

The preferred treatment for corticosteroid-induced psychiatric reactions is tapering of corticosteroids, if possible. Such treatment alone results in a greater than 90% response rate. Corticosteroid-induced delirium often resolves within 5 to 10 days, whereas mood and psychotic disorders usually remit within 3 to 4 weeks [111]. Adjunctive treatment with antipsychotic drugs can help alleviate delirium, mania, and psychotic symptoms (with or without mood disorder). In addition, ECT appears to be effective in depressed patients who do not respond to corticosteroid taper or discontinuation [126]. Although the data are anecdotal, selective serotonin reuptake inhibitors such as citalopram or sertraline may also be beneficial for depression. Lithium was prophylactic against corticotropin-induced mania or depression with psychotic features [127]. Consequently, lithium, and perhaps other mood stabilizers, may be helpful in patients who have had previous corticosteroid-induced psychiatric reactions, and who require courses of high-dose steroids.

Corticosteroid Withdrawal Syndrome

Rapid tapering or discontinuation of corticosteroids can also induce psychiatric reactions by precipitating SLE flares, iatrogenic adrenal insufficiency, or possibly corticosteroid withdrawal syndrome. Corticosteroid withdrawal syndrome is manifested by flulike symptoms, such as headache, fever, myalgias, and arthralgias, and symptoms overlapping with those of adrenal insufficiency: weakness, anorexia, nausea, weight loss, orthostatic hypotension, and sometimes, psychiatric symptoms such as depression, anxiety, agitation, or psychosis [113, 128, 129]. Although it may be difficult to distinguish corticosteroid withdrawal syndrome from iatrogenic adrenal insufficiency or flares of CNS lupus, it is often unnecessary clinically, since all respond to an increase in corticosteroid dosage.

PEDIATRIC AND ADOLESCENT SYSTEMIC LUPUS ERYTHEMATOSUS: PSYCHIATRIC ASPECTS

Primary neuropsychiatric lupus occurs quite commonly in children and adolescents with SLE, usually within the first year of diagnosis [135]. Reported prevalence rates have been variable, ranging from 29 to 95% [135–139], most likely due to differences in diagnostic criteria and patient population. In a prospective study, when only serious neuropsychiatric syndromes were included (i.e., stroke, seizures, chorea, psychosis, delirium, major depression, and significant cognitive impairment), the prevalence of CNS lupus was 76%. Overall, using the 1999 American College of Rheuma-

TABLE 6 Psychiatric Side Effects of Medications Used in Treating Complications of SLE

Medication	Psychiatric side effects
Anticonvulsants	**Sedation, confusion, cognitive disturbance**, agitation, delirium, psychosis, depression, mania, nightmares
Antihypertensive agents, other cardiovascular drugs	
β-blockers	Depression, insomnia, nightmares, ↓ **libido**, (rare) delirium, hallucinations, psychosis
Ca^{2+} channel blockers	(Rare) depression
ACE inhibitors (e.g., captopril)	(Rare) mania, depression, delirium, anxiety, hallucinations
Digoxin	Delirium, visual hallucinations, psychosis, mania, depression, ↓ libido
Thiazides	Depression
HMG CoA reductase inhibitors	(Rare) anxiety, depression, obsessions, delusions
Antibiotics, other antimicrobials	
Fluoroquinolones (e.g., ciprofloxacin)	**Delirium, visual hallucinations, paranoia, agitation**, **anxiety cognitive impairment**, mania, depression, Tourette's-like syndrome
Cephalosporins	Euphoria, delusions, illusions, depersonalization
Trimethoprim-sulfamethoxazole, other sulfonamides	Confusion, delirium, psychosis, hallucinations, depression, euphoria
Clarithromycin	Delirium
Amphotericin B	**Depression**, delirium, psychosis
Metronidazole	Depression, crying spells, agitation, delirium, hallucinations
Opioids	**Delirium** (especially with meperidine), **visual hallucinations,** nightmares, anxiety, **euphoria, depression, sedation**, paranoia, agitation

[b] Common reactions are in boldface type.

tology case definitions, 95% of patients developed neuropsychiatric SLE during a 6-year follow-up period. Mood disorders occurred in 57%, cognitive impairment in 55%, delirium in 35%, anxiety in 21%, and psychosis in 12% [139].

Interestingly, in a study of 140 children with chronic malaise, headaches, abdominal discomfort, and low-grade fever, who were felt to be avoiding school, 52% had a positive ANA, in contrast to 6% of controls. Nearly half of those with positive ANAs had titers greater than 1:160, suggesting underlying autoimmune fatigue [140].

Systemic lupus erythematosus can have particularly devastating ramifications during *adolescence*. Given the preoccupation with appearance and body image, coupled with the intense need for acceptance by peers, adolescents tend to be extremely self-conscious about overt manifestations of lupus and its treatment, such as a malar rash, discoid lesions, alopecia, and corticosteroid-induced moon facies and weight gain. This self-consciousness may culminate in depression and social isolation, or self-adjusting of corticosteroids [56, 141, 142]. Adolescents may also become despondent and anxious about the chronic, unpredictable nature of SLE. Since adolescents often have a sense of invincibility and immortality, they are predisposed to denial of their illness. Denial may be especially prominent in patients with hypertension or renal disease who are relatively asymptomatic. Denial may be exemplified by nonadherence with treatment via discontinuing medication, failing to show for appointments, or dropping out of treatment entirely [143]. *Denial of illness*, coupled with *socioeconomic disadvantage* and *limited education*, is a particularly poor prognostic triad. In response to having a serious illness, adolescents may exhibit irritability or anger, which is directed primarily against their parents, and to a lesser extent, the medical staff [142, 143]. The adolescent's struggle for autonomy and independence may manifest as defiance against treatment recommendations.

Systemic lupus erythematosus in childhood and adolescence also has repercussions for the patient's *parents and siblings*, who may become depressed, anxious, and overprotective of the child, or conversely, may engage in denial and unduly pressure her to be more active. With chronically ill adolescents, parents may have difficulty balancing respect for their child's struggle for autonomy vs the need for ongoing care. Parents' anger at the situation is typically directed at the medical staff, and often involves legitimate frustrations regarding poor communication among multiple caregivers, and the bureaucracy of the health care system. Siblings

may secretly resent the child for being ill, and for requiring disproportionate attention, and may act out or develop disruptive behavior. Consciously or unconsciously, siblings may also harbor guilt that they are healthy [143].

Diagnostic workup in children and adolescents with suspected CNS lupus is similar to that for adults. In pediatric patients, single photon emission computed tomography (SPECT) scan of the brain appears useful, and possibly more sensitive than brain MRI in diagnosing CNS lupus [135, 144]. Serum anti-neuronal antibodies correlate with the course of CNS illness; they are often positive at the onset of symptoms, and normalize as the symptoms resolve [144]. Serial cognitive screening is important in children with SLE, given not only the prevalence of cognitive impairment, but also the difficulty in detecting subtle cognitive deficits or failure to acquire new cognitive skills (i.e., in children, unchanged cognitive ability is abnormal) [138].

Several *interventions* are helpful in working with adolescents with SLE. As with all patients, education is crucial so that the adolescent understands the nature of the illness and rationale for treatment. The patient should be engaged as an active partner in her treatment, especially in decision-making [145]. Identifying the causes of treatment noncompliance, and addressing them in a nonjudgmental manner, is crucial, and is discussed in detail later in this chapter. Clear explanations should be given regarding restrictions on exposure to the sun. In general, patients should be encouraged to be as active as tolerated, and to have as normal a lifestyle as possible. The physician should ask about the patient's sexual activity, and discuss prophylaxis against pregnancy and sexually transmitted diseases, and the impact of SLE on childbearing capacity. Obstacles to care such as illiteracy, additional childcare responsibilities, parents' inability to get time off from work, and lack of transportation, insurance, or prescription coverage, are seemingly mundane nonmedical matters that are often overlooked. Nevertheless, assisting parents with these practical issues can help strengthen the therapeutic bond, and ensure ongoing patient follow-up [143].

Pharmacologic treatment for serious CNS manifestations is similar to that for adults, and includes corticosteroids, pulse cyclophosphamide, and plasmapheresis [136]. Although psychotropic medication use in children with SLE has not been formally studied, the overall approach is similar to that for adults, but with downward dosage adjustment. Except in stroke and rare cases of fulminant cerebral edema, the prognosis for pediatric CNS lupus is generally favorable [135, 136, 142]. (See Chapter 18 for a more detailed discussion of pediatric aspects of SLE.)

RELATIONSHIPS, SEXUAL INTIMACY, AND PREGNANCY IN SYSTEMIC LUPUS ERYTHEMATOSUS: PSYCHIATRIC ASPECTS

Systemic lupus erythematosus can have profound effects on a patient's marital and family relationships, sexuality, and childbearing capacity.

Marriage and Family Relationships

Spouses, other relatives, and friends often have difficulty coping with the patient's illness. Some may be overprotective and unduly limit the patient's independence and autonomy. Conversely, others may minimize the patient's illness and exert too much pressure on her to be active, particularly when she has no overt manifestations of SLE. Frequently, relatives and friends will vacillate between these responses. In response to the patient's illness, children may adopt a caretaker or "parentified" role, or may seek attention by "acting out," or complaining of physical ailments. Depression and anxiety are common in family members of the chronically ill, especially the primary caretakers. Like the patient, family members must grapple with the vicissitudes and unpredictability of the illness, and may need to adjust plans and life goals. Like physicians, they may also have the burden of bearing witness to suffering they are helpless to prevent.

Meeting with the patient and spouse (or partner) together is a beneficial step in educating them about SLE. Couples should be informed that the course and prognosis of SLE are variable and unpredictable. In such a discussion, it is important to be candid yet not pessimistic. The physician should emphasize the need for couples to be flexible in making lifestyle adjustments to cope not only with fatigue and SLE flares, but also remissions. The spouse (or partner) and other family members should also be informed that some symptoms, especially fatigue, may occur without overt signs of lupus.

Sexuality

Decreased libido is common, due to fatigue and debilitation, depression, and medication side effects (especially antihypertensives). Alopecia, malar rash, weight gain, or other changes in body image may also lead to perceived unattractiveness, and adversely affect sexual intimacy.

Pregnancy

Pregnancy tends to be an anxiety-provoking issue for couples, who must decide whether childbearing

warrants the maternal and fetal risks associated with SLE. Women may be at increased risk of SLE flares (usually mild) during pregnancy, especially the second and third trimester, and the postpartum period [146, 147], although this issue is controversial [148]. Some patients with antiphospholipid syndrome have been advised to forego reproduction due to the risk of thrombosis, preeclampsia, and fetal demise. This loss of childbearing capacity compounds the other losses and debilitation due to SLE, and may contribute to depression. Marital and family tension may escalate when a patient or her partner want her to risk jeopardizing her health by becoming pregnant, despite admonitions about possible worsening renal or heart failure, hypertension, or stroke.

Throughout pregnancy, patients may be apprehensive about possible miscarriage or premature delivery, or teratogenic effects from medications. Patients may also be concerned about "transmitting" lupus to their babies. Such concerns can be allayed by close prenatal monitoring, counseling, and patient education. If there is an adverse outcome, the patient may harbor guilt and self-blame. SLE patients, especially those with active nephritis or antiphospholipid syndrome, are more likely to have fetal loss, and may experience grief or become clinically depressed over recurrent miscarriages and stillbirths. Such patients may derive solace from bereavement counseling. (For a more detailed discussion of SLE and pregnancy, see Chapter 22.)

DIAGNOSIS OF PSYCHIATRIC SYNDROMES

Although many clinical signs and symptoms, and lab tests are suggestive of neuropsychiatric SLE, none is diagnostic. Diagnosis is primarily based on a constellation of clinical findings, lab tests, and neuroimaging that are corroboratory, and that exclude comorbid conditions and secondary causes of neuropsychiatric symptoms [88].

Mental Status Exam and Neuropsychiatric Testing

The *mental status exam* is essential in diagnosing psychiatric disturbances in SLE, particularly psychosis, delirium, and cognitive impairment. Not only is it inexpensive and portable, it can also be used serially to detect changes in mental state. The most important elements are assessment of orientation, attention, memory, and visuospatial perception, all of which are encompassed in the Mini-Mental Status Exam [149].

Neuropsychiatric testing provides an objective, more detailed, and more sensitive assessment of cognitive function. It is useful in establishing baseline cognitive status, and then can be repeated to assess any cognitive deterioration, or response to treatment. It also documents specific deficits that may enable patients to qualify for disability [88]. Since the testing is often not adjusted for cultural norms, it tends to overestimate cognitive deficits in minorities such as African-Americans [150]. Unfortunately, neuropsychiatric testing is time-consuming and expensive, and may not be feasible when patients are acutely ill. If no prior testing is available for comparison, it cannot always distinguish new from preexisting cognitive deficits. Even in the absence of active SLE (CNS or systemic flare), or previous documented CNS lupus, neuropsychiatric testing often reveals subtle cognitive abnormalities; consequently, such findings are not necessarily diagnostic of active neuropsychiatric lupus [83]. (See Chapter 28 for a more extensive discussion of cognitive assessment in SLE.)

Laboratory Workup

No laboratory test, or set of tests, is considered diagnostic of neuropsychiatric SLE. Nevertheless, in evaluating a patient for suspected CNS lupus, laboratory studies serve two purposes. First and most importantly, lab tests rule out infection, as well as other complications of SLE or its treatment that can present with neuropsychiatric symptoms. Second, positive laboratory studies confirm the presence of systemic lupus disease activity. While neuropsychiatric lupus often pursues a clinical course somewhat independent of flares in other organs, high disease activity increases the likelihood of primary CNS involvement, since the pathogenesis is shared between the CNS and other target organs. For example, CNS vasculitis might be more likely when the patient is experiencing cutaneous vasculitis than when the dermatologic exam and laboratory values are normal. However, *absence of systemic disease activity does not preclude CNS lupus. Moreover, systemic disease activity seems to have little, if any correlation with certain neuropsychiatric symptoms, particularly fatigue and cognitive dysfunction* [83, 151].

Laboratory tests can also be useful in evaluating psychiatric symptoms in lupus patients with a history of a primary psychiatric illness such as schizophrenia or major depression. Primary psychiatric disorders do not cause elevations in erythrocyte sedimentation rate (ESR) or other markers of inflammation. Accordingly, if the psychiatric symptoms temporally coincide with a markedly increased ESR, medical etiologies, particularly infection and CNS lupus flare, must be strongly considered.

Serum Labs

In evaluating lupus patients with neuropsychiatric symptoms, routine serum labs should include electrolytes, BUN, creatinine, transaminases, liver function tests, complete blood count, thyroid stimulating hormone, and coagulation tests (prothrombin time, international normalized ratio (INR), and partial thromboplastin time). Serologic tests to assess systemic disease activity include ESR, C-reactive protein, complement levels (C3, C4, CH50), and anti-DNA antibodies, all of which are elevated in systemic lupus flares [26]. Serum ANA titers need not be obtained, since they do not seem to correlate with systemic or CNS lupus activity.

Testing serum for *anti-phospholipid antibodies* (including lupus anti-coagulant and anti-cardiolipin) is crucial, particularly in patients with focal symptoms, since the results may determine treatment and prognosis. Failure to diagnose antiphospholipid syndrome in SLE can lead to stroke and other thrombotic complications, seizures, and progressive cognitive impairment [12, 28, 33, 45]. Unlike anti-phospholipid antibody-negative patients, those with antiphospholipid syndrome are treated primarily with anticoagulation rather than corticosteroid or cytotoxic therapy.

Serum anti-ribosomal-P antibodies have been linked to psychosis [17–22] and depression [18, 20]. These antibodies are positive in half of lupus patients who have psychiatric symptoms, but who test negative for antiphospholipid antibodies [152]. Titers parallel the course of illness. Despite this correlation, their usefulness as a diagnostic test in neuropsychiatric lupus is limited by their low positive predictive value: 13–16% for psychosis and depression [20], and for other reasons discussed later. Other serum autoantibodies, including anti-neuronal, anti-neurofilament, and anti-ganglioside antibodies, have not proven to be diagnostic markers for CNS lupus [13, 15, 26, 88]. Other proposed markers, such as serum S100B, an astrocytic calcium binding protein [153], have not been adequately studied.

CSF Analysis

When patients with SLE have neuropsychiatric symptoms, lumbar puncture is indicated (1) to rule out CNS infection, and (2) to assess the degree of lupus activity in the CNS. Routine CSF analysis, including cell count, differential, total protein, glucose, cultures, and cryptococcal antigen, should be obtained. In the absence of CNS infection, CSF pleiocytosis and increased CSF protein are suggestive of CNS lupus [2].

In addition, CSF studies should include oligoclonal bands and CSF IgG, both used in the diagnostic workup of multiple sclerosis. Both positive oligoclonal bands and elevated immunoglobulin index indicate increased local production of immunoglobulin within the CNS (by B-cells marginated within the meninges), even when white cells are not detected in the CSF. Additionally, positive oligoclonal banding in CSF has a narrow differential diagnosis, including neurosyphilis, Lyme disease, multiple sclerosis, Sjögren's syndrome, and CNS SLE. An elevated CSF albumin/serum albumin ratio suggests increased permeability of the blood–brain barrier, a finding suggestive, but not diagnostic of CNS lupus. Increased CSF anti-neuronal antibodies [22, 86], and cytokines interleukin-6 [27, 38] and interferon α [25] have been associated with neuropsychiatric SLE, but are not used diagnostically, for reasons discussed later.

Electroencephalogram (EEG)

In lupus patients with neuropsychiatric symptoms, the EEG is often abnormal, but seldom useful [154]. Most commonly, it reveals diffuse slowing, a nonspecific finding. EEG cannot distinguish primary CNS lupus from other conditions affecting the CNS, nor active from preexisting CNS lupus. Nevertheless, the EEG is helpful in two situations: (1) diagnosing subclinical seizure activity, and (2) differentiating hypoactive delirium (diffuse slowing on EEG) from depression (normal EEG).

Neuroimaging

Neuroimaging is an integral part of the diagnostic evaluation of patients with possible CNS lupus. Neuroimaging modalities can be subdivided into (a) structural studies, including computerized tomography (CT) and magnetic resonance imaging (MRI) of the brain, and (b) functional studies, such as magnetic resonance spectroscopy (MRS), functional magnetic resonance imaging (fMRI), positron emission tomography (PET), and single photon emission computerized tomography (SPECT).

Cranial CT is frequently normal in neuropsychiatric lupus, but commonly reveals cerebral atrophy. Given its lower resolution, and lower sensitivity for detecting white matter lesions, it has generally been supplanted by brain MRI in the evaluation of neuropsychiatric lupus. Nevertheless, CT is useful for diagnosing intracranial hemorrhage and large strokes, and for ruling out brain abscesses or masses [154]. Otherwise, it is indicated only when MRI is not feasible.

Brain MRI is the preferred imaging technique for evaluating neuropsychiatric disease in patients with

SLE [155]. MRI is more sensitive than CT in detecting small focal lesions and white matter changes, edema, inflammation, and acute infarcts, and in quantifying the degree of atrophy. In CNS lupus, the most common finding on MRI scan is small discrete white matter lesions, especially in the subcortical areas, signifying microinfarcts. The brightness of these lesions on T2-weighted images reflects increased water signal, and by implication, increased permeability of the blood–brain barrier. Although such white matter lesions are found in over a third of SLE patients in general, they occur in over half of those with major psychiatric disturbances or neurologic deficits [156]. Other abnormalities on MRI include cerebral cortical atrophy, periventricular or diffuse white matter changes, and macroinfarcts. MRI abnormalities are found in 15–78% of SLE patients with active or previous neuropsychiatric SLE [155]. Among patients with psychiatric symptoms but no focal neurologic findings, less than 50% have MRI abnormalities [2]. Macroinfarcts are found in only one in 20 SLE patients, predominately those with antiphospholipid syndrome [157].

Although MRI is the best available imaging technique for neuropsychiatric symptoms, it is inherently limited since it detects only structural lesions. Accordingly, it cannot be the gold standard for diagnosing a neuropsychiatric SLE flare, whose pathophysiology involves primarily functional impairment. Over time, neurologic damage tends to be cumulative; however, each exacerbation may be associated with only subtle, if any, structural changes (e.g., slight edema, or atrophy, or mild change in volume of white matter lesions) that MRI is not sensitive enough to detect. A second major limitation of MRI is that it cannot reliably differentiate active from chronic lesions resulting from previous neuropsychiatric lupus episodes [158–160]. On MRI, factors suggesting active lesions include brightness on T2-weighted images, enhancement with gadolinium (both signifying increased permeability), and filamentous lesions of the gray–white matter junction [155, 158, 161]. Given the high prevalence of asymptomatic MRI lesions in patients with SLE [160, 162], distinguishing active from residual disease is critical to ascertain which patients might require corticosteroids.

The difficulty in distinguishing active lupus from previous damage is not unique to neuropsychiatric SLE. On the contrary, it is a central problem in evaluating organ system involvement in lupus. For example, interpretation of renal biopsies in SLE involves ascertaining how much of the renal pathology reflects permanent damage (scar) vs potentially reversible disease activity. (See Chapter 30.)

Refinements of MRI have generated imaging modalities that appear promising in distinguishing active from residual CNS lupus, or quantifying disease severity.

1. *Quantitiative magnetic resonance relaxometry* analyzes gray matter T2 relaxation time, which is increased in cerebral edema, a sign of active neuropsychiatric lupus. Since this technique differentiated patients with major neuropsychiatric lupus syndromes (including delirium and psychosis), from those with headache or other mild neuropsychiatric symptoms, it may prove usful in deciding which patients warrant corticosteroid treatment [163].
2. *Magnetization transfer imaging (MTI)* is more sensitive than conventional MRI in detecting and quantifying CNS injury. In patients with a history of neuropsychiatric lupus who were asymptomatic, MTI revealed residual, apparently permanent CNS damage [164]. In addition, volumetric analysis with MTI, which measures brain parenchymal homogeneity, can differentiate patients with active CNS lupus from those with residual disease or multiple sclerosis [165]. Overall brain damage, as measured by volumetric MTI, correlates directly with clinical indices of cognitive and psychiatric functioning [166].
3. *Magnetic resonance spectroscopy (MRS)* is a functional imaging technique that measures levels of brain metabolites. Decreases in *N*-acetylaspartate (NAA) seem to indicate irreversible neuronal injury [167, 168], and correlate with the severity of cognitive impairment. Nevertheless, decreased NAA occurs in both active and residual CNS lupus. Increases in choline metabolites, measured in the Cho peak, correlate with active CNS lupus, brain inflammation, and white matter disease [167], and are reversible, preceding the irreversible increase in NAA [168].
4. *Functional MRI*, which measures hemoglobin oxygen saturation levels in the brain, may prove useful in evaluating SLE patients with neuropsychiatric symptoms, but has not been adequately studied.

Use of these more sophisticated imaging modalities is limited by cost, the need for highly trained personnel for interpretation, and the lack of normative data for SLE patients without overt neuropsychiatric manifestations.

SPECT measures regional cerebral blood flow, and indirectly, metabolism. In active CNS lupus, SPECT most commonly reveals multiple small areas of hypoperfusion, but sometimes shows more focal hypoperfusion, most commonly in the parietal lobe [169, 170]. In SLE patients, the degree of hypoperfusion on SPECT did not correlate with the severity of cognitive impairment [171]. Although SPECT is extremely sensitive in

detecting perfusion abnormalities associated with neuropsychiatric SLE, it lacks specificity. In particular, it cannot distinguish active from residual CNS lupus, or infarct from edema, inflammation, or other reversible processes. SPECT must be compared to a structural imaging modality such as MRI to be interpreted, but lesions on SPECT do not correlate well with those on MRI.

PET, which measures regional oxygen and glucose uptake, has greater resolution than SPECT, but has similar limitations. It remains primarily a research tool, and is quite expensive and not widely available.

Magnetic resonance angiography is useful in evaluating patients with multiple strokes, especially due to medium to large vessel thromboembolic disease, but is not sensitive in visualizing small vessel ischemia [155]. (See Chapters 19, 26, and excellent reviews by Sibbitt [155] and Huizinga [172] for an in-depth discussion of neuroimaging in SLE.)

Overall, in clinical practice, the most crucial role of neuroimaging in evaluating patients presenting with neuropsychiatric symptoms is to rule out subdural hematoma, hemorrhagic stroke (possibly from active CNS vasculitis), or other acute emergency requiring immediate medical or surgical intervention.

Limitations to the Use of Laboratory Tests in Diagnosing Neuropsychiatric Lupus

Despite more sensitive imaging modalities, refinements in neuropsychological testing, and novel CSF autoantibody testing, lab tests play a lesser role in diagnosing neuropsychiatric SLE than in other organ system lupus flares for several reasons—both practical and theoretical. From a practical standpoint, the results of some lab tests, including autoantibody assays, are often not received until after critical treatment decisions have already been made. Consequently, although certain autoantibodies are strongly associated with neuropsychiatric lupus, and thus, may be valid diagnostically, these tests are of little use clinically. While this limitation is potentially remediable, several other factors are inherent to CNS lupus and thus, unlikely to change. First, no single lab test can define psychiatric lupus. CNS lupus encompasses a wide spectrum of syndromes, and seems to have a complex and multifactorial pathogenesis. Paradoxically, as research provides greater insight into the ways in which autoantibodies [47] and cytokines may cause brain disease, the likelihood of a single pathognomonic test decreases. Second, neuropsychiatric manifestations—perhaps because they are caused less by inflammatory processes than by autoantibodies and cytokines acting directly within the CNS—tend to follow a course independent of generalized flares affecting other organs, and independent of laboratory tests reflecting systemic involvement. Finally, and most importantly, the *risk of untreated CNS lupus sets a very high requirement for accuracy of laboratory tests. The negative predictive value of a diagnostic test for active neuropsychiatric SLE would have to be very high—close to that of the ANA itself for lupus—to obviate the need for an empiric corticosteroid trial in a patient with new, or even subacute but serious, psychiatric disease. A 2- to 3-week corticosteroid trial (at doses equivalent to 30–60 mg/day of oral prednisone) has relatively modest side effects relative to the sequelae of untreated neuropsychiatric lupus.* Consequently, risk/benefit analysis heavily favors a treat first (or test-and-treat in parallel) strategy over a test-and-wait strategy.

Summary of Diagnostic Approach

In summary, for lupus patients presenting with neuropsychiatric symptoms, the diagnostic approach focuses on ruling out conditions that may resemble CNS lupus but that require urgent specific treatment. Such conditions include (a) CNS or systemic infection, (b) cerebral infarct or hemorrhage, especially if pt has focal neurologic deficits, (c) antiphospholipid syndrome, emboli from cardiac valvular vegetations, and (d) uremia, hypertensive encephalopathy, or other medical causes of psychiatric symptoms in SLE. Accordingly, routine diagnostic workup includes: complete blood count and serum chemistries, serologic measures of systemic disease activity, coagulation tests and antiphospholipid antibody tests, and CSF tests (primarily to rule out CNS infection). In addition, CSF testing for increased immunoglobulin (usually ordered as part of a multiple sclerosis test battery) is often helpful. Special effort may be required to ensure that the anti-phospholipid workup and CSF immunoglobulin tests have been obtained. Brain MRI is helpful in most patients, except those whose neuropsychiatric symptoms have a clearly identifiable etiology. If a brain MRI cannot be obtained promptly, a cranial CT should be done in the interim to rule out intracranial bleeding.

The accuracy of this diagnostic approach may be enhanced by testing for serum anti-ribosomal P and CSF anti-neuronal antibodies [26], particularly since these tests are strongly correlated with psychiatric manifestations of SLE. However, such tests will not be incorporated into clinical practice until the lab results can be obtained expeditiously.

DIFFERENTIAL DIAGNOSIS

Psychiatric Syndromes in Other Collagen–Vascular, Autoimmune, or Multisystem Diseases

A wide variety of diseases can mimic neuropsychiatric SLE, and must be considered in its differential diagnosis. Such diseases include rheumatological disorders (e.g., Sjögren's syndrome, Behçet's disease, mixed connective tissue disease, undifferentiated connective tissue disease, temporal arteritis, polyarteritis nodosa, rheumatoid arthritis, fibromyalgia, and chronic fatigue syndrome), neurologic diseases (e.g., myasthenia gravis, multiple sclerosis), and other multisystem diseases (e.g., sarcoidosis, celiac disease, hepatitis C). Using serologic parameters, these diseases can be subdivided into three categories.

The first group of diseases is associated with a *medium to high ANA titer* (>1 : 160), and positive anti-double-stranded DNA antibodies, and includes only Sjögren's syndrome, mixed connective tissue disease, and undifferentiated connective tissue disease. (These diseases, like hepatitis C and cryoglobulinic vasculitis, are also characterized by a low serum complement.) Although these conditions may be difficult to distinguish from CNS SLE, establishing a specific diagnosis is less crucial clinically, since the treatment is the same. SSA or anti-Ro antibody identifies 80% of patients with Sjögren's syndrome. Anti-RNP, by definition, is present in 100% of patients with mixed connective tissue disease; however, RNP negative, clinically indistinguishable forms of SLE, scleroderma, and myositis are classified as undifferentiated connective tissue disease.

The second group of diseases is associated with a *low ANA titer* (≤1 : 160), and includes multiple sclerosis, and less commonly, ANA-positive rheumatoid arthritis, sarcoidosis, and hepatitis C. Multiple sclerosis is the most important disease to exclude, since 22–30% of patients have a low positive ANA titer [173, 174], and the disease is commonly associated with white matter abnormalities on brain MRI. In patients with neuropsychiatric symptoms but no systemic signs of SLE such as renal, joint, or skin involvement, the likelihood of multiple sclerosis increases. Neurosarcoid is associated with an elevated CSF angiotensin converting enzyme in 50% of patients, and sometimes, a high opening pressure on lumbar puncture, due to granulomatous obstruction to CSF flow [175].

A third group of diseases has neuropsychiatric manifestations mimicking CNS lupus, but typically has a *negative ANA* (i.e., or has the same prevalence of a false-positive ANA as in the general population). Accordingly, a strongly positive ANA and negative anti-neutrophil cytoplasmic antibodies (ANCA) virtually excludes polyarteritis nodosa, microscopic angiitis, and Wegener's granulomatosus. Likewise, chronic fatigue syndrome, fibromyalgia, and temporal arteritis should not usually be diagnosed in the presence of a positive ANA. In Behçet's disease, neurologic features are often confined to the brain stem, in contrast to the global dysfunction so characteristic of neuropsychiatric SLE. Although aseptic meningitis in Behçet's disease may present with decreased alertness, the ANA is negative. Perhaps the most problematic ANA-negative diseases to distinguish from CNS lupus are those presenting with focal neurologic signs as well as delirium, but no systemic manifestations of SLE. In such patients, possible diagnoses include CNS vasculitis (progressive or benign angiitis limited to the CNS—i.e., PACNS or BACNS, respectively), multiple sclerosis, and CNS infection (including cryptococcal, tubercular, meningococcal, and Listeria meningitis, herpes encephalitis, neurosyphilis, CNS nocardiosis, toxoplasmosis, brain abscesses, and progressive multifocal leukoencephalopathy [2, 55]. Tests crucial in excluding infection include CSF cell counts, routine bacterial, mycobacterial, and fungal stains, cryptococcal antigen, and HSV PCR, and serum HIV. A positive cerebral angiogram is required to diagnose PACNS or BACNS, but does not exclude SLE, and may not be necessary if the patient has either a positive ANA or evidence of CNS infection [176].

In summary, an algorithm with four steps can identify disorders that can mimic neuropsychiatric SLE, and that must be considered in its differential diagnosis: (1) exclude infection (2) ANA titer >1 : 160 and non-CNS features, consider Sjögren's syndrome, mixed connective tissue disease, and undifferentiated connective tissue disease. (3) ANA titer ≤1 : 160, consider Sjögren's syndrome, sarcoidosis, hepatitis C, and less commonly, multiple sclerosis (4) ANA-negative with no systemic, but severe neuropsychiatric or focal neurologic features—consider multiple sclerosis or CNS vasculitis (PACNS or BACNS). This approach to differential diagnosis is delineated in a 1999 monograph by Jennekens and Kater [177], from which Table 7 is abstracted. Vasculitis of various types comes closest to mimicking the range of neuropsychiatric features associated with SLE. As one moves from left to right across the table, the illnesses become less similar to SLE, until the multiple sclerosis column, in which depression and subcortical dementia are the only neuropsychiatric manifestations overlapping with CNS lupus.

TABLE 7 Estimated Frequency of SLE Neuropsychiatric Features over Course of Disease, Compared to Diseases Mimicking SLE[a]

	SLE (%)	Vasculitis (e.g., Wegener's granulomatosis (%)	Sjögren's syndrome (%)	Mixed or undifferentiated connective tissue disease (%)	Antiphospholipid syndrome without SLE (%)	Multiple sclerosis (%)
Total neuropsychiatric syndromes (excluding subtle cognitive deficits, minor symptoms)	30	10	<5	<5	<5	<5
Coma	<5	<5			<5	
Delirium (organic brain syndrome), dementia	12	<5	<5	<5	<5	<5
Psychosis	12			<5		
Major depression	15			<5		20
Seizure, post-ictal state	<5	<5	<5	<5	<5	
Aseptic meningitis	<5		<5	<5		
Infarct, stroke	<5	<5	<5	<5	<5	
Intracranial hemorrhage	<5	<5	<5			

[a] (<5% means the syndrome has been reported in a small percentage of patients with the illness and the frequency of the syndrome in the illness could be more than 1%. Blank means <1% of patients, or insufficient data to allow a literature-based estimate, but thought to be either <1% or not occurring in this illness.)

Psychotropic Drug-Induced Positive ANA: (in Psychiatric Patients without SLE)

Psychiatric patients who are receiving antipsychotic drugs, particularly phenothiazines such as chlorpromazine, may have positive ANAs and anti-phospholipid antibodies [178, 179]. Drug-induced lupus has also been reported with other psychotropic drugs, including carbamazepine, divalproex, other anticonvulsants, and lithium [180–184]. Nevertheless, evaluating such etiologic associations is difficult, since some cases of purported psychotropic drug-induced lupus may represent undiagnosed neuropsychiatric SLE. In drug-induced lupus, CNS manifestations are rare [184], and over 95% of patients have anti-histone antibodies. If the offending drug is discontinued, the lupus symptoms typically resolve within a few weeks, although the ANA may remain positive for over a year.

Somatization Disorder ("Psychogenic Pseudolupus" and Psychogenic Symptoms in SLE)

Systemic lupus erythematosus can be misdiagnosed in "somatizing" patients with multisystem complaints and mildly positive ANAs, which are common in young women. Somatizers crave medical attention, and typically present with a several year history of multiple, vague physical symptoms that have eluded diagnosis. Their symptoms are neither feigned nor deliberately created, but cause considerable social or occupational debilitation. Such patients have repeatedly sought medical care and have often undergone extensive diagnostic workups. The medical interview, itself, can reinforce and shape the patient's symptoms. For example, after being asked about butterfly malar rashes, the patient may adopt this description, thereby "legitimizing" her symptoms.

Interventions focused on alleviating illness tend to be ineffective in somatizers, since their symptoms are either refractory to treatment, or resolve, only to be supplanted by new ones. Such patients are seeking not cure but assurances of ongoing care.

If somatization is suspected, as in a patient who appears less ill than expected despite the plethora of symptoms, the rheumatologist should avoid mentioning SLE as a possibility until there is sufficient objective evidence to corroborate the diagnosis. Somatizers are often dismayed to learn that they do not have SLE or another rheumatologic disease. Where possible, the rheumatologist should tell the patient unequivocally, but with a positive tone, that although the nature of her illness remains unclear, the "good news" is that she does not have lupus. (The patient should also be informed of any other medical conditions with overlapping symptoms, such as fibromyalgia, that have been excluded.) Never-

theless, it is important to validate that her symptoms are real, and that they have impaired her functioning. Accordingly, the rheumatologist should emphasize that the patient will require close follow-up with her primary care physician to optimize her ability to function, despite her illness. Many somatisizers have comorbid anxiety disorders or depression, and may be amenable to psychiatric referral if it is presented as an adjunct to ongoing medical follow-up to help them cope with their illness.

At times, patients with confirmed SLE may exhibit symptoms or signs that, despite extensive diagnostic workup, do not seem attributable to a lupus flare or any other identifiable medical illness. Patients are often anxious about recurrent flares of their illness, and may become particularly attuned to, or overinterpret normal physical symptoms. However, given the vague multisystem manifestations of SLE, diagnosing somatization in a patient with known lupus should be done with caution, after a thorough evaluation for objective signs of illness.

Factitious SLE

Unlike somatizers, patients with factitious SLE fabricate symptoms, and feign or intentionally produce signs of lupus to assume the patient role. This is one variation in the universe of factitious illnesses (sometimes referred to as Munchausen's syndrome). Factitious SLE appears to be rare, but several cases have been reported [185]. Patients have simulated hematuria by pricking their finger surreptitiously to add trace amounts of blood to urine specimens, injected themselves with feces or other contaminants to cause infections, or applied rouge to their cheeks to simulate a malar rash. One patient feigned proteinuria by inserting a packet of protein into her bladder. Despite their physical signs of SLE, these patients had no serologic evidence of an autoimmune disorder. Patients with factitious disorders have often been employed in medical settings, or have health care or laboratory training. They are usually young women who are evasive and engage in subterfuge. Sometimes using aliases, they tend to present to multiple hospitals, and undergo extensive diagnostic tests and medical or surgical procedures. When the factitious nature of their illness is discovered, they typically refuse psychiatric referral, leave against medical advice, or are lost to follow-up. Factors that should engender suspicion of factitious SLE are inconsistent and markedly variable lab results without serologic evidence of SLE (i.e., negative ANA and anti-double-stranded DNA, and normal complement levels), in a patient, especially a young woman, with a health care background.

TREATMENT

Inpatient vs Outpatient Treatment

Inpatient treatment is generally required for SLE patients who are acutely suicidal, severely depressed or manic, psychotic, or delirious.

Suicidal Patients

Although few statistics are available, SLE may be one of several medical disorders associated with somewhat increased risk of suicide [186]. During a 20-year follow-up of 300 patients with SLE, 5 made suicide attempts, one of which was fatal [187]. Attempted or completed suicide has occurred in SLE patients with mood disturbances, insomnia, delirium, or psychosis [188, 189]. All SLE patients with psychiatric symptoms should be asked about hopelessness and suicidal ideation. Inquiring about suicidality will not precipitate suicide or cause a nonsuicidal patient to become suicidal. On the contrary, patients who are contemplating suicide are usually relieved to disclose it to their physicians. If the patient seems imminently suicidal, the physican must take steps to ensure her safety; for example, urgent psychiatric evaluation, and often hospitalization. Delirious patients' behavior is especially difficult to predict, and any suicidal thoughts expressed during delirium should be considered potentially serious. In nonemergency situations, the physician should evaluate the seriousness of the patient's suicidal ideation, and in most cases, arrange psychiatric consultation.

Treatment Modalities

Corticosteroids, Cytotoxic Agents, and Other Immunosuppressants for Primary CNS Manifestations of SLE

Severe neuropsychiatric SLE (e.g., psychosis, delirium), with or without systemic lupus disease activity, is generally treated with high-dose corticosteroids, and sometimes, adjuctive cyclophosphamide [190, 191]. In addition, psychotropic medications are used for symptom management. Despite widespread clinical use of high-dose corticosteroids (e.g., prednisione 1–2 mg/kg/day or methylprednisolone 1 *g* IV daily for 3 days) [2, 88], little research exists on their efficacy in CNS lupus. In patients who are on corticosteroids, determining whether new psychiatric symptoms are corticosteroid-induced or a primary CNS lupus flare is often difficult, and is outlined in Table 4. Cyclophosphamide (0.75–1 g/m^2/month) appeared effective in an uncontrolled trial in patients with severe neuropsychiatric SLE [192]. In a retrospective study, lower doses of cyclophosphamide (500 mg IV very week) were benefi-

cial in nonthrombotic severe CNS lupus. Side effects were mild, including worsening leukopenia with respiratory infection in 2 of 25 patients, but no cystitis, herpes zoster, or ovarian failure [193]. To date, no randomized, controlled trials have been done comparing methylprednisolone vs cyclophosphamide in the treatment of neuropsychiatric SLE [194]. In severe, treatment-refractory CNS lupus, other therapies include intravenous immunoglobulin, and occasionally, plasmapheresis [190]. (see Chapter 47 for an in-depth discussion).

In patients with moderate, new onset, or progressive neuropsychiatric symptoms, empiric practice is to begin prednisone 0.5 mg/kg/day for 2 to 3 weeks, or to double the current prednisone dosage as a 3-day trial [125]. For mild neuropsychiatric SLE, a small controlled study demonstrated that low-dose prednisone (0.5 mg/kg/day for 3 weeks) was beneficial in improving patients' cognition and mood [44]. Alternatively, patients with mild neuropsychiatric symptoms may be observed on psychotropic medications without immunosuppressive or cytotoxic therapy.

For those who respond to corticosteroids or cytotoxic agents, the optimal duration of treatment of neuropsychiatric SLE is unresolved. Chronic use of steroid-sparing medication, such as mycophenolate, azathioprine, or pulse cyclophosphamide for CNS lupus has not been studied in randomized trials, but may be considered in patients with recurrent or progressive neuropsychiatric symptoms.

Anticoagulants for Primary CNS Manifestations of SLE due to Thrombosis

Systemic lupus erythematosus patients with antiphospholipid antibody syndrome and thrombotic CNS complications generally require long-term anticoagulation and antiplatelet therapy [195] (see Chapter 40 for an in-depth discussion).

Psychopharmacologic Treatment

Psychopharmacologic medication is used in treating specific psychiatric symptoms that occur in SLE. (See Refs. 196–198 for excellent reviews of psychopharmacology.)

Antidepressants

Newer antidepressants, most notably the selective serotonin reuptake inhibitors (SSRIs), have been developed that have fewer side effects and low lethality in overdose compared to tricyclic antidepressants. Antidepressants are used in treating depression as well as anxiety. Except possibly in severe melancholic depression, all antidepressants appear to be equally efficacious. In addition, all currently available antidepressants have a delayed onset of action, generally 2–4 weeks (sometimes as long as 8 weeks) from the time the patient reaches a typical therapeutic dosage until the antidepressant (or antianxiety) effect occurs. Antidepressants must be taken daily; they are ineffective when taken prn.

The main differences among antidepressants are in half-life, side-effect profile, and drug interactions. Such considerations often determine the choice of antidepressant in a given patient (see Table 8).

In treating depression, *SSRIs* are generally first line drugs. Commonly used SSRIs include fluoxetine, sertraline, paroxetine, and citalopram. (Fluvoxamine is used only occasionally for depression due to its short half-life and significant drug interactions.) The most common side effect of SSRIs is sexual dysfunction (i.e., anorgasmia, decreased libido, delayed ejaculation, or erectile dysfunction), occurring in ≥33% of patients, and persisting for the duration of treatment. Other side effects are usually mild, and include insomnia (or sedation), headache, nausea, jitteriness, and transient anxiety, which can be minimized with a low initial dose and gradual upward titration. Fluoxetine and sertraline tend to be activating, whereas paroxetine is sometimes sedating, and citalopram is somewhere in-between. Fluoxetine has a very long half-life; consequently, it is particularly useful in patients who take their medications sporadically. In contrast, paroxetine (immediate-release form) has a very short half-life. Patients may experience a "discontinuation syndrome" when they miss a dose, or abruptly discontinue it (or other shorter-acting SSRIs). Discontinuation syndrome is characterized by nonspecific symptoms that are also common in SLE, for example, fatigue, headache, dizziness, and myalgias, as well as nausea, diarrhea, and shock-like sensations. Drug interactions with SSRIs are more common with fluoxetine and paroxetine, which inhibit CYP 2D6, and thus can elevate levels of warfarin, β-blockers, tricyclic antidepressants (risk of cardiotoxicity), and some antiarrhythmics, and inhibit conversion of codeine to more potent opioid metabolites. (Concomitant use of serotonergic drugs, e.g., SSRIs, amitriptyline, chlorpheniramine (TCA-like), meperidine, dextromethorphan, tramadol, and monoamine oxidase inhibitors, including selegiline, can cause serotonin syndrome, characterized by shivering, teeth chattering, fever, diaphoresis, rigidity, hyperreflexia, myoclonus, tachycardia, hypertension, and confusion.) Among the SSRIs, citalopram and sertraline have the fewest drug interactions. The potential for drug interactions is most important to consider in SLE patients on drugs with a low therapeutic index, such as warfarin.

TABLE 8 Choice of Antidepressant[a]

Depression in	Preferred antidepressant	Relatively contraindicated antidepressants
Noncompliant patient	Fluoxetine (long T $^1/_2$)	Paroxetine, (immediate-release), venlafaxine (short T $^1/_2$, even "extended-release" venlafaxine)
Pt on cyclophosphamide		Mirtazapine (risk of agranulocytosis, which may be masked by corticosteroids)
Pt on warfarin	Venlafaxine, citalopram, sertraline	Fluoxetine, paroxetine
Pt on multiple medications	Venlafaxine, citalopram (fewest drug interactions)	Fluoxetine, paroxetine, nefazodone, tricyclic antidepressants
Hx of seizures or stroke	SSRIs	?bupropion (immediate release form in high doses), tricyclic antidepressants
Hypertension	SSRIs	(Venlafaxine can be used provided bp is monitored)
Cardiac disease (esp. conduction disturbance)	SSRIs, mirtazapine	Tricyclic antidepressants
Renal disease	Citalopram, fluoxetine (minimal dosage adjustment)	Tricyclic antidepressants (venlafaxine can be used but at half the typical dosage)
Obesity	Bupropion, sertraline fluoxetine, citalopram	Tricyclic antidepressants, mirtazapine, paroxetine
Insomnia	Paroxetine, trazodone, mirtazapine	Bupropion, fluoxetine, sertraline (but SSRIs can be used concomitantly with low-dose trazodone)
Sedation	Bupropion, fluoxetine, sertraline	Paroxetine, trazodone, nefazodone, mirtazapine, tricyclic antidepressants

[a] Sayal, 2000 [201].

Venlafaxine has SSRI-like actions at low dosage, and shares similar side effects. Additional side effects include constipation, diaphoresis, and mild elevations in blood pressure. It has very few drug interactions. Since even the "extended release" venlafaxine preparation has a short half-life, it can cause an SSRI-like discontinuation syndrome.

Although classified as an antidepressant, *trazodone* is very sedating; consequently, it is more useful for treating insomnia. It is commonly used adjunctively in low doses, for example, 50–100 mg qhs, with activating SSRIs. It can cause orthostasis, and rarely, priapism.

Nefazodone is somewhat sedating, and can improve the quality of sleep. It is not associated with sexual dysfunction or weight gain. Side effects include headache, nausea, dizziness, dry mouth, and rare cases of liver failure [199, 200]. Since nefazodone has a risk of hepatotoxicity, and also has many drug interactions, it should only be used when other antidepressants have been exhausted.

Mirtazapine causes significant sedation and weight gain, but not sexual dysfunction or cardiotoxicity. Rare cases of agranulocytosis have been reported (incidence 1–3/1000), a significant concern in SLE patients who are on cyclophosphamide, and other drugs that can cause neutropenia, for example, carbamazepine, phenytoin, and ACE inhibitors. (Also, since concomitant treatment with corticosteroids might mask the development of agranulocytosis, mirtazapine probably should be used cautiously in SLE patients.)

Bupropion has stimulant-like effects, and may enhance concentration. It also facilitates smoking cessation. Bupropion has few significant drug interactions, and does not cause cardiotoxicity or weight gain. It does not cause (and sometimes alleviates SSRI-induced) sexual dysfunction. Side effects include insomnia, agitation, headache, and dizziness. Although bupropion was purported to increase the risk of seizures, this concern derived from a study of patients with eating disorders on high doses. Seizures have not been associated with the sustained-release form of bupropion. Like SSRIs, bupropion can also inhibit CYP 2D6, and cause similar drug interactions.

Tricyclic antidepressants, such as imipramine, amitriptyline, desipramine, and nortriptyline, are less commonly used. Relative to newer antidepressants, especially SSRIs, tricyclics are less well tolerated due to their side effects: sedation, orthostasis, weight gain, and anticholinergic effects—that is, tachycardia, constipation, urinary retention, blurred vision, dry mouth, and confusion, which can progress to delirium. Furthermore, their quinidine-like effects may cause cardiotoxicity (prolonged QRS and QT intervals), making them potentially lethal in overdose. Because of the risk of

delirium and cardiotoxicity, as well as their photosensitizing effects, they should be used very cautiously in SLE patients.

St. John's wort is a commonly used herbal antidepressant. Since it is a potent inducer of hepatic microsomal enzymes, it can significantly lower the levels of oral contraceptives, and possibly digoxin, warfarin, and many other drugs, and should be avoided by SLE patients.

All antidepressants may precipitate or exacerbate mania in vulnerable patients, especially those with a personal or family history of bipolar disorder. Patients on high-dose corticosteroids may also be at increased risk for mania on antidepressants (unless the patient is already on a mood stabilizer or antipsychotic).

The *most common reason for lack of antidepressant response is inadequate dosage for an insufficient period of time*. An adequate antidepressant trial is at least 8 weeks at the upper end of the typical dosage range. If the patient has a good antidepressant response, the medication should be continued for ~9 months (unless mania/hypomania ensues). Antidepressants, especially those with short half-lives, should then be tapered gradually over several weeks for a single episode of major depression, but long-term treatment is appropriate for recurrent major depression or chronic depression.

Stimulants

Psychostimulants such as dextroamphetamine and methylphenidate are very useful in treating depression in the medically ill. Their primary advantage over antidepressants is their rapid onset of action, generally within 48 h. Psychostimulants are particularly effective in alleviating apathy, fatigue, decreased energy, and poor concentration, all of which are common in SLE. When used in modest doses, psychostimulants have minimal side effects, but higher doses can cause appetite suppression and slight elevations in blood pressure and heart rate. (Very high doses may precipitate psychosis.) Psychostimulants are relatively contraindicated in patients with uncontrolled hypertension, arrhythmias, delirium, or a history of psychosis. Since psychostimulants have no effect on seizure threshold, they can be used in patients with a history of seizures. Amphetamine can prolong the action of warfarin; however, methylphenidate has not been reported to have this effect. Patients with a history of stroke tend to be more sensitive to CNS medications, including psychostimulants, and should be started on a low dose, which is then increased gradually. Tolerance and abuse are rare in medically ill patients without a prior history of substance abuse [202].

Mood Stabilizers

Mood stabilizers such as lithium, carbamazepine, and valproate, are used in the prophylaxis and treatment of mania, depression, and mood lability, including that due to corticosteroids. Because of their side effects, drug interactions, and teratogenicity, they should be prescribed and monitored by psychiatrists or other physicians familiar with their use.

Lithium has been used for mood stabilization and antidepressant augmentation. Lithium has been helpful in alleviating depression in corticosteroid-treated patients with SLE and strokes [203]. Lithium has also prophylaxed against corticotropin-induced mania or depression with psychotic features [127], and corticosteroid-induced mania and psychosis. Common side effects of lithium include nausea, tremor, polyuria (nephrogenic diabetes insipidus), polydipsia, hypothyroidism, acne, leukocytosis, weight gain, and subtle cognitive "dulling." Lithium has a very low therapeutic index. Lithium toxicity is manifested by vomiting, diarrhea, coarse tremor, ataxia, confusion, seizures, and death. Since lithium is renally excreted, and handled similarly to sodium, patients with substantial fluid and electrolyte shifts due to congestive heart failure, renal insufficiency, or diuretics (including thiazides, triamterene, and spironolactone) are at increased risk for lithium toxicity. ACE-inhibitors, angiotensin II receptor antagonists, NSAIDS, and COX 2 inhibitors also increase lithium levels. Lithium is contraindicated in SLE patients with poorly controlled seizures or renal insufficiency (but is typically easy to use in end-stage renal disease). Since lithium can cause ECG changes, it should also be used cautiously in SLE patients with cardiac disease.

Valproate, and its enterically coated form, *divalproex*, are anticonvulsants that have been effective as mood stabilizers. Some patients with SLE and various mood disturbances have had marked positive responses to valproate [204]. Side effects of valproate include nausea, sedation, weight gain ("Depa-bloat"), edema, alopecia, tremor, thrombocytopenia, increased transaminases, and less commonly, hyperammonemia and polycystic ovary syndrome. (Valproate-induced weight gain, and occasionally, ecchymoses and bleeding, may be compounded by similar side effects from corticosteroids.) Serious adverse reactions to valproate include rashes, pancreatitis, and hepatotoxicity, sometimes progressing to hepatic failure in children. Valproate is contraindicated in patients with hepatic disease. Valproate inhibits the metabolism of many drugs, including warfarin.

Like valproate, *carbamazepine* is an anticonvulsant that also has mood-stabilizing properties. Little data

exists regarding its use in neuropsychiatric SLE. Although carbamazepine generally does not cause weight gain, common side effects are sedation, dizziness, ataxia, blurry vision, diplopia, dysarthria, confusion, tremor, nausea, elevated transaminases, and hyponatremia (SIADH). Serious side effects include rash, hepatotoxicity, agranulocytosis, and aplastic anemia. Accordingly, carbamazepine is contraindicated in patients with hepatic disease, and in patients receiving cyclophosphamide or other cytotoxic agents. Since carbamazepine is a potent inducer of hepatic cytochrome P450 enzymes, it induces the metabolism of many other drugs (and itself), thereby decreasing drug levels, including warfarin.

Teratogenicity is a major concern with valproate and carbamazepine (neural tube defects), and to a lesser extent, lithium (Ebstein's anomaly). Accordingly, these medications are contraindicated in pregnancy unless the clinical benefits strongly outweigh the risks. Safer alternatives, such as antipsychotic medication or benzodiazepines, are preferable in treating agitation and mania during pregnancy.

Newer anticonvulsant agents such as *gabapentin*, *topiramate*, and *lamotrigine* have been inadequately studied as mood stabilizers, and little if any data exists regarding their use in SLE. Gabapentin (discussed later) has not been proven efficacious as a mood stabilizer. Topiramate appears to have some mood stabilizing effects, and causes weight loss, rather than weight gain. However, its side effects also include word-finding and cognitive difficulties, which may be problematic since SLE, itself, predisposes to cognitive impairment. Although lamotrigine has mood stabilizing effects, its risk of serious rashes, including Stevens-Johnson syndrome, limits its use.

Benzodiazepines, Other Anxiolytic Agents, and Sedative Hypnotics

Benzodiazepines are used in treating anxiety, agitation (including agitation due to delirium), mania, and insomnia, and also have anticonvulsant and muscle relaxant effects. Unlike antidepressants, they have no latency in onset of action. In selecting a benzodiazepine, the most important considerations are rate of onset and duration of action, and presence or absence of active metabolites.

Short-acting benzodiazepines, such as alprazolam and oxazepam, have the advantage of not accumulating, but have the disadvantages of increased risk of rebound insomnia, interdose anxiety, and withdrawal symptoms, including seizures, with abrupt discontinuation. Longer-acting benzodiazepines, such as clonazepam and diazepam, are less likely to cause rebound insomnia, interdose anxiety, or withdrawal symptoms, but with repeated dosing, levels may progressively increase for up to a week before reaching steady state. Also, long-acting benzodiazepines generally should not be used for insomnia because they cause daytime sedation.

Lorazepam, oxazepam, and temazepam undergo only glucuronidation and have no active metabolites; consequently, they are the preferred benzodiazepines in the elderly or patients with liver disease. Clonazepam also has no active metabolites.

For acute agitation, lorazepam is generally the benzodiazepine of choice because it can be administered PO, IM, or IV, has no active metabolites, and has a long duration of action after a single dose, due to its small volume of distribution in peripheral tissue. (In contrast, after repeated dosing, peripheral tissues become saturated, and the duration of action lessens since lorazepam has a short elimination half-life.) See Table 9 for adjunctive use of lorazepam in treating delirium. For chronic anxiety, long-acting benzodiazepines such as clonazepam are preferred.

The primary risk of benzodiazepines is dependence. Accordingly, except in acute situations, benzodiazepines are relatively contraindicated for treatment of anxiety or insomnia in patients with a history of alcohol or other substance abuse. Risk of dependence is highest with short-acting, high potency benzodiazepines, such as alprazolam. Additional side effects of benzodiazepines are sedation, impaired memory and coordination, and falls, which are of particular concern in SLE patients with osteoporosis due to long-term corticosteroid therapy. Benzodiazepines can exacerbate depression, and occasionally cause disinhibition. Respiratory depression can occur, particularly with rapid IV administration of benzodiazepines, or in patients with pulmonary disease. Benzodiazepine withdrawal is characterized by anxiety, insomnia, tremulousness, tachycardia, hypertension, nausea, agitation, delirium, and seizures, especially with short-acting benzodiazepines such as alprazolam. Benzodiazepines are nonlethal in overdose, except when used concomitantly with alcohol or other CNS depressants.

Buspirone is an antianxiety medication that is chemically distinct from benzodiazepines. It neither cross-reacts with benzodiazepines nor alleviates benzodiazepine withdrawal, and has no anticonvulsant effects. Although less effective than benzodiazepines, buspirone is useful for generalized anxiety, but usually not panic attacks. Its primary advantage is that it does not cause dependence. Buspirone is nonsedating and has few side effects, except for transient increase in anxiety. Like antidepressants, buspirone has the disadvantage of a several week latency in onset of action. It also must be taken daily, and is ineffective when taken prn for

TABLE 9 Treatment Protocol for Delirium (Acute Confusional State)

Initial dosage of haloperidol (mg intravenously or intramuscularly) (For oral dosing, double the IV or IM dose)				
	Severity of agitation			
	Mild	Moderate	Severe	Frequency of dosing
Young–middle-aged patients	0.5–2 mg	2–5 mg	5–10 mg	every 1–4 h (but may dose every 30 min, if necessary)
Elderly patients	0.25–0.5 mg	0.5–1 mg	1–2 mg	Every 2–4 h

If haloperidol is being administered intravenously, obtain a baseline ECG and monitor QTc interval for prolongation. Monitor serum potassium and magnesium.

If agitation persists, double the previously administered haloperidol dose.

If agitation has not resolved after 3 doses, then add lorazepam 0.5–1 mg IV or IM with each dose of haloperidol.

If the patient requires more than either 50 mg IV of haloperidol in 5 h, or 80 mg/day, consider a bolus haloperidol dose of 10 mg , then continuous intravenous haloperidol infusion at 5–10 mg/h.

Once agitation has resolved, determine the total haloperidol and lorazepam dosage the patient has required in 24 h, and administer it in divided doses (every 6-8 h).

If the patient remains stable, haloperidol and lorazepam can then be tapered over the next 3–7 days.

[a] Adapted from Wise and Terrell [208], as cited in Rundell, J.R., and Wise, M.G. [2000]. Concise Guide to Consutation Psychiatry," 3rd ed., p. 40; and [103].

occasional anxiety, in contrast to benzodiazepines. Its short half-life necessitates TID dosing.

Zolpidem and *zalephon* are nonbenzodiazepine medications used in the short-term treatment of insomnia. They appear to have a low (but not zero) abuse potential. Since both zolpidem and zalephon have fairly short half-lives, they generally do not cause daytime sedation. Both can cause sedation and respiratory depression when used concomitantly with benzodiazepines or alcohol.

Gabapentin, an anticonvulsant, appears to have some antianxiety effects. In addition, it is effective in alleviating neuropathic pain. (Whether it has mood stabilizing effects remains controversial.) Its side effects are sedation, dizziness, ataxia, and weight gain, and it has no significant drug interactions. Because of its short half-life, it requires TID dosing.

Herbs such as *kava kava*, which has antianxiety effects, and *valerian root*, which is used for insomnia, should be avoided because of the risk of greater than additive effects with other sedative-hypnotics, including benzodiazepines. Kava kava may also pose a risk of hepatotoxicity.

Antipsychotic drugs are used to alleviate agitation, mania, delirium, and psychotic symptoms, even when corticosteroid-induced. Commonly used antipsychotics include haloperidol, phenothiazines (e.g., fluphenazine, chlorpromazine), and newer agents such as clozapine, olanzapine, risperidone, quetiapine, and ziprasidone. The side effects of antipsychotic drugs, that is, extrapyramidal effects and elevated prolactin (both due to dopamine receptor blockade), sedation, anticholinergic efffects, orthostatic hypotension, and weight gain, are summarized in Table 10. Extrapyramidal side effects include acute dystonic reactions (sudden muscle spasms), akathisia (motor restlessnsess with an irresistible urge to move), and Parkinsonian symptoms (bradykinesia, rigidity, resting tremor, and masked facies). Relative to older antipsychotic drugs such as haloperidol, newer drugs, particularly clozapine, olanzapine, quetiapine, and ziprasidone, have many fewer extrapyramidal side effects, whereas risperidone is intermediate. Although chronic administration of antipsychotic drugs can cause tardive dyskinesia, the risk is minimal with short-term treatment, and is much lower with newer antipsychotic agents. Neuroleptic malignant syndrome is a rare, life-threatening reaction to antipsychotic drugs, and is characterized by rigidity, elevated CPK, and high fever, with tachycardia, fluctuating blood pressure, and confusion. Phenothiazines should probably be avoided in SLE due to the risk of photosensitivity, phenothiazine-induced immunologic abnormalities, including + ANA, and the lack of advantage over haloperidol. Clozapine requires weekly blood

TABLE 10 Side Effects of Antipsychotic Drugs

	Haloperidol	Risperidone	Ziprasidone	Olanzapine	Quetiapine	Clozapine
Extrapyramidal effects	4[a]	2	1	1	0	0
↑ Prolactin	4	3	1	1	0	0
Sedation	1	1	2	2	2	4
Anticholinergic effects	0	0	0	2	0	4
Orthostasis	0	3	1	1	1	4
Weight gain	1	2	0	4	2	4
↑Glucose + ↑triglycerides	0	0	?	2	?1	2
Other serious side effects			↑QT_c interval			*Agranulocytosis* *Seizures* (dose related) ? myocarditis ?cardiomyopathy ? thromboembolism

[a] Note: 4 ≡ severe, 3 ≡ moderate, 2 ≡ mild, 1 ≡ minimal, 0 ≡ none.

monitoring because of the risk of agranulocytosis (1% incidence), and is contraindicated in SLE patients on cyclophosphamide or other cytotoxic agents. Since clozapine also causes decreased seizure threshold (as well as hyperglycemia), and has been linked to myocarditis, cardiomyopathy [205, 206], and thromboembolism [207], it should probably be avoided in SLE. Olanzapine appears to have mood stabilizing effects in addition to its antipsychotic effects, but it can cause hyperglycemia. (Although both clozapine and olanzapine are asssociated with significant weight gain, this issue may not be relevant to short-term treatment.) With most antipsychotic agents, drug interactions are generally not a major concern, except for additive hypotensive or anticholinergic effects when used concomitantly with similar agents. Risperidone levels are increased by fluoxetine and some other SSRIs, and by B-blockers. Because of the risk of prolonged QT interval, ziprasidone should not be used in patients with preexisting prolonged QT, or those receiving class 1a and III antiarrhythmics, sotalol, mefloquine, tacrolimus, and several other drugs. Overall, haloperidol, risperidone, and quetiapine may be the preferred antipsychotics in SLE; however, haloperidol has the major advantage of IM/IV, as well as PO administration.

Electroconvulsive Therapy (ECT)

Electroconvulsive therapy (ECT) is the periodic induction of seizures to treat disorders such as severe depression, mania, and catatonia. Under general anesthesia, an electrical current is applied to the scalp to induce a controlled seizure. In SLE patients, ECT has been helpful in ameliorating catatonia [209], mania, and severe depression with or without psychotic features, including corticosteroid-induced syndromes [126]. Indications for ECT include inability to tolerate, or failure to respond to psychotropic medication, or need for rapid therapeutic response, especially in debilitated patients unable to maintain adequate PO intake. Although there are no absolute contraindications to ECT, relative contraindications include recent acute myocardial infarct, intracerebral hemorrhage, cerebral mass, or increased intracranial pressure. ECT can cause transiently elevated blood pressure and arrhythmias; however, the most common side effects are post-ictal confusion (delirium) and amnesia. Retrograde amnesia (i.e., inability to recall information learned pre-ECT) may persist, and involves patchy loss of memories from the months immediately prior to, and including the period of ECT treatment. Anterograde amnesia (i.e., inability to recall new information) is prominent during the course of ECT treatment, but almost invariably resolves within a few weeks after ECT has been completed [210–212]. Subjective complaints of memory impairment correlate directly with depression, and are often not substantiated on cognitive testing [213]. Since SLE patients may already have underlying cognitive impairment, a cognitive exam should be performed at baseline (pre-ECT), and several months post-ECT.

Psychotherapy, Psychosocial, and Behavioral Interventions

Nonadherence to Treatment: Evaluation and Interventions

To enhance treatment adherence, the rheumatologist must first ascertain the reasons for nonadherence. Nonadherence is exceedingly common, and has multiple causes relating not only to the patient and family, but

TABLE 11 Reasons for Nonadherence to Treatment[a]

- Patient-related factors
  - Socioeconomic
    - **Poverty**
    - Homelessness
    - **Inadequate insurance coverage**
    - **Lack of childcare**, **transportation**, or time off from work
  - Cognitive/educational factors
    - Illiteracy or lack of education
    - **Misunderstanding instructions**
    - **Memory impairment**
  - Psychological factors
    - **Denial of illness**
    - **Defiance** (struggle for autonomy)—especially in adolescents
    - Desire to maintain control
    - Anxiety or specific phobia (e.g., needle phobia), culminating in avoidance of medical care
    - **Depression, sense of futility**
    - **Pessimism regarding efficacy of treatment**
    - Secondary gain from sick role
    - Lack of trust in caregivers
    - **Lack of perceived self-efficacy (patient's belief in own capability of coping with illness and its treatment)**
    - **Erroneous beliefs that undermine treatment**
  - Substance abuse
- Family-related factors
  - Lack of social supports
  - Family undermining treatment
- Physician-related factors
  - **Lack of rapport with patient**
  - **Inadequate patient education**
  - **Poor communication**
  - **Lack of concordance between patient's and physician's priorities**
  - Physician's pessimism regarding patient's prognosis
  - Conflicting advice from multiple caregivers (lack of coordination of care)
- Treatment-related factors
  - **Complicated medication regimen**
  - **Disruptive treatment regimen (adverse impact on lifestyle)**
  - **Intolerable side effects**
  - Prophylactic treatment (in contrast to symptomatic treatment)
  - Chronicity of treatment

[a] Major factors are in boldface type.

also to the physician and the treatment itself (see Table 11). Indigent patients frequently cannot access care due to lack of insurance, and may be unable to afford copays for medication, or bus fare for appointments. Family and friends may fail to support the patient, or directly undermine treatment. Denial of illness often manifests as nonadherence to treatment. Other psychological factors that may impact on compliance include defiance, especially in adolescents, whose rebellion against authority is intensified by their sense of immortality. Despair about the illness, and doubts about the efficacy of treatment tend to be reinforced by experiencing lupus flares despite good treatment adherence, or having no flares despite poor adherence. Many patients feel overwhelmed and perceive themselves as incapable of coping with their illness or following treatment recommendations. In addition, patients may harbor fallacious beliefs that interfere with treatment. For example, the patient may contend that medication should be taken only when she feels ill, that taking medication regularly will cause immunity to it, or that if the prescribed dose is beneficial, an even higher dose will be better [214]. Finally, despite the desire and intent to adhere to treatment, the patient may misconstrue the instructions, especially if she has underlying cognitive impairment.

Treatment nonadherence may also be attributable to physician and treatment-related factors, such as failure to establish rapport with a patient, or educate her about the nature of SLE, rationale for treatment, and risks of nontreatment. If the patient's and rheumatologist's priorities are not in accord, patients will often disregard the treatment recommendations. For instance, to the patient distressed by fatigue, the rheumatologist's focus on hypertension or the long-term risk of renal insufficiency seems irrelevant. Frequently, patients fail to adhere to treatment because the medication regimen is too complex, too disruptive to their lifestyle, or causes side effects that are more distressing than the illness itself [214, 215].

In inquiring about the reasons for treatment nonadherence, the rheumatologist should be nonjudgmental—for example, "Sometimes patients decide not to take prednisone because they are upset about weight gain or other side effects. Has that ever happened to you?" "Sometimes patients stop taking their medication because they are feeling well and don't think they need it. Has that ever happened to you?" "What do you think would happen if you decided to take the medication every day?"

Once the reasons for nonadherence have been elucidated, the rheumatologist should address these issues directly, and enlist the patient as a partner in treatment (Table 12). In engaging the patient, the most crucial step is to ask what is most important to her regarding her care, then reorient the treatment goals in accordance with her priorities. Whenever possible, the rheumatologist should involve the patient in decision-making. It is helpful to delineate the patient's role in her care, particularly the initial steps she can take in pursuing her treatment goals, and the rheumatologist's role in assisting her. If the patient lacks confidence in her ability to carry out treatment recommendations, she may benefit from programs that bolster self-efficacy (see later).

For nearly all patients, treatment adherence varies inversely with the complexity of the medication

TABLE 12 Interventions to Enhance Treatment Adherence

Ascertain why the patient has not been adherent to treatment Be nonjudgmental in asking patient her views and practices Validate patient for being honest Rule out depression, denial
Focus on what is most important to the patient (patient's priorities and concerns)
Enlist patient as an active partner in treatment
Enhance the patient's sense of self-efficacy
Simplify medication regimen
Give explicit verbal and written instructions on medications, dosages, and rationale for each medication in language and format that patient can understand
Defuse adolescent defiance
Give positive reinforcement for any improvements in adherence to treatment

regimen. Accordingly, whenever possible, medication regimens should be simplified by reducing the number of medications prescribed and the frequency of dosing. The rheumatologist should provide clear written instructions detailing the medication regimen. Clarity can be ensured by making simple charts that list the medication name, mg strength/pill, and the number of pills to take each morning and evening. (Color coding of charts and prescription bottles can be helpful.) Dispense pills into pill boxes, or have pharmacy use blister packs. Give practical suggestions for how to remember to take medications (e.g., instructing the patient to put the pill bottle next to her toothbrush or alarm clock).

In working with a defiant adolescent, emphasize (in matter-of-fact, nonchalant way) that it is her choice whether or not to take medication or to come in for appointments, and that she, not you as the physician, will experience the consequences, both positive and negative. Portray the doctor–patient relationship as collaborative, and emphasize that without the patient's participation, treatment cannot proceed. Do not allow medications to become a control issue. Advise parents to adopt the same approach.

Finally, praise patients for even small improvements in adherence to treatment. Focus on what patient is doing right. Ask the patient what she did differently that enabled her to take the medication daily, or cut down on her smoking [214, 215].

Unfortunately, some patients are chronically nonadherent to treatment, despite having access to care, good insight into their illness, and devastating sequelae of SLE. Although seemingly incomprehensible, such noncompliance may emanate from the patient's questioning whether the benefits outweigh the losses in relinquishing current behavior and becoming more treatment adherent.

Motivational interviewing, developed by Miller and Rolnick [216] is exceedingly effective in enabling patients to change detrimental behavior. While this approach requires an in-depth explanation and training, certain aspects are relevant to addressing chronic treatment nonadherence. First, it is important to explore positive or beneficial aspects of nonadherence. Ask, "What's good about not taking your medicine?" or "What do you like most about smoking, or using cocaine?" After getting insight into positive factors reinforcing the behavior, segue into inquiring about "less than positive," or detrimental aspects. For patients who have strong factors perpetuating or reinforcing nonadherence, ask the patient, "What would have to happen for you to consider taking your medication, or quitting smoking?" The response can elucidate the patient's perception of her illness, and her motivation and readiness for change. Above all, avoid adversarial confrontations, which tend to degenerate into battles for control. Pressuring the patient to "comply" with treatment is not only ethically problematic, but also futile and counterproductive. Such approaches intensify the patient's defensiveness about current behavior, making it more impervious to change, or drive the patient out of treatment altogether.

Types of Psychotherapeutic, Psychosocial, and Behavioral Interventions in SLE

Patient and Family Education Regarding SLE

Patient and family education should include discussions about the nature, course, and prognosis of SLE, and rationale for and risks/benefits of treatment. Such discussions are essential to obtain informed consent, engage the patient and family as active partners in the care, and enhance the likelihood of treatment adherence. In discussing such issues, the rheumatologist can glean a sense of the patient's comprehension of the disease, and her primary concerns. Misperceptions about lupus can be corrected, often alleviating patient's and family members' anxiety. Topics such as pregnancy, and the impact of the illness on the family, should be explored. (See previous section on marriage and family relationships.) The rheumatologist can also gain insight into the patient's value system, and her priorities, so that treatment can be focused on achieving shared objectives. The patient may benefit from specific suggestions about what she can do to manage her illness and promote her own well-being. In addition, it is important to delineate the clinical symptoms and signs that warrant concern, and that should prompt her or her family to contact the rheumatologist.

Self-Efficacy and Self-Management Training

Self-efficacy programs develop the patient's confidence in her own ability to do whatever tasks are required to achieve a specific goal [217]. In clinical settings, such training can enhance the patient's ability to cope with chronic illness and its treatment.

Self-management courses, which are derived from self-efficacy theory, conceptualize the patient as central in managing her disease, rather than as a passive beneficiary of treatment. Patients receive training in problem-solving, decision-making, confidence-building, and symptom and stress management [218, 219]. In a longitudinal study of SLE patients attending a self-management program, their learned response to illness changed over time. Depressive symptoms decreased, while perceived self-efficacy increased, suggesting that these skills can be taught [220]. A 4-year follow-up trial in rheumatoid arthritis patients demonstrated that skills training is associated with improved health outcomes [221]. In a 6-month randomized, controlled study [222] of patients with various chronic diseases, including arthritis, those who received self-management training had improved health status and fewer hospitalization days than did those on a waiting list. Most benefits were sustained at longitudinal follow-up 2 years later, despite worsening physical disability, and were associated with enhanced self-efficacy in coping with their illness [223].

Psychotherapy

Psychotherapy can be of considerable benefit in helping patients cope with chronic illness, including SLE. Therapy can help patients explore how SLE has impacted them, and develop ways to adapt and move forward with their lives. Furthermore, for patients with depression and anxiety, numerous studies have demonstrated that psychotherapy in conjunction with psychotropic medication is usually more effective than medication alone. Indications for psychotherapy in SLE are summarized in Table 13. Given the complexity of neuropsychiatric aspects of SLE, the therapist or psychiatrist should maintain close communication with the treating rheumatologist, and collaborate in patient care.

For a patient with SLE, the goals of psychotherapy are to identify and enhance positive coping mechanisms that support and sustain her in spite of her illness. Since the patient is often unaware of such coping strategies, gaining insight into them, and bringing them to conscious awareness, can increase her sense of control. In addition, the therapist should help the patient identify and minimize negative or detrimental coping mechanisms, such as smoking, alcohol consumption, self-isolation, or regressing into the sick role. Although lupus can be devastating, psychotherapy can help the patient reframe it as an opportunity to reorient her priorities toward what is most important. Finally, psychotherapy can illuminate that no matter how many losses she has endured because of her lupus, she still retains the freedom to choose her attitude toward her illness [224].

TABLE 13 Indications for Considering Psychotherapy in SLE

Lack of response to adequate psychotropic medication trial in patient without significant cognitive impairment
Nonadherence to treatment or followup
Relationship issues
Physician–patient tensions
Marital discord
Domestic violence
Parenting or other family difficulties
Maladaptive reactions to illness
Pessimism or demoralization
Anxiety, hypochondriasis, or somatization
Social isolation
Dependency
Regression, e.g., functional impairment disproportionate to severity of illness
Denial
Anger, hostility
Difficulty coping with losses, or with other adverse effects of illness on daily life
Coping with terminal illness

Referrals for Psychiatric Care

Some SLE patients may be upset or angered by referrals for psychiatric care. Patients whose SLE was misdiagnosed as psychosomatic are particularly likely to resent the mental health field, and be sensitive to any implication that psychological factors may impact on their physical illness. In addition, unfortunately, many patients feel that having emotional difficulties, or merely being in psychiatric care is stigmatizing. When psychiatric care is recommended, the patient may be apprehensive that it signifies termination of treatment with the referring rheumatologist. Such concerns can be allayed by reassurance that the rheumatologist will continue to work with the patient, and that the psychiatric care is an adjunct to her lupus treatment. Patients may be more receptive to psychiatric referrals if they have received education about the psychiatric manifestations of lupus and its treatment, and the difficulty that many people have with coping with chronic illness. It is helpful to emphasize that the focus of the psychiatric treatment will be to help her achieve her goals and optimize her functioning in spite of her illness [225].

Patient Support Groups, Telephone Counseling, and Online Resources

Lupus support groups enable patients to meet with others who have experienced the illness firsthand. Many patients find that such groups ameliorate the sense of isolation and provide emotional support. Since the patients have experienced similar struggles, they can genuinely empathize and commiserate with each other, and voice their frustrations, fears, and anger. When another patient suggests a particular coping strategy, it is likely to be more readily accepted than advice from family members or physicians who, though usually well-intentioned, have never had lupus. Often, another patient who is functioning well despite severe lupus is an inspiration, and a role model for others to emulate.

Although support groups are usually beneficial, they can have some potentially detrimental aspects. For example, after encountering patients who have a more severe form of SLE, a patient may become increasingly anxious or depressed regarding her own illness. Some patients become unduly absorbed in other patient's difficulties, and leave feeling more burdened. Most importantly, when support groups are poorly led, patients may excessively dwell on their symptoms, complaints, and debility, thereby intensifying the sense of incapacitation, and reinforcing their identity in the "sick role." Poorly led groups can also degenerate into unconstructive "gripe sessions" in which patients complain about doctors, hospitals, employers, and family without assuming any responsibility themselves for change.

Peer counseling by telephone, where available, can be an additional source of emotional support for SLE patients [226]. It has the advantages of being accessible on demand, and to patients who may not be able to attend support groups. For patients with Internet access, other venues for information and support include online SLE websites, bulletin boards, and chat rooms.

Social Services

Some of patient's suffering may be due to insurance inadequacies, poverty, and other socioeconomic factors that neither medication nor psychotherapy can rectify. Social workers can be invaluable in addressing such concerns, and accessing resources and services for patients. Nevertheless, patients may be reluctant to disclose such matters due to feelings of shame, or a sense that the socioeconomic disparity between them and their physician precludes mutual understanding. Physicians tend to mistakenly attribute noncompliance to patients' failure to face up to their illness and be responsible. Lupus patients who have no stable residence will probably not benefit from discussions about the importance of adequate rest, and those who lack money for bus fare are unlikely to be receptive to being told they must come in regularly for appointments.

Rehabilitation

Physical and occupational rehabilitation are crucial in optimizing patient functioning after strokes or other sequelae of SLE that cause physical debility or involve prolonged recuperation. Rehabilitation generally focuses on helping patients regain the necessary skills for maximal autonomy. Most importantly, it is individualized and tailored to address each patient's needs, goals, and lifestyle.

Spiritual Counseling and Altruistic Endeavors

In coping with serious illness, some patients find that their spiritual beliefs are strengthened, and provide solace and fortitude. Faith in a power beyond oneself has sustained many patients through adversities that would otherwise seem unendurable. Conversely, if a patient blames God for causing her illness or failing to heal her, she may begin to challenge her previously held beliefs, or discard them entirely. Such spiritual issues can be very distressing to patients, and are often best addressed by clergy and pastoral counselors. Patients who have no spiritual or religious inclination will especially rely on their network of relatives and friends for support. Patients should be encouraged to pursue volunteer work or other altruistic endeavors that imbue their lives with meaning.

COGNITIVE DYSFUNCTION IN SYSTEMIC LUPUS ERYTHEMATOSUS

Susan D. Denburg
Lynne Larocque
Judah A. Denburg

OVERVIEW

Considerable progress has been made in understanding cognitive function in various rheumatic diseases, and principally in systemic lupus erythematosus (SLE) [1]. The systematic study of cognitive function in patients diagnosed with SLE began in the 1980s [2–6]; these early studies stimulated considerable interest and investigation internationally which continues to the present time [7–20]. Several groups of investigators have adapted methods for, and implemented the assessment of, cognitive function in cohorts of lupus patients, finding almost invariably that lupus is attended by significant impairment in a number of cognitive domains, even in the absence of overt neuropsychiatric manifestations. Although estimates of prevalence of cognitive impairment have varied, presumably a reflection of differences in patient selection, test batteries, criteria for impairment, and control groups, there is a fair degree of consensus that cognitive function may provide a "window" on the nervous system in SLE, where processes related to lupus itself may interfere with normal higher cortical function and lead to abnormalities in cognition and behavior. Neuropsychiatric SLE has been the subject of several interdisciplinary meetings including a special symposium of the New York Academy of Sciences [21], an ad hoc workshop on nomenclature sponsored by the American College of Rheumatology (ACR) [22], and a workshop convened by the National Institute of Arthritis and Musculoskeletal and Skin Diseases (NIAMS) at the National Institutes of Health in May, 1999. In all these fora, the diagnosis and interpretation of cognitive impairment has been the focus of considerable attention, in the context of discussions about the diagnosis and classification of neuropsychiatric SLE.

This chapter briefly reviews neuropsychological methodology, and examines the data from numerous studies regarding the prevalence of cognitive deficit in SLE patients. The effects of corticosteroid treatment, psychological distress, or non CNS (central nervous system) complications that might account for the high prevalence of cognitive deficit in SLE are discussed. We review existing theories of the pathogenesis of nervous system involvement in SLE and attempt to relate potential pathogenetic mechanisms such as brain cross-reactive antibodies and cytokines to specific kinds of cognitive/behavioral alterations. Finally, we consider the clinical implications of documenting cognitive deficit. Because this chapter focuses on changes in mental functioning and their underlying basis, there is necessarily some overlap with other chapters in this volume dealing with neuropsychiatric complications in SLE.

DIAGNOSIS AND CLASSIFICATION OF NERVOUS SYSTEM INVOLVEMENT IN SYSTEMIC LUPUS ERYTHEMATOSUS

Cognitive function is of interest in SLE primarily because of the high prevalence of nervous system involvement in that disease [23–29]. The documented sensitivity of neuropsychological procedures to subclinical disturbance of CNS integrity in a variety of clinical populations [30] suggests that neuropsychological studies of SLE patients have the potential to contribute substantially both to the evaluation of the more subtle symptoms and complaints of these patients, and to a redefinition of the criteria for diagnosing CNS involvement. Such involvement, frequently termed neuropsychiatric (NP), is typically diagnosed on the basis of clinical neurologic or psychiatric events and syndromes such as seizures, neuropathies, hemiparesis, organic brain syndrome, psychosis, and depression. While these symptoms and signs often represent fairly clear-cut clinical syndromes, patients with SLE experience a wide variety of "softer" neurologic and psychiatric problems including paresthesias, headaches, anxiety, mood swings, and reported difficulties in concentration, memory, and word-finding. Estimates of the prevalence of NP involvement vary widely, ranging from 14 to 75%, reflecting variable diagnostic methodologies and criteria [23–30].

A significant difficulty in establishing diagnostic criteria for NP-SLE is the absence of an acceptable gold standard against which these criteria can be validated; that is, while neurologic, psychiatric and cognitive events occur in the context of SLE, there is little evidence that they are *caused* by SLE. Nevertheless, in an attempt to standardize diagnosis for research purposes, we initially proposed a system for classification of NP symptomatology in SLE [4, 31] based on modification and extension of previous clinical classifications [32–36]. Neuropsychiatric manifestations not clearly attributable to causes other than the disease process itself were divided into "major" or "minor" signs or symptoms, with "focal" or "diffuse" presentations. Subsequently, a consensus process for standardizing the classification of NP-SLE [37] showed a level of agreement among raters regarding items important in the diagnosis of NP-SLE, which increased substantially following clarification of terminology and discussion of clinical scenarios. This process has been refined as part of an ACR-sponsored workshop organized for the purpose of developing a standardized nomenclature system for the neuropsychiatric syndromes of NP-SLE [22]. Through these consensus processes, cognitive dysfunction has been given further definition and clinical importance, both as an independent NP-SLE syndrome and in association with other manifestations of NP-SLE [38], where it may co-occur with the event itself or persist as residual brain compromise. Because of the ubiquity of cognitive dysfunction in SLE, assessment of cognitive function can serve as a standardized approach to assessing the functional integrity of the brain in the context of very diverse clinical NP presentations and even in their absence. Neuropsychological or neurocognitive assessment can also represent a distinct approach to diagnosis and classification of CNS involvement and may eventually facilitate the identification of distinct pathogenetic mechanisms within the broad category of NP-SLE.

The description of functional problems of the nervous system, specifically in the areas of cognition and emotion, has developed as a major research thrust in SLE. To facilitate an understanding of these studies, a *primer* on neuropsychological assessment will be provided.

NEUROPSYCHOLOGICAL ASSESSMENT

Background and General Considerations

Clinical neuropsychology is an approach to studying the functional integrity of the central nervous system. An individual's performance is evaluated on a variety of tests which have been found to be sensitive to the effects of well identified brain lesions, and for which there are prior normative data from healthy individuals, without neurologic, psychiatric, or systemic medical problems [39, 40].

Neuropsychological assessment is not a monolithic entity. Diverse approaches reflect different theoretical frameworks. Some consist of a fixed battery of measures and very specific criteria for identifying impaired CNS function [41, 42]. Others adopt a more eclectic and flexible approach [43], may incorporate procedures from the experimental neuropsychological literature, and tend to include analysis of a patient's test-taking strategies (termed qualitative assessment), because of their diagnostic and rehabilitative implications. The majority of studies of cognitive function in SLE have used an eclectic approach to test selection although, for the most part, there has been limited attention paid to patient test-taking strategies. The *common theme* in all three approaches is that a wide range of functions is assessed, including attention, memory, language, concept formation, visuospatial abilities, executive skills, and motor skills. In addition, there are specific, standardized rules for administering and scoring the tests, and results are analyzed with reference to expected level of performance expressed as normative data, or as an estimate of the individual's premorbid or best level of competence. All approaches in wide use have been validated

in both research and clinical settings with respect to their utility in identifying the presence of disturbed brain function.

Sensitivity of Neuropsychological Assessment

In the general neuropsychological literature, correlations between neuropsychological assessment and findings from brain imaging technology, both structural (e.g., computed tomography (CT), magnetic resonance imaging (MRI)), and functional (e.g., positron emission tomography (PET), quantified electroencephalogram (QEEG), single photon emission computed tomography (SPECT), functional MRI (fMRI)), have been demonstrated [44–47]. Neuropsychological data can be highly sensitive in identifying subtle sequelae (i.e., not readily evident clinically) of CNS events such as stroke or head injury, and in monitoring response to drug treatment [48]. Depending on the tests chosen and the use of appropriate control subjects, these approaches have long been known to be sensitive to the presence of CNS dysfunction in a variety of medical conditions in which no structural lesions are evident, such as solvent or lead neurotoxicity [49], metabolic disorders [50], and anoxia [51]. In these conditions, significant impairments in functional integrity of the brain are indicated by performance deficits which cannot be accounted for by such confounding factors as the presence of significant psychological disturbance. Cognitive measures have also proved to be sensitive to the subtle sequelae of relatively minor head trauma, with neuropsychological deficits correlating with the results from MRI and SPECT, sometimes in the face of negative findings on CT scan [44, 47].

In the case of SLE, both structural and functional brain imaging techniques have been shown to be sensitive to changes associated with clinically defined NP syndromes [52–62]. Some techniques have also been sensitive to changes that may reflect subclinical brain involvement [52, 60, 63–65]. Those studies that have compared neuroimaging approaches with neuropsychological assessment have yielded variable results. For example, we reported a study of three SLE patients with well-defined neurologic syndromes, using PET and neuropsychological assessment at two points in time [66] and found good concordance between data derived from these two methodologies, underscoring the utility of neuropsychological data for delineating the behavioral problems associated with CNS lesions imaged by structural or functional scanning in SLE. One study of cognitive function using a brief screening tool identified a pattern of cognitive function reflective of subcortical pathology [67], consistent with previous imaging studies in SLE [68, 69]. Results of proton magnetic resonance spectroscopic imaging have been found to correlate with brain function assessed via neurocognitive testing [70]. In contrast, abnormalities on routine investigative methods such as CT and conventional EEG were generally not correlated with neuropsychological findings in a sample of NP and non-NP-SLE patients [71], nor were MRI abnormalities associated with neurocognitive findings in patients without overt CNS disease [72]. It is important to note that brain imaging techniques, whether in SLE or in other diseases, cannot directly assess the extent of behavioral/cognitive consequence that may accompany a brain lesion; these may be clinically significant even in the face of minimal findings on neuroimaging.

Goals of Neuropsychological Assessment

Neuropsychological assessment provides a detailed description of a person's cognitive and emotional strengths and weaknesses. As such, it can provide unique and complementary information on which to base decisions regarding diagnosis and treatment. Figure 1 depicts the multiple reasons for undertaking neuropsychological assessment, each of which addresses different but often interrelated clinical needs. Although *diagnosis* of brain involvement is often the focus of a referral question, behavioral evaluation remains very important even in cases in which the lesion is well characterized. This can include possible changes in emotions, since these too are frequently altered by brain dysfunction. Debate exists as to whether these alterations represent a reaction to the loss of skills and competence, or constitute a direct expression of an altered neural

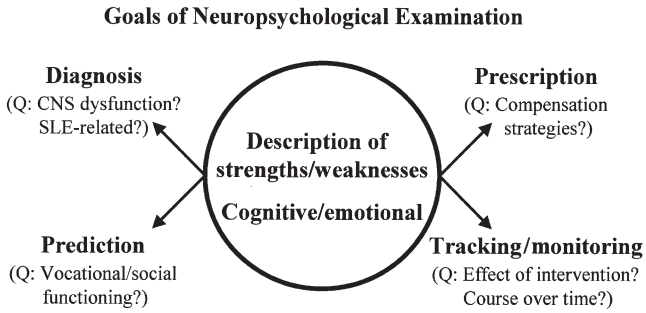

FIGURE 1 Neuropsychological assessment provides a detailed description of a person's strengths and weaknesses. This description facilitates diagnosis, predicts daily functioning, allows the physician to prescribe compensatory or rehabilitative strategies to counteract deficits, and tracks cognitive function over time. Such an evaluation not only monitors the course of disease but can also assess the effects of treatment. (From the *Journal of Musculoskeletal Medicine* **16**, 356, 1999, with permission.)

substrate, as is the case in poststroke depression [73, 74], or disturbances in mood regulation after frontal lesions [75, 76]. An understanding of the resulting alterations in the patient's functional capacity allows the clinician to make *predictions* about daily functioning, although it should be noted that the ecological validity of neuropsychological assessment (i.e., the relationship between deficits elicited during formal assessment and "real life" abilities) is imperfect and requires more study [77–82]. It also allows the clinician to *prescribe* compensatory or rehabilitative strategies to counteract deficits. All of this is necessary to help the patient and family or caregivers anticipate and cope with the functional changes [83–85]. Neuropsychological assessment, by virtue of being standardized, repeatable, and quantifiable, is also a valuable tool for *tracking* the course of disease-related brain function over time as well as the effects of any treatment intervention.

Finally, it is important to note that patients with SLE frequently complain of fluctuating or deteriorating cognitive efficiency. It is recognized that there is often limited concordance between subjective report and objective assessments of cognitive function (e.g., [86]); and further, that perception and report of poor cognitive function can be influenced by depressed mood or anxiety [87, 88]. Nevertheless, the opportunity to confirm or disconfirm a patient's complaints using objective measures that have a certain degree of "face validity" (i.e., they manifestly tap functions about which the patients frequently complain, such as attention, concentration, memory, word-finding, spatial orientation) can have considerable relevance in the clinical management of SLE patients.

NEUROPSYCHOLOGICAL STUDIES IN SYSTEMIC LUPUS ERYTHEMATOSUS

Methodology

Early studies of cognitive function in SLE used selected groups, typically referred for evaluation because of suspected nervous system problems; as such, they were probably not representative of the SLE population as a whole. Accordingly, in our early studies we set out to examine consecutive SLE patients, irrespective of NP presentation, using a comprehensive neuropsychological test battery assessing a wide range of functions subserved by diverse areas of the brain [39, 40]. Given the clinical heterogeneity of NP presentations in SLE patients, clinically significant deficits in individual patients may not correspond to the areas of statistically significant differences identified on group comparisons of SLE patients and controls. For this reason, we undertook in our initial research studies to *adapt and standardize the clinical approach* to identifying neuropsychological deficit in individual patients. Over time, this approach has proved to be more sensitive and fruitful in studying cognitive problems both in SLE and in other diseases with CNS involvement than have group comparisons of patients and controls [4, 5, 89, 90]. The principles underlying this approach to deficit specification are now widely adhered to, although the details may vary across different study centers.

The establishment of consistent and objective criteria for identifying impairment in individual patients required the standardization of the decision rules used in the clinical setting. The details of this approach have been reported previously [4, 5]. Briefly, it consisted of administering a fairly detailed test battery to SLE patients, medical controls (rheumatoid arthritis (RA)), and community controls, converting raw scores to z-scores for ready combination and comparison, grouping scores according to a face valid analysis of the processes involved in the various tests (factor analysis was precluded at this early stage due to limited patient numbers), estimating a premorbid (best) level of functioning for each individual, and comparing performance on each of the 17 cognitive summary variables against this "best estimate." A discrepancy greater than 2 standard deviations (SD) defined a given score as impaired; this modified criterion for identifying impairment was justified by the finding of highly significant correlations in normal individuals between premorbid estimates and many of the summary variables [5]. The test profile as a whole was designated as significantly impaired (quantitatively) if 3 or more of these 17 summary scores were impaired. This *criterion for overall impairment*, reflecting a moderate extent of intertest variability, was *established empirically*; that is, it yielded the best discrimination between our 35 normal controls and the first 21 SLE patients with diagnosed active NP symptomatology at the time of testing. With this quantitative criterion, 6% (2/35) of the protocols from our normal controls reflected significant impairment, which compared very well with the 9% prevalence of impairment in a much larger *control* group of young men in a multicenter study of polydrug abusers evaluated with the Halstead-Reitan battery and its associated decision criteria for impairment [91].

In accordance with the "process approach" to assessment, we also developed a criterion for designating test protocols as *qualitatively* impaired. This involved the examiner rating each patient's test-taking behavior with respect to the degree of cognitive control, using such indicators as confabulation, perseveration, and rule-breaking. Protocols with a rating of 5 or 6 on a scale of 0 to 6 were designated as showing significant qualitative impairment. Our criteria were sufficiently specific that high interrater reliability was achieved for

these judgements [5]. This qualitative approach was not adopted in other centers, and so was subsequently eliminated from analyses to facilitate data comparison with other centers [1]. Nevertheless, it yielded interesting and converging data, which will be reviewed briefly later, and contributed to the utility of the assessment as a tool in clinical management.

Prevalence of Cognitive Impairment in SLE

Studies of cognitive function in SLE have yielded overall prevalence estimates ranging from 17 to 59% for *quantitatively* defined cognitive dysfunction (see Table 1) [4, 6–8, 11, 12, 19, 20, 67, 92–98]. These studies have involved fairly diverse study samples in terms of the proportion of patients with active or inactive NP involvement (i.e., current or previous NP event), which may reflect, in part, different referral patterns to the clinics from which patients have been drawn. They have also used very different sets of neuropsychological tests, measuring different aspects of cognitive functioning. Most importantly, they have adopted different criteria for defining impairment; for example, whether current performance was compared with a premorbid level of function and/or with normative data and whether the sensitivity and specificity of the selected cutoff was addressed in relation to an appropriate control group varied considerably across studies. Nevertheless, despite the widely divergent prevalence estimates, there appears to be a consensus that even in the absence of overt NP symptoms, a sizable proportion of SLE patients can be shown objectively to have significant cognitive problems.

The importance of careful attention to the sensitivity and specificity of a test battery, and the value of converging data regarding cognitive impairment, can be illustrated by reference to findings from our own laboratory. In our initial study of cognitive function in SLE [4], 55% of a sample of 62 clinic patients was categorized as cognitively impaired on quantitative criteria alone, with 67% of the active/inactive NP groups, 38% of the never NP group, and 6% of the community controls so designated. When either quantitative or qualitative criteria were used for evaluating the test protocols, over 80% of patients with active NP symptomatology (active NP-SLE) showed significant impairment, compared to 14% of the normal controls. This corresponded to a sensitivity of .81 and a specificity of .86 for the procedures (described previously) used as a diagnostic test for identifying CNS dysfunction. These values were as good as, if not better than, those obtained with other procedures that were being routinely used at that time for diagnosing ongoing NP involvement [99–101]. Following this first published report of cognitive function in SLE, we made a minor change to the

test battery which resulted in an increased rate of impairment in the healthy controls, using the original criterion of three or more impaired summary scores. A new criterion of four or more impaired scores, adopted to maintain a 6% rate of impairment in the community controls, was then applied to the data from 169 SLE patients, including 95 classified as never NP [20]. Figure 2 depicts the percentage of patients and controls impaired according to this more conservative cutoff. It also depicts the percentage of patients and controls categorized as showing impaired performance on the Cognitive Laterality Battery (CLB), an experimental battery with a large normative database and consisting of eight subtests measuring specific verbal and visuospatial functions [102]. A criterion of two or more scores greater than 1.64 SD below normative values (without consideration of premorbid levels) resulted in a 7% impairment rate in healthy controls on the CLB; this same criterion yielded 33% impairment in the never NP group and 59% in the active/inactive NP group [103]. Figure 2 highlights the strong *convergence of data* regarding the prevalence of cognitive impairment in SLE obtained using different test batteries, administered to somewhat different patient samples, using different criteria for defining impairment, while maintaining an acceptably low rate of impairment in healthy controls.

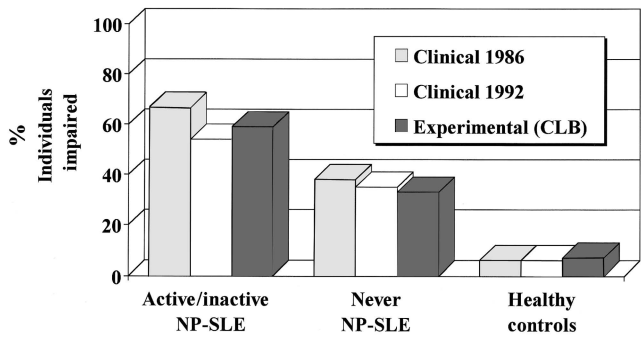

FIGURE 2 A comparison of impairment rates in SLE patient subgroups and healthy controls using different test batteries and different impairment criteria. Clinical 1986: Clinical neuropsychological battery; active/inactive NP-SLE ($N = 36$), never NP-SLE ($N = 26$), healthy controls ($N = 35$). Impairment is defined as 3 or more scores >2 SD below estimated premorbid score [4]. Clinical 1992: Clinical neuropsychological battery; active/inactive NP-SLE ($N = 74$), never NP-SLE ($N = 95$), healthy controls ($N = 35$). Impairment is defined as 4 or more scores >2 SD below estimated premorbid score [20]. Experimental (CLB): Cognitive laterality battery [102], 1994; active/inactive NP-SLE ($N = 28$), never NP-SLE ($N = 12$), healthy controls ($N = 29$). Impairment is defined as 2 or more scores >1.64 SD below normative data (without consideration of premorbid levels) [103]. (From Denburg *et al. Ann. N.Y. Acad. Sci.* **823**; 44, 1997, with permission.)

Another source of converging evidence for impaired cognition in SLE can be found in our early data obtained using a *qualitative* rating, designed to capture aspects of test-taking behavior that were considered pathonogmonic of brain lesions (e.g., rule-breaking, perseveration) [40]. The data from the qualitative assessment alone yielded a gradient of impairment which paralleled the quantitative estimates of impairment in the active/inactive and never NP-SLE groups and healthy controls. (As with the quantitative estimates, the qualitative results for the active and inactive NP groups could not be differentiated and were combined.) Thus, 55% of the active/inactive NP, 17% of the never NP, and 11% of the controls received a "severe" (impaired) rating; conversely, only 5% of the active/inactive NP group, in contrast to 34% of the never NP group and fully 54% of controls, were rated as showing "none-to-mild" qualitative problems. Interestingly, the majority (51%) of the never NP group was rated as showing "moderate" degrees of qualitative impairment. While this was not rated as impaired performance, it represented a fair degree of compromise in "cognitive control." Qualitative analysis was discontinued to facilitate cross-study comparison and because of its time-consuming nature. Nevertheless, such an approach, which has the advantage of providing converging data within patients, may warrant reconsideration as a means of more fully describing the cognitive dysfunction documented in SLE.

Types of Cognitive Deficit in SLE

Studies of cognitive functioning in SLE have yielded data regarding the prevalence and/or type of cognitive deficit in this patient population. Examination of these different studies, which have adopted very different approaches to deficit specification, suggests that the cognitive deficits shown by SLE patients are fairly wide-ranging [5], in keeping with the heterogeneity evident in their clinical NP presentation and consistent with the likelihood of more than one pathogenetic mechanism underlying CNS involvement [23–26]. This diversity in type of cognitive problem demonstrated in SLE patients as a whole, is also evident within the NP and non NP subgroups. Preliminary data from early unpublished studies of cognitive function in selected groups of SLE patients referred for suspected nervous system involvement [2, 3], suggested group deficits in motor speed, new learning, and concentration, in keeping with the subjective reports of many SLE patients. Problems that have subsequently been identified in more representative patient samples include attention and concentration, various aspects of verbal and nonverbal memory including working memory, verbal fluency/

productivity, visuospatial skills, psychomotor speed, and cognitive flexibility [5, 7, 8, 10, 12–20, 92, 97, 98, 104–107]. Table 2 represents a schematic summary of the types of cognitive deficit identified in the majority of studies where these were noted. Deficits were grouped according to areas of function following the factor analytic model proposed by Ryan *et al.* [108] and adopted in our own studies [109]. When we examined the types of cognitive problems that occurred significantly more frequently in SLE patients than in healthy controls, we were struck by the commonalities that existed in deficit areas across patient groups, *irrespective of major NP involvement*. Thus, even never NP patients were demonstrating significant levels of deficit, ranging from 25 to 39%, in such areas as visuospatial skills, verbal and nonverbal memory, and verbal fluency [110]. It is interesting to note that a study using a highly abbreviated cognitive screening tool identified a *pattern* of cognitive function consistent with subcortical dysfunction, even in SLE patients whose overall performance did not fall in the deficient range [67].

Course of Cognitive Function in SLE

One of the striking findings in early studies of cognitive function in SLE, besides the significant impairment in almost 40% of never NP patients, was the high prevalence (74%) of cognitive impairment (quantitatively defined) in *inactive* NP-SLE patients, whose NP symptomatology had been quiescent for at least 4 weeks (and more typically for several years) at the time of testing [4]. The degree of impairment was as severe for these patients as for those with active NP symptoms, with an average of greater than four cognitive summary scores impaired in both groups. While cognitive functioning does appear to improve clinically over time in many individuals who have had an NP event, it appeared that significant *residual* cognitive compromise was being documented in these patients.

Prospective longitudinal data on the natural history of cognitive deficits in SLE are, at present, limited. Two groups of investigators have reported fluctuating cognitive impairment within patients over 1- [9], 2- [111], and 5- [112] year follow-up periods. This has been interpreted to suggest that cognitive dysfunction is not a significant factor in SLE, either as a manifestation of current nervous system involvement, or as a harbinger of future involvement. The conclusion that cognitive impairment can be explained on the basis of coexisting psychiatric disorder [111] is not in keeping with the findings of most cognitive studies, either in SLE or in other medical disorders with proposed neuroimmune pathogenesis, such as acquired immune deficiency syndrome (AIDS) [113] or multiple sclerosis (MS) [114, 115]. Methodological problems further complicate these conclusions: for example, relatively brief follow-up periods, insufficient attention to anticipated test–retest gains, the possible role of steroids in cognitive improvement,

and relatively large patient attrition. Nevertheless, it is important to consider that NP-SLE and its associated cognitive problems may represent a range of reversible and nonreversible brain-related abnormalities, as has been observed in MS [116]. Just as there are well-documented fluctuations in other systemic manifestations, serological measures, and overall disease activity index scores in SLE, cognitive function need not follow an inexorable downhill course in order to serve as an index of current CNS status, and possibly, in some instances, as a risk factor for CNS deterioration. Moreover, it is possible that even seemingly reversible or fluctuating cognitive dysfunction can eventuate in irreversible cognitive compromise in the long term.

We continue to follow patients in a longitudinal study examining both the course of cognitive function over time and the contribution of various parameters, such as specific autoantibody positivity, to cognitive decline, and to the emergence of major NP events. Data on the first 47 originally never NP patients are depicted in Table 3; 35 of these patients retained their never NP status (Group 1: "never-to-never" NP), while 12 had an intervening NP event during the approximately 4-year follow-up interval (Group 2: "never-to-active/inactive" NP). The Group 1 NP patients showed a small overall improvement at Time 2 ($\Delta = +.24$) that fell within 1 SD of the mean control group change ($+.17 \pm .21$); the Group 2 NP patients showed an overall decline ($\Delta = -.20$) that was almost 2 SD below the control group change. We also examined significant change within individuals, defined using the criterion of greater than 1.64 SD beyond the mean change of a group of 11 healthy controls. The patterns of changed performance of the two groups and of individuals within the groups showed only a trend toward significance, reflecting the variability *within* groups, irrespective of NP event. Most interesting, however, is the finding that the Group 2 patients, whose members were originally categorized as never NP-SLE, showed significantly poorer cognitive performance at baseline, *prior* to any overt NP event ($t = 2.46$, $p = .02$). This suggests an hypothesis that cognitive dysfunction, however subtle, might be a harbinger of more serious NP events in SLE.

Interpretation of Cognitive Impairment

In the neuropsychological evaluation of medical patients, impaired test performance, rather than being a reflection of the disease process itself, could potentially result from confounding factors such as the adverse side effects of medication, emotional distress, or simply the "nonspecific" effects of medical illness and/or constitutional symptoms at the time of testing. The following sections address the issue of whether any of these factors likely contributes significantly to the presence of cognitive impairment. The bulk of the evidence so far indicates that their contribution is not substantial, suggesting that the cognitive impairment documented in SLE may, instead, constitute an autoimmune/inflammatory, SLE-related CNS dysfunction.

Corticosteroids

Corticosteroids are regularly prescribed for many of the complications of SLE. However, various sources have suggested that corticosteroid therapy could plausibly contribute to the presence of cognitive impairment in SLE patients; these include the documented association between corticosteroids and psychosis [117, 118], the significant improvement in cognitive functioning that has been reported on discontinuation of steroid therapy in individuals with diseases other than SLE

TABLE 3 Longitudinal Cognitive Data in Originally Never NP-SLE

	Performance change				
	Individual data[a]			Group data[b]	
NP group	↑[c]	=[d]	↓[e]	Time 1	Time 2 – Time 1
Group 1 (never-to-never; $N = 35$)	29%	51%	20%	.01 ± .76	.24 ± .64
Group 2 (never-to-active/inactive; $N = 12$)	8%	42%	50%	–.46 ± .49	–.20 ± .81

[a] Significant change is defined as >1.64 from mean change of controls ($N = 11$).

[c] ↑, improved performance.
[d] =, no change in performance.
[e] ↓, decline in performance.

[119], the cognitive deficits that have been described following acute administration of corticosteroids in experimental animals and humans (reviewed in [120]), and the site-preferential effects of corticosteroids on hippocampal neurons [121–123].

In our original data, we found no significant association between being on or off steroids at the time of testing and being designated as cognitively impaired (25/35 vs 16/28; $\chi^2 = 1.18$, n.s.) [4]. Moreover, none of the correlations between steroid dosage and the 17 cognitive summary variables was significantly negative, as would be expected if steroids adversely affected performance [4]. In fact, the one significant correlation indicated better retrieval of information from remote memory, with increasing steroid dosage. Only one study to date has documented an association between cognitive impairment and steroid use in SLE patients that was independent of generalized disease activity [7]; corticosteroid use did not correlate with changes in cognitive function over a 1-year follow-up period in this same cohort of patients [9]. A significant association has been reported between pulse methylprednisone and chronic cognitive dysfunction [124] and between steroid dose or use and isolated tests of auditory attention [16]. Nevertheless, the vast majority of studies have found no significant association between cognitive impairment and either steroid therapy per se [2, 4, 8, 10, 16, 19, 71, 94–97, 112, 125] or steroid dosage [2, 4, 7, 12, 17, 71, 94, 96]. A similar conclusion has been reached with respect to the possible effects of corticosteroids on the memory impairment documented in patients with MS [126].

On the basis of retrospective data that suggested improved cognitive performance in association with steroid use [127], we undertook a series of single patient drug/placebo trials, using measures of cognitive function, mood, and disease-related symptomatology as end points. Using relatively low-dose steroids (0.5 mg/kg) in patients without active NP-SLE but with cognitive complaints, we documented significant gains in these different domains in five of the eight patients who completed the 6-month trial, no change in two patients, and significant decline in one patient with a fixed neurologic lesion [128]. Of particular note is the fact that the specific memory problems that have been associated with high-dose corticosteroid use in healthy volunteers (i.e., errors of commission) [129] were not noted to be elevated in these patients. *Variable response to steroid medication may reflect a variable neural substrate, with positive drug effects occurring in the context of underlying inflammation.* In support of this, we have found that immunosuppression with cyclophosphamide in an animal model of NP-SLE attenuates leukocyte infiltration in the brain and reduces levels of autoantibodies, while improving behavioral abnormalities [130, 131].

Physical Illness

The contribution of chronic disease and/or constitutional symptoms to cognitive impairment has been addressed in virtually all studies of cognitive function in SLE, initially through the use of such disease activity indices as the Lupus Activity Criteria Count (LACC) [132] and more recently the Systemic Lupus Erythematosus Disease Activity Index (SLEDAI) [133]. It should be noted that we found a high level of concordance between the data obtained using these two indices of disease activity in a random sample of 20 SLE patients [134]. The majority of studies to date have demonstrated no association between cognitive dysfunction and disease activity, irrespective of the index of disease activity chosen [7, 8, 10, 12, 14, 16, 17, 71, 94, 97, 98], particularly when NP symptoms are eliminated from the calculation of the activity index, and when patients with active NP involvement are eliminated from the study sample so as to focus on the presence of active systemic disease apart from the brain [134]. In addition to the absence of a significant association between an overall designation of cognitive impairment and disease activity, we reported neither an increased risk of impaired performance in any particular area of cognitive function in the presence of active disease nor a significant association between cognitive impairment and the involvement of any specific organ system, including renal involvement [134]. Such observations make it unlikely that nonspecific inflammatory mechanisms (e.g., cytokines released during renal or joint involvement) are sufficient causes of cognitive impairment in SLE; these may, however, play a role in other behavioral abnormalities such as depression (see later), and thus, interact with brain-specific immune mechanisms in the development of cognitive dysfunction in SLE. It remains to be seen whether potentially more sensitive indices of disease status, such as subjective measures of pain or fatigue [135], may correlate with cognitive dysfunction in SLE. It is important to consider, however, that these parameters may not only represent potential interfering effects of systemic disease on cognition but may also reflect aberrant CNS processes and hence might correlate with subclinical nervous system compromise, as reflected in cognitive dysfunction [136].

Psychological Distress

Emotional or psychological distress, whether as a component of a clinical psychiatric syndrome or in its absence, occurs commonly in chronic rheumatologic disorders [136–138], and has been documented in a significant proportion of SLE patients, independent of

clinical psychiatric or neurologic syndromes [4, 12, 92, 139–141]. Because clinically significant psychological distress is often accompanied by significant performance deficits [38, 40, 142–144], the contribution of psychological distress to the cognitive impairment documented in SLE has been addressed in a number of studies. It is important to point out that psychological distress, which may include depressed and/or anxious mood and which is typically assessed using self-report inventories, must be differentiated from clinical psychiatric syndromes. The relationship of each to cognitive function should not be equated; failure to draw this distinction can lead to an oversimplification of the findings in SLE. While cognitive problems frequently accompany psychiatric disorders, the attempt to explain cognitive deficits in SLE on the basis of coexisting psychiatric disorders [145] is not consistent with findings from most of the studies in the area (see later).

In our original studies, we assessed emotional status with the Minnesota Multiphasic Personality Inventory (MMPI) because of its demonstrated sensitivity to the presence of generalized psychological disturbance, despite it being well established that it is not useful for assigning psychiatric diagnoses [146]. Our initial criterion for significant distress was the presence of two or more significant elevations (above a T-score of 70) on the clinical scales, excluding those scales which are characterological in their interpretation and relatively insensitive to the presence of acute distress [4]. We subsequently [5] eliminated two additional scales which contain many items reflecting somatic concerns, because of the strong likelihood that physically ill patients might show elevations simply by reporting their physical status accurately, leading to an overestimation of the prevalence of emotional disturbance (cf [147]). Using a criterion of two or more elevations on the remaining six clinical MMPI scales, we found significant distress in 34% (24/70) of SLE patients relative to 9% of nonmedical controls. The association between the presence of significant distress and cognitive impairment was not statistically significant; the frequency of significant impairment was as great in nondistressed (27/46) as in distressed (17/24) patients. Moreover, when only those patients with distress and/or impairment were considered, 67% (34/51) of these women were distressed *or* impaired but *not both*. Of the three nonmedical controls whose responses suggested significant distress, only one also showed cognitive impairment [4]. These findings strongly suggested that emotional distress was unlikely, by itself, to be a predictor of cognitive impairment and that cognitive distress was not a necessary response to the experience of being cognitively impaired.

With a few exceptions [97, 148], the majority of cognitive studies in SLE that have examined emotional status have found no significant association between cognitive dysfunction and psychological distress [5, 17, 94, 95, 98, 112, 125, 149], consistent with findings in other medical disorders with major neurologic involvement, such as AIDS [113] and MS [90, 114]. Interestingly, although one study documented equivalent rates of cognitive impairment in the SLE and RA patient samples [12], the SLE patients were rated as significantly more distressed than were the RA patients (42 vs 9%), making it particularly difficult to attribute the findings of cognitive impairment to distress. Comparing SLE patients to chronic whiplash patients reporting subjective cognitive complaints, Waterloo *et al*. documented better cognitive performance in the whiplash patients despite higher scores on measures of mood and depression, again suggesting that chronic disease and depression cannot account for cognitive dysfunction [16].

Rather than considering the effects of depressed mood or clinical depression on cognitive function in SLE, and given the strong likelihood of finding cognitive deficits in patients diagnosed with clinical depression [142–144], it might be possible to use neuropsychological methodology to address the question of whether depression that occurs in the context of SLE is, at least in part, reflecting primary brain involvement in SLE, rather than or in addition to the effects of chronic illness [138] or a coincidental depression, given the demographics of the SLE population (i.e., young women in their childbearing years) [150].

Support for the ideas that depression reflects primary CNS involvement in SLE comes from studies relating its occurrence to specific autoantibodies with potential pathogenetic significance, such as anti-ribosomal P antibodies [151] or to neurologic events [152]. Consistent with this view, it should be noted that in our original studies, the patients with major psychiatric symptomatology, whether active or inactive at the time of testing, showed the same degree of cognitive impairment as those with major neurologic symptomatology. When these groups were compared directly on both the original test scores and the summary scores, there was only one significant difference; given the large number of comparisons, this likely represented a chance finding. These studies are contrasted with those that attribute depression and other psychiatric manifestations in SLE largely to social stressors and to the effects of chronic illness [8, 111, 139, 153, 154]. This latter view has been supported by findings that depression appears to occur no more commonly in SLE than in RA [140, 154] or in hospitalized patients with diverse medical conditions [155].

It is possible that examination of the quality of depression in SLE, rather than its prevalence, might yield clues with respect to underlying mechanism. For

this reason, we undertook a pilot study of 11 SLE patients with clinical depression, 7 nondepressed SLE patients, and 8 depressed psychiatric outpatients. No differences have been found between the two depressed groups with regard to symptom endorsements on several self-report symptom inventories, suggesting that the clinical presentation of depression in the two groups may be indistinguishable. In contrast, the depressed SLE patients performed significantly more poorly than the depressed and/or nondepressed control groups on measures of sustained mental effort, verbal and nonverbal learning, and visuospatial planning [156]. These data highlight the potential value of neuropsychological approaches in studying the nature and etiology of depression, which constitutes a fairly common NP manifestation in SLE. Based on these pilot data, we are currently examining cognitive function in SLE patients with and without depression and in nonmedical depressed controls to assess the differences in areas of deficit, antibody and cytokine profiles, and treatment responsiveness.

PATHOGENESIS OF COGNITIVE AND BEHAVIORAL ABNORMALITIES IN SYSTEMIC LUPUS ERYTHEMATOSUS

The type of cognitive deficit demonstrated by SLE patients has been noted to be wide-ranging and variable according to the numerous studies cited earlier. Attempts to relate cognitive deficit to underlying pathogenetic mechanisms have been made, with varying success. Before these are discussed (see Neuropsychological Correlates of Specific Anti-Brain Antibodies), a review of potential mechanisms will be presented. It should be noted that procedures which would allow us to define more homogeneous groups of SLE patients (e.g., those with deficits in particular cognitive areas), should prove more fruitful for exploring immunopathogenetic mechanisms underlying disturbed brain function; these may include the effects of both brain-reactive autoantibodies and/or dysregulated proinflammatory cytokines on the neural substrate.

Common Lymphocyte/Brain Antigens

The biological underpinnings of a relationship between autoimmunity, as manifested clinically in SLE, and nervous system disease rest historically on observations of antigens common to the lymphoid and nervous systems [157–161]. The notion has been advanced that lymphocyte antigens, shared with brain tissue, become targets of the autoimmune response in SLE, thus leading to a "cross-reaction" of the immune response with elements of the nervous system; such autoantibody-mediated neuronal dysfunction or cytotoxicity could lead to subclinical or clinical neuropsychiatric disease, including cognitive dysfunction [31, 100, 162–167]. Whether or not antibodies directed against common lymphocyte/brain antigens can account for more than a limited number of clinical NP-SLE manifestations/syndromes remains controversial [26, 56, 168–170]. Indeed, because of advancing knowledge on the existence of multiple—and thus probably, noncausal—autoantigen-autoantibody reactions, and even of several, alternative (nonantibody) mechanisms which may be operative in SLE (see later), the preeminence of cross-reactive lymphocyte-brain autoantibodies in the pathogenesis of NP-SLE, and its attendant cognitive and behavioral problems, has receded more recently.

Nonetheless, there is a rationale for the presence of lymphocyte/brain antigens; some of these are shared with microbial antigens [171], while others, such as thymic-brain antigens [157], may be involved in disturbed neuroimmunoregulation [172], since helper T cells bear on their surface the antigenic marker CD4, a specific receptor for human immunodeficiency virus (HIV) [173, 174]; this CD4 is also present on cells from the brain which HIV can enter [175, 176], so that antibodies to CD4 may provide an explanation for some aspects of neuropsychiatric disease, including NP-SLE. In fact, the model of HIV-induced autoimmunity may explain the development of many autoantibody-directed reactions in SLE [177–179]. Likewise, the suppressor T lymphocyte marker molecule, CD8, has been identified on myelin-producing oligodendrocytes [180], providing a possible explanation for involvement of T suppressor cells in the demyelinating autoimmune disorder, MS [181]. Given that T suppressor cell lymphopenia and lymphocytotoxic antibodies are common in SLE [163, 164, 172, 182], it can be proposed that some cases of NP-SLE, including neurocognitive disorder, may be due to T cell/brain cross-reactive autoimmune responses, resulting in neuronal or glial cell loss, demyelination, and/or inflammation in the brain.

Bacterial and Other Nonprotein Antigens

Numerous other candidate bacterial antigens which are also present in brain, while not in and of themselves lymphocyte/brain antigens, have been proposed as providing explanations for cross-reactive autoimmune responses which may be directed against the nervous system in SLE [171]. An interesting class of nonprotein antigens which may be present on formed elements of the blood (including lymphocytes), as well as in brain, includes phospholipids. Anti-phospholipid antibodies represent the targeting by the immune response of a

very important antigenic family in SLE, presumably leading to vasculopathy, thrombosis, and/or infarction with focal neuropsychiatric deficits (extensively reviewed as "the anti-phospholipid antibody or lupus anticoagulant syndrome") [183–186]. Some of these antibodies may be directed at endothelial antigens and thus putatively eventuate in vasculopathy [187], leading to cognitive dysfunction (see later).

Specific Antigens on Neuroglia and Lymphocytes

Several potential lymphocyte/brain antigens have been studied by immunoprecipitation techniques [165, 188–192]. Many SLE patients have significant elevations of autoantibodies which bind to neuroblastoma cells [192, 193] or which are lymphocytotoxic *in vitro* [165, 166, 182, 190]; the nature of the surface antigens against which IgG class antibodies are directed in sera and in cerebrospinal fluid of SLE patients has been explored [31, 191–194]. Neuronal antigens identified include 50-kDa and 97-kDa proteins on the surface of neuroblastoma cells [191, 192, 195]. There has been an interesting report of a specific brain autoantigen (LBA-1) identified through cloning and expression of a unique sequence present in mouse (MRL) brain, and distributed in the hippocampus, hypothalamus, and cingulate gyrus [196]. Whether this antigen is specifically and causally involved in the development of behavioral abnormalities in this mouse model remains to be determined; autoimmune targeting of the LBA-1 antigen as a sufficient cause of NP-SLE needs to be proved. This subject has been reviewed extensively [197, 198].

In addition, certain surface proteins on lymphocytes, either from the peripheral blood or on CD4+ lymphocytic cell lines, have been shown to be targeted by a large majority of lupus sera with autolymphocytotoxic activity [165]. Both a 52- to 55-kDa moiety and a 32- to 34-kDa moiety can be shown, by immunoprecipitation and radiolabeling, to be present on the surface of helper T cells and be bound by autoantibodies present in these sera [191]. Moreover, these reactivities correlate positively with the presence of NP-SLE and/or cognitive impairment, suggesting (but not proving) a causal role in certain individuals with SLE [199]. The possibility that these antigens are specifically expressed in certain areas of the central nervous system has been raised on the basis of the patterns of serology and cognitive dysfunction observed [167, 199] (and see later).

Several other antigens have been proposed as potentially involved in the pathogenesis of NP-SLE, based on correlative studies of serology with imaging in SLE patients [200]: these include the gliotypic antigen, GFAP (glial fibrillary acidic protein), and the neutrophil serine protease, PR-3 (c-ANCA). Confirmation of the roles of these antigens in NP-SLE awaits larger, prospective studies.

Brain Cross-Reactive Antigens in Other Diseases

More cogency for the argument of antigenic localization and autoantibody-mediated disease comes from elegant studies done by Posner and Furneaux [201] on the pathogenesis of paraneoplastic syndromes. Both 62- and 34-kDa proteins, termed Yo, are precipitated by an autoantibody present in serum and CSF of patients with subacute cerebellar degeneration syndrome associated primarily with gynecological carcinomas [201]. The specificity of this antibody for Purkinje cells in the cerebellum, and antigen extractability from both Purkinje cells and the tumors in these patients, support its role in the syndrome's pathogenesis. Another antigenic target, Hu, is a 35- to 40-kDa band immunoprecipitated by antibodies present mainly in patients with oat cell carcinoma and a syndrome of limbic encephalitis characterized by total loss of memory as well as sensory neuropathy [201]. Such a syndrome has been described in a patient with SLE but without attribution to any specific neuronal or lymphocyte autoantibody or to anti-Hu [202]. Whether or not Yo or Hu represent any of the target antigens in NP-SLE remains to be determined. However, the concept that a distinct neuropsychiatric syndrome and cognitive dysfunction can eventuate from specific autoantibody responses, localizable to some but not all areas of the brain, is attractive and can potentially explain some of the cognitive deficits found in SLE patients, whether or not they go on to develop overt neuropsychiatric disease.

Other potential models for localized brain dysfunction in relation to autoimmunity include: tropical spastic paraparesis associated with HTLV-1 infections [203]; chorea after rheumatic fever [204]; and, various types of neuropathy associated with monoclonal gammopathies directed against myelin [205].

Phospholipid Antigens

The subject of the anti-phospholipid antibody syndrome, its clinical as well as pathogenetic consequences including neuropsychiatric diseases, has been reviewed extensively elsewhere in this volume. The question of whether or not anti-phospholipid antibodies, via a thrombotic or thromboembolic mechanism, can account for cognitive deficits is being addressed in several ongoing and proposed studies of cognitive function in SLE patients with anti-phospholipid antibodies, either lupus anti-coagulant or anti-cardiolipin antibodies. Of

interest from the point of view of pathogenesis is the finding that several of these patients have evidence for an acquired protein S deficiency in association with surrogate markers for ongoing thrombosis [206]. Low to therapeutic doses of sodium warfarin are able to reverse this coagulopathy; whether or not cognitive function also improves in these patients remains to be elucidated in clinical studies.

Other Mechanisms: Apoptosis

The notion that disordered apoptosis occurs in SLE derives from the presence of an animal model, the MRL-lpr mouse, in which a mutated Fas receptor leads to lymphoproliferation and manifestations of autoimmunity (see later). Moreover, great interest has developed in apoptosis as a mechanism in human SLE in studies and reviews by Rosen and co-workers [207–211]. It has been demonstrated by these investigators that autoantibodies in SLE, some of them for ubiquitous nuclear antigens, can target these proteins on the cell surface as blebs on apoptotic cells. This has afforded a new way of looking at typical autoantibody–autoantigen reactions in SLE as potentially pathogenic: double-stranded DNA (dsDNA); extractable nuclear antigens (ENA) such as Ro and La; ribonuclear proteins; and, ribosomal proteins—the latter which have been implicated in depression and psychosis syndromes in NP-SLE (P antigens) [151, 212, 213]—could each potentially be a target of autoantibody response on the surface of an apoptotic cell in the neural substrate, thus leading to cognitive and/or behavioral abnormalities. Although this hypothesis is attractive, and could explain some of the findings in the MRL-lpr model to be discussed later, there is very little information at present causally relating disordered apoptosis and autoantibodies directed against dsDNA or ENA in the development of NP-SLE or of cognitive dysfunction in SLE patients. There is a syndrome of Fas/APO-1 (CD95) mutation leading to clinical manifestations somewhat like SLE [214] but, to date, there has been no study of the relationship of this syndrome to cognitive dysfunction. The area of apoptosis and its relationship to cognitive and behavioral abnormalities in SLE would be worthy of further investigation.

Another, similar mechanism relates to disordered clearance of apoptotic cells by macrophages, as proposed by Herrmann *et al*. [215]. In this situation, there is purported aberrant presentation of autoantigens because of access of antigen-presenting cells to nuclear antigens, rather than the bleb-on-surface hypothesis proposed previously. The underlying causes of this disordered presentation are not yet clear, and its relationship to cognitive dysfunction in SLE is unknown.

Finally, while there have been a plethora of descriptions of abnormal cytokines in SLE, and relationships of various of these to NP-SLE (as described elsewhere in this volume), a report suggesting the association of an imbalance in interleukin-10 (IL-10) promoter haplotypes to the development of NP-SLE is of interest [216]. While IL-10 in general is an immunosuppressive cytokine for several prominent T helper cell type 2 (TH2) responses, as exemplified by its role in allergic inflammation, there is some reason to propose that IL-10 may *favor* the development of autoimmunity; diseases such as SLE could thus be construed to result from a predominent TH1 response. More studies and information on the roles and interactions of immunoregulatory cytokines in the development of NP-SLE and its attendant cognitive dysfunction are warranted.

Behavioral Abnormalities in Lupus-Prone Mice

In spontaneous SLE syndromes in mice, including the NZB/W, MRL/lpr, and BXSB strains, there is not only a high prevalence of behavioral abnormalities but also of antibodies directed against brain extracts, homogenates, or tissue [217], along with an upregulation of proinflammatory cytokines such as interleukin (IL)-1 and interleukin (IL)-6 [218]. While examination of the specificities of these antibodies or behavioral effects of these cytokines is developing, the presence of brain-reactive antibodies, brain leukocyte infiltrates, and/or upregulated cytokines can be shown to be related to learning deficits in aging and/or autoimmunity [103, 131, 217–221]. Avoidance learning, for example, has been shown to be defective in murine lupus, and this is associated with the presence of brain-reactive antibodies [217, 222]. Anxiety-like behavior in NZB/W mice has likewise been related to upregulated cytokines, possibly interferons [223], and not simply a result of neuronal ectopies [224, 225]. Some of the latter behavioral abnormalities can, in fact, be ameliorated by chronic, soluble interferon-γ receptor treatment [226]. To what extent brain autoantibodies and cytokines interact to cause (or ameliorate) learning and behavioral abnormalities in lupus-prone mice is the subject of active investigation [218].

Studies using the MRL/lpr murine model have demonstrated the coemergence of autoantibodies against nuclear antigens and specific behavioral disturbances including perseveration, motor incoordination, disruption of nocturnal/diurnal rhythms, and hesitancy or "emotionality" [218, 227–231]. These abnormalities appear before the onset of overt manifestations of lupus such as lymphadenopathy, arthritis, renal disease, or

anemia [227–229]. The animals have high systemic levels of brain-reactive antibodies and proinflammatory cytokines; however, the higher antibody titres in the MRL/lpr compared to the congenic MRL/$^{++}$ strain are not sufficient to account for the wide range of behavioral and learning abnormalities. Findings suggest that the development of depressive-like symptomatology and other illness behaviors in MRL-lpr mice can be reproduced in MRL^{++} and control mice by transgenic upregulation of IL-6 expression [231, 232]. Furthermore, reductions in neuronal cell mass and dendritic arborization of neurites in MRL-lpr mice are associated with infiltrations of T and B cells in the brain [131, 233], and with increased apoptosis of both T cells and neuroglia [234] in these animals. Treatment with the immunosuppressive drug, cyclophosphamide, or with an IL-6 receptor antagonist can reverse the dendritic changes and improve some of the abnormal behavior (AABS) in the MRL-lpr mouse model [130]. Thus, multiple mechanisms may be involved in the development of AABS.

Table 4 lists possible mediators of cognitive dysfunction in SLE, based on a synthesis of data from human and animal work.

NEUROPSYCHOLOGICAL CORRELATES OF SPECIFIC ANTI-BRAIN ANTIBODIES

Previous studies of the relationship between anti-brain antibodies and CNS involvement in SLE have defined such involvement on the basis of major neuropsychiatric syndromes. Relatively little attention was paid to subclinical nervous system involvement such as might be indicated by neuropsychological impairment.

In order to reduce the cognitive heterogeneity evident in the SLE population, cognitive status, as a marker of nervous system involvement, has been examined in relation to specific autoantibodies that react with nervous system antigens. Significant associations have been documented between an overall designation of cognitive impairment and positivity for neuronal (NA) [31], lymphocytotoxic (LCA) [165], and anti-phospholipid (aPL) [109] antibodies, as well as between sequential changes in cognitive function and neuronal antibodies [235]; negative findings in this area have also been reported, using different criteria for cognitive impairment [19, 236]. Of special interest in terms of subgrouping patients, have been the findings of associations between antibodies and specific cognitive function; these include LCA positivity and visuospatial deficits [167, 199], and aPL positivity and a pattern of cognitive dysfunction characterized by difficulties with verbal memory, productivity, and speeded output (Table 5) [109, 237–239], even in the never NP patient group [109] (although one study found aPL positive patients to have worse performance in virtually all areas of function with increased duration of disease [239].) While

TABLE 4 Pathogenetic Mechanisms Possibly Involved in the Development of Cognitive Dysfunction in SLE

Mediator(s)	Mechanism(s)
Brain-specific autoantibodies	Interference with neurotransmission Neuronal cytotoxicity and cell loss Loss of neuronal plasticity
Anti-phospholipid antibodies	Thrombosis/ischemia/infarction Vasculopathy (endothelial dysfunction)
Cytokines	
Proinflammatory (e.g., IL-6)	Neuronal cytotoxicity and cell loss Loss of neuronal plasticity
Immunoregulatory (e.g., IL-2)	Microgliosis

cross-sectional associational studies raise hypotheses regarding the mechanism(s) of cognitive dysfunction in SLE, (e.g., that ongoing aPL-related microthrombotic events or vasculopathy can lead to CNS compromise manifested as cognitive dysfunction), longitudinal data are essential for their confirmation. In this regard, antibody data from our ongoing longitudinal study (see earlier) are promising. Specifically, rates of NA and LCA positivity at baseline were equivalent in the "never-to-never" and "never-to-active/inactive" NP groups; however, positivity for aPLs, measured both as lupus anticoagulant (LA) and anti-cardiolipin antibody (aCL), differed significantly between the two groups.

In addition to the specific cognitive deficits found in association with specific antibodies, we have documented significant verbal memory problems in all three antibody positive groups. This is consistent with the high prevalence of verbal memory problems documented in our original sample of SLE patients [5] and in studies from other centers (see Table 2). It also raises the possibility of another pathogenetic mechanism, possibly involving autoantibodies specific to brain areas that mediate memory, in particular medial temporal areas. The suggestion that specific immunological involvement underlies the neuropsychological deficits apparent in both paraneoplastic limbic encephalopathy and SLE has been raised [240]; the nature of that mechanism has yet to be delineated. The role of other immunological factors also warrants investigation. For example, the proinflammatory cytokine, IL-6 has been shown to contribute uniquely to measures of learning beyond the effects of depression, prednisone therapy, and hormonal measures [125].

THERAPEUTIC IMPLICATIONS OF COGNITIVE DYSFUNCTION IN SYSTEMIC LUPUS ERYTHEMATOSUS

Medical Intervention for Acute CNS Involvement

The general practice with respect to CNS manifestations in SLE that appear to be primary (i.e., cannot be explained on the basis of toxic, metabolic, infectious, or other causes), continues to be to treat the condition with increasing doses of corticosteroids. However, it should be possible to rationalize an approach on the basis of tests aimed at delineating the pathogenetic mechanisms involved in each case. Thus, a pattern of clinical and/or cognitive findings suggesting vasculopathy and/or focal abnormalities, in the presence of anti-phospholipid antibodies, might warrant anticoagulation and/or antiplatelet drugs. Encephalopathy or "diffuse" syndromes, primarily involving psychiatric or behavioral disturbances and significant cognitive abnormalities, in the presence of antibodies against neurons or lymphocytes, or elevated cytokine levels, might be treated with corticosteroids and/or immunosuppressives. A retrospective analysis of the utility of pulse doses of cyclophosphamide in refractory cases of NP-SLE is instructive [241], as are reports of intrathecal immunosuppressives [242, 243]; however, effects on cognitive function of these interventions are unknown. Nevertheless, depending on the particular clinical NP picture, and in the absence of compelling data regarding an autoimmune/inflammatory mechanism, consideration must always be given to the potential efficacy of anticonvulsants, neuroleptics, or antidepressants.

Controlled trials of corticosteroid therapy in NP-SLE are nonexistent. The heterogeneity of NP manifestations, the frequent lack of association between such manifestations and other evidence of disease activity, and the variability of markers of NP activity, together make evaluation of the efficacy of steroid therapy in NP-SLE difficult. Further, because of the likelihood of diverse pathogenetic mechanisms underlying NP-SLE [23–26], patients may well show marked differences in their response to corticosteroid treatment. One prospective, single patient (N of 1) trial to examine the efficacy of relatively low-dose corticosteroids on CNS functioning, as reflected specifically in cognitive and mood status, has been reported and discussed previously [128]. The issue is best addressed through prospective, multicenter clinical trials of corticosteroids, immunosuppressives, and/or anticoagulants in patients with SLE, including cognitive end points to assess effects on brain function and functional indices to assess impact on everyday functioning [244, 245].

Long-Term Functional Issues

Changes in mental status can be a strong indicator of developing CNS involvement that may require medical intervention. Clinicians should also be aware of the handicap posed by residual/subclinical cognitive deficits, once an acute episode has been treated and resolved. Effective care in any chronic illness such as SLE must take into account the difficulties in daily life that are a consequence of functional impairment. SLE patients regularly complain of diminished cognitive efficiency, which may or may not correlate well with objectively documented cognitive deficit [86, 87, 136]. The lack of a reliable correlation may be due to a number of factors, including concomitant depressive symptomatology [87], but should not, a priori, invalidate the subjective functional complaints. The therapeutic implications of identifying chronic or even transient CNS

dysfunction are as important for SLE patients as for any other group with CNS compromise, such as MS [246] or head injury [247]. Most patients and family members respond positively to having specific deficits defined and their impact on daily life explored. Diminished retention of information, poor attention, distractibility, social withdrawal, and lability of mood can be easier to live with and compensate for, once identified and recognized as manifestations of subtle alterations in CNS function, rather than being perceived as carelessness or characterological faults. Memory and organizational dysfunction, when unrecognized, potentially compromise the patient's ability to adhere to prescribed treatment strategies. Together with a general reduction in mental efficiency, these impairments can have a significant impact on occupational functioning [244, 245]; activities that were previously well within the patient's competence may become highly demanding and very fatiguing. Although measures of impact are beginning to be included in studies of cognitive function in SLE (e.g., [112]), considerably more work needs to be done applying well-validated measures of daily function in large scale cognitive studies, before the question of impact of cognitive deficit can be answered. For some patients who experience significant dysfunction, adjustments in the home or work environment and schedule may substantially facilitate their ability to function productively and remain fully involved. However, for other individuals, more extensive changes may be needed, along with appreciable modifications in expectations and activities, in order to accommodate substantially reduced mental capacities. Cognitive rehabilitation techniques, as used with patients who have sustained head injury or other neurologic disorders, may be appropriate for a subset of SLE patients whose impairment persists or worsens over time [248]. Even in those patients who have never had major neurologic or psychiatric symptomatology, cognitive impairment (as a reflection of brain compromise) may predict increased susceptibility to adverse CNS side effects of prescribed medication, such as hypnotics and anxiolytics. Moreover, alcohol and sleep disruption may have a much greater impact on the performance of these patients than would be the case if there were no compromise of CNS integrity [249, 250].

FUTURE DIRECTIONS FOR COGNITIVE STUDIES IN SYSTEMIC LUPUS ERYTHEMATOSUS

Research over the last almost two decades has focused on identifying the extent and nature of cognitive dysfunction in SLE, using diverse batteries of clinical neuropsychological tests that have proven utility in identifying compromised brain function. However, the ability of these tests to identify specific functional deficits is limited, owing in particular to their multifactorial nature. Individual tests tend to tap a variety of skills at different levels of complexity, making it difficult to specify the particular function that is impaired. A few isolated studies have used experimental measures to tap subtle problems in attentional capacity and information processing in SLE [14, 15]. They postulated that these problems might underlie the cognitive deficits documented by the clinical tests and might account for the subjective experience of cognitive dysfunction experienced by many SLE patients; the latter is not always corroborated by conventional neuropsychological tools. The use of experimental tests, as well as the analysis of patterns of responses on clinical neuropsychological tests, should be pursued as this approach has proved to be productive in the study of a variety of patient populations, such as MS, HIV, chronic fatigue syndrome (CFS), and depression, when standard neuropsychological measures have not necessarily identified significant deficits or been able to localize the underlying lesion [251–258]. The modification of current methods and the adoption of new experimental approaches represent important directions for future investigation. The selection of tests should be hypothesis-driven, based on existing cognitive data in SLE and on the underlying models of cognitive deficit that would relate to proposed pathogenetic mechanisms [259].

Longitudinal studies are essential to assess the predictive utility of various risk factors that have been associated cross-sectionally with NP involvement (e.g., autoantibodies, cognitive dysfunction) and to identify key factors associated with cognitive improvement or decline. In addition, multicenter randomized controlled intervention trials should be undertaken where the existing data support them: for example, the use of anticoagulant therapy in aPL positive patients [183–186] with the inclusion of cognitive data as an end point [109, 237–239].

The heterogeneous presentation of NP-SLE complicates studies of its pathogenesis. Neuropsychological measures that correlate specifically with a postulated pathogenetic mechanism (e.g., autoantibodies) can serve to limit the focus of study to subsets of patients. The same can be accomplished by differentiating the larger patient group into discrete clinical presentations (e.g., stroke, depression) that may then be studied in relation to cognitive and biological correlates, the latter augmented through the use of structural and functional brain imaging. Neuropsychological measures may themselves be subjected to statistical approaches for

subgrouping patients for further study of clinical correlates and underlying mechanisms [260, 261].

Finally, another important direction in cognitive research in SLE is the development of brief, well-validated test batteries (e.g., [114, 262]). This would have clinical utility for routine patient monitoring, as well as research utility, as part of large, multicenter investigations of the assessment, etiology, and treatment of NP-SLE. The development of a consensual approach to brief neuropsychological assessment was one of the foci of an ad hoc workshop on nomenclature and classification sponsored by the ACR [22]. A 1-hour battery was proposed, using existing clinical tests to assess the areas of complex attention, memory, visual–spatial processing, language, psychomotor speed, motor speed and dexterity, and executive function. A subjective measure of cognitive function and an assessment of impact on daily living were also recommended. There remains the need to validate such a short battery against a full neuropsychological assessment and to collect norms on healthy controls in order to ensure its diagnostic efficacy and capacity to identify clinically significant change over time. Until this is done, the use of a brief cognitive battery in the clinical setting remains problematic in the absence of appropriate professional consultation. Nevertheless, the consistent use of such a battery across various study centers would greatly facilitate future research efforts and, ultimately, clinical approaches to NP-SLE. The various ways that cognitive data might contribute to future studies of NP-SLE are summarized in Table 6.

TABLE 6 Future Directions: Cognition as a "Tool" to Study NP-SLE[a]

Longitudinal studies: risk factors for NP involvement, including cognitive dysfunction
Randomized controlled trials of steroid/anticoagulant/immunosuppressive therapy in subsets of patients defined by NP-SLE presentation and/or potential pathogenetic mechanisms (e.g., aPL)
Depression as a primary manifestation of NP-SLE
Statistical approaches to subgrouping patients according to cognitive profiles
Experimental cognitive paradigm to specify underlying cognitive deficits
Validation of brief cognitive batteries for clinical use and research applications
Collaborative studies using cognitive and imaging approaches

[a] All of the research directions outlined above would be facilitated and enhanced through multicentered collaborations.

SUMMARY

Broad-based neuropsychological assessment strategies have proved to be sensitive to the presence of cognitive impairment in patients with SLE, and have uncovered significant impairment even in patients without overt neurologic or psychiatric symptomatology. Although responses to self-report questionnaires indicate emotional distress in a fair number of SLE patients, a significant association between the presence of cognitive impairment and distress is not evident. Moreover, the documented cognitive impairment cannot be attributed to possible adverse side effects of corticosteroids, and is not strongly associated with the presence of active disease. Thus, cognitive impairment, when documented in SLE patients, most likely reflects central nervous system dysfunction; this may be residual, in the case of patients with inactive CNS symptomatology, or perhaps an early marker or predictor of CNS involvement, in the case of patients who have never had major CNS symptomatology. It is important to note that there is limited concordance between the deficits that are identified by directly comparing control and SLE groups and the deficits that are identified in individual test protocols, applying decision criteria commonly used in clinical neuropsychological assessment. This suggests a relatively limited clinical utility for data from group studies, no matter what the patient population, unless there is a well established homogeneity in neurologic presentation.

Thus, the cognitive deficits described in SLE patients, most probably due to no other process but SLE itself, represent an extremely important index of central nervous system dysfunction, probably related to, or as a consequence of, immunological mechanisms such as brain-specific autoantibodies, "neurotoxic" or "neuroactive" cytokines, and/or inflammation. Attempts to reliably investigate the pathogenesis of NP-SLE in its clinical or subclinical manifestations and ascribe it to an autoimmune and/or inflammatory process would be considerably enhanced by the use of standardized neuropsychological assessments of brain function complemented by brain imaging studies, particularly if this enabled the identification of patient subgroups, across various centers. Such multicenter studies also have the potential to validate brief cognitive batteries that would be relevant to the assessment and monitoring of cognitive function in clinical practice.

LUPUS ERYTHEMATOSUS AND THE SKIN

Daniel Mimouni
Carlos H. Nousari

INTRODUCTION

The term *lupus* (Latin for wolf) was used in the medieval period to describe several skin disorders. Some disorders were related to wolflike facies and others to skin lesions resembling wolf bites. These dermatoses included *lupus vulgaris*, a form of cutaneous tuberculosis; *lupus pernio*, a nasal form of cutaneous sarcoidosis, and *lupus erythematosus* (LE), an autoimmune disease.

Cazenave, a French dermatologist and Kaposi, a Hungarian dermatologist, respectively, were the pioneers in describing the cutaneous and systemic involvement of LE. See Rowell [1] for a comprehensive review and discussion of the historical aspects of cutaneous LE.

The importance of thorough dermatologic evaluation for a correct diagnosis and management of LE has been indisputably established since the original description of the disease. This chapter is intended to provide the practicing physician with a practical, yet comprehensive approach for the diagnosis and management of patients with cutaneous manifestations of LE (CLE).

CUTANEOUS FORMS OF LUPUS ERYTHEMATOSUS

Clinical and Immunopathologic Correlation

In addition to a complete history, a methodical physical examination of the skin is mandatory in LE patients. "A literal head-to-toes" screening is a practical and reliable approach to the skin examination. For example, one should start at the head, with a careful examination of the scalp searching for various forms of alopecia and discoid lesions of the ear canals. The exam should extent out to the acral areas such as the hands where periungual telangiectasia or palmar discoid lesions are common. We will discuss in more details more specific findings throughout this chapter where we illustrate a practical, location-oriented approach (Table 1).

To complete the evaluation of the patient, a skin biopsy for routine histology and direct immunofluorescence examination as well as pertinent serologic studies are mandatory. The routine histologic examination of skin biopsies requires a careful reading of a representative specimen, deep incisional sampling in subcutaneous LE, or erythematous, scaly areas in discoid LE (DLE).

The direct immunofluorescence evaluation (DIF) is an extremely helpful diagnostic tool in the assessment of autoimmune skin diseases. This technique consists of an evaluation of bound immunoglobulin and complement on frozen sections using fluoresceinated antisera. This technique is extremely helpful in the interpretation of lesional LE. In the past, the identification of immunoreactants using DIF in nonlesional, non sun-exposed areas was named Lupus band test (LBT) [2, 3]. This LBT was used as predictor of systemic disease. However, with a better understanding of the disease and more reliable tests including antinuclear antibodies,

TABLE 1 Skin Examination, Location, Lesion in Lupus Erythematosus

Head
Scalp
Alopecia: scarring (DLE) vs nonscarring (telogen effluvium)
Ear
Helix—DLE, lupus perniosis (earlobe)
Ear canal—DLE
Cheek
Butterfly (malar rash)—SLE
DLE
Lupus panniculitis
Photosensitivity (in all photodistributed areas)
Mouth
DLE
Aphthous ulcers
Trunk and proximal extremities
Psoriasiform and annular SCLE plaques
Photosensitivity
Poikiloderma
Urticarial vasculitis
Lupus panniculitis
DLE
Distal extremities
Small (palpable and nonpalpable purpura) and medium-sized vasculitis (nodules, ulcers, livedo reticularis [MVV and APLsx])
Palms and soles
DLE
Periungual telangiectasia
Chilblain—lupus perniosis
Small and medium sized vasculitis (digital infarcts)

and complement activation products, among others, the LBT has been abandoned.

In addition to the immunopathologic assessment, a pertinent serologic evaluation is of major importance. For example; the presence of anti-Ro antibodies in neonatal LE or subacute CLE or ANA in the setting of a butterfly eruption are powerful adjunctive diagnostic tools [4]. From a practical perspective, the clinical forms of cutaneous LE are classically divided into: (1) chronic cutaneous (CCLE), including DLE, lupus tumidus and lupus profundus, (2) subacute cutaneous lupus erythematous (SCLE), with annular and psoriasiform variants, and (3) acute systemic LE (ACLE), demonstrating a diffuse, erythematous butterfly eruption. The latter two are more commonly associated with systemic disease. However, all forms of cutaneous LE fall into a spectrum where overlapping skin manifestation is the most common clinical scenario. For didactic purposes we will continue this nomenclature throughout the chapter.

CHRONIC CUTANEOUS LUPUS ERYTHEMATOSUS

Discoid Lupus Erythematosus

Definition

Disk-like plaque lesions.

Clinical Findings

Classic DLE lesions, the most common form of CCLE, are present in 15–30% of SLE (data reviewed in Sontheimer and Provost [2]). Approximately 5% of patients presenting with isolated localized DLE will subsequently develop overt and fulminant systemic lupus erythematosus (SLE) [5]. DLE can present in infants and the elderly; however, it is most common between 20 and 40 years of age. It has a female: male ratio of 3:1, significantly lower than that of SLE and other forms of CLE such as SCLE. An increased prevalence in African-Americans has been well established.

Significant increases of human leukocyte antigen (HLA) B7, B8, Cw7, DR2, DR3, DQW1, and a significant decrease in HLA-A2 has been reported for DLE patients [6]. The combinations of HLA-Cw7, DR3, DQW1, and HLA-B7, Cw7, DR3 conferred the maximum relative risk (7.4) for DLE.

Immunodeficiency states are known to have an increased incidence of autoimmune disorders. DLE also occurs with increased frequency in female carriers of x-linked chronic granulomatous disease, common variable immunodeficiencies, and C1q, C2, and C4 deficiencies [7, 8].

Discoid lupus erythematosus lesions are discrete, erythematous well-defined plaques covered by an adherent scale that extends into dilated hair follicles. Hyperpigmentation is often present in the initial phases; however, eventual loss of pigment occurs in the center of older, scarred lesions. The plaques slowly expand, with active indurated erythema at the periphery, leaving depressed scars, telangiectasias, and depigmentation that are often permanent. The central atrophic scarring is very characteristic. These lesions occur most often on the head and neck areas, in particular the ear canal (Fig. 1) and scalp (Fig. 2) should always be examined. It should be noted that lichen planopilaris of the scalp may mimic both the clinical and histopathological picture of DLE.

The term *localized DLE* is used to describe those patients who have lesions only on the head or neck. *Generalized DLE* is the preferred designation when lesions are present both above and below the neck (Figs. 3, 4, 5). Of the patients with localized DLE, 90–95% will continue to have disease limited only to the skin [5,

FIGURE 1 Discoid lupus erythematosus lesion of ear canal showing atrophic erythematous plaques with postinflammatory hyperpigmentation.

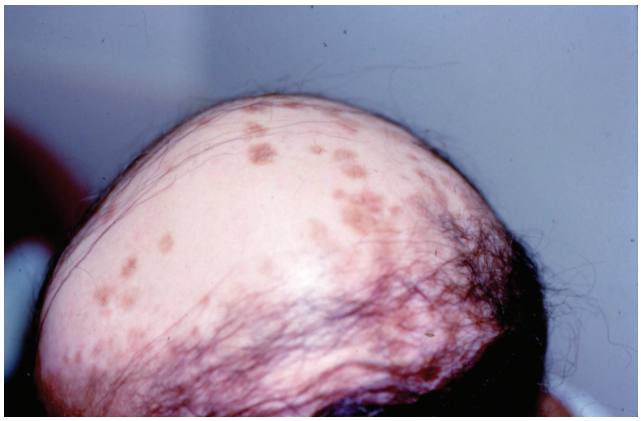

FIGURE 2 Burnt out discoid lupus erythematosus lesions of the scalp showing scarring alopecia with postinflammatory hypo- and hyperpigmentation.

FIGURE 3 Generalized discoid lupus erythematosus with extensive disfiguring facial involvement.

FIGURE 4 Generalized discoid lupus erythematosus with trunkal lesions.

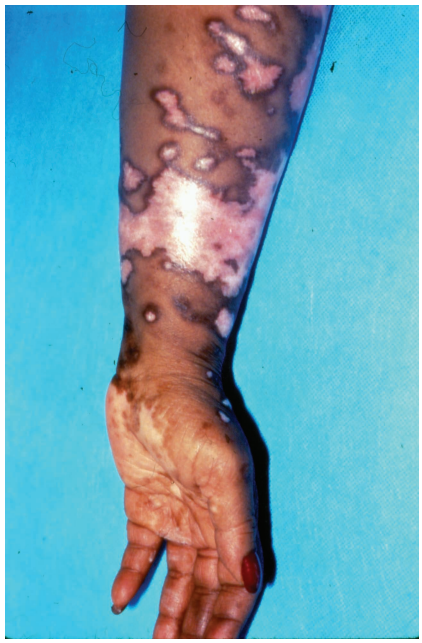

FIGURE 5 Generalized discoid lupus erythematosus with large lesions affecting arms and hands.

FIGURE 6 Palmoplantar discoid lupus erythematosus with diffuse atrophic erythematous scaling lesions affecting the palms.

9–15]. Although laboratory abnormalities such as positive anti-nuclear antibody (ANA), false positive tests for syphilis, leukopenia, and increases in the erythrocyte sedimentation rate suggest low-grade systemic disease, aggressive or life-threatening systemic LE rarely develops. Patients with generalized DLE appear to be at somewhat higher risk for having or developing SLE compared with localized DLE [14–16].

Palmoplantar and mucosal DLE lesions lack specific clinical features (Fig. 6). One of the main reasons is the lack of hair follicles at those sites, hence, the absence of follicular plugging as a cardinal clinical sign. One the most common clinical and histologic misdiagnoses given to patients with palmoplantar and mucosal DLE is lichen planus. Patients with palmoplantar DLE commonly have periungual involvement leading to nail dystrophy. The lack of pruritus in these cutaneous LE lesions attests firmly against a diagnosis of lichen planus.

The clinical and even histologic similarities between LE and lichen planus in mucous membranes are more striking and challenging. However, a few clinical tips often help in the differentiation: (1) Primary mucosal DLE is extremely rare, and is virtually always occurring in the setting of cutaneous DLE. (2) Oral DLE is most commonly seen in the buccal mucosa [17]. The vast majority of these patients have concomitant labial DLE. Similarly, conjunctival DLE often complicates patients with eyelid DLE.

Relationship with SLE

Patients tend not to develop clinical and/or serologic evidence of SLE; however, approximately 5% of patients presenting with isolated localized DLE will subsequently develop full-blown SLE [5]. Table 2 summarizes the predictors of associated systemic disease in patients with DLE.

TABLE 2 Predictors of Systemic Disease in Patients with DLE Lesions

Generalized DLE lesions
Palmoplantar DLE
DLE in setting of genetic complement deficiencies
DLE associated with constitutional symptoms
DLE associated with acute phase reactants or complement activation
DLE setting with a nonspecific ANA at significant titers (fine speckled >1:320)
DLE setting with a specific ANA (Anti Sm, Ro)
DLE in male patients?

Immunopathology

Routine Histology

All of the clinical presentations of DLE have a common dermatopathologic finding: A lymphocytic dominant, bandlike infiltrate at the dermal–epithelial junction (also referred to as interface infiltrate or lichenoid infiltrate). This infiltrate usually disrupts the basement membrane and epithelial basal cell layer (vacuolar degeneration). Other findings include periadnexal infiltrates, thickening of the basement membrane, dermal mucin deposition, and epidermal atrophy. All of these findings may be valuable but are not constant features.

DIF

Virtually all DLE lesions have deposition of immunoreactants at the basement membrane zone (BMZ) of the epidermal–dermal junction [18]. However, false negative and positive results are sometimes observed, primarily due to technical factors.

Any immunoreactant can be observed at the BMZ, however, by far the most common in DLE is granular "ribbon-like," coarse IgM deposits along the BMZ. IgG, IGA, and C3 are occasionally observed (Fig. 7). The immunologic findings of early lesions are more prominent at the adnexal BMZ pilosebaceous unit than at the epidermal BMZ.

Prognosis

The natural history is variable; however, in most of the cases the DLE will eventually resolve without therapy [19–21]. Therefore, the necessity of therapy is dictated by (1) The prevention of permanent atrophy and potential disfiguring sequellae (2) The potential benefit of systemic therapy in preventing new lesions.

It has been suspected that around 15% of patient with DLE would develop or already have systemic disease [19]. However, generalized DLE and palmo-

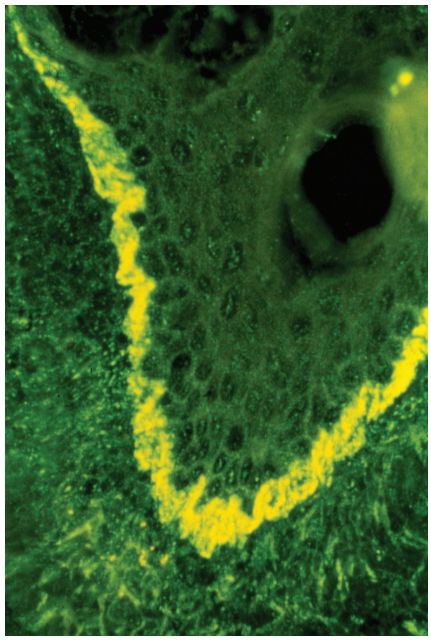

FIGURE 7 Direct immunofluorescence examination of a discoid lupus erythematosus lesion. There is a thick granular band of IgM deposited along the dermal–epidermal junction.

FIGURE 8 Face of a patient with lupus tumidus showing erythematous, edematous, infiltrative plaques on the cheeks.

plantar DLE have a higher frequency of constitutional symptoms and evidence of overt systemic disease than other subsets of DLE. Oral mucosal DLE lesions can degenerate into squamous cell carcinoma, as can be seen in long-standing cutaneous DLE lesions [22]. Any degree of nodular asymmetry within a mucosal DLE lesion should be evaluated for the possibility of malignant degeneration.

LUPUS Tumidus

Definition

Swollen, puffy lesions.

Clinical Findings

This frequently underrecognized subset of LE is characterized by urticaria-like papules, nodules, or plaques favoring head and neck areas, upper trunk, and proximal extremities. Plaques are commonly 2–4 cm with rounded or annular configuration (Fig. 8).

In contrast to classic urticaria, lesions in lupus tumidus (LT) are nonpruritic and last longer than 24–48 h [23]. As opposed to DLE and SCLE, lupus tumidus lesions lack the epidermal changes of hyperkeratosis, atrophy, depigmentation, and follicular plugging. The prevalence of this subset of LE is unknown; however, it seems to be higher in the Asian population. Several conditions included under the rubric of benign lymphocytic infiltrates of the skin may represent misdiagnosed cases of lupus tumidus.

Relationship with SLE

Patients tend not to develop clinical and/or serologic evidence of overt SLE; however, nonspecific findings such as low titer ANA, myalgias, intermittent mild cytopenias, and elevated ESR are not uncommon.

The sun-exposed location, higher prevalence in summertime, and benefit of some patients with sunblocks are indirect evidence of a sun-related variant in at least some of these patients. However, despite the higher association of anti-Ro antibodies in Asians, this feature has not been consistently found in non-Asians [24–26].

Immunopathology

Good clinicopathologic correlation and high index of suspicion of this variant is necessary to achieve a correct diagnosis. The histologic features are dominated by a perivascular and periadnexal lymphocytic infiltrate with minimal interface dermatitis. The presence of mucin in these specimens is an important histologic clue for the diagnosis [27, 28]. Although increased mucin is not a specific finding, it supports the diagnosis in the context of the more specific clinical findings.

Lupus tumidus may be interpreted as a variant of LE with dermal predominance. Benign lymphocytic infiltration, Jessner's lymphocytic infiltration, polymorphous light eruption, and reticular erythematous

mucinosis should all be included in the differential diagnosis [23]. However, It is noteworthy to mention that several cases of the so-called Jessner's lymphocytic infiltration and other "benign" lymphocytic infiltrates of the skin may have been misdiagnosed cases of LT.

DIF

Due to the scant or even lack of interface dermatitis in these lesions, deposition of immunoreactants at the BMZ is not usually observed. However, DIF remains an important tool in excluding other conditions that may clinically mimic LT, for example, urticarial vasculitis and annular lesions of SCLE.

Prognosis

Generally good. The lesions tend to resolve with or without treatment over years. Most of the patients respond to antimalarials and sunblocks.

Lupus (Profundus) Panniculitis

Definition

Lupus erythematosus of the skin with primarily and predominantly involvement of the subcutaneous fat (panniculus) [29–32].

Clinical Findings

The lesions of lupus panniculitis (LP) are deep, firm nodules and plaques with or without overlying DLE features. They occur primarily in areas prone to trauma, namely, on the cheeks, shoulders, thighs, and breast; however, any area can eventually be involved (Fig. 9). LP may produce breast nodules that mimic carcinoma clinically and radiologically (i.e., lupus mastitis) [33].

FIGURE 9 Girl with extensive atrophic plaques of lupus panniculitis (profundus) affecting the cheeks, and discoid lupus erythematosus plaques in the nose and eyes.

As older lesions of LP resolve, deep depressions and dystrophic calcification that at times can produce extensive ulcerations are not uncommonly encountered.

Most of the patients present with one or two lesions. However, generalized cases can also be seen, especially in the setting of hereditary complement deficiencies [34]. As opposed to patients with localized disease, most, if not all, patients with generalized LP have concomitant DLE overlying or elsewhere [35]. The lack of this feature should prompt the reevaluation of the diagnosis of LP in the setting of a lobular lymphocytic panniculitis.

It has been shown that other connective tissue diseases including morphea, dermatomyositis, and overlap syndrome may have inflammatory panniculitis lesions that are both clinically and histologically indistinguishable from LP [36]. The differential diagnosis includes other causes of panniculitis: (1) neoplastic; (2) inflammatory; and (3) infectious.

1. In the neoplastic category, the main disease for consideration is the subcutaneous panniculitis T-cell lymphoma. The vast majority of cases have been initially misdiagnosed primarily in the setting of hemophagocytosis-associated cytopenias and constitutional symptoms.

Several clinical clues aid in the differentiation: (A) absence of DLE lesion overlying the panniculitis or elsewhere in the setting of numerous panniculitic plaques, (B) the presence of significant constitutional symptoms (e.g.: fever, myalgias), (C) absence of significant serologic findings, (D) severe cytopenias in the setting of LE, (E) significant increase of LDH in absence of evidence of hemolytic anemia, and (F) atypical histopathology for LP.

2. In the inflammatory category: alpha 1 anti-trypsin deficiencies, pancreatitic panniculitis, sarcoidosis, factitial disorders, the so-called Weber Christian disease, and /or cytophagic panniculitis (the two last disorders have been definitively proved to be reclassified as LP, subcutaneous lymphomas, or any of the aforementioned inflammatory panniculitides) [37]. All these diagnoses require careful clinicopathologic correlation.

3. Infectious: deep-seated common bacterial pathogens, mycobacteria, and fungal pathogens are the most common mimickers of LP.

Relationship with SLE

Like in DLE and LT, most of the patients with LP do not have overt SLE symptoms. However, patients with generalized lesions have an increased incidence of smoldering or even overt SLE.

Immunopathology

The cardinal histologic feature of LP is lobular-predominant lymphocytic panniculitis. There are no specific features; however, follicular aggregates with germinal center formation, significant plasma cell infiltrates, and hyalinization of fat lobules and vessels, with variable interface dermatitis of the adnexal and/or epidermal BMZ are very characteristic. Only the few patients with significant interface dermatitis of the epidermal and/or adnexal BMZ would have granular deposits of immunoreactants.

The presence of the following features strongly argue against the diagnosis of LP and favor the most serious differential diagnosis, namely: subcutaneous panniculitic lymphoma: (1) cytologic atypia, (2) karyorrhexis, (3) lymphocyte rimming around adipocytes, (4) histiocytes with cytophagia, and (5) evidence of monoclonality in the T/NK cell infiltrate [38]. As in any inflammatory skin disease, to achieve a correct final diagnosis, it is mandatory to conduct a thorough clinicopathologic correlation.

Prognosis

The lesions of LP as a rule resolve spontaneously. In most patients this occur within 3–4 years. Because of the visible locations and cosmetic implications, effective immunosuppressive and/or immunomodulatory drugs should be started promptly. It is imperative that any kind of surgical or reconstructive procedure be done after complete and sustained remission.

SUBACUTE CUTANEOUS LUPUS ERYTHEMATOSUS

Definition

Cutaneous form of the disease that clinically and immunopathologically oscillates between DLE and SLE. It is strongly associated with photosensitivity and anti-Ro antibodies.

Clinical Findings

Clinical findings are ill-defined, noninfiltrative plaques favoring trunk and proximities, with predilection for, but not limited to sun-exposed areas. Two clinical subsets have been described: (1) annular and, (2) psoriasiform. The former tend to have less epidermal involvement and occasionally an urticarial configuration (Figs. 10 and 11). Frequently, the annular form will have a centripetal location as opposed to the psoriasiform which often presents with significant scales and more centrifugal distribution (Fig. 12). It is mandatory to include the psoriasiform SCLE subset in the differential of psoriasiform dermatitis, especially before enrolling a patient for phototherapy. The "Rowell syndrome" (erythema multiforme-like lesion in LE) represent in the majority of the cases the annular variant of SCLE.

A subset of drug-induced, Ro positive LE has been described in the literature (Table 3 illustrated the cutaneous LE variants in the presence of anti-Ro). As opposed to the classic anti-histone induced LE these patients have striking cutaneous findings. These lesions are the same as SCLE lesions and/or diffuse photosensitive erythema. The most common implicated drugs are: anti hypertensives (hydrochlorothiazide, angiotensin converting enzyme inhibitors, calcium

FIGURE 12 Papulosquamous lesions of subacute cutaneous lupus erythematosus. These lesions frequently involve the upper chest, upper back, shoulders, extensor surfaces of the arms, and dorsum of the hands and fingers and have a psoriasiform configuration.
