Others; statins, interferons, minocyclin

channel blockers), antifungals (terbinafine, griseofulvin), and interferon (Table 4) [39–43].

Genetic deficiencies of various complement components, including C2, C3, C4, and C5, as well C1 esterase inhibitor, have been associated with both SCLE and DLE.

Relationship with SLE

Approximately one-half of these patients can be classified as having SLE by the American College of Rheumatology revised criteria; however, serious central nervous system disease or progressive renal disease is uncommon. Most of these patients are anti-Ro antibody positive. A significant number of these patients have smoldering systemic disease. Interestingly, the incidence of overt Sjögren's syndrome, another subset of LE strongly associated with anti-Ro, is not commonly seen in SCLE patients. Women with SCLE and anti-Ro antibodies represent the highest risk group for the development of neonatal LE in their offspring [44].

Immunopathology

The interface dermatitis in the annular variant is often patchy, without significant periadnexal infiltrates, mucin deposition, or follicular plugging. More obvious histologic evidence of the disease is seen in the psoriasiform variant.

Direct immunofluorescence evaluation has a highly characteristic immunofindings: granular IgG with fine specking "dustlike" [45] deposits along the BMZ and throughout the lower epidermis [29]. Although this is a very sensitive finding, it is not specific, and can be seen in SLE patients. Variable granular C3 or another immunoreactant can also be seen.

Prognosis

A quarter of these patients will develop overt SLE. However, the vast majority will have variable sign and symptom throughout the course of the disease. Although complete resolution is common with or without therapeutic intervention, relapses are almost the rule in these patients. It is imperative to identify the drug-induced variant since discontinuation of the drug is commonly associated with complete resolution of the disease. As will be discussed in the treatment section, photoprotection is the most important therapeutic measure.

Neonatal LE

Definition

Neonatal LE (NLE) is defined by the presence of cutaneous LE lesions in the newborn with or without systemic involvement.

Clinical Findings

Neonates from mothers with anti-Ro and/or RNP1 SLE develop cutaneous disease. The most common and characteristic eruption is a periorbital "owl-eye" appearance (heliotrope-like) with erythematous and violaceous, often-scaly patches. However, other lesions,

including annular scaly plaques and cutis marmorata, are also commonly seen in these newborns. Overall, the cutaneous lesions in NLE favor head and neck areas and extremities. The cutaneous manifestations of NLE as a rule would resolve spontaneously in less than a year. Systemic involvement is seen in less than 20% of NLE and includes: (1) cardiac disease, namely heart block. When this complication occurs it is permanent; (2) transient hematologic findings including cytopenias; and (3) increased liver enzymes [46].

Relationship with SLE

Virtually all mother and neonates are anti-Ro positive. About a third of these patients may have concomitant anti-RNP1. There is no clear association between the autoantibodies and the clinical features of NLE patients. It is not clear whether children with past medical history of NLE are at higher risk for developing any form of LE in their adulthood.

Immunopathology

Histologic examination shows interface dermatitis, and DIF demonstrate granular IgG deposits along the BMZ and throughout the lower epidermis. These immunofindings are identical to those seen in SCLE lesions.

Prognosis

Cutaneous, hematologic, and hepatic complications resolve spontaneously and do not impose a significant clinical challenge. Conversely, high index of suspicion about this diagnosis is required since, the cardiac complications are permanent and potentially life threatening. The influence of treating the mother to decrease the incidence of NLE is unknown; however, effective management including sun-protection, antimalarials, and immunosuppressive therapy throughout pregnancy is highly recommended.

ACUTE CUTANEOUS LUPUS ERYTHEMATOSUS

Definition

Cutaneous form of LE in the setting of active systemic disease.

Clinical Findings

These cutaneous lesions occur always in the setting of "overtly" active systemic disease. The most common presentation is usually overlapping cutaneous lesions. The typical lesions are classified as follow: (1) Butterfly malar rash, (2), erythematous maculopapular scaly rash (3) mucosal apthae, (4) photosensitivity, (5) diffuse nonscarring alopecia (telogen effluvium), and (6) vasculitis

1. **Butterfly eruption** (Figs. 13 and 14) has been traditionally underscored as cutaneous finding of LE. One of the most common misdiagnoses in a butterfly eruption is rosacea. The following clinical features help distinguishing these two entities: (1) butterfly malar LE eruption rarely occurs as a sole manifestation of active cutaneous LE. This type of eruption has a strong association with photosensitivity, and therefore virtually all of these cases would have other cutaneous photosensitive findings. (2) Butterfly malar LE eruption is a manifestation of SLE and always occurs in the setting of "systemic disease." In the past other distinguishing features were overemphasized including: involvement of the nasolabial fold, significant telangiectasias without poikiloderma, and presence of follicular pustules, more features that favor rosacea or seborrheic dermatitis over LE, However, these "clinical pearls" often lead to misdiagnoses, and should be utilized with great caution.
2. **Diffuse maculopapular eruption** (Fig. 15) is often scaly and more prominent in photoexposed areas;

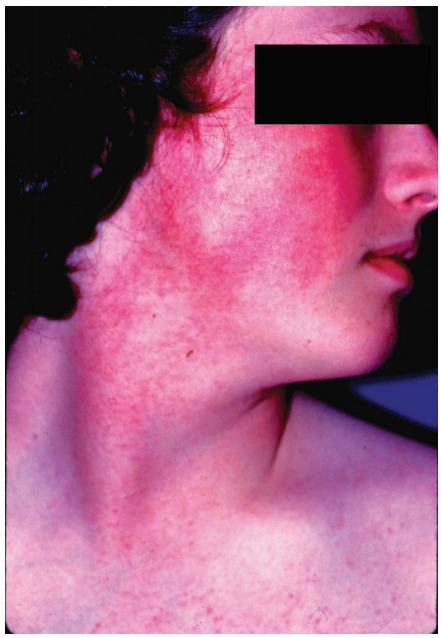

FIGURE 13 Localized acute cutaneous lupus erythematosus in a patient with a flare of systemic lupus erythematosus showing a photosensitive diffuse erythema of the face with a butterfly configuration.

FIGURE 14 Acute cutaneous lupus erythematosus in a patient with a flare of systemic lupus erythematosus showing a photosensitive diffuse erythema of the face with a butterfly configuration with periorbital, perioral, and nasolabial fold sparing.

FIGURE 15 Same patient as in Fig. 14 with a diffuse maculopapular and scaly eruption affecting the face, trunk, and upper extremities. Note the sparing of the dorsal aspects of the interphalangeal and metacarpophalangeal joints.

however, covered areas are commonly involved. This manifestation often but not always occurs in the presence of the butterfly eruption.

3. **Recurrent aphthous stomatitis** (RAS) in the setting of SLE is a common feature. These ulcers have a variable degree of pain, the size varies from a few millimeters (minor) to centimeters (major). Since, RAS affects up to 20% of normal people, this mucosal finding should be taken cautiously. The presence of active SLE, atypical location for aphthae, for example, palate, and absence of family history of RAS, favor SLE-associated RAS over idiopathic aphthae.

Photosensitivity, **alopecia**, and **vasculitis** will be discussed in other sections of this chapter.

Immunopathology

The immunopathology is interface dermatitis without significant hyperkeratosis or epidermal atrophy, without significant mucin deposition or periadnexal infiltrates. DIF is positive in all patients and is manifested by granular IgG and C3 along the BMZ (Fig. 16). Other immunoreactants can also be seen. Often *in vivo* ANA is seen in these specimens.

In the past the term LBT was used to predict or diagnose SLE. This test should be abandoned due to the highly frequency of erroneous results and availability of more accurate tests to diagnose SLE.

Prognosis

Acute cutaneous lupus erythematosus has no relationship with any specific ANA. However, anti-Ro and

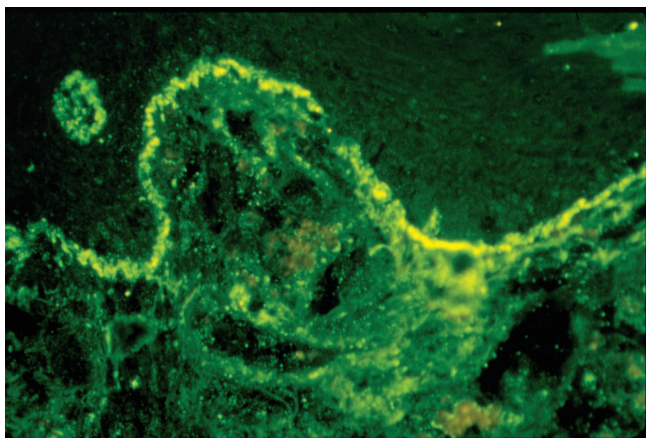

FIGURE 16 Direct immunofluorescence evaluation of lesional skin in a patient with acute cutaneous lupus erythematosus showing granular IgG deposition along the basement membrane zone.

anti-DsDNA and anti-RNP are commonly found in these patients. Photoprotection and antimalarials are helpful as adjuvant therapy. Topical steroids are pointless since an immune complex mediated disease should be treated by systemic immunosuppressive therapy.

PATHOGENESIS OF CUTANEOUS LUPUS ERYTHEMATOSUS

Increasing evidence suggests that autoantigen-specific T cells play a role in the pathogenesis of other organ-specific autoimmune disorders such as autoimmune thyroiditis and multiple sclerosis. Autoreactive T cells could also play a role in the pathogenesis of forms of CLE such as DLE that are not associated with specific autoantibodies. Evidence suggests that T cells in CLE lesions are oligoclonal and are predominately of the $CD4^+$ Th1 phenotype, supporting the idea that antigen-driven T-cell proliferation is occurring within such lesions [47]. T cells recognizing autoantigens being presented by epidermal Langerhans cells might help explain the decreased numbers of Langerhans cells in areas of active CLE inflammation. Epidermal keratinocytes in CLE lesions often express class II histocompatibility antigens as well as adhesion molecules involved in T-cell binding interactions such as intercellular adhesion molecule 1 (ICAM-1). Epidermal basal cell CD40 ligation by infiltrating T cells could contribute to the altered epidermal kinetics that have been observed in CLE lesions (hyperproliferation, normal early differentiation, premature terminal differentiation).

The pathogenic effects of UV (ultraviolet) light in cutaneous LE are poorly understood. Proposed mechanisms include neoantigen formation and autoantigen modulation, exaggerated release of immune mediators, and perturbation of cutaneous immunoregulatory circuits [48, 49]. Ultraviolet light has been suggested to induce the expression of "neoantigens" that could become the target of a dysregulated immune attack. It has also been shown that UVB can displace autoantigens such as Ro/SSA and the related autoantigens, La/SSB and calreticulin, from their normal locations inside epidermal keratinocytes to the cell surface. Evidence suggests that UV-induced keratinocyte apoptosis may be a major mechanism responsible for this aberrant pattern of cell-surface autoantigen expression [50]. Cell-surface expression would allow Ro/SSA, La/SSB, and calreticulin autoantibodies present in the circulation to bind to the autoantigens that are normally sequestered from the humoral immune response inside cells. Autoantibody binding to the exposed antigens could result in tissue injury through complement-mediated lysis or antibody-dependent cell-mediated cytotoxicity. Infection by some viruses also appears to be capable of inducing cell-surface expression of Ro/SSA, La/SSB, calreticulin, and related autoantigens in cells undergoing viral-induced apoptosis. It is possible that cellular mechanisms other than UV-induced apoptosis are responsible for perturbed autoantigen expression in epidermal keratinocytes and that humoral factors other than anti-Ro/SSA might also be involved in the pathogenesis of LE photosensitivity.

Ultraviolet light may also cause an exaggerated release of immune mediators such as interleukin-1 (IL-1), tumor necrosis factor (TNF-α), prostaglandin E, proteases, oxygen-free radicals, and histamine in genetically predisposed individuals with LE. IL-1 receptor antagonist and TNF-α gene polymorphism has been implicated as a genetic factor in CLE. Aberrant expression of adhesion molecules, such as ICAM-1, could also play a role in the pathogenesis of LE photosensitivity. Ultraviolet light may also directly affect immunoregulatory cells, such as cutaneous T cells that normally help suppress "abnormal" patterns of cutaneous inflammation. These and related issues have been discussed elsewhere in greater depth than is possible here [48, 49, 51–53].

Other Clinical Presentations

Photosensitivity

Photosensitivity has been defined by the American College of Rheumatology within its 11 classification criteria set for SLE as "Unusual skin reaction from exposure to sunlight, by patient's history or physician's observation [54]." This rather broad definition could include a heightened response to UV-induced erythema (i.e., a decreased minimal erythema dose), an abnormally prolonged UV-induced erythema phase (i.e., the sunburn that does not resolve at a normal rate), the elicitation or exacerbation of CLE skin lesions, or the elicitation or exacerbation of completely unrelated photosensitive skin conditions (e.g., acne rosacea, polymorphous light eruption, photoallergic contact dermatitis). In fact, work has suggested that as many as 50% of SLE patients also suffer from polymorphous light eruption, a benign photodermatosis without systemic manifestations [55]. The subjective aspect of the American College of Rheumatology's definition of photosensitivity and its lack of specificity raise serious questions as to its usefulness in either clinical or experimental studies, and it has been argued that some type of quantifiable end point determined by phototesting should be included in the definition of LE photosensitivity [56, 57]. Exposure to sunlight or artificial sources

of UV irradiation (unshielded fluorescent lighting, some photocopiers) is a well-recognized and frequent precipitating factor for both the systemic and cutaneous manifestations of LE (see Sontheimer [48] for a comprehensive review of all aspects of LE photosensitivity). Patients with SCLE and ACLE are especially photosensitive, whereas those with DLE show less photosensitivity. The presence of anti-Ro/SSA autoantibody is an additional risk factor for LE photosensitivity, thus the high rate of photosensitivity in patients with SCLE lesions. Early studies demonstrated that CLE lesions could be provoked in the clinically normal skin of patients with both SLE and CLE by repeated delivery high doses of UVB to the same test site. More recent studies have argued that UVA can also induce CLE lesions, especially SCLE [58–60]. In addition, long wave UVA-I has been reported to be capable of playing a role in SLE photosensitivity [56], an observation that is somewhat contradictory to the more recent work suggesting that UVA-I phototherapy might be of therapeutic value in CLE and SLE. Mononuclear cell accumulation in dermal perivascular areas has been the first recognizable pathologic change in UV-induced LE skin lesions. Deposition of Ig and complement components at the dermal–epidermal junction has been observed to follow the appearance of perivascular cellular inflammation in UV-challenged skin arguing against a primary, initiating role for such immune deposits in the pathogenesis of LE-specific skin disease.

From a practical perspective it is wise and prudent to assume that all CLE patients have variable degrees of photosensitivity most commonly to UVB, but also to UVA and visible light. A good history and physical examination is reliable and more practical than phototesting for the diagnosis and management in CLE patients.

Cutaneous Vasculitis

The definition of cutaneous vasculitis has remained a challenge for the clinician as well as for the dermatopathologist. A more comprehensive and practical definition is the following: "*cutaneous vasculitis is an idiopathic, complex, and dynamic inflammatory disorder in which the architecture of the cutaneous blood vessels is disrupted by inflammatory cells and the clinical presentation correlates with the size of the affected blood vessels.*" Each concept in this definition has important clinical application and will be developed in some extent throughout this section. However, we will concentrate on the certain subsets of cutaneous vasculitis that LE patients may develop.

Small Vessel Vasculitis (SVV)

The most useful classification in cutaneous vasculitis is that based on size of the predominantly affected vessels. Small vessels in the skin are venules, capillaries, and arterioles. They are commonly located in the upper dermis, have a poorly developed muscular layer, and they measure less than 50 μm in diameter.

When these vessels are involved, patients will present with purpuric and/or urticarial lesions. The purpuric lesion can be palpable (papules, vesicles, pustules, small superficial ulcer) or nonpalpable (macules and patches). They commonly affect dependent areas, for example, lower extremities as opposed to urticarial vasculitis (UV) lesions which tend to favor trunk and proximal extremities. Unlike classic urticaria, UV lesions are nonpruritic, last longer than 48–72 h, often leave postinflammatory hyperpigmentation, and have associated constitutional symptoms and acute phase reactants [61, 62].

Medium Sized Vasculitis (MVV)

Medium-sized vasculitis affects larger muscular vessels and is commonly located in the deep dermis, dermal subcutaneous, and subcutaneous tissue. There are four clinical presentations in this variant: nodules, large ulceration, livedo reticularis, and digital infarcts.

Large vessel vasculitis such as giant cells arteritis does not often complicate the skin. Some of the pure cutaneous SVV can complicate LE patients, such as Henoch-Schonlein purpura (IgA vasculitis), and cutaneous leukocytoclastic angiitis (hypersensitivity vasculitis). The most common triggers in these vasculitides are infections and drugs, thus LE patients may be at higher risk. However, the discussion of these vasculitides is beyond the scope of this chapter.

Specific Subsets of Cutaneous SVV in LE Patients

Urticarial vasculitis (UV) is the only entity in this group of pure SVV. Urticarial vasculitis is traditionally classified in normocomplementemic UV (NUV) and hypocomplementemic UV (HUV) variants. It is worth mentioning that if more sensitive complement tests than C3, C4, CH50, such as C3a, C5a, and C3bi, are used in UV, several cases formerly classified as NUV would be switched to HUV. NUV is a subset of cutaneous leukocytoclastic angiitis, is triggered by drugs, infection, or chronic inflammatory processes, does not often have systemic involvement, and resolves with or without treatment. Therefore, chronic cases of NUV without known trigger should prompt the revision of the diagnosis of vasculitis [62].

Hypocomplementemic UV on the other hand, is thought by many authorities to be a subset of SLE [63, 64]. Unlike NUV, HUV is commonly associated with systemic involvement, acute phase reactant, positive ANA serology, and distinctive immunopathologic features on the skin.

Both NUV and HUV are a neutrophil-predominant SVV of the skin. DIF is commonly negative in NUV; however, it is positive in virtually all HUV patients. The immunofindings of HUV are characterized by heavy granular IgG and C3 in and around small dermal vessels and also along the BMZ (LBT-like feature) (Fig. 17). It is believed that all patients with HUV have anti-C1q antibodies that appear to be pathogenic [65]. HUV patients should be treated with systemic immunosuppressive therapy.

Lymphocytic Vasculitis (LV)

This vasculitis is a rare SVV that often presents as pigmented purpura resembling Schamberg's disease. The so-called benign hypergammaglobulinemic purpura of Waldenstrom and LV fall into the category of cryoglobulinemia type 2 or 3. Biopsies of very early lesions in these patients will show leukocytoclastic vasculitis. As the lesions evolve, lymphocytes rapidly replace neutrophils. In these patients it is very common to find anti-Ro positive, rheumatic factor positive, polyclonal gammopathy, and occasional monoclonal spike. Lesions rapidly disappear without the need of any intervention [66].

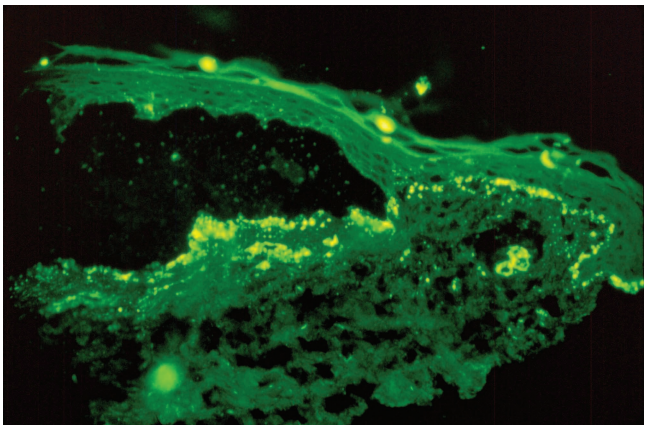

FIGURE 17 Direct immunofluorescence evaluation of an urticarial lesion in a patient with hypocomplementemic urticarial vasculitis syndrome revealing a characteristic granular IgG deposition around superficial dermal vessels as well as at the basement membrane zone (lupus band testlike feature).

The Previously Identified Connective Tissue Disease (CTD)-Associated Vasculitis

These can present as SVV (purpuric lesion) with or without MVV (PAN-like, nodules, ulcers, livedo, digital infarcts) (Fig. 18). This vasculitis is always seen in the setting of systemic and overt SLE.

Systemic involvement due to CTD vasculitis is also common. Peripheral and central nervous system, gastrointestinal, renal, and cardiovascular are not uncommonly affected systems. The histologic features correlate with the size of the clinically affected blood vessel leukocytoclastic SVV for purpuric lesions, and necrotizing MVV for PAN-like, nodules, ulcers, livedo, and digital infarcts. DIF shows IgG and C3 in and around small and medium dermal vessels, usually with a strong *in vivo* ANA (Fig. 19).

Another vasculitis that affects small and medium vessels is cryoglobulinemia type 2 and 3, often seen in LV as previously mentioned. This cryovasculitis syndrome is commonly associated with chronic infections like viral hepatitis, HIV, and lymphoproliferative diseases. CTD are rare causes of cryoglobulinemia. Therefore, the presence of well-documented cryoglobulin in LE patients should prompt the exclusion of underlying

FIGURE 18 Patient with overtly active systemic lupus erythematosus and with CTD-associated vasculitis presented with palpable and nonpalpable purpuric lesion on the lower extremities. Cryoglobulin, rheumatoid factor, and ANCA were all negative. The patient had high titers of ANA, and anti-RNP, and severe hypocomplementemia.

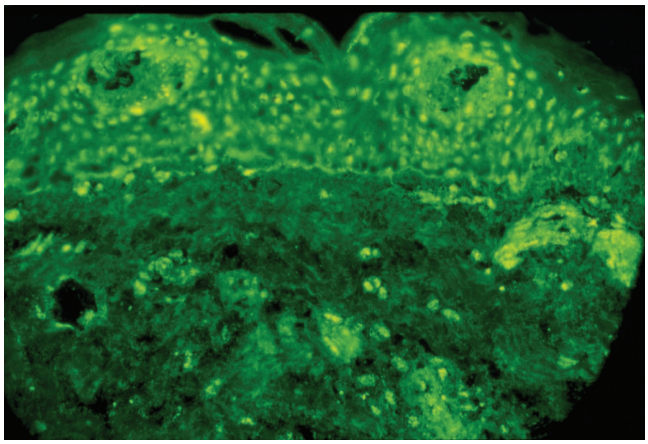

FIGURE 19 Direct immunofluorescence evaluation of the purpuric lesion of the patient in Fig. 18 showing heavy granular IgG deposition around superficial dermal vessel and strong *in vivo* ANA in keratinocytes and dermal cells.

viral infection or lymphoproliferative disease, especially in patients with Sjögren's syndrome [61].

Perniosis

Chilblains lupus perniotic LE lesions initially develop as livid patches and plaques on the toes, fingers, face, and ears that are precipitated by cold, damp climates [67, 68]. These *Chilblains lupus perniotic* lesions both clinically and pathologically overlap DLE and classic Chilblain. Chilblains lupus patients often have typical DLE lesions elsewhere. Approximately 20% of patients presenting with chilblain LE later develop SLE.

Raynaud's Phenomenon

Raynaud's phenomenon (RP) in SLE patients has ranged between 18 and 46% [2, 10, 69, 70]. Among the CLE patients, RP is more prevalent in patients with SLE, SCLE, and generalized CCLE. The presence of periungual telangiectasia, involvement of the thumbs, toes, ears, and nose by RP, ice-picked scars of the pulp, presence of high titers of ANA, and anti-RNP, and nucleolar antibodies are all predictors of LE-associated RP [71].

Degos-like Lesions

There is growing evidence that this ill-defined and controversial entity is a final common pathway. The classic clinical description of Degos is of white porcelain atrophic rounded macules surrounded by telangiectasia (Fig. 20). Patients with the Degos disease can

FIGURE 20 Degos-like lesions in the palms of a patient with generalized discoid lupus erythematosus. Histologic examination of these lesions revealed typical features of discoid lupus erythematosus.

have associated gastrointestinal infraction with perforation, and CNS infarcts [72].

Patients with cutaneous and systemic Degos are likely to have systemic vasculitides (polyarteritis nodosa, etc.) or thrombophilic disease (antiphospholipid syndrome, etc.) or simply SLE. Biopsies of the cutaneous lesion of Degos disease show either vasculopathy or vasculitis with a wedge of dermal necrosis and in some specimens, DLE-type interface dermatitis. Careful clinicopathologic correlation is required when the physician encounters cutaneous lesions that fit into the classic description of the so-called Degos disease.

Antiphospholipid Syndrome (APLS) [73, 74]

Patients with APLS have a primary thrombo-occlusive vasculopathy. One of the former dermatologic syndromes describing APLS was called Sneddon's syndrome describing livedo reticularis and multiple cerebral infarctions. The dermatologic presentation correlates with either arterial, venous, and capillary thrombosis phenomena.

Arterial

Arterial occlusive disease presents with: livedo reticularis (Fig. 21), arterial ulcers, digital infarcts, atrophie blanche, and Degos-like lesions. Livedo reticularis is a mottling eruption accentuated by cold, partly blanchable on pressure, or warming. Severe stage of livedo

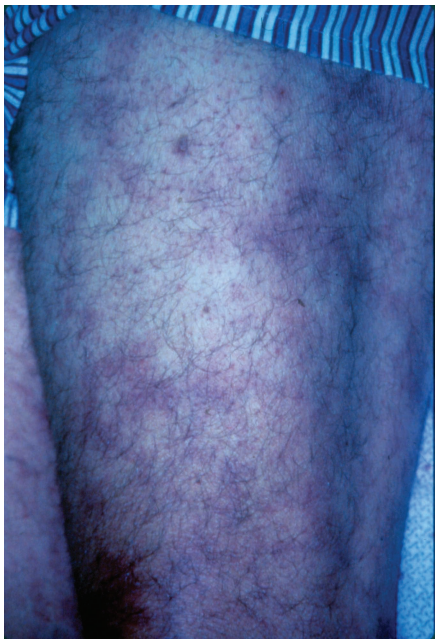

FIGURE 21 Livedo reticularis on proximal lower extremities in a patient with systemic lupus erythematosus and antiphospholipid syndrome. This mottling pattern was partially blanchable on pressure or warming.

FIGURE 22 Lateral face and neck of a patient with smoldering systemic lupus erythematosus (SLE) and with bullous SLE lesions presenting as grouped tense and ruptured blisters resolving with atrophic scarring favoring flexural and head and neck areas.

reticularis is called livedoid vasculopathy and these patients present with ulcerations that heal with stellate scaring (atrophie blanche).

Leg ulcer and digital infarcts are clinically indistinguishable from MVV. Thus, ancillary diagnostic tests are mandatory for a correct diagnosis.

Venous

Venous occlusive disease presents with venous ulcers, lipodermatosclerosis, or superficial thrombophlebitis.

Capillary

A rare and severe presentation of APLS is the so-called catastrophic antiphospholipid syndrome (CAPS) where patients with APLS develop a DIC like picture with purpura fulminans after triggers such as surgeries, discontinuation of anticoagulant, or administrating procoagulant. These skin lesions demonstrate extensive areas of hemorrhagic skin necrosis [75].

Bullous Lesion in LE

Bullous lesions of several types occur in LE (data reviewed in Yell and Wojnarowska [76] and Sontheimer [77]) (Fig. 22). As mentioned, subepidermal bullae may develop in SCLE and ACLE lesions as a reflection of hyperacute injury to the epidermal basal layer that can occur as an extension of LE-specific histopathologic injury. This is the most common mechanism of bulla formation in LE patients. These are extremely photosensitive patients with extensive and active cutaneous and often systemic disease.

Histologically these bullous lesions show severe interface dermatitis with vacuolization and separation of the epidermis thru the BMZ. DIF shows heavy granular IgG, IgM, and C3 deposits along the BMZ (Fig. 23). Two rare overlap autoimmune skin syndromes can complicate LE patients: (1) epidermolysis bullosa acquisita (EBA) and, (2) pemphigus foliaceus (PF). When EBA and PF complicate LE the syndromes are called bullous SLE (BSLE) and pemphigus erythematosus (PE), respectively.

Patients with BSLE develop erythematous vesicles and bullae favoring head, neck, and flexural areas that heals with scars. Half of these patients may have scarring mucositis affecting the mouth and other mucosal membranes. Histologically, it is characterized by an often neutrophils-rich, subepidermal blister. In DIF studies, as opposed to the granular immunostaining seen in the LE interface dermatitis, these bullous SLE patients have a thick linear IgG and sometimes IgA and C3 along the BMZ. All of the patients have been shown to have circulating and tissue bound anti type VII collagen, the principal constituent of the anchoring fibrils [78].

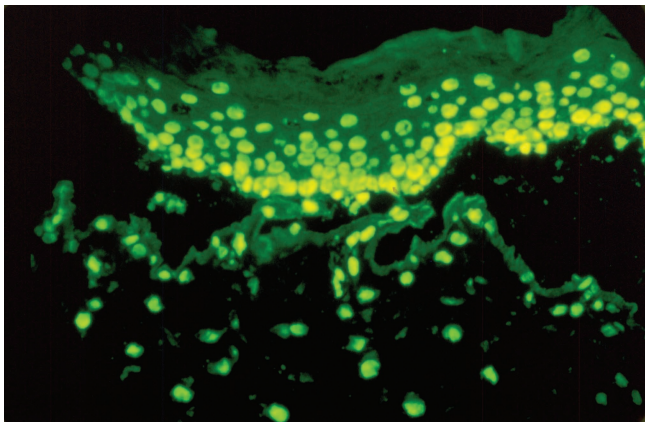

FIGURE 23 Direct immunofluorescence evaluation of the blister of patient in Fig. 22 showing thick linear IgG along the floor of the splited basement membrane and also strong *in vivo* ANA. Serologic investigation detected high titer of anti-type VII collagen (epidermolysis bullosa acquisita immunofindings) and anti-RNP (SLE finding).

Patients with PE typically present with superficial scaly lesions and occasionally blisters in a background of photosensitive erythema affecting head, neck, trunk, and proximal extremities without mucosal involvement (Fig. 24).

Histologically PE is characterized by a combination of an (often subtle) interface dermatitis, and subcorneal acantholytic blisters. DIF studies show a combination of granular immunoreactants along the BMZ (interface LE) and IgG deposits on the epidermal cell surfaces (PF-like) (Fig. 25) [76, 79–81].

Miscellaneous Lesions

Several miscellaneous lesions have and continue to be reported in LE patients. Most of those lesions are coincidental findings and not true associations with LE. We will review some of the most common dermatoses proven to be associated with LE.

Neutrophilic Dermatosis

Sweet Syndrome and Pyoderma Gangrenosum (PG)

These two dermatologic disorders fall into the group of neutrophilic dermatosis, characterized by significant neutrophilic infiltrates of the dermis and fat, without overt vasculitis. These are reactive disorders in which the underlying disease is often a chronic inflammatory disease, or autoimmune disease, or neoplasia. The most common disease associated is inflammatory bowel disease, although patients with CTD and arthritis occasionally present with neutrophilic dermatosis.

FIGURE 24 Pemphigus erythematosus showing confluent erythematous superficial blistering eruption on the upper back. The patient had smoldering photosensitive SLE. No mucous membrane lesions were identified in this patient.

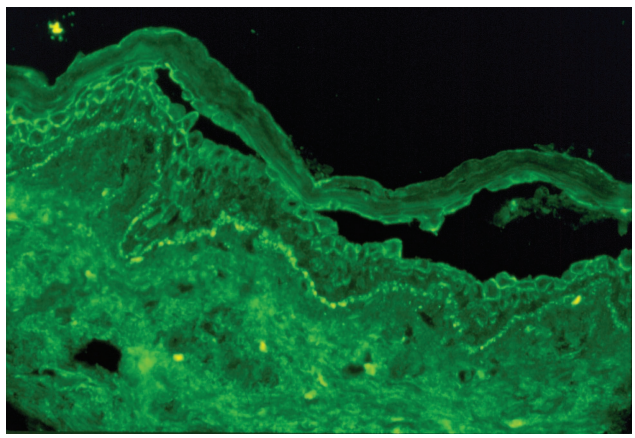

FIGURE 25 Direct immunofluorescence evaluation of the upper back of patient in Fig. 24 showing a heavy granular IgG deposits along the basement membrane zone (LE immunofinding) as well as IgG on the keratinocyte cell surfaces (Pemphigus-type). Serologic investigation detected high titer of anti-desmoglein 1 antibodies (pemphigus foliaceus) and anti-Ro (LE finding).

Pyoderma gangrenosum is characterized by painful lesions that eventually ulcerate. They have a distinct violaceous overhanging border and clean granular base. The lesions typically affect lower extremities. The clinical picture demonstrates a distinct absence of fever, or regional lymphadenopathy, unless the lesions become secondarily infected.

Sweet's lesions are urticarial and nonpruritic affecting the head, neck, and acral areas and are commonly associated with fever.

When a variant of the neutrophilic dermatoses is associated with an underlying disease, the lesion tends to be recurrent, persistent, and in an atypical location [82, 83].

Churg-Strauss Granuloma

This is also called cutaneous extravascular necrotizing granuloma (CENG) or better termed PNGD (palisade neutrophilic and granulomatous dermatosis). These are lesions that clinically and histologically mimic rheumatoid nodules.

The presence of ulceration, absence of rheumatoid factor, and significant histologic evidence of vasculitis in the specimen are features that help differentiating PNGD from rheumatoid nodules. These lesions, originally found in Churg-Strauss granuloma, have been found in different vasculitides, arthritides, and CTD [84].

Erythema Elevatum Diutinum (EED)

Erythema elevatum diutinum (EED) is a rare form of pure cutaneous vasculitis. It is characterized by chronic papule, plaques, and fibrin on extensor surfaces. Although half of the cases are idiopathic and do not have an underlying disease, three conditions have been associated with this vasculitis: (1) paraproteinemia, (2) HIV, and (3) rheumatoid arthritis and other CTD including SLE. Histologic findings include small polymorphonuclear predominant small vessel vasculitis with significant edema and later lipid deposit and fibrosis.

Alopecia

Hair loss is one of the most common nonspecific cutaneous signs of SLE. Alopecia can be classified as either scarring or nonscarring, depending on whether the scalp skin is permanently altered by the disease process. Scarring alopecia is usually caused by DLE. Diffuse, nonscarring alopecia occurs during the acute exacerbations of SLE. The nonscarring type of alopecia that is observed in lupus patients, termed lupus hair is simply a manifestation of telogen effluvium that may appear in the setting of any systemic disease. Diffuse nonscarring alopecia is usually transient; however, occasionally it can be persistent, particularly in those patients who have persistent active clinical disease [85].

Treatment

Management of patients with multisystem disease is dictated by the type of involvement. Since ACLE skin lesions are almost invariably present in patients with active SLE and respond to the same measures that are required for suppressing the systemic involvement, skin-directed treatment is usually unnecessary. The comments pertaining to therapy that follow apply especially to CCLE and SCLE. It is important to realize that these two forms of CLE usually respond to the same treatment approach, the major difference being that SCLE lesions tend to be more numerous and widespread compared with CCLE and are therefore less amenable to local therapy.

Topical Therapy

1. The potency of topical corticosteroids is based on their vasoconstrictor effect. The recommended initial topical treatment to LE lesions is medium-strength agents, such as triamcinolone acetonide 0.1% cream or ointment. However, the superpotent class I fluorinated topical corticosteroids, such as clobetasol propionate 0.05% or betamethasone dipropionate 0.05%, are often required to produce the greatest benefits. As a rule, ointments are generally more efficacious than creams in delivering the active chemical into the skin, but patients tend to find the cream-based preparations less greasy and therefore more acceptable cosmetically for regular use. A careful use of these agents is needed because of the possible atrophy effect of corticosteroids on a lesion that is already atrophying. Intralesional application of corticosteroids is highly unnecessary.
2. Sun protection: UVB and also UVA protection. Patients are advised to minimize sun exposure and to use sunblocks that protect for both UVB and UVA. This protection may be achieved with the combined use of physical blocking agents such as titanium dioxide–zinc oxide, and traditional sunscreen with a sun protecting factor of at least 45 with avobenzone [86].
3. Others: FK506 (tacrolimus) is a relatively new agent with potent immunomodulatory effect. In a more recent study, tacrolimus was effective for the treatment of some patients with cutaneous LE [87].

Systemic Therapy

The indications for systemic therapy include: extensive cutaneous disease, failure of topical therapy, associated constitutional symptoms (mainly articular symptoms), and photosensitivity. All of these manifestations should prompt the addition of antimalarials.

Hydroxychloroquine (HCQ)

The recommended dose is 6.5 mg/kg/day (usually 400 mg/day). It is crucial to keep in mind that hydroxychloroquine takes at least 3–4 months to start showing beneficial effect. It has been suspected but not fully proved that smoking may decrease its effectiveness. The major concern with the use of antimalarials is the potential retinal toxicity. However, evidence suggests that this is extremely unlikely when daily doses of hydroxychloroquine 6.5 mg/kg/day are not exceeded. The traditional approach has been to have an ophthalmologic examination carried out prior to treatment and again every 6–12 months during treatment to detect the early, potentially reversible changes of antimalarial retinopathy. However, such guidelines have been debated as being perhaps overly cautious [88–91].

Performing G6PD screening is largely unnecessary. The role of the antimalarials in the treatment of CLE is probably more important as agents used to keep patients in remission. Some practitioners claim that the addition of another antimalarial such as quinacrine may increase effectiveness. However, the benefit of this combination remains to be proved.

The significant ocular toxicity of chloroquine and similar effectiveness as HCQ lead to almost the complete discontinuation of this drug in the pharmacologic armamentarium in the treatment of CLE [92–94].

Thalidomide

The recommended dose is 1.5–5 mg/kg/day. This drug is highly effective in the treatment of DLE. The main concerns with the use of this drug are its teratogenicity and sensory neuropathy. However, the incidence of nerve damage is highly overreported and we recommend a baseline nerve conduction study (NCS) and follow up with NCS periodically. Avoidance of doses higher than 100 mg for more than 6 months largely reduces this risk. The teratogenicity is monitored by the so-called S.T.E.P.S (System for Thalidomide Education and Prescribing Safety) program that provide a strict follow-up system. Other possible and common side effects are hypothyroidism, sedation, and constipation [95–98].

Retinoids

Hyperkeratotic lesions usually present in palmoplantar DLE and may respond to the addition of topical or systemic retinoids [99].

Immunosuppressive Drugs

Immunosuppressive drugs are largely unnecessary. They may be considered in patients with extensive cutaneous disease, failure to topical and antimalarial therapy, associated constitutional symptoms, or severe articular symptoms. In this treatment group, systemic corticosteroids play a major role. For example, 1 mg/kg/day of prednisone in DLE patients is very effective. The prednisone should be tapered off over 3–4 months. Adjuvant steroid sparing agents that have proven effectiveness are azathioprine 2–3 mg/kg/day, mycophenolate mofetil (MMF) 25–35 mg/kg/day, and leflunomide 0.3 mg/kg/day [100].

The major and most worrisome side effect of azathioprine is myelosuppression, which usually manifests as leukopenia, although thrombocytopenia and anemia have been reported as well [101]. This adverse reaction is relatively rare, occurring mainly in patients with very

TABLE 5 Clinical Approach for the Management of CLE

Chronic cutaneous LE
DLE
Localized: topical corticosteroids and antimalarials and retinoids (hypertrophic LE)
Generalized: antimalarials, thalidomide, sun protection, and systemic corticosteroids, leflunomide, azathioprine or MMF (severe cases)
Lupus tumidus
Sun protection, antimalarials, thalidomide, systemic corticosteroids, leflunomide, azathioprine, or MMF (severe cases)
Lupus panniculitis
Antimalarials, thalidomide, systemic corticosteroids, leflunomide, azathioprine or MMF (severe cases)
SCLE and ACLE
Sun protection, antimalarials, thalidomide, systemic corticosteroids, leflunomide, azathioprine, or MMF (severe cases)
Cutaneous NLE
Sun protection, topical corticosteroids
Lupus perniosis: cold protection, and antimalarials, thalidomide, systemic corticosteroids, leflunomide, azathioprine or MMF (severe cases)
Others
Urticarial vasculitis
Normocomplmenetemic: usually no specific treatment required
Hypocomplemenetemic: systemic corticosteroids, leflunomide azathioprine, or MMF, alkylating agents
Lymphocytic vasculitis
Usually no specific treatment required or systemic corticosteroids, leflunomide, azathioprine, or MMF (severe cases)
Bullous SLE
Systemic corticosteroids, leflunomide, azathioprine, or MMF, alkylating agents (severe cutaneous or mucosal disease)
Erythema elevatum diutinum
Systemic corticosteroids and Dapsone, leflunomide, azathioprine, or MMF (severe cases)

low or absent thiopurine methyltransferase activity. Other possible side effects of azathioprine are toxic hepatitis, pancreatitis, hypersensitivity syndrome (azathioprine-induced shock), and drug fever [102–106]. MMF has a better safety profile than azathioprine, but is much more expensive.

Alkylating agents are largely unnecessary and paradoxically are not proved to be effective in the cutaneous forms of LE. Other immunomodulators agents including calcineurin inhibitors [107, 108], methotrexate [109], gold [110, 111], clofazimine [112], and dapsone [113–115] are inconsistently effective. The goal of immunosuppressive therapy is to achieve the safest and most effective regimen. Currently, this goal can be achieved by a synergistic combined therapy. A relatively effective combination for all forms of CLE is photoprotection, topical steroids antimalarials, and thalidomide. For severe cases, the addition of an antimetabolite to the previous regimen will achieve the highest synergistic effect.

A practical approach for the management of CLE is shown in Table 5. We believe that anti-TNF drugs such as etanercept and infliximab will have an important role in the treatment of CLE [116] as well as new analogs of thalidomide, IMiD (immunomodulatory and inhibitors drugs) drugs, that are 100–1000 times more potent than thalidomide in regulating cytokine production by peripheral blood mononuclear cells and providing a costimulatory signal for T-cell proliferation [117]. Also other biological modifiers targeting T cells harboring specific homing cell receptors that have been used in other dermatologic disorders may have an important role in the therapy of CLE.

SYSTEMIC LUPUS ERYTHEMATOSUS AND THE KIDNEY

James E. Balow
Dimitrios T. Boumpas
Howard A. Austin III

INTRODUCTION

It is well recognized that renal involvement contributes substantively to the morbidity of patients with systemic lupus erythematosus (SLE). While patients rarely die directly from uremia or lack of access to renal replacement therapies in modern times, early treatment of lupus nephritis and prevention of end-stage renal disease are important objectives in management of patients with SLE. Premature death due particularly to cardiovascular complications is the result of several components of lupus nephritis, including protracted nephrotic syndrome, hypertension, chronic renal insufficiency, and infection diathesis.

Given the diversity in types and severity of clinical manifestations of extrarenal SLE, it should not be surprising that an equally broad range of pathologic processes affects the kidney in this disease. Unfortunately, many forms of lupus renal disease, including severe forms of glomerulonephritis, are asymptomatic, easily overlooked by the clinician, and insidiously progressive. In this context, it is imperative that clinicians who undertake the care of patients with SLE must have in-depth knowledge of the diverse clinical and pathologic manifestations of lupus renal disease. Effective treatment depends on recognition of early phases of renal disease, prior to the stages of scarring, atrophy, and fibrosis.

DEFINITIONS AND MANIFESTATIONS OF LUPUS RENAL DISORDERS

Certain forms of renal involvement contribute to the diagnosis of SLE according to the widely accepted criteria of the American College of Rheumatology [1]. The diagnosis of a renal disorder includes the presence of: (a) persistent proteinuria of greater than 0.5 g/day (or greater than 3+ urine dipstick reaction for albumin), or (b) cellular casts, including red blood cell (RBC), hemoglobin, granular, renal tubular cell, or mixed casts. These elements are important in classification of SLE, particularly as standards for inclusion of patients in research studies. It must be emphasized that, while these laboratory criteria define the minimal threshold of kidney disease, there are many other clinical features which are important in the management of lupus nephritis [2–4].

CLINICAL SYNDROMES AND LABORATORY MANIFESTATIONS

To ascertain early renal involvement, patients with known or suspected diagnosis of SLE should undergo urinalysis screening at regular intervals because the onset of lupus nephritis is frequently asymptomatic. Furthermore, they should be queried about nocturia or

foamy urine. While nonspecific, nocturia may date the onset of glomerular or tubular dysfunction. Foamy urine suggests substantial proteinuria. Both symptoms warrant standard urinalysis and renal function tests [5]. Microscopic hematuria is mostly discovered by screening urinalysis in lupus nephritis. In SLE, macroscopic hematuria is relatively rare; it usually indicates very severe renal involvement and warrants expeditious assessment of renal function and degree of proteinuria. Rapidly progressive glomerulonephritis (RPGN) is defined as doubling of serum creatinine in less than a 3-month period, usually in the context of proliferative glomerulonephritis and cellular crescents in the renal biopsy.

Proteinuria is primarily a reflection of the extent of involvement of peripheral glomerular capillary loops. Thus, the degree of proteinuria tends to increase incrementally from mesangial to focal proliferative to diffuse proliferative lupus nephritis; membranous nephropathy which by nature involves essentially all glomerular capillary loops is characteristically accompanied by heavy proteinuria. Nephrotic range proteinuria is defined as proteinuria greater than 3.5 g/day; this degree of proteinuria usually causes the nephrotic syndrome which includes hypoalbuminemia, hyperlipidemia and, in the absence of diuretics, peripheral edema.

Renal failure, by convention, refers to loss of glomerular filtration function. In SLE, renal failure is primarily caused by the hypercellularity and inflammation within the glomerulus, though nephrotoxic drugs and other prerenal and postrenal causes of azotemia must always be considered. Sudden, acute renal failure is exceptional; rapidly progressive renal failure (RPGN as defined previously) occurs in a small fraction of lupus patients. Mostly, renal function fluctuates in parallel with remissions and exacerbations of lupus nephritis; chronic renal insufficiency results from cumulative damage and loss of nephrons, ultimately producing end-stage renal disease (ESRD). Renal tubular dysfunction, such as impaired urine concentrating ability and renal tubular acidosis, is rarely clinically significant or demanding of therapy.

URINALYSIS

Examination of urine is one of the most important and effective methods to detect and monitor the activity of lupus nephritis [5, 6]. There are no simple methods to standardize completely urinalysis testing, particularly given individual patient differences in fluid intake, urine concentrating ability, urine pH, and level of renal function. Early morning, mid-stream, clean catch urine samples (preferably the second voiding of the day but obtained while the patient is still fasting) are recommended in order to ensure reasonably concentrated and acidic urine specimens. Dipstick tests generally give reliable results; however, vitamin C supplements may produce false-negative dipstick reaction for blood, emphasizing the need for complementary microscopic analysis of the urine sediment. Given the fact that the typical lupus patient is both young and female, the clinician must guard against wrong inferences that hematuria is related to menstrual bleeding. It is recommended to perform urinalysis 3 or more days prior to or after cessation of menstrual periods.

The urine specimen should be processed expeditiously, lest the urine sediment deteriorates. Bacterial overgrowth may render the urine alkaline, which in turn causes rapid deterioration of urinary casts. The specimen should not be refrigerated to avoid precipitation of crystals which greatly interferes with microscopic analysis. Given the importance of cellular casts in defining and monitoring lupus nephritis, we use 50 ml (which is larger than conventional volumes) of urine for preparation of urinary sediments. The decanted pellet of sediment is stained with one drop of Sedi-Stain (Becton-Dickinson, Franklin Lakes, NJ). Using this large volume technique, we set the threshold for microscopic hematuria at >10 RBC per high power field (hpf).

The morphology of urinary red blood cells helps to distinguish upper and lower urinary tract disorders. Dysmorphic (misshaped, fragmented) erythrocytes (Fig. 1) indicate inflammatory glomerular or tubulointerstitial disease, while monomorphic (normal) erythrocytes indicate bleeding in the lower tract (e.g., infection, urolithiasis, tumors). Erythrocytes, leukocytes, and renal tubular epithelial cells are separately counted. Polarized light is used to detect free fat (doubly refractile fat bodies) and oval fat bodies (renal tubular epithelial cells containing fat droplets); lipiduria results from abnormal glomerular permeability to lipoproteins and possibly tubular epithelial cell injury caused by resorption of "toxic" filtered proteins. Granular, and fatty casts reflect proteinuric states; RBC, white blood cells (WBC), and mixed cellular casts reflect inflammatory (nephritic) states (Fig. 2); broad and waxy casts reflect chronic renal failure (Fig. 3). A telescopic urine sediment contains the full range of cells and cast elements; it reflects elements of global nephron (glomerular and tubular) dysfunction with ongoing active disease superimposed on chronic renal damage.

Accurate urinalysis requires careful and expeditious processing of the urine sample, good quality controls, and experienced personnel. It is important to remember that community-based clinical pathology laboratories for various reasons are frequently unable to identify

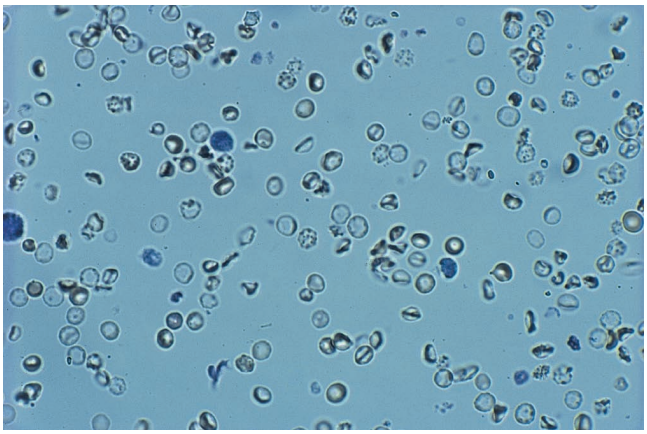

FIGURE 1 Dysmorphic red blood cells (RBC) in urine. RBC are of variable size and shape. Pattern strongly suggests hematuria of upper urinary tract origin.

pathologic casts [7]. This undoubtedly stems in part from the high volume throughput of urine samples for general screening purposes. There are two approaches to improve the reliability of urinalysis. First, the clinician should "flag" urine specimens from patients at substantial risk of lupus nephritis. Second, the clinician should, whenever feasible, personally review (and verify) the results of the microscopic urinalysis.

RENAL FUNCTION TESTS

Glomerular dysfunction is usually more prominent and clinically important than tubular dysfunction in lupus nephritis. Serum creatinine is the most widely used screening test to detect abnormalities of glomerular filtration. It is important to recognize that the normal range of serum creatinine is rather wide and that the relationship between serum creatinine and creatinine clearance, as a surrogate for glomerular filtration rate (GFR), must be determined for individual patients. Serum creatinine is affected not only by GFR, but also by age and muscle mass. The following nomograms quite reliably predict GFR from several basic clinical and laboratory parameters [8]:

Cockcroft-Gault formula

$$\mathrm{GFR}\,ml/min = \frac{(140 - \mathrm{age}\ yr)}{(\mathrm{serum\ Cr}\ mg/dL)} \times \frac{(\mathrm{weight}\ kg)}{72} \times 0.85\ (\mathrm{for\ women}) \qquad (1)$$

MDRD (four variable) formula

$$\mathrm{GFR}\,ml/min = 186.3 \times (\mathrm{serum\ Cr})^{-1.154} \times (\mathrm{age})^{-1.203} \times 1.212\ (\mathrm{if\ black}) \times 0.742\ (\mathrm{if\ female}) \qquad (2)$$

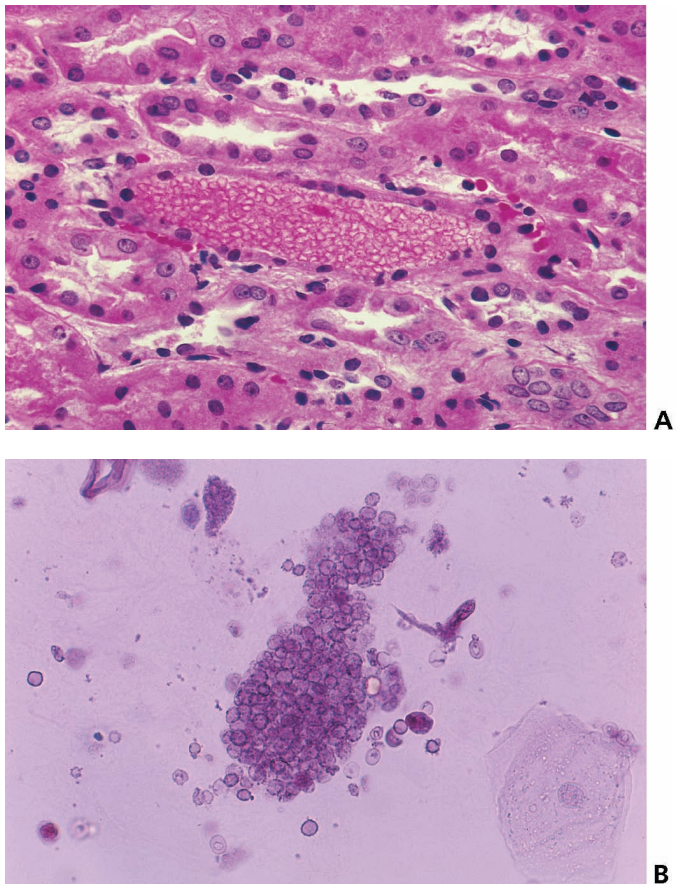

FIGURE 2 Red blood cell (RBC) casts. (**A**) RBC cast *in situ* within renal parenchyma. (**B**) RBC cast in urine sediment.

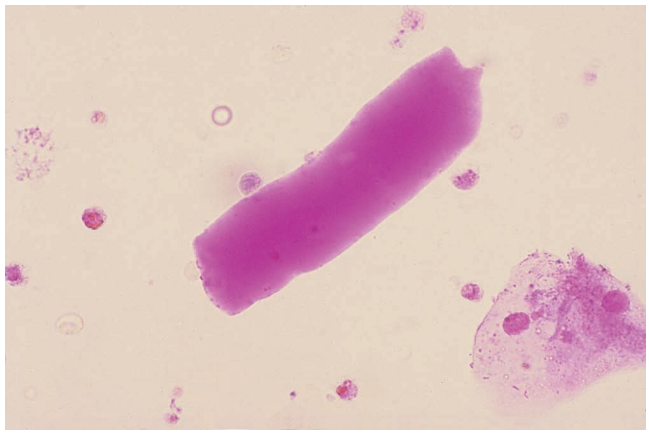

FIGURE 3 Broad, waxy cast in urine sediment. These casts indicate chronic nephron damage.

Another practical alternative for measuring changes in GFR over time is based on analysis of change in reciprocal of serum creatinine. Because creatinine excretion should be nearly constant, changes in the reciprocal of serum creatinine are directly proportional

to changes in creatinine clearance, as is evident in the following clearance formula:

$$\text{Creatinine clearance} = \frac{\text{creatinine excretion}}{\text{serum Cr}} = \text{Constant} \times \frac{1}{\text{serum Cr}} \quad (3)$$

When measuring standard creatinine clearance, one should be mindful that the major variability of the test stems primarily from errors in urine collection (volume). Patients must be explicitly instructed. Examining creatinine excretion is useful in assessing the completeness of urine collection and the reliability of the data used to calculate creatinine clearance. Creatinine excretion should be consistent on replicate collections and/or should approximate population averages for creatinine excretion, which in males is approximately 20 mg/kg/day and in females is approximately 15 mg/kg/day. Substantial deviations from either of these two standards should raise suspicion about the reliability of that particular test for estimating creatinine clearance.

Tests of true GFR (e.g., inulin, DTPA clearance), renal plasma/blood flow (e.g., para-aminohippurate, PAH, clearance), and filtration fraction (ratio of GFR to renal plasma flow) are sometimes used to enhance the accuracy and precision of measurement of changes in renal function [5]. These methods may identify substantial alterations in renal functions that are not recognized by standard methods. They are also sensitive measures of the effects of treatment on lupus nephritis. Because these tests are very labor intensive, expensive, and may involve radionuclides, they are seldom used outside the research setting.

Proteinuria is a critically important index of glomerular dysfunction. Timed collection of urine protein (usually over 24 h and in conjunction with creatinine clearance) represents the gold standard. However, test-to-test variability in proteinuria is common; this is mostly due to collection errors and differences in physical activity (bed rest tends to reduce and heavy exercise tends to increase proteinuria). Reproducibility is important before conclusions are drawn that clinically significant changes in proteinuria have occurred. We generally obtain three 24-h urine collections to document average basal proteinuria and creatinine clearance before initiating treatment.

Spot urine protein/creatinine ratio has been used as a simpler method to estimate the degree of proteinuria over time. The numeric ratio approximates the number of grams per day of proteinuria. This method has steadily gained wider application due to its simplicity and convenience [9]. Urine protein electrophoresis is of limited importance and rarely performed as part of the standard evaluation of the patient with known lupus nephritis. Proteinuria is usually of glomerular origin and unselective (mirroring serum protein concentrations). Isolated tubular proteinuria (nonalbumin) is rare. Measurement of microalbuminuria (30–300 mg/day) has not been thoroughly investigated but is generally not considered as a standard screening test in patients with suspected lupus nephritis.

Reduction in proteinuria is an important measure of favorable response to treatment in lupus nephritis [10–15]. Complete remission of abnormal proteinuria is defined as return to completely normal levels (i.e., <0.2 g/day, or urine protein/creatinine ratio <0.2). Partial remission of proteinuria is commonly defined by urine proteins of <0.5–1.0 g/day, or urine protein/creatinine ratio <0.5–1.0. Proteinuria may persist after remission of glomerular disease; this is referred to as "fixed" proteinuria due to irreversible damage to glomerular capillaries.

Laboratory abnormalities of renal tubular functions are common in lupus nephritis. Because they tend to be mild and do not warrant specific interventions, it is not usually cost-effective to document specific renal tubular cell dysfunctions in SLE. Decreased maximal urinary concentrating capacity may contribute to nocturia and may account for the tendency toward easy dehydration. Minor defects in urinary acidification (documented by acid-loading tests) are also common, but clinically significant renal tubular acidosis is rare.

RENAL BIOPSY

There are widely divergent views about the benefits of renal biopsy in lupus nephritis [16–19]. In research studies, documentation of renal pathology is considered essential. In clinical practice, neither an "always" nor a "never" approach to renal biopsy seems prudent. On the one hand, renal biopsy should *not* be considered as a method for diagnosis of SLE, nor should renal biopsy ordinarily be performed in lupus patients lacking clinical evidence of renal abnormalities. Although not absolute, there is a general consensus that most patients should have documentation of renal pathology prior to initiation of cytotoxic drug therapy. The decision to initiate cytotoxic drugs is often informed by results of a renal biopsy [20]. We agree with the opinion of Esdaile that ". . . watchful waiting is often an unwise course for management of lupus nephritis" [21]. Table 1 summarizes indications for renal biopsy and related issues in patients with lupus nephritis.

Beyond screening for a significant bleeding diathesis and urinary tract infection, renal ultrasound is

TABLE 1 Considerations Regarding Renal Biopsy in Lupus Nephritis

Renal biopsy is rarely useful in establishing a *diagnosis* of SLE in patients without laboratory evidence of renal disease, or in establishing lupus as the cause of nephritis in patients without other criteria for diagnosis of SLE
Renal biopsy may offer marginal or no incremental benefit in patients with recent onset glomerulonephritis characterized by a "full house" profile of severe disease (i.e., definitive diagnosis of SLE, nephritic syndrome, nephrotic syndrome, hypertension, and azotemia)
The standard clinical indications for renal biopsy include: nephritic urine sediment, especially cellular casts, and proteinuria >1.0 g per day
Interpretation of discordant clinical and laboratory parameters of active glomerulonephritis (e.g., discrepancies or ambiguities in urinalysis, proteinuria, lupus serologies, renal function tests) is often facilitated by the results obtained from renal biopsy
Renal biopsy findings often provide the underpinnings for describing prognosis and formulating therapeutic programs, particularly in patients deeply concerned about the risks of cytotoxic drug therapy
Studies have shown that biopsy findings, more often than clinical parameters, prompt the decision to institute cytotoxic drug therapy

TABLE 2 World Health Organization Classes of Lupus Nephritis

I.	Normal, or minimal glomerular abnormality No glomerular abnormalities on light microscopy
II.	Mesangial nephropathy Mesangial expansion, including hypercellularity, increased matrix, and immune complex deposits
III.	Focal proliferative glomerulonephritis Predominantly segmental hypercellularity ± necrosis compromising the circulatory space of capillary loops in ≤50% of glomeruli; mesangial and subendothelial immune complex deposits
IV.	Diffuse proliferative glomerulonephritis Characteristically global but irregular hypercellularity, ± necrosis, ± cellular crescents affecting >50% of glomeruli; variable sclerosis, atrophy, fibrosis; mesangial and subendothelial (± subepithelial) immune complex deposits
V.	Membranous nephropathy Generalized thickening of capillary loops; mesangial and subepithelial immune complex deposits
VI.	Sclerosing nephropathy Predominantly hyalinized glomeruli, tubular atrophy, interstitial fibrosis; no (or very rare) immune complex deposits

commonly used to assess the size of the kidneys prior to considering renal biopsy. Estimated kidney length less than three-fourths of expected normal size is associated with increased risk and decreased diagnostic yield. Percutaneous renal biopsy is usually performed under the guidance of a kidney imaging modality. Ultrasound is the most widely used technique, but computed tomography offers more precise (albeit more expensive) visualization. Operator experience is crucial to success of the procedure, because several potential shortcomings can compromise the interpretation and yield of the renal biopsy. It is important to obtain renal cortex containing 10 or more glomeruli for reliable interpretation of lupus nephritis. If biopsies are obtained by interventional radiologists (as a pure service function), it is important that the operator clearly understand the critical nature of sample size and tissue handling.

The renal biopsy specimen must be expeditiously processed in fixatives (or cooled on ice) at the biopsy table, lest autolysis of tissue ensues. In the patient with definitive diagnosis of SLE, priority for dividing and allocating samples should be given in the following order: (1) light microscopy specimen in formalin fixative, (2) electron microscopy specimen in glutaraldehyde fixative, and (3) immunofluorescence specimen on iced saline.

It is important that kidney biopsies be analyzed by experienced renal pathologists and reviewed in detail with the clinician responsible for the patient (preferably over the microscope and/or in a biopsy conference). At a minimum, renal biopsy reports should contain the World Health Organization (WHO) classification of lupus nephritis (Table 2) [22–27] and descriptions (preferably semiquantitative scores) of the elements comprising Activity and Chronicity Indexes which are further described later. A synopsis of the characteristic features and clinicopathological correlations of the different WHO classes of lupus nephritis is shown in Table 3.

PATHOLOGY OF LUPUS NEPHRITIS

There are few guidelines which can replace experience in recognizing and accurately describing renal biopsy pathology. The spectrum of pathologic changes in lupus nephritis is extremely broad, and categorization by the major WHO classes does not capture all the key features, especially degrees of activity (potentially treatable) and chronicity (irreparable damage) [27]. It is important to be able to recognize normal glomeruli; the glomerular capillary loops should appear thin and widely patent, with inconspicuous cellularity (Fig. 4). The glomerular mesangium, which seems to be the principal site of early lupus pathology, normally exhibits ≤3 contiguous nuclei and a small amount of matrix, best seen with periodic acid Schiff (PAS) stain. One can be misled about mesangial abnormalities if the microscopic

sections are thick (normally tissue sections should be <4 μm).

Normal or Minimal Mesangial Abnormality (Class I)

By light microscopy, glomeruli may appear normal or show minimal mesangial expansion. Immune deposits are seen in the mesangial areas by immunofluorescence and electron microscopy. There are few cases with Class I lupus nephropathy described in published series due to the absence of clinical indications for biopsies in such patients.

Mesangial Nephropathy (Class II)

Mesangial nephropathy is diagnosed by several criteria: expansion of the mesangial stalk due to increased cellularity and matrix substance by light microscopy

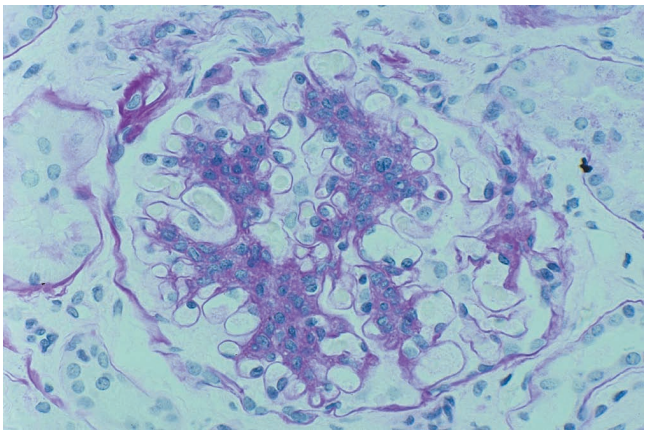

FIGURE 5 Mesangial nephropathy (WHO Class II). Note the expansion of mesangial cells and matrix without substantive encroachment on capillary loop space (PAS stain).

(Fig. 5), as well as deposition of immune complexes by immunofluorescence and electron microscopy (Fig. 6). Capillary loops remain patent and there are no other active or sclerosing lesions compromising glomerular capillary circulation and filtration. Mesangial nephropathy can be considered the least common denominator of lupus nephritis. In some cases, mesangial nephropathy represents intrinsically mild disease; in others, mesangial nephropathy is an early stage in the progression to the following more severe forms of lupus nephritis.

Focal (Class III) and Diffuse Proliferative (Class IV) Lupus Nephritis

Proliferative lupus nephritis primarily represents glomerular changes which burgeon forth from the back-

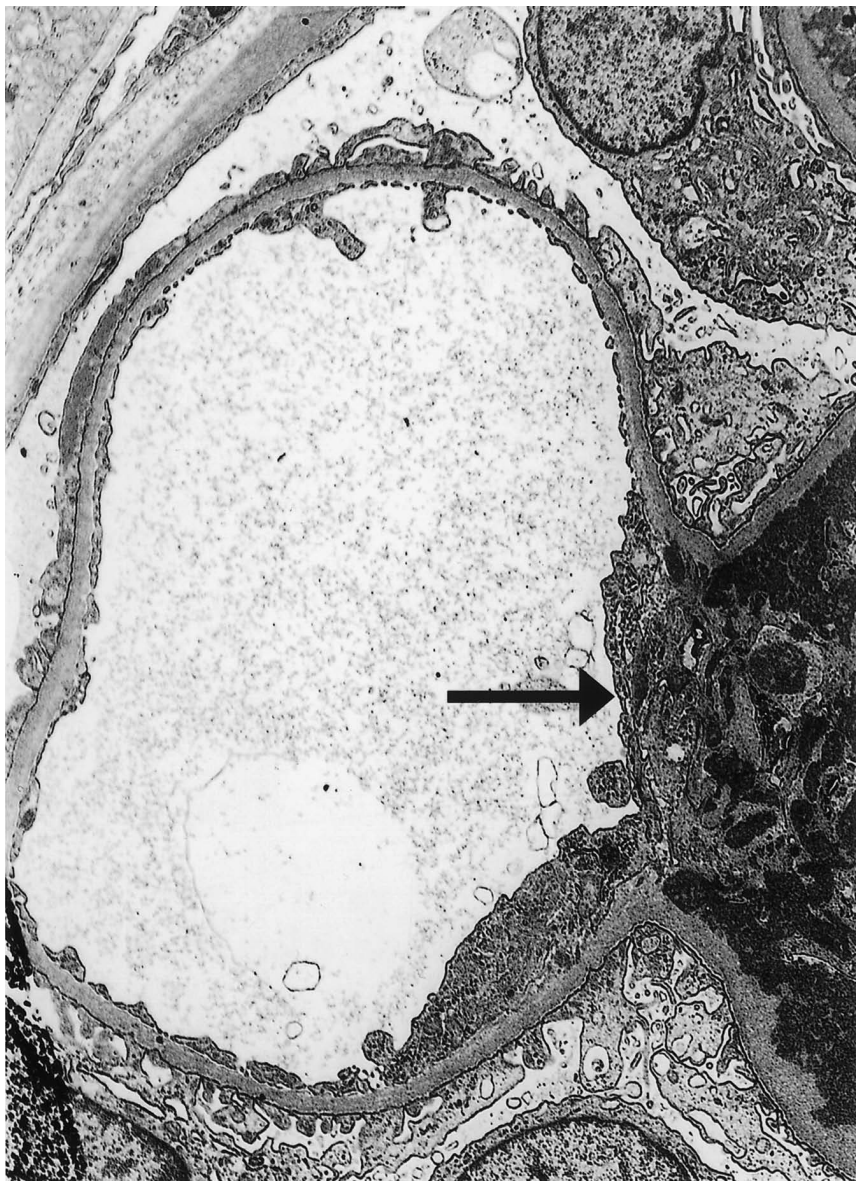

FIGURE 6 Ultrastructural appearance of mesangial deposits (arrow). The black staining deposits are admixed with gray mesangial matrix. Note the normal appearance of the peripheral capillary loops. Electron micrograph courtesy of Dr. Sharda Sabnis, Nephropathy Section, Armed Forces Institute of Pathology, Washington, D.C.

ground of mesangial nephropathy. Focal (Fig. 7) and diffuse (Fig. 8a–c) proliferative lupus nephritis are qualitatively similar and differ mostly in extent and severity of proliferative and inflammatory lesions. Conceptually, focal and diffuse proliferative lupus nephritis represent mild and severe glomerular disease, respectively. The conventional dividing line is defined by pathologic lesions that reduce glomerular capillary loop space in the minority (Class III) or majority (Class IV) of nephrons. However, it should be stressed that, even in diffuse proliferative lupus nephritis, the distribution of proliferative lesions is highly irregular, both within and among glomeruli. The increased glomerular cellularity is due to proliferation of mesangial and endothelial cells plus leukocytic infiltrates (polymorphs and macrophages). Visceral epithelial cells may enlarge and exhibit degenerative change, but are thought to have limited (if any) capacity to proliferate.

Immune complex deposits fill the mesangial interstices and extend peripherally along the subendothelial aspect of the glomerular capillaries (Fig. 9). It is not clear whether this extension of deposits is an "overflow" phenomenon, or whether focal and diffuse proliferative, in contrast to mesangial, lupus nephritis are caused by unique species of immune complexes with a special affinity for capillary basement membranes. By indirect immunofluorescence microscopy, the deposits can be shown to contain IgG, IgA, IgM, C1q, and C3 (the so-called, full house immunofluorescence of proliferative lupus nephritis). When present, fresh cellular crescents or true microvascular thrombi usually contain fibrin.

There is a subset of diffuse proliferative lupus nephritis in which there are both subendothelial deposits and extensions of mesangial matrix peripherally around glomerular capillaries. The matrix extension produces double contours in capillary loops and an overall pattern of lobulation of the glomerulus. This form of lupus nephritis is called membranoproliferative (or mesangiocapillary) glomerulonephritis after the idiopathic variety of glomerulonephritis with similar appearance.

In severe forms of proliferative lupus nephritis, heavy subendothelial deposits give rise to classic, deeply eosinophilic, and PAS-positive, "wire loop" lesions in glomerular capillaries. Massive immune deposits filling capillary loops give rise to hyaline thrombi, which are "thrombi" by appearance only. The pathogenesis of these immunoglobulin-containing lesions is uncertain, but they are particularly frequent in cases with cryoprecipitable circulating immune complexes. These hyaline thrombi have also been given the more

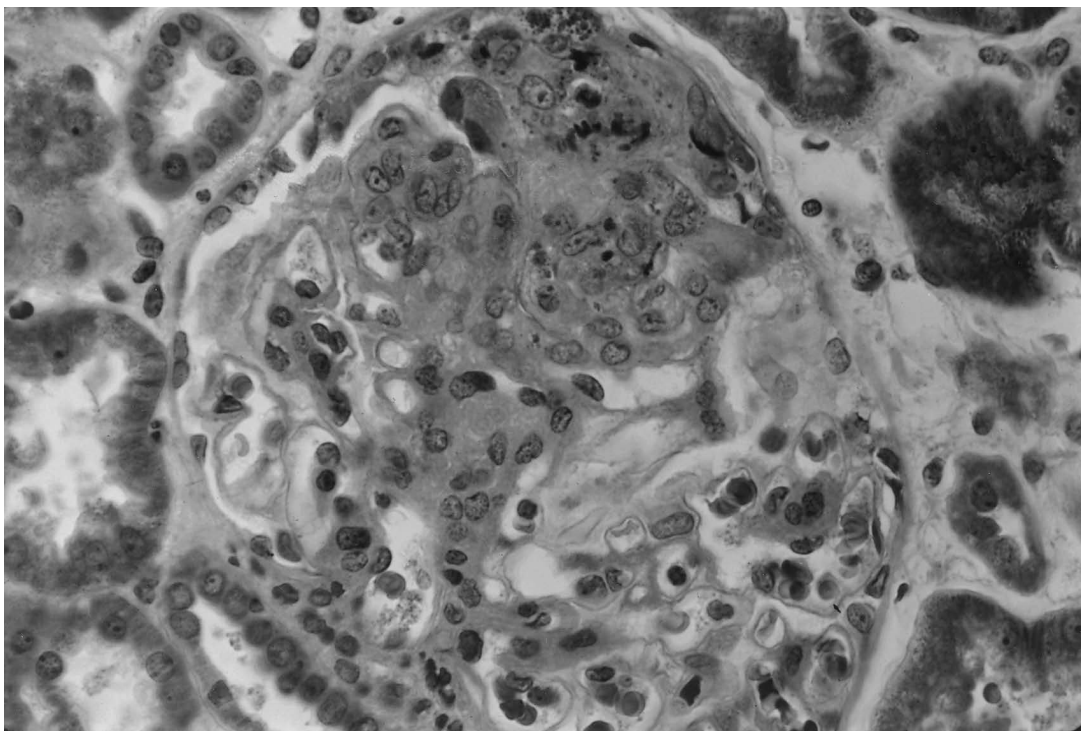

FIGURE 7 Focal proliferative lupus nephritis (WHO Class III). Glomerulus shows segmental proliferation with karyorrhexis and fibrinoid necrosis (H&E stain).

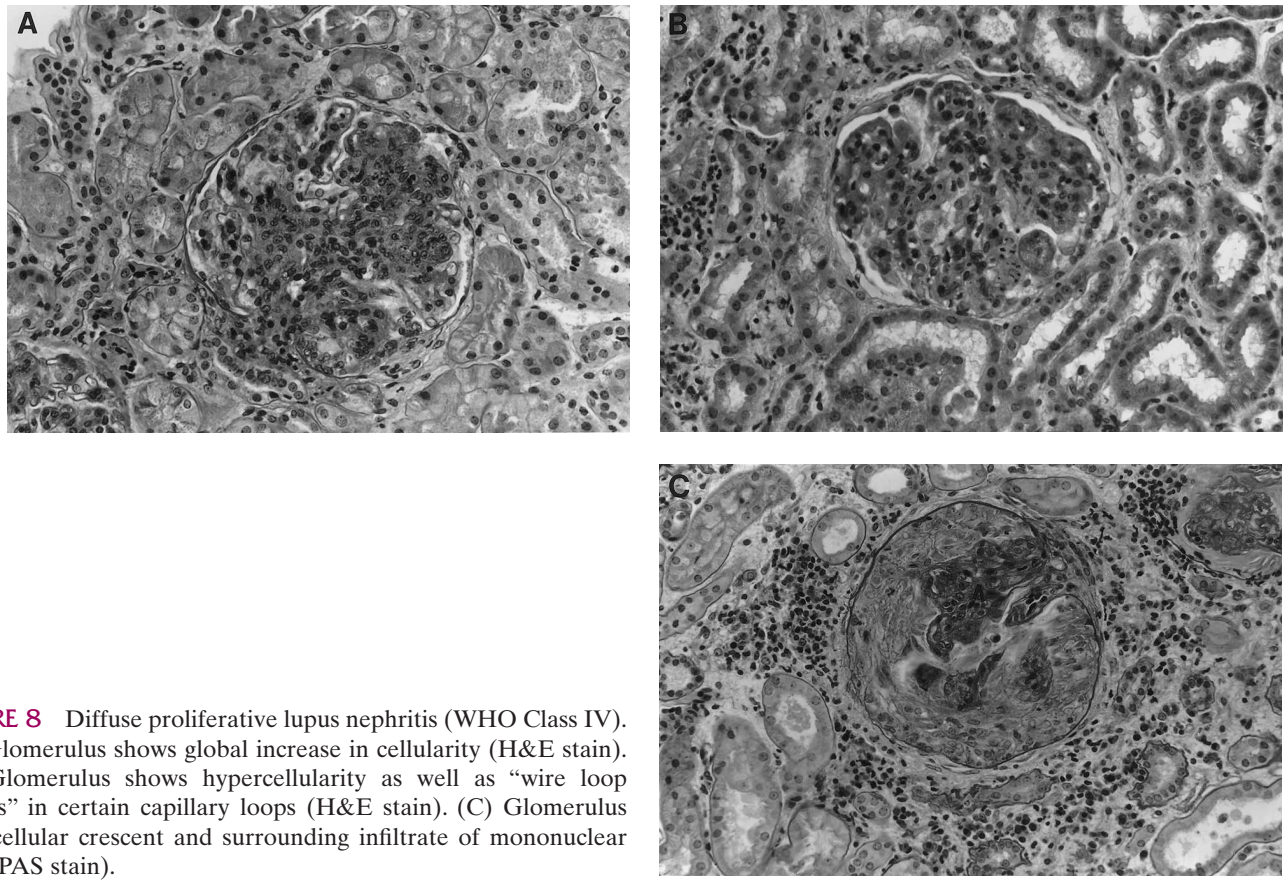

FIGURE 8 Diffuse proliferative lupus nephritis (WHO Class IV). (A) Glomerulus shows global increase in cellularity (H&E stain). (B) Glomerulus shows hypercellularity as well as "wire loop lesions" in certain capillary loops (H&E stain). descriptive name of immunoglobulin microvascular casts [28].

The hyaline thrombi lesions overlap and may be admixed with those of true fibrin thrombi which arise from the thrombotic diathesis seen in certain lupus patients. It is not entirely resolved whether or not antiphospholipid antibodies increase the frequency of glomerular microvascular thrombosis [29, 30]. Fibrin thrombi are seen in rare cases where the syndrome of thrombotic thrombocytopenic purpura is superimposed on SLE (see later). It is notable that in some cases of segmental necrotizing lupus nephritis, there are very sparse immune complex deposits, leading to the suggestion that this lesion may sometimes arise from a cell-mediated immune process or represent a pauci-immune glomerular disease equivalent to that of renal vasculitis [31].

Severe inflammation within glomerular capillaries may lead to cellular destruction with nuclear fragmentation (karyorrhexis) and fibrinoid necrosis (smudgy, brightly eosinophilic clumps of plasma products). Hematoxylin bodies may form when there is heavy nuclear debris, but these lupus-specific lesions are quite rare in rapidly fixed needle biopsy specimens (in contrast to surgical biopsies and autopsies). When relatively mild, segmental inflammation may produce local adhesions of glomerular capillaries to Bowman's capsule. When severe, inflammation, and particularly fibrinoid necrosis, may be followed by frank rupture of glomerular capillaries with hemorrhage into Bowman's space and formation of exuberant cellular crescents. Cellular crescents are aggregates comprised of two or more layers of cells which line one-fourth or more of the interior circumference of Bowman's capsule. Cellular crescents are comprised of a combination of proliferating epithelial cells and infiltrating macrophages [32]. Circumferential crescents are thought to doom affected glomeruli to obsolescence. In general, increasing numbers of cellular crescents have proportionally more adverse effects on prognosis.

Membranous Lupus Nephropathy (Class V)

Membranous nephropathy is defined most rigorously by the presence of subepithelial (epimembranous) deposits along peripheral glomerular capillary loops (Fig. 10). These deposits may be seen with trichrome stains under high-power light microscopy, but are more

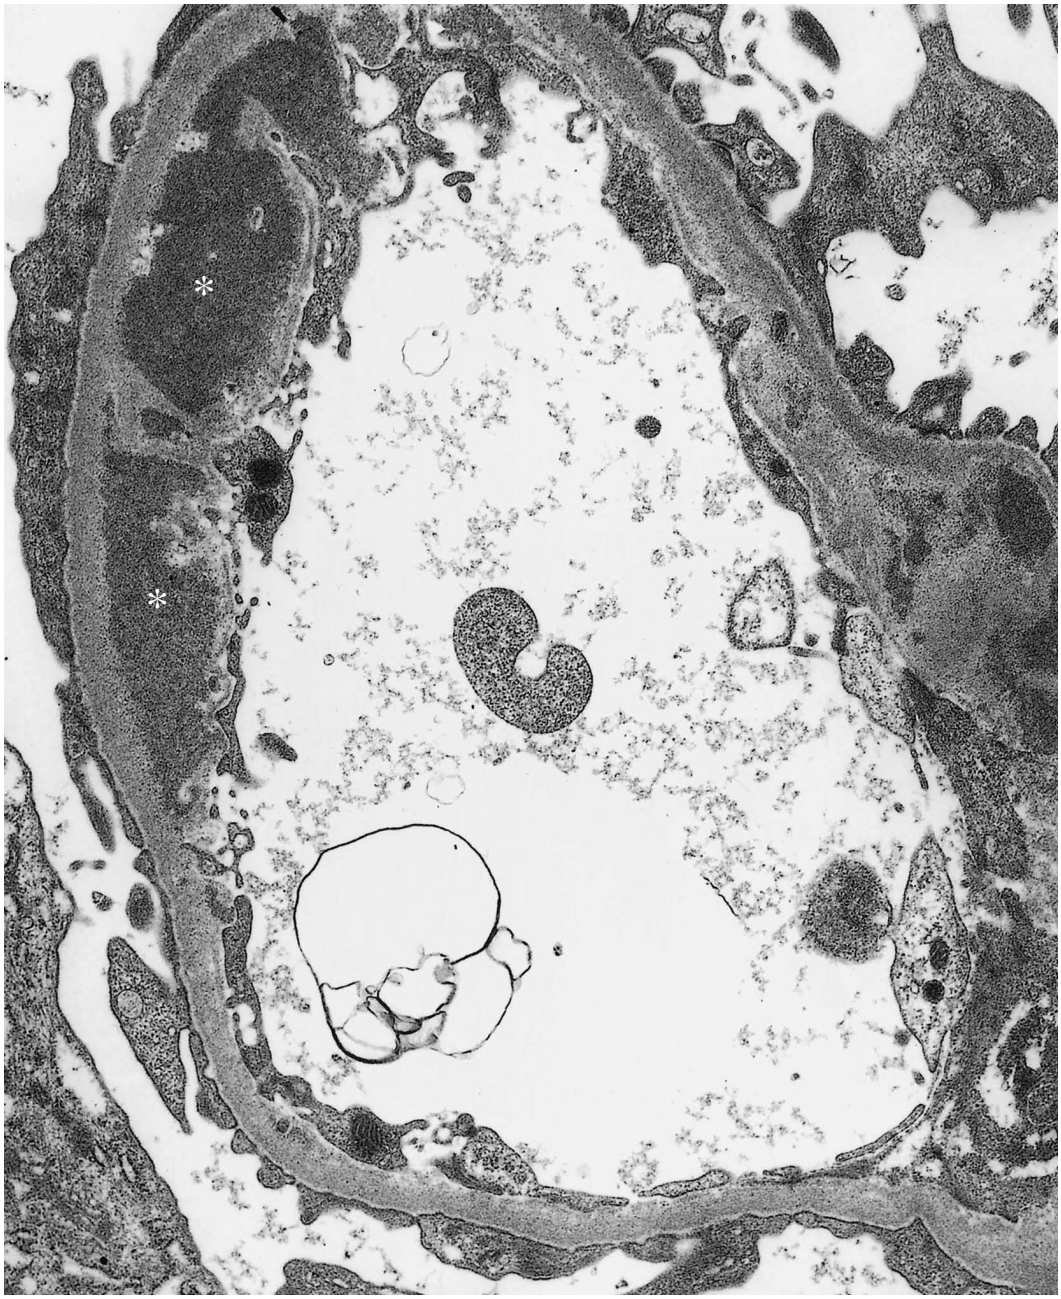

FIGURE 9 Ultrastructural appearance of subendothelial deposits (asterisks). The dark staining deposits are between the glomerular basement membrane and the endothelial lining of the capillary loop. Electron micrograph courtesy of Dr. Sharda Sabnis, Nephropathy Section, Armed Forces Institute of Pathology, Washington, D.C.

readily demonstrated by electron microscopy (Fig. 11). Early in the course, capillary loop thickening per se may not be apparent on light microscopy. In progressive stages, membranous nephropathy is characterized by capillary loop thickening and, with silver stains, the appearance of basement membrane spikes projecting outward between subepithelial immune deposits. In advanced stages, deposits may become fully incorporated within thickened basement membrane and finally undergo dissolution, leaving the membrane with a "moth-eaten" appearance. Mixed membranous and proliferative classes of lupus nephritis sometimes coexist, and membranous nephropathy is occasionally complicated by crescent formation.

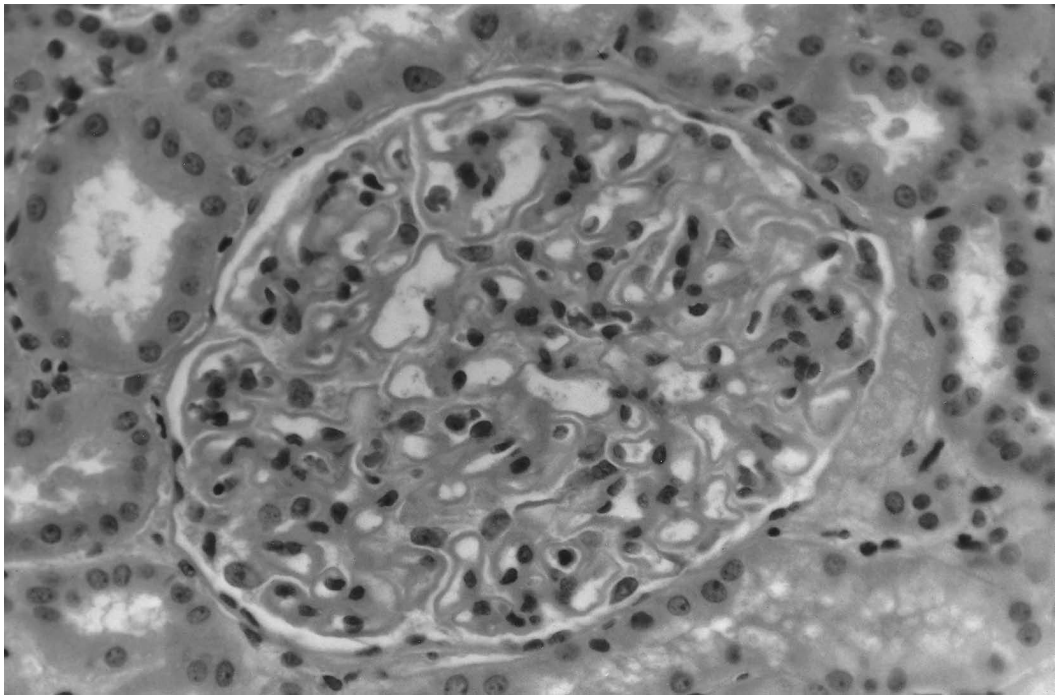

FIGURE 10 Membranous lupus nephropathy (WHO Class V). Glomerulus shows diffuse thickening but retained patency of peripheral capillary loops (H&E stain).

Sclerosing Nephropathy (Class VI)

Inclusion of this category was a late addition to the classification of lupus nephritis. It basically represents a stage rather than a specific type of lupus nephritis. Class VI reflects late stage, irreversible renal damage with advanced glomerulosclerosis, tubular atrophy, and interstitial fibrosis (Fig. 12a,b). Class VI may evolve from any prior form of severe lupus nephropathy, as well as from coincidental hypertensive, vascular, or drug-induced nephropathies. First definition of lupus nephropathy at this late stage represents neglect on the part of the patient or physician and should be exceptional.

Tubulointerstitial disease is an important component of the pathology of lupus nephritis. Indeed, interstitial scarring and atrophy are among the strongest predictors of prognosis in most glomerulonephritides, including lupus nephritis. Interstitial infiltrates of predominantly mononuclear cells (lymphocytes, plasma cells, and macrophages) are seen in the majority of cases of lupus nephritis [33]. In general, the degrees of infiltrates are proportional to the severity of the glomerular disease. Occasionally, interstitial infiltrates have been found in the absence of substantive glomerular disease. The role of mononuclear cell infiltrates in the pathogenesis of lupus nephritis is unclear. Immune complexes are frequently deposited in a peritubular location (along tubular basement membranes) and sometimes in the walls of peritubular capillaries. Whether these deposits originate from reabsorbed tubular proteins, circulating immune complexes, or locally from antibody secreting plasma cells is uncertain.

It is a reasonable hypothesis that whole nephron injury and drop out can be a bidirectional process. On the one hand, massive glomerular destruction and sclerosis could lead to downstream vascular compromise and tubular atrophy. On the other hand, primary tubular damage, either from intraluminal processes (e.g., "toxic" proteinuria) or from peritubular processes (e.g., immune complexes or cytotoxic lymphoid cells), could produce cast nephropathy, tubular dilatation, and upstream glomerular injury [34]. The relatively poor correlation of interstitial inflammation with renal outcome suggests the primacy of glomerular processes in the pathogenesis of tubulointerstitial scarring, atrophy, and fibrosis in lupus nephritis.

Assessment of the integrity of the tubulointerstitial areas is facilitated by surveying sections stained by PAS stain, which highlights tubular basement membranes. Normally, there should be little interstitial space between tubules. Thickening of tubular basement membranes is one of the best indications of impending tubular atrophy; this is followed by deposition of waxy casts, shrinkage, and drop out of tubules. Trichrome stains, which render collagen a blue color, are best for estimating interstitial fibrosis.

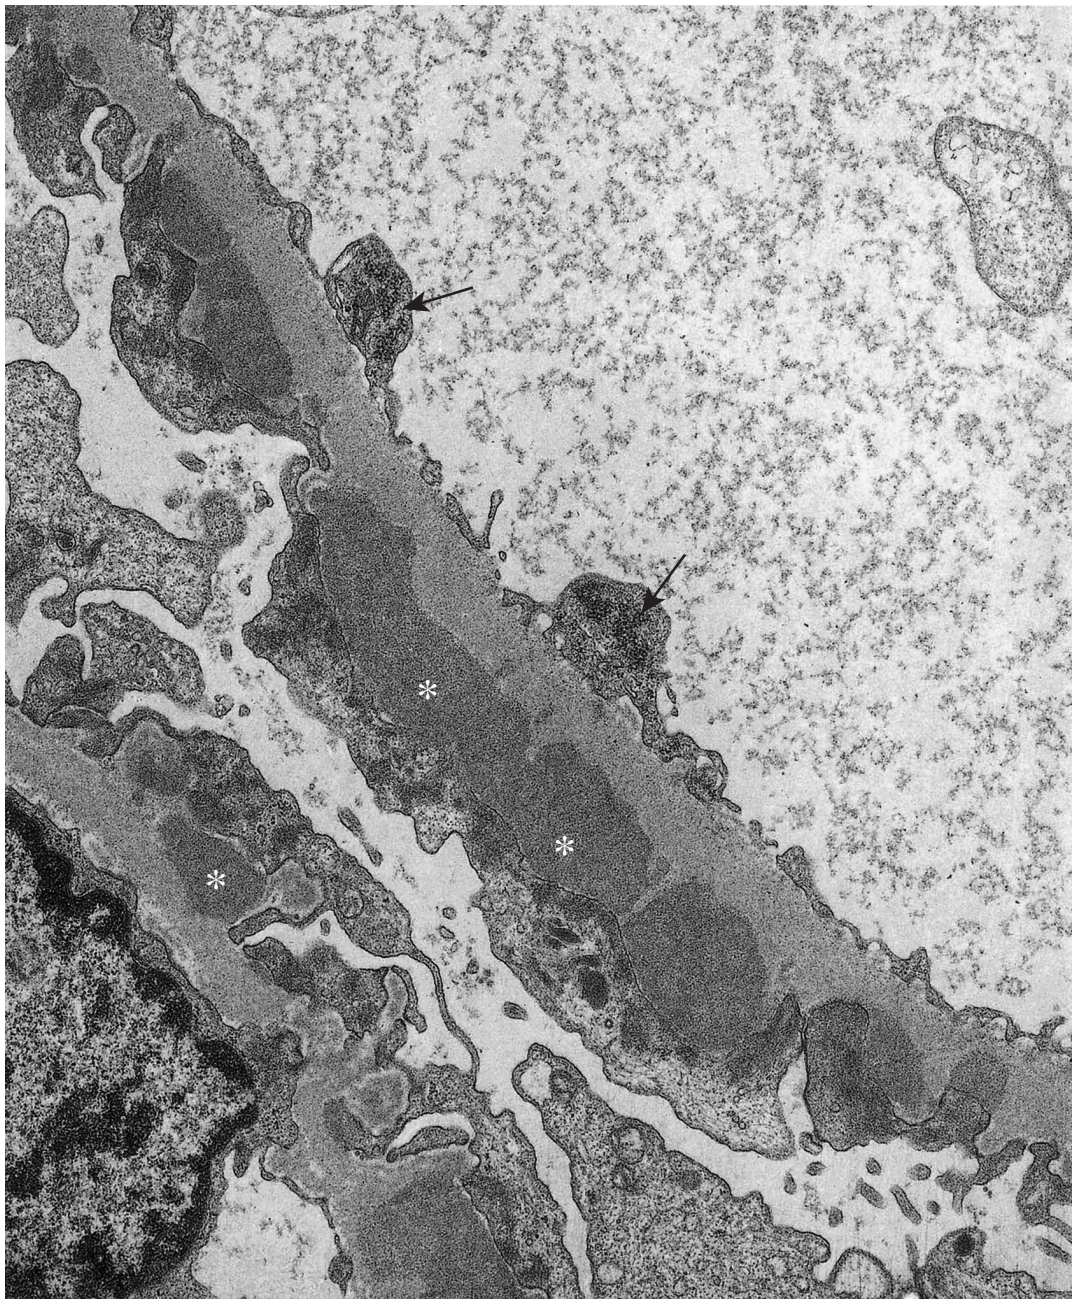

FIGURE 11 Ultrastructural appearance of subepithelial deposits (asterisks). The dark staining deposits are on the external (epimembranous) aspect of the glomerular basement membrane. The foot processes of the epithelial cells are fused. Note the presence of tubuloreticular structures in two endothelial cells (arrows). Electron micrograph courtesy of Dr. Sharda Sabnis, Nephropathy Section, Armed Forces Institute of Pathology, Washington, D.C.

Hypertensive arteriolosclerosis is relatively common in biopsies of lupus nephritis, but it is usually anticipated from clinical findings of poorly controlled blood pressure. Frank extraglomerular vasculitis is rare but well documented; the impact of necrotizing vasculitis on a prognosis in lupus has not been well studied.

ACTIVITY AND CHRONICITY INDEXES

Description of the balance of activity and chronicity in the pathology of lupus nephritis is enhanced by two related approaches. Subsets of WHO Class III focal

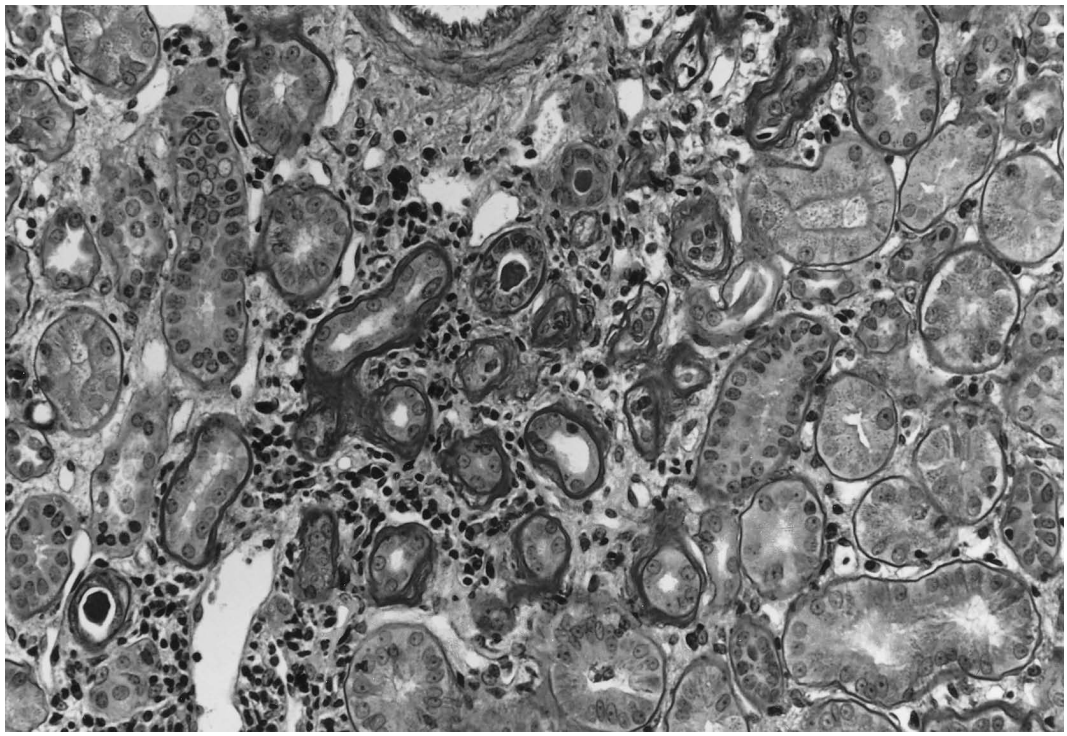

FIGURE 12 Advanced chronic lupus nephropathy. Thickened tubular basement membranes indicate tubular atrophy. Peritubular interstitial infiltrates of mononuclear cells are present (PAS stain).

proliferative lupus nephritis have been proposed which specify whether the lesions are primarily active (IIIa), mixed active and sclerosing (IIIb), or primarily sclerosing (IIIc); similarly, subsets of WHO Class IV diffuse proliferative lupus nephritis have been proposed which specify whether lesions are pure proliferative (IVa), predominantly active (IVb), mixed active and sclerosing (IVc), or predominantly sclerosing (IVd) [18, 27].

Our preferred approach is to classify the glomerular disease by major WHO class and to supplement description of the biopsy by semiquantitative scoring of disease activity and chronicity (damage) in a checklist fashion (Table 4) [35–39]. In early stages of lupus nephritis, cases fit more comfortably into one of the major WHO classes. During the evolution of lupus nephritis and under the disease-modifying influences of treatment, it becomes increasingly difficult to find a category to accommodate all the essential biopsy findings. In these cases, a synopsis of activity and chronicity features becomes particularly useful in capturing the essence of the biopsy appearance. Another utility of the activity and chronicity indexes is as a measure of change in renal pathology over time. That lupus nephritis undergoes transitions among major WHO classes is well known. However, changes in disease activity and chronicity within a given WHO class of renal pathology are even more common [40]. Here again, the activity and chronicity indexes allow one to capture the balance of pathologic changes when repeat renal biopsies are undertaken. Most, but not all, centers have found excellent reproducibility of scoring activity and chronicity and have incorporated these tools into their renal biopsy report forms.

PATHOGENESIS OF LUPUS NEPHRITIS

Detailed descriptions of the immunopathogenesis of SLE, and particularly those of murine lupus nephritis, are covered elsewhere in this volume. Clearly, cell mediated immune responses are involved in facilitating the production of autoantibodies, and possibly even for direct injury to the kidney. Studies of the genetic and immunologic basis of SLE and lupus nephritis have been greatly facilitated by murine models [41, 42]. A provocative study based on knock out of the Fc γ-chain receptor in the NZB/W model of murine lupus nephritis demonstrated an uncoupling of immune complex formation and kidney damage. Animals lacking functional Fc receptors had equivalent deposition of immune complexes in the kidney, but had markedly reduced glomerular inflammation, indicating that Fc receptors were more important in host responses to

TABLE 4 Renal Biopsy Activity and Chronicity Indexes

Activity Index (maximum score 24)
Hypercellularity: Segmental or global endocapillary hypercellularity that reduces the circulatory volume of glomerular capillary loops[a]
Leukocyte exudation: Three or more polymorphonuclear leukocytes per glomerulus[a]
Karyorrhexis/fibrinoid necrosis (weighted ×2): Karyorrhexis: pyknotic and fragmented nuclei; fibrinoid necrosis: amorphous, eosinophilic, plasma-derived debris within solidified capillaries[b]
Cellular crescents (weighted ×2): Proliferation of extracapillary epithelial cells and infiltrating macrophages creating two or more layers of cells occupying one-fourth or more of the circumference of Bowman's capsule[b]
Hyaline deposits: Wire loop lesions: eosinophilic material of a homogenous consistency along the luminal surface of capillary loops; Hyaline thrombi: more extensive globular, PAS positive material occupying the entire lumen of the capillary[a]
Interstitial inflammation: Infiltration of mononuclear cells (lymphocytes, plasma cells, macrophages) into tubulointerstitial spaces[a]
Chronicity Index (maximum score 12)
Glomerular sclerosis: Glomerular capillary collapse with attendant expansion and solidification of mesangial matrix (segmental or global pattern)[b]
Fibrous crescents: Structures composed predominantly or exclusively of fibrous tissue lining Bowman's capsule[b]
Tubular atrophy: Atrophic changes identified by thickening of tubular basement membranes, with or without tubular epithelial cell degeneration; separation of residual tubular cells is observed.[a]
Interstitial fibrosis: Deposition of periglomerular and peritubular fibrous tissue[a]

[a] Scored on a scale of 0–3+ representing absent, mild, moderate, and severe lesions, respectively.

[b] Scored on a scale of 0–3+ according to presence of lesions in none, <25%, 25–50%, and >50% of glomeruli, respectively.

TABLE 5 Overview of Major Pathogenetic Mechanisms in Lupus Nephritis

Autoantibody production
Some evidence of aberrant or dysregulated B-cell clones producing autoantibodies
Strong evidence for T-dependent, B-cell production of pathogenic autoantibodies to a limited number (~30) of autoantigens
Aberrant expression and activity of B- and T-cell costimulation molecules, CD40-CD154 (CD40L) and CD80/86-CD28, promote dysregulated autoantibody production
Immune complex injury
Deposition of preformed soluble circulating immune complexes in the kidney
Excessive circulating immune complexes is due to both overproduction and impaired reticuloendothelial system clearance
In experimental animal models, deletion of the gene for the γ-chain of the Fc receptor ameliorates nephritis, in spite of immune complex formation and complement activation in the kidney; these experiments indicate that effector mechanisms involving Fc receptors are more important in host responses to immune complexes than for the localization of complexes in the kidney
African-Americans, but not Europeans, with lupus nephritis have an increased frequency of the R131 allele of the human Fcγ receptor which less efficiently recognizes immune complexes containing IgG2 (which are potent activators of complement); however, a meta-analysis showed that Fcγ receptor polymorphisms represented risk for SLE but have no clear effect on susceptibility to lupus nephritis
In situ formation of immune complexes by antibody reaction with constitutive kidney antigens or to antigens planted in the renal parenchyma; this mechanism has been proven for the subepithelial deposits in animal models of membranous nephropathy, but remains unproven in human nephropathies
Injury produced mainly by local activation of complement components with production of leukocyte chemotactic factors (producing hypercellularity and/or necrosis) and formation of membrane attack complex, C5b-9 (increasing glomerular permeability)
Cell mediated immune responses and injury
Cellular interactions (T cells, B cells, antigen presenting cells, resident renal cells) are mediated by both cell-to-cell contact (surface activation and adhesion molecules) and soluble factors (e.g., tumor necrosis factor, interleukin-1)
T cells are characteristically present in interstitial infiltrates, but the role of direct T-cell-mediated injury in the pathogenesis of lupus nephritis is uncertain

immune complexes than to the localization of complexes in the kidney [43].

The following brief overview will focus on the role of autoantibodies and immune complexes (Table 5). This is based on the proposition that lupus nephritis is the prototype of immune complex diseases of the kidney [44–46]. SLE is a complex multisystem disease which develops from a massive overproduction of polyclonal antibodies and impaired clearance of immune complexes. Many of the antibodies are autoreactive and are used in the diagnosis of SLE. Tissue damage results from deposition of pathogenic immune complexes which triggers interacting cascades of inflammation, vasculopathy, and sclerosis.

The classic paradigm is that in disease-prone lupus patients, persistently high levels of circulating immune complexes leads to their egress into the interstices of the mesangium. It is not clear whether the low level of mesangial receptors (e.g., Fc receptors) for components of immune complexes facilitates localization of complexes, or whether the escape of complexes from the blood occurs because of the absence of a structural basement membrane barrier between the circulatory space and the mesangium interstices. Under some circumstances, a steady-state balance of deposition and

disposal (local degradation or exit through renal lymphatic channels) of complexes may produce limited mesangial reaction and no (or minor) clinical signs of renal disease. In others, either due to increasing flux and/or to particular nephritogenic potential of immune complexes, inflammation and mesangial cell activation, with proliferation and production of excessive extracellular matrix, arise to constitute the pathology of mesangial nephropathy. The details of mesangial injury and repair are complex and the subject of intense current investigation in experimental models, which are reviewed elsewhere in this volume. Clinical experience suggests that there may be two forms of mesangial nephropathy: one represents an "intrinsically" benign or compensated mesangiopathic process with little tendency to progress (stable Class II); the other represents mesangial immune complex disease in transition to pathology affecting the peripheral capillary loops (Classes III–V).

As noted previously, it is not clear whether complexes which deposit beneath the endothelium of peripheral capillary loops have qualitatively distinct properties from those with a predilection for the mesangium. One model holds that overload of mesangial clearing mechanisms leads to accumulation of complexes, first at the base or paramesangial areas of the capillary and then more peripherally. Another model holds that localization to the mesangium vs the basement membrane is determined by physicochemical properties of the complexes. Immune complexes with dominant cationic charge and affinity for the anionic basement membrane structures are found with increased frequency in subjects with more severe lupus nephritis. Charge–charge interactions with basement membrane sites may involve free antigens or antibodies or immune complexes. A hypothesis holds that free nuclear antigens released during apoptosis may be "planted" on basement membranes (perhaps via cationic histones) with formation of immune complexes by anti-nuclear antibodies *in situ*.

The nature of the nephritogenic complexes in proliferative lupus nephritis remains controversial. DNA–anti-DNA complexes have long been considered leading suspects [47]. Antibody eluates for lupus kidneys have higher anti-DNA reactivity per unit of immunoglobulin than that of circulating immunoglobulin. Among lupus patients, there are reasonable correlations between anti-DNA antibodies and nephritis activity. However, individuals without anti-DNA may have severe nephritis and others with high titers of anti-DNA may have no evidence of lupus nephritis. Antibodies to endothelial antigens have been reported, but there is no consensus that they play a pivotal role in the pathogenesis of lupus nephritis. Similarly, antiphospholipid antibodies were considered logical candidates to contribute to lupus nephritis. However, these autoantibodies do not produce nephritis in patients with primary antiphospholipid syndromes, nor do they correlate well with morphologic features of lupus nephritis.

The pathogenesis of lupus membranous nephropathy poses a further challenge. Here complexes aggregate on the outer (subepithelial) surface of the glomerular basement membrane. The access of circulating immune complexes to this site is difficult to envision. Moreover, levels of circulating immune complexes correlate poorly with the presence of subepithelial deposits. Experimental models of membranous nephropathy suggest potential mechanisms for forming subepithelial deposits. In the Heymann model, antibodies directed against constitutive antigens on the podocytes of glomerular epithelial cells leads to *in situ* formation of complexes, aggregation, capping, shedding, and finally binding of the complexes to the basement membrane [48]. Other models involve "planting" of antigens in the glomerular basement membrane to which subsequent antibody exposure leads to *in situ* formation of subepithelial immune complexes. Unfortunately, neither model has been proven applicable in human membranous nephropathy. No antibodies derived from plasma or eluted from kidneys affected by membranous nephropathy have shown clear reactivity with normal human kidney antigens. In short, the pathogenesis of human lupus membranous nephropathy remains an enigma.

It seems likely that no species of antigen or antibody is singularly responsible for nephritogenicity in lupus nephritis. Clearly, proof of nephritogenic antigens is essential for planning clinical experiments in tolerance induction, such as would be relevant to a clinical trial using artificial constructs of DNA [49]. However, current therapies focused mainly on nonspecific or polyclonal immunosuppression are not limited by lack of definitive knowledge of the hierarchy of candidate antigens and autoantibodies.

COURSE OF PROLIFERATIVE LUPUS NEPHRITIS

In contemporary clinical practice there are few opportunities to observe the true natural history of lupus nephritis. The occasional patient, unwilling or unable to access health care, may demonstrate the catastrophic consequences of untreated lupus nephritis, a situation presumably equivalent to that reported in

patients throughout the first half of the twentieth century [50]. Descriptions of the course of lupus nephritis should be recognized, not as natural history studies, but rather as the effects of treatment on the course of this disease.

The dramatic improvement in patient survival at mid-century was undoubtedly attributable to new diagnostic tests for SLE, development of corticosteroids, antihypertensives, and antibiotics. For approximately two decades into the second half of the twentieth century, improved longevity led to increases in the proportion of patients that succumbed to the renal failure of lupus nephritis. Data accumulated by the pioneers in this field showed a mean survival of less than 2 years after diagnosis of proliferative lupus nephritis [22, 23, 51]. Attempts to thwart progressive lupus nephritis with corticosteroids produced modest benefits, and often debilitating and life-threatening toxicities arose during treatment. During that era, renal biopsy led to improvement of prognostication based on recognition of the different classes of lupus nephritis. Experienced clinicians recommended intensive corticosteroid therapy for diffuse proliferative, but not for focal or membranous, forms of lupus nephritis [24–26, 52, 53]. Unfortunately, the bulk of patients with clinical evidence of renal disease had diffuse proliferative lupus nephritis and the prognosis, though modestly improved from earlier times, remained poor with corticosteroid treatment alone. Anecdotes and small series suggested additional benefit of cytotoxic drugs, recognized in oncology clinics for their (undesirable) immunosuppressive properties and in the laboratory as being effective modulators of immune reactions in experimental models.

Due to the subtle and gradual improvement in prognosis of patients, it was recognized by investigators both at the NIH and Mayo in the late 1960s that controlled trials would be necessary to ascertain the true renal risk/benefit of alternative therapies for proliferative lupus nephritis. In early studies, both short-term (months) [54–58] and long-term (years) [59–61] treatment regimens of cytotoxic drugs stabilized lupus nephritis more effectively than did corticosteroids alone (described in detail later). Continued observation in these controlled trials demonstrated objective benefit of cyclophosphamide over corticosteroid controls only in the long-term treatment protocols [40, 62, 63]; 10-year renal survival improved from approximately 50% with prednisone alone to approximately 90% with sustained cyclophosphamide treatment.

The conclusions of the NIH studies extolling the benefits of cytotoxic drugs for proliferative lupus nephritis have been challenged in two ways. Some reports have suggested that extremely favorable renal outcomes can be achieved with only brief courses of (or even without) cytotoxic drugs (Fig. 13) [28, 64–70]. As shown, the 5-year renal survival (without end-stage renal failure) ranges dramatically, from over 90% to less than 30%, in various centers within the United States and Europe. It is notable that the three series with the worse outcome include predominantly Black patients. One of the most favorable outcomes was reported from an Italian registry of over 650 patients most of whom did not receive cytotoxic drugs; the 5-year renal survival was approximately 88% [65]. At the other end of the spectrum of arguments, some reports have indicated that the intense regimen of cytotoxic drugs is ineffective in controlling lupus nephritis, at least in certain subsets of patients. The study of pediatric lupus nephritis treated with pulse cyclophosphamide showed a dismal 5-year renal survival of <30% in a population that was predominantly Black [70]. Dooley *et al.* [67] has reported substantially poorer than expected outcomes among Black patients treated with pulse cyclophosphamide. These investigators noted that the 5-year renal survival was 58% in Blacks and 95% in non-Blacks (Fig. 14). The differences were not explained by differences in frequency or severity of hypertension or in renal histopathology. Interestingly, analysis of racial subsets in our own controlled trials did not yield a difference between Black and non-Black patients in the frequency of favorable responses to cyclophosphamide [71]. These observations may be identifying important differences among patient populations and could limit the ability to extrapolate a universal benefit of cyclophosphamide therapy. This hypothesis clearly warrants further testing in therapeutic studies controlled for the effects of race [72].

Cameron has analyzed the overall trends in survival among patients with diffuse proliferative lupus nephri-

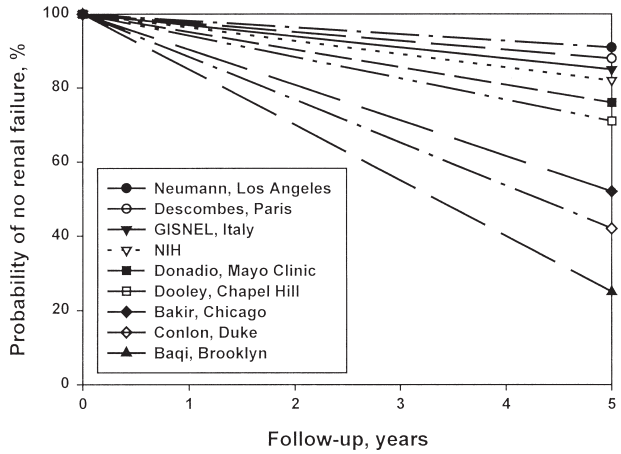

FIGURE 13 Risks of developing end-stage renal disease (ESRD) at 5 years in patients with diffuse proliferative lupus nephritis treated at nine different centers [28, 64–70].

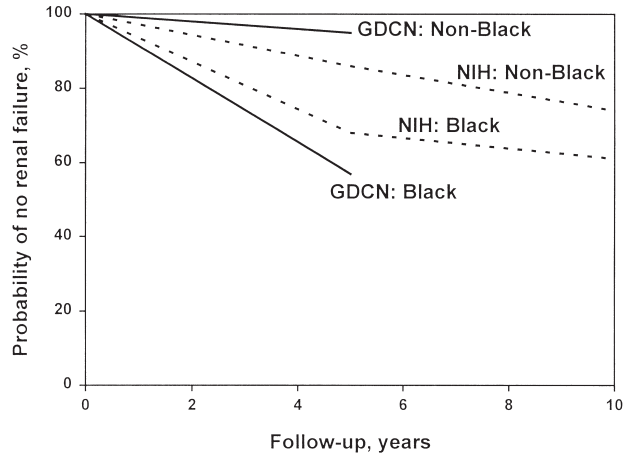

FIGURE 14 Effect of race on risk of developing end-stage renal disease (ESRD) in Black and non-Black patients with diffuse proliferative lupus nephritis treated in the Glomerular Disease Collaborative Network (GDCN) [67] and at the NIH [96].

tis [73]. Five-year patient survival estimates synthesized from several publications rose from 17% before 1970, to 55% during the period 1970–1979, and to >80% after 1980. There is general agreement that cytotoxic drugs have had less impact on patient survival than on renal survival in patients with SLE and lupus nephritis.

COURSE OF LUPUS MEMBRANOUS NEPHROPATHY

The renal prognosis of classic lupus membranous nephropathy (with no more than mesangial expansion) is generally more favorable than proliferative lupus nephritis. However, if one incorporates proliferative lupus nephritis under the rubric of lupus membranous nephropathy, as was suggested in the 1985 version of the WHO classification system (reviewed in Ref. 27), delineation of prognosis has become more complex and one must consider distinct renal prognosis for each subset. Indeed, using this earlier approach to classification, some investigators have reported that membranous subsets with diffuse proliferation (Vc) or with sclerosis (Vd) have a substantially worse five-year renal survival than patients with classic lupus membranous nephropathy [66, 74, 75]. Again, our preference for biopsies with mixed membranous and proliferative histologies is to categorize them as proliferative lupus nephritis with commensurate considerations of prognosis and treatment. Preliminary studies of the impact of race on prognosis of lupus membranous nephropathy have been reported [76]. In a comparatively large study of 60 patients with lupus membranous nephropathy, Black race was a predictor of renal failure. In a smaller study, Bakir *et al*. [68] found no apparent effect of Black race on the prognosis of lupus membranous nephropathy. As with proliferative forms of lupus nephritis, continued search for the explanation(s) of the worsened renal prognosis among Blacks is clearly warranted [77–79].

PROGNOSTIC INDICATORS

Demographic, clinical, laboratory, and pathologic features of lupus nephritis influence the course of lupus nephritis (Table 6) [44, 71, 73, 80–88]. Some parameters which correlate statistically with renal outcome may not be directly responsible for disease progression, but simply represent surrogates for less well defined pathogenic factors that determine prognosis (e.g., anemia as a surrogate for overall severity of SLE). Multivariate statistical methods are widely used to define independent prognostic factors. The predictive value of hematocrit, platelet count, serum creatinine, complement levels, hypertension, and renal biopsy data have been demonstrated in this fashion. Some of these factors are present at diagnosis and will remain static; others wax and wane during the course of lupus nephritis and reflect a changing prognosis. A composite of prognostic factors is useful in assessing severity and developing a rational plan of therapy for lupus nephritis. In general, the larger the number of factors, the more unfavorable the renal outcome and the stronger the indications for aggressive immunosuppressive drug therapy. Clinical and histologic evidence of severe, active lupus nephritis or active superimposed on chronic, irreversible parenchymal injury represent the most ominous prognostic features.

As the treatment and long-term survival of patients with lupus nephritis have improved, it should not be surprising that the impact of factors at disease onset assume less predictive value. Thus, time-dependent parameters (e.g., serologic parameters, urinary sediment, proteinuria, and serum creatinine) and those present later in the course of the disease (e.g., relapses of nephritis) may be of greater prognostic importance than those present at the onset of lupus nephritis. Finally, the challenge for the clinician is to negate, to the extent possible, the negative impact of the predictors of adverse prognosis by effective therapeutic intervention. A reanalysis of data from a NIH clinical trial provides evidence that contemporary regimens of immunosuppression can achieve this goal. Patients with extensive chronic irreversible histologic changes on renal biopsy

TABLE 6 Factors Associated with Adverse Prognosis and High Risk of Renal Progression in Lupus Nephritis

Demographic
Black race
Hispanic ethnicity
Male gender[a]
Extremes of age at onset of SLE[a]
Limited access to health care
Clinical
Hypertension
Severe extrarenal (especially neuropsychiatric) lupus activity
Failure to achieve remission or marked delay to renal remission
Multiple relapses of lupus nephritis
Pregnancy
Laboratory
Nephritic urinary sediment
Azotemia
Anemia
Thrombocytopenia
Thrombotic microangiopathy (with or without anti-phospholipid antibodies)
Hypocomplementemia (especially falling levels)
High anti-DNA (especially rising titers)
Persistent severe nephrotic syndrome (atherosclerotic and thrombotic diathesis)
Renal pathology
Contracted kidney size[b]
Proliferative glomerulonephritis (WHO Class III, IV)
Mixed membranous (V) and proliferative (III–IV) glomerulonephritis
Cellular crescents (>25% of glomeruli)
Fibrinoid necrosis (>25% of glomeruli)
Very high activity index
Moderate-to-high chronicity index[b]
Combinations of active (cellular crescents) and chronic features (interstitial fibrosis)
Extensive subendothelial deposits

[a] There is controversy regarding the level of impact of these prognostic factors.

[b] These prognostic factors per se are not indications for treatment.

Modified from: Balow *et al.* (2003). Lupus Nephritis. In "Therapy in Nephrology and Hypertension" (Brady and Wilcox, Eds.), 2nd ed., p 158. W.B. Saunders, London.

(chronicity index >3) are at increased risk for progressive deterioration of renal function. A relatively effective treatment (30 months course of pulse cyclophosphamide) modulates this risk to a greater degree than a short course (6 months) of pulse methylprednisolone (Fig. 15). Figure 15 illustrates the impact of prognostic factors and therapeutic intervention on renal function outcome.

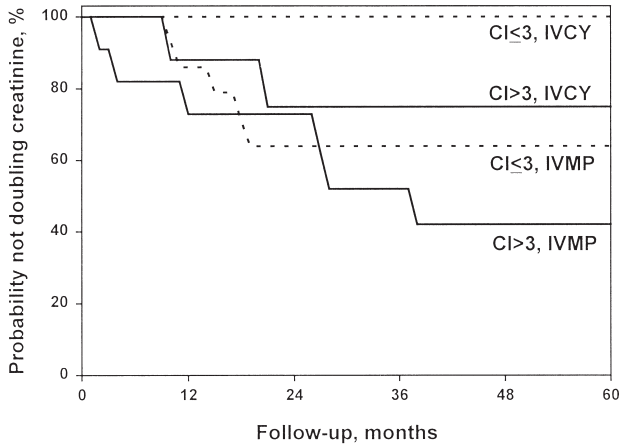

FIGURE 15 Prognostic impact of therapy and renal histology. The differential effectiveness of pulse methylpredniso lone and pulse cyclophosphamide according to the degree of chronicity on renal biopsy is shown. Substantial underlying chronic renal damage increases the probability of doubling serum creatinine with either pulse therapy, but particularly pulse methylprednisolone.

APPROACHES TO TREATMENT OF LUPUS NEPHRITIS

There is no panacea for SLE, nor for lupus nephritis. However, modern treatments offer the prospect of sustained remissions and substantial longevity. Numerous therapeutic options are available for management of lupus nephritis, including immunosuppressive drugs, adjunctive therapies for secondary complications of renal disease, and a variety of experimental agents (Table 7). While our opinions on the uses and effectiveness of each option for treatment of lupus nephritis are summarized in this table, we acknowledge that individual perspectives on these therapeutic modalities vary widely.

EVIDENCE FROM CONTROLLED TRIALS OF THERAPY FOR LUPUS NEPHRITIS

Because of the intrinsic diversity in severity and rates of progression of lupus nephritis among various patient populations, controlled clinical trials have been absolutely essential in defining the objective risk/benefits of particular therapeutic interventions in SLE and lupus nephritis. Objective proof of the value of experimental interventions depends in large measure on randomized design and comparison of outcome frequencies between experimental and concurrent (rather than historical) control groups. It is imperative to continue to use this

TABLE 7 Therapeutic Options for Management of Lupus Nephritis

- Immunosuppressive drug therapy
  - Prednisone
    - Initiate at 1.0 mg/kg/day
    - Continue for no more than 8 weeks (except when extreme clinical conditions mandate)
    - Taper to alternate day therapy in doses of 0.25 mg/kg every other day
    - Use alternative immunosuppressive drugs rather than continued daily prednisone therapy, whenever possible
    - Maintain assiduous surveillance and protection against steroid-induced osteoporosis (i.e., exercise, adequate calcium, vitamin D, bisphosphonates)
  - Methylprednisolone pulse therapy
    - Initiate at 1.0 g/m^2 daily for 3 days for severe activity (rapidly progressive renal failure, crescentic glomerulonephritis)
    - Option to repeat pulse doses at monthly intervals
    - May combine with pulse cyclophosphamide in severe or refractory cases
  - Cyclophosphamide
    - Intermittent pulse therapy has highest therapeutic index
    - Conventional daily cyclophosphamide therapy (2 mg/kg/day) is mostly avoided, or used for <3 months (see Table 9 for details on administration of pulse cyclophosphamide)
  - Azathioprine
    - Alternative agent in SLE
    - Mostly used for extrarenal disease, in mild lupus nephritis, as maintenance after period of improvement induced by cyclophosphamide, or as a steroid sparing agent in patients who require sustained high doses of prednisone or in those unwilling to accept or unable to tolerate cyclophosphamide treatment
  - Mycophenolate mofetil
    - Preliminary results suggest it may be a useful alternative to cyclophosphamide for induction therapy (controlled trial in progress)
    - Alternative to azathioprine for maintenance therapy
  - Methotrexate
    - Mostly used as adjunct or alternative anti-inflammatory therapy for extrarenal manifestations of SLE
    - Use in lupus nephritis is limited because renal dysfunction enhances risk of side effects
  - Cyclosporine
    - Mostly used in low doses (e.g., <5 mg/kg/day) in lupus membranous nephropathy
    - Limited use in proliferative lupus nephritis
  - Plasma exchange
    - Controlled trials have not demonstrated benefit of plasmapheresis in lupus nephritis
    - Mostly used for microangiopathic complications of lupus, such as vasculopathy of superimposed thrombotic thrombocytopenic purpura
  - Intravenous immunoglobulins
    - Expensive, short-term therapy
    - Mostly used in lupus for immune mediated thrombocytopenia or refractory CNS disease
- Adjunctive therapies for secondary complications of renal disease
  - Angiotensin antagonists, including angiotensin converting enzyme inhibitors (ACEI) and angiotensin receptor blockers (ARB)
    - Glomerular proteinuria persisting after control of active nephritis may be decreased by these agents (this must be balanced against their potential adverse effects on GFR and serum potassium)
  - Other antihypertensives
    - Treatment of hypertension and drug choices follow standard guidelines
    - Use blood pressure goals appropriate for age of patient
  - Lipid-lowering drugs
    - For control of hyperlipidemia of nephrotic syndrome
    - Usually start HMG-CoA-reductase inhibitors and fibric acid derivatives if nephrotic
- Experimental therapies
  - Sirolimus (rapamycin)
    - Immunosuppressive and antiproliferative properties
    - Limited observations in human SLE
  - Leflunomide
    - Anecdotal experience only
  - Adenosine analogs (cladrabine, fludarabine)
    - Limited pilot studies in SLE and refractory lupus nephritis
  - DNA toleragen (LJP-394)
    - Preliminary studies suggests marginal benefits in most patients
    - May be larger benefit in patients with high titer anti-DNA
  - Autologous stem cell transplants
    - Encouraging preliminary results
    - Intense immunoablative conditioning associated with high risk
    - Appropriate patient selection remains a major challenge
  - Monoclonal antibodies
    - Anti-T-cell: several small pilot studies (no definitive recommendations)
    - Anti-B-cell (e.g., rituximab): pilot studies in progress
    - Anti-complement C5b-9: pilot study in progress
  - Costimulation inhibitors
    - Anti-CD154 (CD40 ligand): preliminary data suggest some efficacy, but studies halted due to thromboembolic complications
    - CTLA4-Ig: effective in lupus mice, especially in combination with cyclophosphamide; pilot human studies (psoriasis) suggest good therapeutic index; no studies in human lupus

Modified from: Balow *et al.* (2003). Lupus Nephritis. In "Therapy in Nephrology and Hypertension" (Brady and Wilcox, Eds.), 2nd ed., p 159. W.B. Saunders, London.

design methodology if we are to advance the state of the art in treatment of lupus nephritis [89].

Animal models of SLE (reviewed elsewhere in this volume) have been extremely valuable in screening a wide range of new therapies for human lupus nephritis. In general, the murine models respond better and to more therapies than do human patients, but overall the responses to treatment are quite well correlated. In murine lupus, major benefit has been realized with cyclophosphamide, total lymphoid irradiation, and bone marrow transplantation. Moderate benefit has been observed with a host of interventions, including immunosuppressive drugs (e.g., corticosteroids, azathioprine, mycophenolate, methotrexate, cyclosporine, tacrolimus, rapamycin), monoclonal antibodies (particularly against activated T cells and nephritogenic idiotypes), as well as an array of cytokine antagonists, modulators of inflammation, anticoagulants, fibrinolytic agents, and dietary manipulations (Table 7).

Corticosteroids

The reader may be surprised that no controlled clinical trials have ever been performed to prove unequivocally the value of corticosteroids over simple supportive therapies, nor have there been any studies directly comparing conventional prednisone with methylprednisolone pulse therapy. Indeed, it is unlikely that prospective clinical trials comparing placebo, low-dose, and high-dose corticosteroids for lupus nephritis will ever be performed, due to the potentially confounding effects of the standard clinical practice of using high-dose corticosteroids as first line treatment for the myriad of extrarenal manifestations and complications of SLE. The best advice for the practitioner is not to withhold corticosteroids for fear of complications, but rather to test regularly the feasibility of reducing doses (preferably to alternate day) and to be willing to substitute alternative immunosuppressive drug strategies if clinical response is delayed. Physicians treating patients with SLE and lupus nephritis should always be inclined to reduce dosages of corticosteroids to the lowest necessary for disease control in order to minimize risk of their insidious complications. Indeed, the substantial toxicity of prolonged high-dose corticosteroids is one of the most compelling reasons for continued exploration of alternative immunosuppressive therapies.

Azathioprine

Early human studies, including controlled trials, showed azathioprine to be, at best, of modest benefit as an adjunct to corticosteroids in lupus nephritis [54, 55, 90–92]. At the present time, azathioprine is used as principal therapy in patients with severe lupus nephritis who decline cyclophosphamide or for treatment of milder forms of lupus nephritis. Particularly in European centers, azathioprine is typically used as maintenance therapy following an initial 2- to 3-month induction course of cyclophosphamide [44].

Cyclophosphamide

Cyclophosphamide is considered one of the most potent immunosuppressive drugs both in murine models and in human lupus nephritis. Table 8 summarizes, in a chronological fashion, a series of controlled trials addressing the benefits of various forms of cyclophosphamide in treatment of lupus nephritis. Conclusions from studies of the efficacy of cyclophosphamide depend heavily on the duration of treatment. Short courses of daily cyclophosphamide were more efficacious than prednisone alone in decreasing activity of lupus nephritis [56, 57, 59–63]. Maintenance with prednisone alone did not protect against late risk of renal failure, while continuation of cyclophosphamide with prednisone as maintenance therapy was associated with decreased risk of late renal failure [62]. The counterbalancing cumulative toxicity of prolonged daily therapy has generally constricted the use of cyclophosphamide to short courses of therapy in lupus nephritis.

Pulse Cyclophosphamide

The risk/benefit advantage of pulse cyclophosphamide over daily oral cyclophosphamide has been amply demonstrated in clinical oncology, and in a vasculitis study wherein increased complications of daily cyclophosphamide were noted [93]. Proof of a comparable advantage of pulse cyclophosphamide over corticosteroids alone in human lupus nephritis was realized incrementally in long-term studies. Several regimens of cyclophosphamide, including conventional dose oral therapy, low-dose combination of cyclophosphamide and azathioprine, and intermittent pulse cyclophosphamide were superior to prednisone alone in controlling clinical activity of nephritis, in attenuating renal pathologic changes over time [40], and ultimately in reducing the risk of developing end-stage renal failure [62]. While any regimen containing cyclophosphamide was superior to corticosteroids alone, increased toxicities of daily cyclophosphamide has rendered intermittent pulse administration the preferable approach to cyclophosphamide therapy.

TABLE 8 Chronology of Controlled Trials of Cyclophosphamide Therapy in Lupus Nephritis

Steinberg and Decker, 1974 [59]: Decker *et al*., 1975 [60]: Extended courses of oral CY (up to 4 years) produced higher rates of improvement in extrarenal lupus activity, lupus serologies, and urinary abnormalities than prednisone alone

Donadio *et al*., 1978 [57]: Donadio *et al*., 1982 [58]: Short courses (6 months) of oral CY produced higher rates of improvement and stability of lupus nephritis than did prednisone alone; the benefits of short courses of oral CY were not sustained during extended follow-up (no differences in late risk of ESRD)

Dinant *et al*., 1982 [61]: Extended courses (treatment beyond remission) of combined oral AZ and CY or quarterly pulse IV-CY produced higher rates of improvement in urine sediment, proteinuria, and lupus serologies than prednisone alone

Balow *et al*., 1984 [40]: Analysis of the evolution of renal pathology; cytotoxic drugs afforded better protection against worsening of scarring, atrophy, and fibrosis; prednisone alone was associated with worsening of chronicity features in proportion to the interval between biopsies

Austin *et al*., 1986 [62]: Extended treatment (beyond renal remission) with pulse IV-CY significantly reduced risk of progression to ESRD compared to prednisone alone

Steinberg and Steinberg, 1991 [63]: Additional observation of patients in previous study; sustained courses of oral CY, combined low-dose oral AZ and CY, or pulse IV-CY decreased the risks of ESRD compared to that of prednisone alone

Boumpas *et al*., 1992 [96]: IV-CY reduced the risks of doubling creatinine from that of a short course (6 months) of monthly IV-MP; extended course (30 months) of pulse IV-CY reduced the risk of renal relapse compared to a short course (6 months) of IV-CY

Lewis *et al*., 1992 [121]: Plasmapheresis with prednisone and short courses (2 months) of oral CY did not improve clinical outcomes compared to prednisone and oral CY alone

Sesso *et al*., 1994 [97]: Limited courses (10 months) of pulse IV-CY or pulse IV-MP (monthly ×4 and quarterly ×2) showed no differences in risks of doubling creatinine or of developing ESRD

Gourley *et al*., 1996 [98]; Illei *et al*., 2001 [99]: Extended courses (up to 3 years) of pulse IV-CY or combination pulse IV-CY and pulse IV-MP produced higher rates of renal remission than did extended courses (up to 3 years) of monthly pulse IV-MP; remission achieved slightly more rapidly with combination pulse therapy

Wallace *et al*., 1998 [122]: Plasmapheresis synchronized with pulse IV-CY offered no clinical advantages (in lupus activity scores or rates of adverse events) over pulse IV-CY alone

Chan *et al*., 2000 [13]; Chan *et al*., 2001 [118]: Comparison of mycophenolate with conversion to maintenance azathioprine at 12 months and daily oral cyclophosphamide with conversion to maintenance azathioprine at 6 months; at 12 months, there were no differences in favorable and unfavorable renal outcomes between the two treatment arms; however, after an additional year of follow-up into the azathioprine maintenance phase of treatment, there was a significantly greater risk of relapse in the subjects originally treated with mycophenolate induction therapy

Houssiau *et al*., 2002: Compared high-dose (≤1.5 g) pulse cyclophosphamide monthly for 6 months followed by 2 quarterly doses *vs* low doses (0.5 g fixed dose) of pulse cyclophosphamide fortnightly for 6 doses; after median follow-up of 3.5 years, there were no substantive differences in the proportions of favorable and unfavorable renal outcomes

Additional studies have examined whether pulse methylprednisolone [94, 95] might improve on the efficacy of standard prednisone and meet the efficacy of pulse cyclophosphamide. No differences were found in short-term (6 months) studies comparing pulse methylprednisolone and pulse cyclophosphamide [96, 97]. However, the NIH study showed that an extended course of pulse cyclophosphamide (30 months) was superior to pulse methylprednisolone in reducing the probability of doubling serum creatinine, as well as being superior to short-term cyclophosphamide in reducing the probability of relapse of lupus nephritis [96]. A subsequent NIH study compared extended courses of pulse methylprednisolone alone, pulse cyclophosphamide alone, or in combination. Renal remission occurred more rapidly with combination pulse therapy and was least likely with pulse methylprednisolone alone [98, 99]. These and other uncontrolled studies [100–106] favor the use of pulse cyclophosphamide in patients with proliferative lupus nephritis.

In summary, neither pulse methylprednisolone (of any duration) nor short-term pulse cyclophosphamide are as efficacious as extended courses of pulse cyclophosphamide. Short courses (3–6 months) of either daily or intermittent pulse cyclophosphamide tend to produce responses of limited duration. Thus, some form of maintenance therapy appears essential to reduce the risk of relapsing lupus nephritis [107–111].

Studies comparing azathioprine and cyclophosphamide as maintenance therapies are in progress. Early results (after 8 months) of an ongoing controlled trial in the Netherlands have suggested that a regimen of pulse methylprednisolone and azathioprine is comparable to a regimen of pulse cyclophosphamide [112]. Azathioprine continues to be used in many centers around the world as maintenance therapy—often after patients have had substantial improvement or achieved remission of lupus nephritis with cyclophosphamide therapy. Preliminary results of an ongoing controlled clinical trial in the United States have suggested that azathioprine may be as effective as quarterly pulse cyclophosphamide for maintenance therapy [113].

Mycophenolate Mofetil

Based principally on studies showing greater efficacy of mycophenolate over azathioprine in reducing transplant rejection, several investigators began exploring the use of mycophenolate in lupus nephritis (particularly for patients adverse or refractory to cyclophosphamide) [114–117]. There are several issues impinging on the decision to use mycophenolate. Among the most attractive attributes of mycophenolate is its lack of

gonadal and urinary bladder toxicity (compared to cyclophosphamide).

A controlled trial showed that induction therapy with mycophenolate was comparable to daily oral cyclophosphamide for achieving remission [13]. In a preliminary follow-up report, these investigators found that relapses following conversion to maintenance azathioprine therapy were more common in patients initially treated with mycophenolate than with cyclophosphamide [118]. These results suggest that cyclophosphamide induction confers a longer period of stability than does mycophenolate. Sustained treatment with mycophenolate, or a more effective alternative than azathioprine, may be necessary to reduce the tendency to early relapse. If long-term maintenance is necessary, the extremely high cost of mycophenolate could become a practical limitation. Prospective studies in progress should address the effectiveness of lower cost azathioprine as maintenance therapy following induction of remission by either cyclophosphamide or mycophenolate. It is noteworthy that a prospective, multicentered clinical trial is in progress comparing mycophenolate to standard pulse cyclophosphamide as induction therapy for proliferative lupus nephritis [119].

Plasmapheresis

Plasmapheresis has been studied in several controlled trials of SLE and lupus nephritis. The earliest study showed no clinical differences between sham and real plasmapheresis [120]. Subsequent studies showed no benefit of adding plasmapheresis to standard immunosuppression with prednisone and a short course of cyclophosphamide [121]. Preliminary results of a controlled trial involving synchronized plasmapheresis and pulse cyclophosphamide also failed to demonstrate a benefit of plasmapheresis [122–124].

TREATMENT OF PROLIFERATIVE LUPUS NEPHRITIS

Among the various immunosuppressive drugs presented, cyclophosphamide has been shown to have one of the highest therapeutic indices for proliferative lupus nephritis, based on evidence gained in controlled trials in both murine and human disease. In general, short courses (e.g., 2–6 months) of cyclophosphamide, either in conventional daily doses or in intermittent pulse doses, improve the activity of lupus nephritis, but there are high probabilities of exacerbation without some form of maintenance cytotoxic drug therapy. Prospective studies of alternative maintenance therapies are clearly needed. Because of the acknowledged cumulative risk of toxicity with conventional therapy, daily oral cyclophosphamide is no longer considered a viable option for extended maintenance therapy.

Table 9 describes our approaches to administration of pulse cyclophosphamide therapy. It is critically

TABLE 9 Recommendations for Administration of Pulse Cyclophosphamide Therapy

Estimate glomerular filtration rate (GFR) by standard methods

Calculate body surface area (m^2): $\mathrm{BSA} = \sqrt{\frac{\mathrm{Height\,(cm)} \times \mathrm{Weight\,(kg)}}{3600}}$

Cyclophosphamide (Cytoxan) (CY) dosing and administration:
- Initial dose CY is 0.75 g/m^2 (*important note*: start with 0.5 g/m^2 of CY if glomerular filtration rate is less than one-third of expected normal)
- Administer CY in 150-ml normal saline iv over 30–60 min (*alternative*: equivalent dose of pulse CY may be taken orally in highly motivated and compliant patients)

Obtain WBC at days 10 and 14 after each CY treatment (*note*: advise patient to delay taking prednisone until after blood tests are drawn to avoid transient steroid-induced leukocytosis)

Adjust subsequent doses of CY to keep nadir WBC above 1500/μl (escalate CY to maximum dose of 1.0 g/m^2 unless WBC nadir falls below 1500/μl)

Repeat CY doses monthly (every 3 weeks in patients with extremely aggressive disease) for 6 months, then quarterly for 1 year *after* remission is achieved; remission is defined by: inactive urine sediment, proteinuria <1 g/day, and a state of minimal or no activity of extrarenal lupus (also, ideally, normalization of serum complement and anti-DNA).

Protect bladder against CY-induced hemorrhagic cystitis:
- Induce diuresis with 5% dextrose and 0.45% saline (e.g., 2 liters at 250 ml/h) and encourage frequent voiding; continue high-dose oral fluids through 24 h; counsel patients to return to clinic if they cannot sustain ingestion of enteral fluids
- Give mesna (Mesnex) (each dose 20% of total CY dose) intravenously or orally at 0, 2, 4, and 6 h after CY dosing (*note*: use of mesna strongly urged whenever sustained diuresis may be difficult to achieve, or if pulse CY is given in outpatient setting)
- If patients anticipated to have difficulty with sustaining diuresis (e.g., severe nephrotic syndrome) or with voiding, insert a 3-way Foley catheter with continuous bladder flushing with standard antibiotic irrigating solution (e.g., 3 liters) for 24 h to minimize risk of hemorrhagic cystitis

Antiemetics (usually administered orally):
- Dexamethasone (Decadron) 10-mg single dose *plus*:
- Serotonin receptor antagonists: Granisetron (Kytril) 2 mg concurrent with CY dose and 1 mg after 12 h; alternative: Ondansetron (Zofran) 8-mg tid for 1–2 days (more expensive)

Monitor fluid balance during diuresis: if patient develops progressive fluid accumulation, use diuretics to reestablish fluid balance

Modified from: Balow *et al*. (2003). Lupus Nephritis. In "Therapy in Nephrology and Hypertension" (Brady and Wilcox, Eds.), 2nd ed., p 160. W.B. Saunders, London.

important to adjust the dose of pulse cyclophosphamide according to renal function [3]. Decreased glomerular filtration rate prolongs the half-life of cyclophosphamide and its metabolites; inappropriately high doses can be associated with life-threatening bone marrow suppression. It is unproven whether cyclophosphamide effectiveness is within limits proportional to the degree of induced leukopenia. We recommend that doses of cyclophosphamide should be increased gradually to achieve moderate leukopenia at the expected 10- to 14-day nadir. Use of arbitrarily low doses of cyclophosphamide, which do not affect white blood counts, often leads to ambiguity whether the lack of expected clinical response is due to cyclophosphamide resistance or to inadequate dosing.

Protection of the urinary bladder against the toxicity of cyclophosphamide metabolites is accomplished by forced diuresis, mesna treatment (to bind the toxic metabolite, acrolein), frequent voidings, and diuretics (as needed) for at least 8–12 h after pulse cyclophosphamide. Newer antiemetic drugs (serotonin receptor antagonists) have virtually revolutionized the control of nausea and greatly improved the tolerability of repeated doses of pulse cyclophosphamide. Table 10 contains a synopsis of potential side effects of pulse cyclophosphamide therapy, including ovarian toxicity [125–127]; perspectives on cancer in lupus patients is also included [128–130].

An outline of practical approaches to treatment of diffuse and severe focal proliferative lupus nephritis is shown in Table 11. These therapeutic guidelines address initial approaches to treatment based on severity of nephritis, recommendations for transition to maintenance immunosuppressive drug therapies, alternative induction and maintenance regimens, and suggestions for duration of treatment. Table 12 contains a set of guidelines for discontinuation of cytotoxic drugs in situations where treatment of lupus nephritis has failed.

TABLE 10 Potential Toxicities of Pulse Cyclophosphamide

Nausea/vomiting: Currently, minimal problems with use of serotonin receptor antagonists
Alopecia: Mild, diffuse hair thinning common; cosmetically severe alopecia is exceptional
Infection: Bacterial, fungal, and pneumocystis infections increased by excessive or prolonged leukopenia (<1500 per μl); risk of herpes zoster, papilloma infections moderately increased
Hemorrhagic cystitis: Minimal risk (compared to conventional cyclophosphamide); risk reduced by diuresis, frequent voiding, mesna
Bladder fibrosis, bladder carcinoma: Low risk with intermittent pulse cyclophosphamide
Gonadal failure: Risk proportional to age of patient and cumulative dose of cyclophosphamide; potential benefit of preemptive gonadal suppression with leuprolide (Lupron) is undefined
Teratogenesis: Rare case report with cyclophosphamide during unrecognized pregnancy; N.B.: patients should be screened for pregnancy prior to each dose cyclophosphamide
Cardiac: Myocardial toxicity with congestive heart failure is rare at cyclophosphamide doses ≤1.0 g/m^2
Pulmonary: Pulmonary fibrosis exceedingly rare at cyclophosphamide doses ≤1.0 g/m^2
Hepatic: Anecdotal cases of severe hepatocellular injury with pulse cyclophosphamide
Metabolic (SIADH): Rare complication but potential cause of water intoxication during planned diuresis; monitor intake and output following cyclophosphamide pulse therapy
Bone marrow: Rare aplastic anemia, myelodysplasia
Malignancy: Small, but apparently real, increase in incidence of malignancies (e.g., leukemia/lymphoma, gynecologic, and skin cancers); relative risk is low

TREATMENT OF LUPUS MEMBRANOUS NEPHROPATHY

Historically, lupus membranous nephropathy was considered to be an intrinsically mild form of lupus nephritis that did not merit specific treatment. Pure forms of lupus membranous nephropathy (those with only background mesangial expansion) were noted to have low risk of progression to end-stage renal failure [25, 26, 73, 74, 131, 132].

Against these comments about the generally favorable renal outcomes of lupus membranous nephropathy, it has become apparent that the typically persistent nephrotic syndrome of this disease substantially increases the risk of thromboembolic [133] and atherosclerotic [134, 135] complications, which in turn jeopardize patient survival. These issues have been analyzed in most detail in idiopathic membranous nephropathy, but similar considerations apply in lupus membranous nephropathy. Currently, the motivation to treat patients with membranous nephropathy are based, at least in part, on the goal of reducing the risks of thrombotic and atherosclerotic complications. However, the fact that the risk of end-stage renal failure approximates 20% at 10 years after diagnosis strengthens the rationale for interventions in lupus membranous nephropathy.

A perspective on the treatment of lupus membranous nephropathy involved a retrospective analysis of outcomes in 19 patients treated with prednisone alone or in combination with alternating months of pulse methylprednisolone and chlorambucil [136]. Of 8 patients treated with prednisone alone, 3 achieved complete and one partial remission; 7 subsequently relapsed

TABLE 11 Treatment of Diffuse (and Severe Focal) Proliferative Lupus Nephritis

I. Recommended Initial treatment
  A. Moderate disease: defined by limited number and severity of risk factors (Table 6)
    1. Prednisone (1.0 mg/kg/day): limited trial (up to 8 weeks)
      a. If *complete* response occurs, including clearing of cellular casts and proteinuria, normalization of complement, and minimal lupus activity, simply taper prednisone to alternate day (~0.25 mg/kg) and monitor for flares of nephritis.
      b. If no or incomplete response to prednisone, or nephritis worsens, start monthly pulse cyclophosphamide (follow protocol below for severe disease).

  N.B.: Do not delay this therapeutic decision beyond 8 weeks because of a partial response to prednisone
  B. Severe disease: defined by presence of a constellation of high-risk factors (Table 6)
    1. Prednisone (1.0 mg/kg/day tapered) plus:
    2. Monthly pulse cyclophosphamide (0.75 g/m^2) (0.5 g/m^2 if GFR is less than one-third normal) for 6 months; increase dose of cyclophosphamide by up to 0.25 g/m^2 increments, to maximum of 1.0 g/m^2 unless total leukocytes fall below 1500/μl at the 10 to 14-day nadir point.

II. Recommended transition to maintenance immunosuppressive drug therapy or early discontinuance of induction therapy (at 6 months)
  A. In selected patients, pulse cyclophosphamide may be stopped and treatment continued with alternate day prednisone (0.25 mg/kg) alone. Such patients have exquisitely responsive nephritis (defined by complete clearing of cellular casts and proteinuria, normal complement, and minimal lupus activity within the first 6 months). Limited duration of cyclophosphamide therapy is also important for patients giving high priority to maintaining fertility while accepting the risk of low-grade activity of lupus nephritis.
  B. The majority of patients with proliferative lupus nephritis will not be in full remission at 6 months. Convert this group to maintenance pulse cyclophosphamide every 3 months (doses adjusted by same guidelines used during the induction therapy phase).

  N.B.: Microscopic hematuria often does not clear for several months, even when most other clinical parameters have remitted; by itself, microscopic hematuria is usually not a sufficient reason to abandon a particular therapeutic program

III. Alternative induction and maintenance treatment regimens
  A. Induction therapy: prednisone (1.0 mg/kg/day tapered) plus:
    1. Pulse methylprednisolone 1.0 g/m^2 daily for 3 doses; may repeat pulses at monthly intervals and continue for 6–12 months if there is steady progress toward remission.
    2. Mycophenolate mofetil, 0.5–2.0 g/day; titrate dose as tolerated (GI side effects mostly dose limiting; low to moderate risk of bone marrow suppression.
    3. Daily oral cyclophosphamide, 2 mg/kg/day for 2–6 months (risks greater gonadal and urinary bladder toxicities).
    4. Oral pulse cyclophosphamide, ranging from 0.5 g weekly to 1.0 g/m^2 monthly (in highly motivated, fastidiously compliant patients).
  B. Maintenance therapy: alternate day prednisone (~0.25 mg/kg) plus:
    1. Azathioprine, 2 mg/kg/day.
    2. Mycophenolate mofetil, 0.5–2.0 g/day.

IV. Duration of therapy
  A. Cyclophosphamide: continue quarterly maintenance cyclophosphamide treatments for 1 year *after* remission of lupus nephritis is achieved [defined by: inactive urine sediment, proteinuria <1 g/day, and a state of minimal or no activity of extrarenal lupus (and, ideally, normalization of serum complement and anti-DNA)]. Patients with isolated fixed proteinuria or persistently elevated anti-DNA (i.e., without other supportive signs of active lupus nephritis) may be considered in remission. If uncertainty persists, findings on repeat renal biopsy may be extremely useful in defining status of renal disease and indications for ongoing therapy.
  B. Alternate day prednisone: tapered in very small increments to discontinuance if the patient has been in sustained complete remission for >3 years.

Modified from: Balow *et al*. (2003). Lupus Nephritis. In "Therapy in Nephrology and Hypertension" (Brady and Wilcox, Eds.), 2nd ed., p 161. W.B. Saunders, London.

and 3 doubled serum creatinine. Of the 11 patients treated with corticosteroids and chlorambucil, 7 achieved complete and 4 partial remission; only one relapsed and one doubled serum creatinine. The authors suggested that combination treatment with corticosteroids and chlorambucil is more effective than prednisone alone and that a prospective clinical trial is warranted in lupus membranous nephropathy. Other studies have supported the use of low-dose cyclosporine in lupus membranous nephropathy [137, 138].

Our group has been conducting a prospective controlled trial (now closed to accrual) comparing alternate day prednisone alone or in combination with pulse cyclophosphamide (alternate months) or with low-dose cyclosporine A for 1 year in patients with lupus membranous nephropathy and baseline of >2 g/day of proteinuria. Preliminary results show that both pulse cyclophosphamide and cyclosporine A are more effective than alternate day prednisone alone in inducing remission of proteinuria. More sustained remissions were seen after completion of pulse cyclophosphamide than after discontinuing cyclosporine A [139].

Current options for treatment of lupus membranous nephropathy are shown in Table 13. Patients with mixed

TABLE 12 Guidelines for Discontinuation of Cytotoxic Drugs if Treatment has Failed

Failure to achieve remission of nephritis
Continuous activity after protracted (e.g., 4 years) therapy
Consider that *complete* renal remission may be delayed more than 2 years
Do not abandon therapy if renal disease is active after the first 6–12 months, unless there is definitive worsening of disease
Beware of suboptimal cyclophosphamide treatment protocols, especially inadequate doses (<1.0 g/m^2) and/or lags in treatment intervals
Development of advanced chronic renal insufficiency
Prolonged (≥3 months) dialysis-dependent renal failure, not explained by other factors
Steadily rising serum creatinine ≥6 mg/dl
Inactive urine sediment with broad and/or waxy (renal failure) casts
Contracted kidney size (<3/4 of expected normal)
Renal biopsy showing exclusively scarring, atrophy, and fibrosis

TABLE 13 Treatment of Lupus Membranous Nephropathy

Mixed membranous and proliferative nephropathies
Treat as proliferative lupus nephritis (see Table 11)
Membranous nephropathy with nephrotic range proteinuria
First line treatment is usually high dose alternate day prednisone (e.g., 1–2 mg/kg) for 2 months; taper to ~0.25 mg/kg alternate days within 3–4 months
Optional adjuncts to prednisone therapy
Cyclosporine A, ≤5 mg/kg/day
Pulse cyclophosphamide, ≤1 g/m^2 every 1–3 months
Oral cyclophosphamide, 2 mg/kg/day
Methylprednisolone/cyclophosphamide given cyclically on alternate months: pulse methylprednisolone, 1.0 g/day for 3 days followed by prednisone (0.5 mg/kg/day) for the balance of the month; alternate with oral cyclophosphamide (2 mg/kg/day adjusted as needed for leukopenia) for 1 month; three cycles of each therapy are given over a 6-month period.
Membranous nephropathy with nonnephrotic proteinuria
Treat according to extrarenal disease activity; monitor carefully for evidence of progression to nephrotic syndrome or to mixed membranous and proliferative nephropathy

Modified from: Balow *et al*. (2003). Lupus Nephritis. In "Therapy in Nephrology and Hypertension" (Brady and Wilcox, Eds.), 2nd ed., p 162. W.B. Saunders, London.

membranous and proliferative nephritis should be treated the same as those with proliferative disease. As described previously, we believe there is ample justification for treatment of patients with membranous nephropathy and nephrotic range proteinuria. Alternate day prednisone is the first line treatment and may be worth a limited trial as single therapy. Patients failing to achieve remission of proteinuria should be considered for adjunctive cyclosporine or an alkylating agent. Until the results of prospective trials are definitive, the choices are optional. Indications for treatment of patients with nonnephrotic proteinuria are ambiguous and most would treat according to extrarenal manifestations, while continuing to monitor renal parameters diligently.

MONITORING PATIENTS WITH LUPUS NEPHRITIS

Selected serological tests are very useful for monitoring activity of lupus nephritis and in guiding treatment. While anti-nuclear antibodies (ANA) are cardinal markers for diagnosis of SLE, titers of these antibodies are not useful in gauging either the severity or the activity of lupus nephritis. Anti-DNA antibodies correlate better with both type and activity of lupus nephritis. Anti-DNA antibodies occur more frequently and in higher titers in proliferative (Class III or IV) than in membranous (Class V) nephropathy. However, there are many exceptions to this rule. High titers of anti-DNA can occur in patients with little nephritis, and severe nephritis can occur in patients with no or low-titers of anti-DNA antibodies. In general, *changes* in anti-DNA titers are more valuable clinically than their absolute levels. Rising anti-DNA titers are true harbingers of exacerbation of lupus nephritis [44]. However, we do not consider the correlation to be strong enough to recommend preemptive treatment for isolated changes in anti-DNA titers. Patients with only rising titers of anti-DNA warrant intensified monitoring for evidence of clinical signs of lupus flares. Other antibodies, such as antinucleosome and anti-C1q, are under study for assessment of their use in monitoring activity of lupus nephritis [140].

Monitoring serum complement components is extremely useful in management of lupus nephritis. Complement components are more readily available and reliable than measures of hemolytic complement. C3 and C4 complement components are both useful in following activity of lupus nephritis; because trends in their values are rarely discordant, C3 is the preferred choice for monitoring patients with lupus nephritis. Even more reliably than rising levels of anti-DNA antibodies, *falling* levels of serum complement components predict impending flares of lupus nephritis. Moreover, the absolute level of complement components is more predictive of immunologic activity than is the absolute level of anti-DNA antibodies. The historical practice of using serum complement levels as one of the cardinal determinants for ongoing treatment has been largely abandoned. At the present time, patients with either

rising anti-DNA antibodies and/or falling complement levels should be compulsively monitored for other early clinical signs of activity at which point preemptive treatment should be promptly instituted.

Other laboratory parameters for monitoring lupus nephritis have been examined in the research setting. Measurement of circulating immune complexes (by a wide range of tests) has generally been abandoned as a cost *ineffective* method of monitoring patients with SLE or lupus nephritis. Measurement of the late complement membrane attack complex, C5b-9, has been suggested as a method for monitoring activity of idiopathic membranous nephropathy. Its potential use in monitoring activity of proliferative or membranous lupus nephropathy has not been studied. Experimental studies have suggested that plasma and urinary cytokines (e.g., interleukin-6) or their receptors (e.g., interleukin-2 receptors) may predict lupus activity, but these tests are not widely used in the clinic at the present time [44].

REMISSION

There are no universal criteria for remission of lupus nephritis. Whether it would be useful to distinguish partial and complete remissions has not been thoroughly studied. However, it is evident in reading the literature that there is great ambiguity about the concepts of remission. Until consensus is formed on clinically validated definitions of remission, there will be wide variations in descriptions of the natural history of lupus nephritis.

Currently, the notion of *partial* remission of lupus nephritis is important in deciding the transition from cyclophosphamide (induction) therapy to maintenance (azathioprine, quarterly pulse cyclophosphamide, or prednisone alone). In severe lupus nephritis, we think there is reasonable justification to move from cyclophosphamide induction to either of the lower-intensity cytotoxic drug therapies if there is partial remission (i.e., objective improvement in urine sediment and renal function). However, we do not believe that partial remission should be accepted as a criterion to discontinue cytotoxic drug therapy unless there are other contraindications. Our studies found a very high rate of relapse with early discontinuance of cytotoxic drug therapy and we would continue therapy for several months after *complete* remission of lupus nephritis.

In proliferative lupus nephritis, we define complete remission as clearing of active elements from the urine sediment, reduction of proteinuria to <1 g/day, inactive extrarenal disease and, ideally, normalization of lupus serological tests (complement components and anti-DNA). One should be aware that up to 20% of patients may not achieve a complete remission after even 3 years of immunosuppressive drug therapy [99, 111]. We generally continue quarterly pulse cyclophosphamide for 1 year beyond complete remission as the best method of reducing risk of relapse of lupus nephritis. It is noteworthy that antinuclear antibodies (ANA) become negative in a tiny fraction of patients, including those in sustained clinical remission. Hence, we would not use the ANA in defining remission or making decisions about discontinuing treatment.

A small portion of patients develop "fixed proteinuria" as a result of severe, irreparable injury to glomerular basement membranes. Proteinuria of this cause is usually <2 g/day, but occasionally may be in the nephrotic range. In a patient with otherwise quiescent SLE and lupus nephritis (by clinical, serological, and urine sediment criteria), it may be difficult to define fixed proteinuria of a nonimmunologic cause without a renal biopsy. The typical biopsy shows marked thickening and lucency of glomerular basement membranes without substantial immune complex deposits. Failure to recognize persistent proteinuria in this context can lead to over treatment of patients and needless exposure to serious toxicities.

RELAPSE

One of the most perplexing aspects of the natural history of lupus is its remitting and relapsing course. Modern treatment neither cures lupus, nor completely prevents exacerbations. Furthermore, each major exacerbation is expected to leave residual and cumulative irreversible (often subclinical) damage. The more episodes of relapse, the greater is the likelihood of irreversible damage and progression to permanent renal failure.

Exacerbations of lupus nephritis can emerge from a state of partial remission (improvement from initial baseline disease activity) or from a state of complete and sustained remission. Approximately one-third to one-half of patients have a relapse of nephritis after achieving partial or complete remission of proliferative lupus nephritis [107–111]. In aggregate, these studies showed that the relative risk of renal functional deterioration was much greater for nephritic flares than for proteinuric flares. Thus, nephritic exacerbations clearly have adverse effects on renal prognosis, while proteinuric exacerbations have much less prognostic importance. These observations argue in support of strategies to minimize probabilities of flares of nephritis.

The role of repeat renal biopsy and the optimal therapy of exacerbations of lupus nephritis are unde-

fined. However, a study of repeat renal biopsy after 6 months of treatment indicated that stabilization and improvement of renal disease was predicted by improvement in morphologic parameters, particularly inflammation, interstitial fibrosis, and glomerular scarring [141].

Nephritic flares with modest increases in proteinuria (e.g., <2 g/day) and without concomitant rise in serum creatinine are usually managed without a renal biopsy and with an empiric trial of moderate dose prednisone (e.g., 0.5 mg/kg) for 4–6 weeks followed by gradual tapering. Failure to completely resolve within 2 months should prompt reevaluation, possibly with information from repeat renal biopsy (particularly if activity of the urinary sediment is ambiguous), and consideration of cytotoxic drug therapy. With steroid-resistant nephritic flares, we usually re-cycle therapy using the same guidelines as proposed for initial immunosuppressive drug therapy.

Management of incipient flares of lupus nephritis is controversial. One controlled trial has suggested that rises of anti-DNA activity predict impending flares which could be averted by preemptive boosts in corticosteroid therapy [107]. While many agree with the general value of monitoring anti-DNA (or other serologic) activity, most clinicians would use this information as motivation to intensify clinical screening for supportive signs of lupus activity prior to boosting therapy. Several studies have shown that cyclophosphamide is more effective than steroids alone in preventing renal flares. However, the risk/benefit of prolonged maintenance courses of cyclophosphamide remains controversial. Also, the possible equivalence of maintenance azathioprine to quarterly pulse cyclophosphamide in preventing relapses continues under study. In the interim, we advise continuation of quarterly pulse cyclophosphamide for 1 year beyond clinical and serological remission as the best method of reducing risk of relapse of lupus nephritis.

HYPERTENSION

Hypertension is a significant problem in SLE. The prevalence of hypertension is highest in patients with diffuse proliferative and sclerosing lupus nephritis and is associated with an increased risk of progressive renal failure, as well as cardiovascular disease. Severe nephritis contributes to hypertension diathesis by producing high renin and angiotensin II states, as well as by inducing salt and water retention. Angiotensin converting enzyme inhibitors (ACEI) or angiotensin receptor antagonists plus diuretics offer effective blood pressure control in most patients. There is also evidence that these agents may be renoprotective by reducing intraglomerular pressure which, in turn, reduces proteinuria and downstream injury to renal tubular cells [142, 143]. Patients starting on ACEI or angiotensin receptor antagonists must be monitored carefully for several weeks after initiation for development of hyperkalemia and azotemia which may confound interpretation of the course and activity of lupus nephritis. Calcium channel antagonists may be preferable to angiotensin inhibitors in Black lupus patients. The full range of adrenergic antagonists and vasodilators, including minoxidil, may be necessary for effective control of hypertension. Older antihypertensives, such as hydralazine and alpha methyldopa, are rarely used due to their tendency to aggravate SLE and the availability of excellent alternative medications.

The most effective monitoring of blood pressure is accomplished by the patient. Patients developing hypertension should be encouraged to keep their own logbook of blood pressure readings, with instructions on when to contact the medical team for medication adjustment. The target for effective blood pressure control is age-dependent. In adults, the traditional guideline of blood pressure of <140/90 mm Hg has been revised downward to values of <120/75 [144].

HYPERLIPIDEMIA AND CARDIOVASCULAR RISKS

Hypercholesterolemia is mostly the consequence of nephrotic syndrome, though the pathophysiology is not completely understood [145]. Hyperlipidemia appears to have two adverse consequences: increased cardiovascular risk and possibly (though unproven) enhanced renal injury. The increased risk of cardiovascular events in lupus is clearly multifactorial, including corticosteroids, hypertension, increased LDL cholesterol, reduced HDL cholesterol, elevated lipoprotein (a), anticardiolipin antibodies, and elevated homocysteine levels [146–148]. Management of cardiovascular risk factors in lupus patients is described to a limited extent in Table 7 and, in general, should follow conventional therapeutic guidelines.

THROMBOTIC DIATHESIS

Thrombotic diathesis is often multifactorial in patients with lupus nephritis. The most important factors are nephrotic syndrome and anti-phospholipid antibodies. Nephrotic syndrome is associated with increased synthesis of clotting factors (e.g., fibrinogen) and loss of fibrinolytic factors (e.g., protein S) in the

urine. The precise mechanism(s) by which anti-phospholipid antibodies produce a thrombotic diathesis is not completely understood (anti-platelet agents are used prophylactically and anticoagulant agents are used following clinically apparent thromboses). Patients with persistent nephrotic syndrome and/or anti-phospholipid antibodies should be carefully informed about the importance of early recognition of and prompt intervention for thromboembolic events. Increased levels of plasma homocysteine have been reported to increase the risk of venous thrombosis, in the general population, and of stroke and arterial thrombosis in lupus patients. Although clear practice guidelines have not been established, it seems reasonable to measure plasma homocysteine and to prescribe folate supplements (e.g., 2 mg/day) if the levels of homocysteine are substantially elevated.

RENAL VASCULOPATHIES IN LUPUS NEPHRITIS

Extraglomerular renal vascular lesions are commonly seen in lupus nephritis [28–30]. Immune complex deposition (with or without necrosis) within arterioles and small arteries is frequent in immunofluorescence studies of renal biopsies. By light microscopy, subintimal eosinophilic, PAS-positive deposits are common, even in the absence of hypertension. This process may extend to a non-inflammatory necrotizing vasculopathy and to a true necrotizing vasculitis, though there is no direct evidence that the latter is an immune complex initiated process. True vasculitis is, indeed, rare in biopsies of patients with lupus nephritis. The prognostic impact of necrotizing vasculitis in the kidney is unclear, but most would treat this condition aggressively with corticosteroids and cytotoxic drugs.

A thrombotic thrombocytopenic purpura (TTP-like) microangiopathy occasionally develops in patients with lupus nephritis. The absence of immune complexes in vessel walls underscores that the fibrin thrombi represent a true microvascular thrombotic process. It is critical to recognize this diagnosis early because it is associated with very poor prognosis. Treatment with plasma exchange is indicated as in cases of idiopathic TTP [149].

PREGNANCY AND LUPUS NEPHRITIS

A comprehensive review of the interactions between disease activity and pregnancy in lupus patients is included elsewhere in this volume. Pregnancy is normally associated with increased glomerular perfusion. Glomerular hyperfiltration is associated with fall in serum creatinine. Lack of fall in serum creatinine is abnormal and indicates significant underlying renal disease.

Patients with normal renal function and sustained remission of lupus nephritis (i.e., inactive urine sediment and proteinuria <1 g/day) incur low risks of exacerbations of either lupus or renal disease and have high probability of successful pregnancies [150–152]. At the other extreme, in patients with active nephritis and impaired renal function pregnancy is associated with substantial risks of developing exacerbations and irreversible renal failure. A study in patients with various forms of glomerular and tubulointerstitial diseases showed that a serum creatinine ≥1.4 mg/dl at the time of conception was associated with significant worsening of maternal renal function, proteinuria, and hypertension, as well as fetal prematurity and growth retardation [153]. Overall, 10% of these women developed end-stage renal failure within the first postpartum year; the risk rose to 35% in women with baseline creatinine ≥2.0 mg/dl. Patients with moderate to severe renal function impairment contemplating pregnancy should be fully informed about both maternal and fetal risks. Overall for SLE patients, there is increased risk of fetal loss, prematurity, and intrauterine growth retardation in the fetus. The risk is the same in patients with inactive lupus nephritis. With renal functional impairment, the risks increase for both the fetus and the mother. If pregnancy occurs in a patient with substantial renal involvement, consultation with high-risk obstetricians and nephrologists should be undertaken.

LUPUS NEPHRITIS IN CHILDREN

The natural history of lupus nephritis in children is controversial. Study results have varied from the course of disease in children being described as better in some instances and worse in others than comparable classes of lupus nephritis in adults. Indeed, one study showed a dismal renal survival of 29% at 10 years in a cohort of 56 pediatric patients with lupus nephritis [68]. While not specifically analyzed in this study, the high risk of renal failure may have been affected by racial factors (previously discussed); more than 64% of patients were Black and less than 10% were White.

The natural histories, indications for treatment, and outcomes are similar in children and adults with lupus nephritis (Fig. 16), though most studies have not analyzed the confounding issue of race on the outcomes of pediatric aged patients [154–157]. It is apparent that

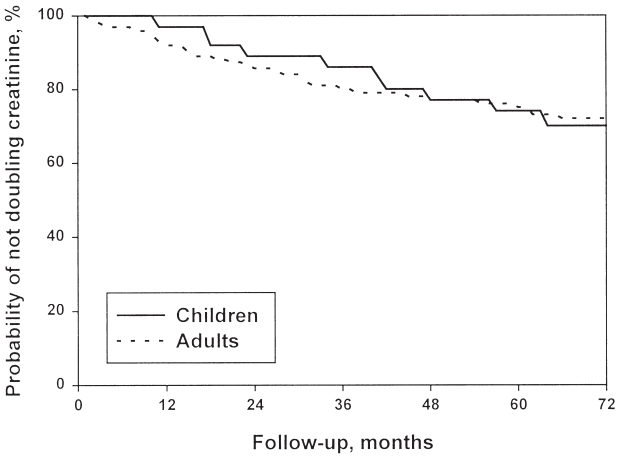

FIGURE 16 Comparison of the courses of lupus nephritis in children and adults. Probability of not doubling serum creatinine among 166 patients with lupus nephritis participating in controlled clinical trials at NIH [62, 96].

children have greater capacity to compensate for glomerular damage than do adults. Thus, children and adults with comparable proportions of obsolescent glomeruli have greater and lesser potential, respectively, for compensatory hypertrophy in less involved glomeruli (presumably with increased single nephron hyperfiltration) and in overall preservation of renal function.

CHRONIC RENAL INSUFFICIENCY

Progressive renal insufficiency in lupus evolves from two fundamentally different processes: nephron damage from the various immunopathologic lesions and from maladaptive compensatory mechanisms. By uncertain mechanisms, focal nephron loss evokes compensatory hypertrophy and hemodynamic changes in less involved glomeruli. Hypertrophy, increased blood flow, and hydrostatic pressure temporarily improve glomerular filtration, even to normal levels. It is not uncommon to find normal GFR in patients with loss of a substantial proportion of the total nephron population. Histologically, glomeruli with several-fold increased volumes are scattered among obsolescent nephrons. Experimental models of renal ablation and high protein intake have shown increased blood flow and elevated intracapillary pressures; the latter, in turn, augment proteinuria and glomerulosclerosis and culminate in progressive decline of GFR. The contributions of these maladaptive processes in progressive human diseases, including lupus nephritis, have not been proven. However, these experimental observations form the basis of clinical recommendations for stringent blood pressure control, particularly with ACEI, and low protein diet in patients with chronic renal insufficiency.

TABLE 14 Management Issues in Patients with Chronic Renal Insufficiency

Minimize exposure to nephrotoxic drugs: radiologic contrast, prostaglandin inhibiting analgesics (e.g., ketorolac), and chronic non-steroidal anti-inflammatory drugs (contribution to chronic renal failure is controversial)
Salt intake: avoid severe salt restriction (will worsen azotemia if there is renal salt wasting)
Potassium: avoid salt substitutes; carefully monitor potassium when initiating ACEI; prescribe low potassium diet as dictated by serum electrolytes
Protein: use low protein diet (0.6 g/kg/day) during chronic renal insufficiency (creatinine >2)
Phosphate: decrease intestinal absorption of phosphate by using calcium carbonate *with* each food intake (titrating dose to maintain normal serum phosphorus, without hypercalcemia)
Acidosis: metabolic acidosis is usually mild; occasionally requires $NaHCO_3$ or bicitra if serum bicarbonate is <18 mEq/liter (e.g., start with 10–20 mEq of base per day)
Anemia: correct iron or folate deficiencies; use erythropoietin (e.g., 80–100 units/kg given 2–3 times per week) for symptomatic anemia or to keep hematocrit >30%

Once chronic renal insufficiency arises in patients with advanced lupus nephritis, control of other pathophysiologic processes must be addressed, ideally in consultation with nephrology (Table 14). Control of hyperphosphatemia is critically important in order to prevent insidious secondary hyperparathyroidism. The patient should be thoroughly instructed in renal diets and nutrition, particularly regarding potassium and phosphate contents of various foods. Calcium salt supplements are a good method to simultaneously reduce dietary phosphate absorption and ensure adequate calcium intake. Calcium carbonate (e.g., starting with 650 mg taken during meals) is an effective method to control hyperphosphatemia. Multivitamins, including folate, are usually prescribed. Vitamin D supplements may also be appropriate, particularly in advanced renal insufficiency when renal production of active 1,25-dihydroxy-vitamin D may be significantly impaired. Erythropoietin production declines with progressive renal insufficiency; epogen treatment is warranted for symptomatic anemia or to maintain hematocrit above 30%.

END-STAGE RENAL DISEASE

With advancing renal failure, it is important to anticipate the need for vascular access for hemodialysis. If hemodialysis is anticipated within several weeks, protection of arm veins is critically important to facilitate creation of A-V fistulas, which are far preferable to synthetic grafts. On the other hand, too early placement of vascular access can be injudicious because of the risk of spontaneous thrombosis and the need for reoperation. Overall, it is advisable to refer the patient early for evaluation by a dialysis team. The timing depends on the rate of deterioration of renal function, as well as difficulties in fluid, blood pressure, potassium, and phosphate regulation. In the otherwise well controlled and clinically stable patient, dialysis is usually initiated when serum creatinine rises above 8–10 mg/dl.

DIALYSIS

The choice of dialysis modality is mostly dependent on patient preference. Peritoneal dialysis is an option for management of end-stage lupus nephritis and may offer the patient greater independence. Patients treated with either peritoneal dialysis or hemodialysis may experience clinically significant lupus activity, many components of which may be difficult to distinguish from complications of uremia per se.

Serological tests, including complement and anti-DNA may be useful in this regard. It has generally been held that lupus becomes inactive during sustained uremia. However, this varies considerably, depending mostly on the rate of progression to uremia. When renal failure develops rapidly, active lupus is more likely to persist for a considerable time on dialysis. When renal failure develops insidiously over an extended period, lupus activity tends to subside gradually in a process often described as "burning out."

Definitive lupus flares are generally treated with a trial of corticosteroids, but the whole armamentarium of immunosuppressive therapy may be needed to control serious complications of SLE in dialysis patients. Cyclophosphamide must be used in reduced dose due to impaired renal excretion in order to avoid severe bone marrow toxicity. Small daily cyclophosphamide doses (e.g., ≤100 mg) or pulse doses (e.g., 0.5 g/m^2 given 8–12 h before the subsequent dialysis) have been successfully used. The clinician must be particularly mindful that in the context of chronic dialysis, the constellation of active lupus requiring corticosteroids and cyclophosphamide places patients at particularly high risk of death from sepsis.

There are conflicting data regarding survival of lupus patients during chronic dialysis therapy [158–161]. Most series have suggested that survival of patients with end-stage renal failure due to lupus nephritis is equivalent to that for the overall ESRD population. Some have reported reduced survival. Pediatric patients in particular seem to have reduced survival on dialysis (155). Most series have lacked appropriate adjustments for age and sex. Thus, it remains uncertain whether a background of SLE has an adverse effect on the survival of patients on chronic dialysis.

RENAL TRANSPLANTATION

Many patients with end-stage renal failure due to lupus nephritis have undergone renal transplantation [44, 162–165]. The optimal timing for renal transplantation varies widely. Practices vary from those where patients are maintained on chronic dialysis for 12 or more months to ensure sustained quiescence of lupus activity (clinical and serological), to those where renal transplant is performed in the patient in remission without their ever being treated with dialysis therapy. The latter option is acceptable providing that the patient has been in sustained remission of SLE during the late stages of chronic renal insufficiency.

Some physicians have been reticent to recommend renal transplantation at all. This is based largely on outdated historical experience indicating decreased patient and graft survivals and, to a lesser extent, concern about recurrence of lupus nephritis in the allograft. Most contemporary series indicate that patient survival following renal transplantation is approximately the same in lupus patients and controls (there is a caveat that not all comparisons of survival were controlled for age and sex). Similarly, the preponderance of studies have suggested that renal allograft survival following transplantation for lupus nephritis is comparable to those for other renal diseases. However, some studies have presented data indicating poorer than expected graft survival in patients with underlying SLE. One study by Lochhead *et al*. in 80 lupus patients showed marked differences in allograft survival depending on the donor source [164]. With cadaver donors, 5-year graft survival in lupus patients was only 41% compared to 71% in unselected controls. Also, noteworthy in the lupus cohort was that graft survival from living related donors improved to 89% at 5 years. The authors suggested an increased role of living related over cadaver grafts in lupus patients.

Some studies indicate that lupus patients with renal transplants did not fare as well as patients with other causes of renal failure [165]. However, review of a much

larger data sets from the United States Renal Data System (USRDS) and the North American Pediatric Renal Transplant Cooperative Study has shown that both patient and graft survival are comparable for lupus and nonlupus cohorts [166, 167]. Though traditional teaching is that recurrence of lupus nephritis in the renal allograft is rare, a study suggests that pathologic evidence of recurrence is relatively common [168], but fortunately, recurrent lupus nephritis seems not to be an important cause for graft loss.

REFERRAL GUIDELINES AND USE OF CONSULTANTS

Given the typically insidious nature of renal involvement, substantial damage can easily accrue before lupus nephritis is recognized by either the patient or the nonvigilant physician. It is commonplace that subspecialists become too narrowly focused on isolated components of SLE. Checklists are useful tools for monitoring patients with SLE; they decrease the risk of failure to ascertain important (particularly subclinical) components of the disease.

A multidisciplinary approach to diagnosis and treatment of patients with SLE and lupus nephritis is optimal. Regular interchange among experienced clinicians, particularly about interpretation of ambiguous findings and if only in conference settings, offers the best opportunity to achieve comprehensive management of lupus patients. At the same time, it is critically important that one physician assumes a primary or care coordinator role in order to enhance communication with the patient, to prevent fragmentation of diagnosis and treatment, and to distill divergent opinions offered by consultants. In the case of severe lupus nephritis, it is important that rheumatologists and nephrologists share diagnostic and therapeutic decisions.

FUTURE DIRECTIONS AND EXPERIMENTAL THERAPIES

Patients and physicians alike continue to hope for "curative" treatments for patients with SLE and lupus nephritis. Many investigators envision that reconstitution of the disordered immune system is the most likely avenue to this end. Translational work has begun employing different methods aimed at overhauling the immune system of patients with severe and conventional treatment-refractory SLE. Availability of therapeutic granulocyte colony stimulating factor (G-CSF) has allowed immunoablative regimens involving extreme doses of cyclophosphamide (e.g., 200 mg/kg) with or without adjunctive fludarabine, total body irradiation, and antithymocyte globulin to be tested [169–174]. Results to date are encouraging, but these immunoablative and reconstituting regimens are associated with substantial morbidity, high costs, and not insignificant risk of failure, relapse, and death [175]. Appropriate selection of candidate patients to undergo these experimental approaches remains a major challenge.

CARDIOVASCULAR SYSTEMIC LUPUS ERYTHEMATOSUS

Michelle Petri

The first recognition of cardiac involvement in lupus was a report by Kaposi in 1872 of cardiac irregularity and dyspnea [1]. The pathologic study of cardiac lupus dates from the report of Libman and Sacks [2] of verrucous endocarditis. Ironically, they did not recognize the association of verricous endocarditis with systemic lupus erythematosus (SLE). It is now understood that all three layers of the heart (pericardium, myocardium, and endocardium) can be involved by lupus.

Cardiac involvement in SLE is often forgotten, because it is not a common cause of flare. In our prospective study of flare, serositis was present in only 7 to 9% of flares [3]. However, the words of Brigden *et al*., written in 1960, remain true today: "Heart lesions develop in nearly all patients at some time during the course of their disease when life is prolonged by modern. . . . therapy" [4]. This chapter will review the cardiac manifestations of active lupus, but will also emphasize a growing source of morbidity and mortality in SLE patients, accelerated atherosclerosis.

CARDIAC MANIFESTATIONS OF ACTIVE SYSTEMIC LUPUS ERYTHEMATOSUS

Pericarditis

Clinical Features

Pericarditis is the most common cardiac manifestation of active lupus, although often it is not evident clinically. Although pericarditis can occur at any time during the course of SLE, it tends to be one of the earlier cardiac manifestations, and can even be the first manifestation of lupus [5]. Pericarditis was the presenting sign of lupus in 4 of 28 patients who ultimately developed it in one series [6]. Pericarditis in SLE presents in the typical way, with precordial pain, usually positional (aggravated by lying down), often with a pleuritic quality, and sometimes with dyspnea. Coexistent pleurisy and/or effusions are common, occurring in 14 of 28 cases in one series [6]. Pericarditis usually appears as an isolated attack or as recurrent episodes, with or without symptoms [4]. Patients may have fever and tachycardia. Friction rubs are rare, perhaps because they are present often for only a few hours and are missed. The "classic" pericardial friction rub has three components, occurring with ventricular contraction, atrial contraction, and at the end of rapid ventricular filling [7]. In a French series, of 28 cases of pericarditis, 23 had pain, 12 had a rub, and 4 required pericardiocentesis because of tamponade [6].

Patients with pericardial effusion (as opposed to thickening) are more likely to have pericardial pain and active lupus elsewhere [8, 9]. In one study, only the patients with moderate or severe pericardial effusion had clinical or electrocardiographic evidence of pericarditis [9]. When present, pericardial effusions are usually small and do not cause hemodynamic problems.

Pericardial tamponade has been reported, however, even in treated patients [5]. Earlier studies may have included SLE patients with uremia as the cause (or a contributing factor to) pericardial tamponade [7]. In the modern era, most pericardial effusions do not cause hemodynamic problems [8]. Pericardial hemorrhage (from vasculitis) caused fatal pericardial tamponade in one anticoagulated patient [10]. Constrictive

pericarditis is very rare [11]. Only four cases of constrictive pericarditis have been reported [12–14]. One 17-year-old male with constrictive pericarditis was admitted with ascites, without any prior history of pericarditis [11]. In two of the four cases constrictive pericarditis developed in spite of corticosteroid therapy [11, 14]. All four known cases have occurred in males [11].

Diagnosis

If a patient presents for the first time with pericarditis, it is usually impossible to invoke SLE as the cause until appropriate laboratory tests, suggesting the diagnosis, return. However, patients with idiopathic pericarditis more often give a history of recent viral infection, and are more often male. In idiopathic pericarditis there is usually a leukocytosis, whereas a finding of leukopenia would suggest SLE [7].

Pericardial friction rubs may be heard in sicker and untreated patients, but are often absent in milder cases, especially those patients already on corticosteroid and/or NSAID treatment. A significant rise in jugular venous pressure is unusual [4].

In one series, most patients showed electrocardiographic evidence of acute or chronic pericarditis [5]. The diagnosis of pericarditis can be confirmed by EKG findings of elevated ST segments and tall T waves (although slight T-wave changes or transient elevation of ST segments are most characteristic), or by cardiac echocardiogram findings of pericardial effusion or thickened pericardium. Serial electrocardiograms may show a progression of changes in pericarditis. Initially, a diffuse elevation of ST segments (without reciprocal ST segment depression) is found. This is followed by a lowering of ST segments back toward baseline and subsequent T-wave inversion. In most cases, T waves then return to normal [7]. In the days before echocardiograms, the diagnosis of pericarditis was based on the presence of a pericardial friction rub in 71%, diagnostic evolutionary EKG changes in 33%, and on evidence of pericardial effusion in 50% [12]. Effusions may be accompanied by a drop in voltage. After severe attacks T waves may not recover their original voltage [4]. In the series of Godeau *et al*., of 28 total cases, 5 had low voltage, 10 had ST changes, and 20 had repolarization changes [6].

Both effusion and thickening are frequent in echocardiogram studies [15, 16]. Most effusions are mild. In one study, of 19 patients with pericardial effusions, 5 were moderate or severe and 14 were mild [9]. The echocardiographic findings of pericardial thickening have been described [15], and diagnostic criteria exist [17]. Echocardiography (two-dimensional echocardiogram and Doppler echocardiography) is the modality of choice in evaluating pericardial disease, because it is both noninvasive and sensitive [18]. However, echocardiography may be an insensitive technique in diagnosing pericarditis when it is not accompanied by effusion or thickening. For example, in one study, only 42% of the patients with previous pericarditis had an abnormal echocardiogram [19].

Prevalence

The frequency of pericarditis depends on the modality of diagnosis. Published series of patients (Table 1) [4–6, 8, 12, 15, 16, 19–44] find pericarditis in 12–47% of living SLE patients. However, at any one time (cross-sectional analysis), only a minority of SLE patients, 3%, had a pericardial effusion [44]. In general, the echocardiogram is more sensitive than clinical diagnosis, with 19–54% of patients having pericardial effusion or thickening. The echocardiogram is an essential tool in the clinical management of sick patients with cardiac lupus, because clinical diagnosis alone may be faulty. For example, in one patient with a rapidly enlarging heart, pericardial friction rub, and paradoxic pulse, there was no pericardial effusion [35]. Pericardial abnormalities are the most common echocardiographic finding in SLE patients [8, 41]. However, significant pericardial disease is uncommon, even using echocardiograms, being found in only 7% in one study [9]. Autopsy studies find a much higher prevalence of pericardial involvement, ranging up to 61–100% (Table 1).

Pathology

Pericardial fluid in SLE is usually exudative, the amount of fluid varying from 100 to more than 1000 cc [5]. White blood counts are in the 30,000 range, primarily neutrophils [45]. Although not helpful in patient management, the fluid may contain anti-DNA and have low complement levels [46]. Hunder *et al*. found complement-fixing material in pericardial fluid in SLE, which was felt to be immune complexes [47].

At autopsy, a diffuse or focal fibrinous pericarditis, often with many hematoxylin bodies, with or without effusion, is found. In the series of Brigden *et al*., the layers of the pericardium were obliterated with occasional deposits of fresh fibrin or effusion [4]. In another autopsy study, of 11 cases, 6 had acute pericarditis and 5 had chronic obliterative pericarditis (2 of these had pericardiomediastinal adhesions) [22]. The histophathology in a case of constrictive pericarditis showed fibrosis and mild chronic inflammation, with IgG, IgM, and complement deposition on immunofluorescence [11]. Immunopathogenetic analyses of pericardium in 2 of 9 patients in an autopsy series

demonstrated the vascular deposition of immunoglobulin and complement [38]. Pericardial lesions were present in an additional 4 patients in the autopsy series, as well [38]. On histopathology, small pericardial blood vessels were surrounded by an infiltrate of lymphocytes, plasma cells, macrophages, and rare polymorphonuclear leukocytes. On immunofluorescence, IgG was present in a predominantly granular pattern around small pericardial vessels [38]. Thus, Bidani and colleagues concluded that immune complex deposition was the cause of pericarditis [38].

Treatment

In early studies, pericarditis usually responded quickly to corticosteroids, with serial chest x-rays showing rapid and radiologic evidence of resorption of fluid [4]. Shearn commented in his review that the "often transient nature of pericarditis makes evaluation of therapy for this condition most difficult [5]. However, many studies have noted pericardial effusion developing or persisting even with corticosteroid treatment, such as the autopsy study of Kong *et al*., in which 11 of 12 patients with pericardial effusion had taken corticosteroids [35]. Occasional patients progressed to the point of tamponade [5]. Nonsteroidal anti-inflammatory drugs are helpful for mild cases of pericarditis. Patients presenting with pericardial tamponade may necessitate pericardiocentesis. Pericardiocentesis in one patient with pericardial tamponade punctured the left anterior descending coronary artery, resulting in death [35]. Refractory cases of large pericardial effusions may benefit from a pericardial window.

Myocarditis

Clinical Features

Myocarditis, as recognized clinically, is rare in SLE. The clinical detection of myocarditis ranges from 3 to 15%, although it appears to be much more common in autopsy studies, suggesting the largely subclinical nature of the myocardial pathology. Patients may present in florid congestive heart failure, or more subacutely with tachycardia and dyspnea.

Most myocarditis in SLE is subclinical. Myocardial abnormalities were found in 20% of patients using echocardiograms, but only one patient with an echocardiographic pattern of myocarditis developed myocardial dysfunction clinically [9].

Even autopsy studies have shown that myocarditis usually does not lead to cardiac dilatation [22]. Brigden *et al*. had no patient in whom congestive heart failure was attributed solely to myocarditis [4]. Shearn had only one patient with heart failure attributable to myocarditis [5].

However, other series have found myocarditis as a cause of congestive heart failure. Harvey *et al*. [24] found that myocarditis was the cause of heart failure in 8 of their 9 patients. Hejtmancik *et al*. found myocarditis to be the major cause in 6 of their 10 cases [12]. Kong *et al*. had 17 patients with cardiomegaly; at autopsy, 15 had myocarditis, but of varying degrees of severity [35].

The differential diagnosis of congestive heart failure in SLE would include myocarditis, but also anemia, renal failure, pulmonary disease, atherosclerotic heart disease, coronary arteritis, valvular disease, and hypertension.

Diagnosis

In an understatement, Shearn said, "The clinical recognition of myocarditis is difficult" [5]. In our most recent case, the patient, who had a hematologic and renal flare, was not recognized to have myocarditis as well until she presented in congestive heart failure. Myocarditis should be considered in patients with tachycardia not due to fever, in patients with a third heart sound (S3), in patients with abnormal EKGs, in those with new murmurs or conduction disturbances, and in those with congestive heart failure [5]. Brigden *et al*. suggested that prolongation of the conduction time of either P–R, QRS, or Q–T interval would have been evidence of myocarditis (in the absence of another cause of ventricular hypertrophy), but that they did not encounter these EKG changes in their series [4]. Hejtmancik *et al*. made a clinical diagnosis of myocarditis in 21% of their patients (after first excluding hypertension and coronary artery disease), based on (1) cardiac enlargement, (2) conspicuous ventricular gallop, and (3) electrocardiographic abnormalities [12]. Kong *et al*. found myocarditis at autopsy in 15 of their 16 patients with gallop rhythm [35]. The diagnosis of myocarditis can be supported by the finding of global hypokinesis on cardiac echocardiogram and confirmed by right ventricular endomyocardial biopsy [48, 49].

Prevalence

In large series of patients, the clinical diagnosis of myocarditis has been made in up to 21% (Table 2) [5, 6, 8, 9, 12, 19, 22, 24, 27, 29, 31, 34–38, 41, 44, 50, 51]. More recent series that relied on clinical detection suggest the frequency does not exceed 14% [6, 37]. Autopsy studies, mainly done in the 1950s and 1960s, frequently found myocarditis. More recent postmortem studies [27, 34,

38], reflecting the era of corticosteroid treatment, found much lower frequencies, from 0 to 8%.

Echocardiographic studies cannot definitively diagnose myocarditis, but global hypokinesis, in the absence of other known causes, is strongly suggestive. Large echo series have found frequencies of global hypokinesis between 5 and 20%. However, segmental areas of hyopkinesis on echocardiogram can also be indicative of myocarditis [52]. Newer imaging modalities, such as magnetic resonance, are largely unstudied [53].

Pathology

A common misperception is that myocarditis in SLE is a myositis. CPK levels are usually normal [52, 54]. In fact, only one study found any association with myositis elsewhere [51]. Myocarditis in SLE is a complicated process, with arteritis or arteriopathy, not primary disease of the myocardial fibers, playing a major role [55]. Kong *et al*. found pathologic evidence of myocarditis (fibrinoid and collagenous degeneration, interstitial edema, necrosis, and/or cellular infiltration) in 15 of 30 autopsies [35]. The cellular infiltrates of myocarditis consist of foci of interstitial plasma cells and lymphocytes [4]. Immunofluorescence studies confirm that the etiopathogenesis is vascular. In one study, most of the immune deposits were present in the walls of blood vessels of the myocardium [38]. Immunofluorescence studies of endomyocardial biopsies reveal perivascular deposits of IgG and vascular deposits of C3 [52].

Treatment

Myocarditis that comes to clinical attention is usually an urgent situation. Treatment with high-dose intravenous methylprednisolone (such as the "pulse" regimen, 1000 mg daily for 3 days), followed by high-dose IV or oral corticosteroid maintenance therapy, is indicated. The addition of intravenous "pulse" cyclophosphamide, in refractory cases, may be helpful. Supportive therapy for congestive heart failure, including diuresis, digoxin, and afterload reduction (such as with angiotensin converting enzyme (ACE) inhibitors) may be necessary. Anticoagulation should be considered in those patients who have progressed to the stage of cardiomyopathy. Efficacy of therapy can be assessed by serial echocardiographic studies or right ventricular endomyocardial biopsies [56]. In one patient, response

to corticosteroid therapy was confirmed by both endomyocardial biopsy and cardiac catheterization [52]. Nihoyannopoulos *et al*. followed one patient in whom corticosteroid treatment improved diffuse ventricular hypokinesis [19].

Left Ventricular Dysfunction

Clinical Features

Although ventricular dysfunction is commonly found in SLE patients, it is usually subclinical. For the clinician, ventricular dysfunction has a long differential diagnosis, including myocarditis, arteritis, hypertension, and atherosclerotic disease. Ventricular dysfunction is most likely to come to the attention of the clinician through a physical examination finding of gallop rhythm, new murmur, or congestive heart failure; a chest X-ray finding of cardiomegaly; EKG changes; or by an echocardiogram done for other purposes (valvular disease or pericarditis). However, the literature on left ventricular dysfunction is largely an echocardiographic one, emphasizing subclinical degrees of diastolic and/or systolic dysfunction.

Diagnosis

The diagnosis of subtle degrees of left ventricular diastolic or systolic dysfunction is made echocardiographically. Left ventricular systolic function can be evaluated by the ventricular ejection fraction. Diastolic function can be determined by the diastolic descent rate of the anterior mitral leaflet, the ratio of mean systolic velocity to mean diastolic velocity in the left ventricular posterior wall, and the ratio of peak mitral inflow velocity during the atrial filling period to that in the early filling period [57]. Routine M-mode echocardiography may miss the mild degree of dysfunction present in SLE, leading one group to use computer-assisted analysis of digitized echoes [58].

Prevalence

Echocardiographic studies (Table 3) [8, 12, 15, 16, 19, 27, 37, 40–42, 44, 59–62] show that 4 to 71% of SLE patients have some degree of left ventricular dysfunction. Some of the segmental abnormalities found may be due to past myocardial infarctions. Autopsy studies [12, 27] have also shown a large range of frequencies,

with 11 or 43% of SLE patients having cardiomegaly or congestive heart failure.

Initially, it was thought that left ventricular systolic function was not affected or affected only mildly by SLE [44, 57, 58, 61], or, if there was a difference, that it was due to hypertension, coronary artery disease, or other comorbid processes [63]. However, SLE patients may have systolic dysfunction that only becomes apparent with exercise [59].

Diastolic dysfunction, although subclinical, is found more consistently [57, 61]. Giunta *et al*. found that disease duration was longer in patients with diastolic dysfunction [61]. Similarly, Enomoto *et al*. found that diastolic function deteriorated progressively with age [57]. In contrast, several groups have found that disease activity is a major determinant of diastolic dysfunction [8, 33, 58, 64].

Pathology

The coronary catheterization study of Strauer *et al*. [64] found multiple abnormalities in the five SLE patients studied, including: (1) increased end-diastolic pressures; (2) decreased contractility; (3) decreased left ventricular ejection fraction; (4) increased left ventricular stiffness; and (5) reduction of coronary vascular reserve. This suggests that multiple mechanisms contribute to ventricular dysfunction. There has been one case report of endomyocardial fibrosis presenting as congestive heart failure and restrictive cardiomyopathy [65].

Corticosteroid therapy could contribute to ventricular dysfunction through multiple mechanisms, including fatty infiltration [27, 51]. A second potential factor is hypertension aggravated by corticosteroids [66]. Deterioration in diastolic function over time [57, 63] could be due to these processes or to progressive atherosclerosis. Several studies [8, 40] have found abnormal left ventricular function in patients without coronary artery disease or hypertension, but in the setting of active disease, suggesting that the mechanism was lupus myocarditis.

Treatment

Because left ventricular dysfunction studies are primarily echocardiographic, treatment has not been adequately studied. However, ther is one report of ventricular function (measured echocardiographically) worsening with active lupus and improving with corticosteroid treatment [33]. However, the ventricular dysfunction that progressively worsens in inactive patients might be best addressed by aggressive risk factor (hypertension, hyperlidemia, smoking) modification and pharmacologic therapy [63].

Valvular Disease

Clinical Features

Verrucous endocarditis can affect valve leaflets, papillary muscles, and the mural endocardium, as initially described by Libman and Sacks [2]. However, Libman and Sacks [2] and Gross [23] found the tricuspid valve involved most often, whereas more recent studies have found the mitral valve (followed by aortic) to be most affected. In the corticosteroid era, valvular vegetations are found less frequently. Shearn found that none of 11 patients who received corticosteroids had verrucous endocarditis, but that 4 patients, who died before corticosteroid therapy was available, did [5]. In their landmark autopsy study, Bulkley and Roberts also commented on the rarity of vegetations in corticosteroid treated patients [27]. Occasionally, the presentation may be fulminant, with congestive heart failure due to mitral regurgitation [67], or brain emboli secondary to valvular vegetations.

Verrucous endocarditis (vegetations, "Libman-Sacks") affects the mitral valve most frequently, followed by the aortic valve. The presence of vegetations predisposes patients to bacterial endocarditis [4, 68]. Although verrucous endocarditis can produce both systolic and diastolic murmurs, these are rarely of sufficient hemodynamic importance to cause congestive heart failure.

There is virtually no correlation between the presence of verrucous endocarditis and cardiac murmurs. shearn found that systolic nurmurs occurred in 70% of SLE patients [5]. Most murmurs were low intensity, and were heard loudest (47%) at the apex. Because murmurs were also associated with fever, infection, tachycardia, and anemia, the differential diagnosis of a new murmur was complex. Systolic murmurs were heard in each of the four patients who were later found to have Libman-Sacks endocarditis, but the murmurs did not have any unique quality [5]. Griffith and Vural heard murmurs in only two of six patients with Libman-Sacks endocarditis, and, vice versa, found Libman-Sacks endocarditis in only two of seven patients with systolic murmurs [22].

Diastolic murmurs occur in only 4% of SLE patients [20, 26]. The differential diagnosis of diastolic murmurs in SLE includes rheumatic or congenital heart disease, bacterial endocarditis, Libman-Sacks endocarditis, and left ventricular dilatation. In general, even when the valvular vegetations of Libman-Sacks endocarditis are

large, they do not involve the line of closure, and therefore should not deform the valve. Even involvement of the chordae tendineae should not be sufficient to distort the valve. There are several documented cases, however, in which Libman-Sacks endocarditis appeared to be the only explanation for a diastolic murmur [2, 24, 69]. Two of the four patients with Libman-Sacks endocarditis in Shearn's series had a diastolic murmur suggestive of mitral stenosis. However, diastolic murmurs were also heard in two patients without Libman-Sacks endocarditis [5].

It is rare for valvular disease in SLE to be clinically significant. In a series of 421 patients, only 1 to 2% had significant morbidity or mortality. Of the 14 cases with available pathology, only 6 had evidence of SLE valvulopathy, either verrucous vegetations or valvulitis with necrosis and vasculitis [70].

Diagnosis

Transesophageal echocardiogram is the modality of choice in terms of sensitivity in detecting valvular disease due to either lupus or anti-phospholipid antibody syndrome [42, 62]. Most previous series used M-mode echocardiography or two-dimensional Doppler echocardiography and are not completely comparable. Patients with new murmurs or with valvular abnormalities on echocardiogram should have blood cultures to rule out bacterial endocarditis.

Prevalence

The prevalence of valvular disease in SLE is very high (Table 4) [8, 9, 12, 15, 16, 19, 27, 35, 37, 41, 44, 57, 61, 62, 71–76]. Valvular disease, for the most part, however, is mild and asymptomatic.

Pathology

Valvular disease occurs predominantly as vegetations (what was termed Libman-Sacks endocarditis in the past), or thickening (that can present as either a regurgitant or stenotic lesion). The mitral valve is affected most often, followed by the aortic valve. Mitral and aortic regurgitation are the most common findings, with stenotic lesions very rare. Aortic cup sclerosis has been identified as a common lesion [77].

The typical valvular and mural endocarditis lesions, which are verrucous, occur as a single vegetation or as mulberry-like clusters. When occurring on valves, the vegetations are often on the ventricular surface, near, but not distorting, the line of closure [78].

The original histologic description of Libman-Sacks endocarditis [23, 68] emphasized the multiplication of endothelial cells, proliferation of Anitschow myocytes, and infiltration of mononuclear cells in the valve ring and valve base, especially the valve pocket. Aggregations of hemosiderin were frequent, along with some fibrosis. Cells underwent karyolysis to form hematoxylin bodies. The mural endothelium was affected, especially near the mitral valve [4].

A more recent description of Libman-Sacks endocarditis was based on two patients who underwent aortic valve replacement. Histologic studies showed three distinct zones, an outer exudative layer of fibrin, nuclear debris, and hematoxylin-stained bodies; a middle organizing layer of proliferation of capillaries and fibroblasts, and an inner layer of neovascularization. Immunofluorescence showed immunoglobulin and complement deposition in the walls of small junctional vessels in the inner zone of neovascularization, suggesting that circulating immune complexes were critical in the development of the vegetations [78]. Bidani *et al*. found immunoglobulins and complement deposition in the valve stroma and vegetations in one patient with Libman-Sacks endocarditis [38].

It is not clear whether Libman-Sacks endocarditis evolves into the valvular thickening that is the second important form of SLE valvulopathy. In modern series, valvular thickening is found more commonly than vegetations (Table 4) [8, 44, 61]. Galve *et al*. found that patients with Libman-Sacks endocarditis were younger, had shorter disease duration, and had received less corticosteroid therapy than those with thickened valves [71]. The patients with valvular thickening were more likely to have stenotic or regurgitant lesions and to require valve replacement [71]. Some authors have expressed concern that corticosteroid treatment might increase the chance that a valve would develop thickening. Changes in valve thickening can occur over time, with valve thickening resolving or new valve thickening appearing [71, 79].

Studies are conflicting on the role that anti-phospholipid antibodies play in the development of the vegetations of Libman-Sacks endocarditis [80]. Valvulopathy is common in the primary anti-phospholipid antibody syndrome, usually found in about a third of patients in large series [62, 73, 76, 81–86]. Thrombus formation, usually on the mitral valve, can be massive and require valve replacement [87]. Mitral and/or aortic valve thrombus (or vegetations) can also be a precipitant of embolic strokes. In SLE patients, some series have shown significantly more valvulopathy in those with anti-cardiolipin antibody [9, 19, 61, 72, 82, 88, 89]. However, other equally large series have found no difference [62, 73, 75, 76, 90–94]. In patients with the secondary form of anti-phospholipid antibody syndrome and valvulopathy, there is deposition of

immunoglobulin and complement, but in addition there is binding of anticardiolipin antibody [95].

Fenfluramine/Phentermine

Some non-SLE patients with obesity, treated with the appetite suppressant drugs fenfluramine/phentermine in combination [96], fenfluramine alone [97], and dexfenfluramine alone [98], have developed valvulopathy. In the series of Connolly *et al*., 24 women developed valvular disease after an average 12 months of therapy, but one after 1 month of therapy [96]. Mitral, aortic, and tricuspid valves were affected. Eight of the patients also had developed pulmonary hypertension. In the patients who underwent valve replacement, a plaque-like substance of proliferating myofibroblasts in an exuberant extracellular matrix encasing the leaflets and choidal structures, resembling carcinoid or ergotamine valvular disease, was found [96]. Whether SLE patients exposed to appetite suppressant drugs have developed valvular heart disease is unknown. Fenfluramine and dexfenfluramine were withdrawn from the market by the FDA in September, 1997.

Treatment

Systemic lupus erythematosus patients with large, sterile vegetations should be anticoagulated to lessen

embolic complications. We have used high-dose corticosteroids for 4 to 6 weeks to shrink vegetations, but this approach is controversial [80]. Some studies have suggested that corticosteroid treatment may contribute to ultimate valve thickening, but this is unproven.

Arrythmias and Conduction Disturbances

Clinical Features

The strongest association of SLE with conduction disturbance is congenital heart block, usually in the setting of maternal anti-Ro and anti-La [99, 100]. Both myocarditis [101] and cardiomyopathy [102] can occur in addition to fetal congenital heart block. The most common cardiac arrhythmia in adult SLE is sinus tachycardia (Table 5) [12, 22, 25, 32, 37, 103, 104].

Diagnosis

The diagnosis of arrhythmias is likely to be biased in that patients who have active SLE and who are hospitalized are more likely to have electrocardiograms performed. Accurate ascertainment of arrhythmias would likely require continuous electrocardiographic monitoring. Arrhythmias are found more commonly in SLE patients with pericarditis and myocarditis.

Prevalence

Approximately 10% of adult SLE patients have conduction disturbances [6, 37, 103]. There are only a few cases of adult SLE complete heart block with anti-Ro and/or anti-La [105–107].

One of the most common arrhythmias is sinus tachycardia, found in 6 to 100% of patients (Table 5) [29]. One group has suggested that sinus tachycardia is a manifestation of active disease [108].

Pathology

Autopsy studies have found arteritis of the sinus node, vascular occlusion, vasculopathy [34], and fibroblastic replacement of the sinoarterial and atrioventricular nodes [107].

Treatment

Systemic lupus erythematosus patients with life-threatening conduction defects can be treated with permanent pacemakers [106].

Coronary Arteritis

Clinical Features

Coronary arteritis is extremely rare in SLE. In some cases, it has been found at autopsy, with no clinical correlate during life. The most common clinical presentation is angina and/or myocardial infarction, in a child or young adult who does not have a long history of corticosteroid therapy. There is no clear correlation with extracardiac disease activity, although it has been present in some cases [109–112]. Three of eight SLE patients who had a coronary artery aneurysm had no physical or laboratory evidence of active SLE [111]. Aortic aneurysms can also occur in SLE [113].

Diagnosis

It is often difficult to distinguish coronary arteritis from accelerated atherosclerosis. Serial coronary angiography has been proposed as the most useful diagnostic modality [109, 114]. Arteritis is suggested when coronary aneurysms are found, if there are smooth focal lesions, or if there are rapidly developing stenoses [109, 114]. However, Wilson *et al.* described a patient with rapidly progressive coronary artery occlusions in whom only advanced atherosclerosis was found at autopsy [111]. Thrombosis or spasm can further confuse the interpretation of coronary angiograms [115].

Prevalence

There are few studies that allow any estimate of the prevalence of coronary arteritis (Table 6) [4, 12, 35, 55, 109–112, 114, 116–122]. In one study in the 1960s, 6 of 16 patients were found to have arteritis at autopsy [12]. Otherwise, case series do not have more than 3 patients. The cases identified have a predilection for pediatric patients or very young adults, with rare exceptions [123]. Unfortunately, where follow-up is given, the outcome is

usually death. This is quite paradoxical, in that autopsy studies indicated that arteritis rarely resulted in myocardial infarction.

Pathology

Histopathology demonstrates transmural vasculitis [110] with both lymphocytic and neutrophilic infiltration of a thrombus in the case described by Homcy *et al*. [109]. Immunofluorescence studies demonstrate immunoglobulin and complement deposition in coronary arteritis [118].

Treatment

The differentiation of coronary arteritis from atherosclerosis is essential for appropriate management. Coronary artery bypass surgery, angioplasty, or stent placement would be considered in patients with severe atherosclerotic disease, but would be contraindicated in patients with coronary arteritis. Case reports suggest that corticosteroid therapy can have rapid benefit in patients with coronary arteritis. Patient 4 in the series of Homcy *et al*. had refractory angina with arteritis suggested on serial coronary angiograms [109]. Corticosteroid therapy resulted in relief of angina and angiographic improvement [109]. Not all patients with coronary arteritis do as well on corticosteroids, however. Heibel *et al*. describe a patient with coronary arteritis who was treated with prednisone and cyclophosphamide, but had new myocardial damage after starting therapy [114]. Angina did not resolve for 3 weeks [114]. A 16-year-old girl, treated with 120 mg of prednisone, died of cardiac arrest, and had fibrinoid necrosis of extramural coronary arteries [110].

Pulmonary Hypertension

Clinical Features

Pulmonary hypertension is note frequent in SLE patients, in contrast to mixed connective tissue disease and scleroderma, particularly limited scleroderma ("CREST"). It is usually asymptomatic, discovered on a screening echo Doppler. Rare SLE patients will present with chest pain, dyspnea, or even pedal edema and be found to have pulmonary hypertension.

In one series of SLE patients, those with pulmonary hypertension by Doppler (14% of the group) had a shorter duration of SLE and corticosteroid therapy and a higher prevalence of Raynaud's phenomenon [124]. A 5-year follow-up study of these patients documented a gradual worsening, with 45% having pulmonary hypertension by Doppler [125].

Diagnosis

Diagnosis is best made by Doppler echocardiography, which can estimate right ventricular systolic pressure if the patient has a small amount of tricuspid regurgitation. Doppler echocardiography has a close correlation with simultaneous right heart catheterization measurement of pulmonary artery pressures. Owing to its invasive nature, right heart catheterization is more appropriately reserved for symptomatic patients, and to guide therapy. Ventilation perfusion scans, to rule out the possibility of multiple pulmonary emboli, are important.

Prevalence

The advent of echo Doppler allowed for sensitive, noninvasive screening for pulmonary hypertension, usually using a cutoff of right ventricular systolic pressure (RVSP) of 30 mm Hg or more (Table 7) [4, 8, 12, 37, 40, 44, 124, 126, 127]. Earlier studies, that determined the prevalence clinically, found a cumulative frequency of only 2–9%. These studies would only be able to detect late clinical manifestations of pulmonary hypertension and would underestimate the true prevalence.

TABLE 7 Prevalence of Pulmonary Hypertension

Crozier *et al*., 1990 [40]	Echocardiography	50	2
Leung *et al*., 1990 [8]	Echocardiography	75	1
Sturfelt *et al*., 1992 [44]	Echo (RVSP >30 mm Hg)	68	16

Pathology

The cardiac indices in the patients in the series of Simonson *et al*. were low, suggesting increased pulmonary vascular resistance as the cause [124]. Several lines of evidence suggest that pulmonary hypertension may be a complication of pulmonary artery vasospasm. Raynaud's phenomenon is more common in SLE patients with pulmonary hypertension [126, 128]. Primary pulmonary hypertension occurs in patients with Raynaud's phenomenon [129–132]. Cold-induced pulmonary artery spasm has been found in some scleroderma patients (with Raynaud's) [133, 134]. However, other mechanisms may operate as well, including pulmonary vasculitis [135], anti-phospholipid antibody syndrome [128], and interstitial lung disease [126].

Treatment

Effective treatment is now available for severe pulmonary hypertension with the advent of continuous intravenous prostacyclin and its analogs [136]. The endothelin-receptor antagonist bosentan is effective for pulmonary hypertension secondary to connective tissue disease [137]. Patients with severe pulmonary hypertension should also be anticoagulated [138].

Fenfluramine/Phentermine

Because morbid obesity is common in SLE patients who require chronic corticosteroid therapy, some were exposed to appetite suppressant therapy. The association of pulmonary hypertension with appetite suppressant drugs dates to the use of the drug aminorex in Europe in 1967 to 1972 [139]. A second outbreak of pulmonary hypertension occurred in association with dexfenfluramine (Redux) and fenfluramine (Pondimin) [140]. The odds ratio for pulmonary hypertension for just 3 months use of these drugs was 2.3 [141]. The combination of appetite suppressant drugs used most in the United States, fenfluramine and phentermine, has also commonly been associated with pulmonary hypertension with short-term use [142]. In animals, these drugs cause dose-related increases in pulmonary artery pressure [143], perhaps by inhibition of potassium current in vascular smooth muscle cells or the vasoconstrictor action of serotonin [143]. The extent to which morbidly obese SLE patients have been exposed to these drugs, and whether pulmonary hypertension has newly evolved or worsened in them, is not known. Dexfenfluramine and fenfluramine were removed from the U.S. market in September, 1997.

Hypertension

Clinical Features

Hypertension was not a major feature of early series of SLE patients (Table 8) [4, 12, 22, 24, 35, 40, 41, 103, 144, 145]. Today, however, it is a major clinical challenge.

Several studies found that hypertension was more common in those with underlying lupus nephropathy [5]. All patients with hypertension in the series of Armas-Cruz *et al*. [20] and 86% of those in the series of Estes and Christian [29] had lupus nephritis. Pollack and Kant found a correlation of mean diastolic blood pressure and increasing renal damage [146].

Budman and Steinberg, however, found that hypertension can occur in SLE in the absence of important renal disease [144]. Approximately two-thirds of their hypertensive patients had creatinine clearances greater than 60 cc/min and nonnephrotic range proteinuria [144]. Others have found an association with corticosteroids [147], and, specifically, a worsening of hypertension by corticosteroids [4, 5]. Hypertension is especially likely to develop or worsen when patients with nephropathy are given corticosteroids [148]. Kaplan and colleagues reported an inverse correlation of hypertension and rheumatoid-like arthritis [149].

We examined the relationship of prednisone and blood pressure using the Hopkins Lupus Cohort database, in which patients are seen on a quarterly basis [150]. Using regression methods appropriate for longitudinal data, we found that an increase in prednisone dose of 10 mg led to an increase in mean arterial pressure, adjusting for all other factors that affect blood pressure [150].

In the Hopkins Lupus Cohort database, hypertension is an independent predictor of coronary artery disease [151] and poor renal outcome [152]. In addition, it is one of the strongest predictors of preterm birth in lupus pregnancy [153].

Prevalence

Although earlier studies, perhaps because of shortened survival, did not find a high prevalence of hypertension, more recent studies have found a high frequency (Table 8), up to 50%.

Treatment

Consensus has been reached on the treatment of hypertension in the general population [154], emphasizing that the previous cutoff of 140/90 does not identify all patients who truly have hypertension. In the future, treatment may be offered sooner to those with lower levels of hypertension.

Because many hypertensive patients with SLE will have underlying renal disease, an important long-term benefit of ACE-inhibitors may be the lessening of renal scarring reported in diabetic nephropathy [155]. ACE-inhibitors are usually well tolerated in SLE, although an occasional patient may develop an ACE-inhibitor-induced chronic cough. Patients unable to tolerate ACE-inhibitors are candidates for angiotensin receptor antagonists. More recently, in the general population an angiotensin receptor antagonist, losartan, was found to prevent more cardiovascular morbidity and mortality than a beta-blocker for a similar reduction in blood pressure [156].

Coronary Atherosclerosis in SLE

Cliniclal Features

Coronary atherosclerosis ("premature" or "accelerated" atherosclerosis) is a clinical conundrum of the modern era of lupus management. Patients present, usually starting in their early 40's, with angina, myocardial infarction, or sudden death. However, patients have presented in their early 20's with coronary atherosclerosis [157]. In observational cohorts, the prevalence is 6 to 12%, but up to 40% are affected if more sensitive testing is done in asymptomatic patients [158, 159]. The risk of myocardial infarction in young women with SLE is increased 52-fold [160]. Young SLE women are 2.27 times more likely to be hospitalized for myocardial infarction, 3.80 times more likely for congestive heart failure, and 2.05 times more likely for stroke, than non-SLE women [161]. The differential diagnosis includes coronary arteritis, thrombosis secondary to the anti-phospholipid antibody syndrome, or coronary vasospasm.

Diagnosis

The antemortum diagnosis of coronary artery disease is an example of the potential utility of high technology [162], noninvasive testing, but the lack of wide screening of asymptomatic SLE patients is due to the high costs. Coronary angiography remains the gold standard, but would not be appropriate for screening. Exercise EKGs lack both sensitivity and specificity [163–166]. In the carotid distribution, extensive studies have been done using carotid duplex [167–169]. In these prevalence studies, the prevalence of plaque has varied from 15 to 40%. Risk factors for plaques have included, in one study, age, duration of lupus, blood pressure, LDL, and prednisone treatment [167]. In a second study, risk factors for carotid intima media thickness included increased oxLDL, anti-oxLDL, triglycerides, lipoprotein(a), decreased HDL, increased homocysteine and the lupus anticoagulant [169].

Rest and perfusion myocardial SPECT scans are currently one of the most sensitive and specific means of assessing the presence of atherosclerosis, but they are expensive [170–173]. Using dual isotope myocardial

perfusion imaging (DIMPI), one study found that 40% of all women with SLE and 35% of SLE women with no cardiovascular events had abnormal scans. The perfusion defect was reversible in 90% [174].

In a single photon emission computed tomography (SPECT) study comparing SLE patients who were symptomatic vs asymptomatic for cardiovascular disease, 27 of the 33 symptomatic SLE patients had abnormal scans, but also 12 of 28 asymptomatic patients [175]. Using TI-201 perfusion tomoscintigraphy, with exercise, 11 of 15 SLE patients had transient perfusion abnormalities, but only one out of three had changes consistent with atherosclerosis. This suggests that disorders of the microcirculation occur in addition to atherosclerosis of major coronary arteries [176]. More recently, prevalence studies have been done using electron beam or helical computerized tomography to detect coronary calcification.

The very earliest stage, vascular stiffness, has also been examined. Using pulse wave velocity in premenopausal SLE patients, elevated C3, elevated anti-DNA, leukopenia, hypertension, and carotid plaque were found to be predictors [177]. Using high-resolution brachial ultrasound, less endothelium-dependent dilation was found in SLE patients than in controls [178].

Prevalence

Myocardial infarction was not common in the early autopsy series [35], but was a major feature of the Bulkley and Roberts [27] and subsequent autopsy series [179], especially those from Toronto [180, 181]. Prospective studies, from disparate populations, have found, using the clinical detection of angina and/or myocardial infarction, frequencies on the order of 7 to 9% (Table 9) [6, 8, 12, 22, 27, 35, 37, 38, 44, 60, 151, 179–186]. Cross-sectional or retrospective studies using more sensitive screening studies (such as nuclear medicine myocardial scans), have found reversible (exercise-induced) ischemia in 11 to 23% [44, 60], suggesting that this is a more realistic estimate.

Pathogenesis

Immune Complex or Arteritis

Although coronary arteritis is rarely detected antemortum, autopsy studies have detected it frequently (Table 9) [22, 27, 35, 38, 179–181]. In fact, both arteritis and atherosclerosis have been found within a single patient, suggesting that arteritis might have predisposed to the later development of atherosclerosis [12]. Animal models also suggest that this contributes to atherosclerosis. Vascular injury, through immune complexes, followed by exposure to atherosclerotic risk factors, can lead to atherosclerosis in animal models [187–190]. Immunization of rabbits with heat-shock protein 60/65 leads to aortic intima atherosclerosis [191]. Coronary vasculopathy and myocardial infarctions are found in murine lupus models, often in association with anti-cardiolipin antibody [192–196]. Immune complexes from lupus sera accelerated uptake of cholesterol by smooth muscle cells [197]. One small study in human SLE suggested that patients treated with corticosteroids had less intimal proliferation in their coronary vessels, suggesting that suppression of arteritis initially might lead to less atherosclerosis later [198].

Anti-phospholipid Antibodies

Anti-phospholipid antibodies could contribute to coronary artery disease through thrombosis [199] or vasculopathy [200]. The association of anti-phospholipid antibodies with coronary artery disease has been shown in some [201] but not all studies (Table 10) [201–212]. We have found that the lupus anticoagulant is associated with angina/myocardial infarction [168], but not carotid plaque. Lupus anticoagulant was increased in SLE cases with cardiovascular disease vs those without [169].

Anti-phospholipid antibodies may function also as antibodies against oxidized lipoproteins [213], an additional mechanism (the "oxidative modification hypothesis") [214] by which they might contribute to atherosclerosis. In one study, anti-oxLDL was higher in SLE cases with cardiovascular disease [169]. However, several studies have failed to find an association of anti-oxLDL with arterial thrombosis [215], arterial disease [216], or atherosclerosis [217].

Finally, one of the plasma protein targets of anti-phospholipid antibodies, β_2 glycoprotein I, may be an important control against atherosclerosis that is perturbed by anti-phospholipid antibodies [218]. Anti-β_2 glycoprotein I accelerates uptake of oxLDL *in vitro* [219]. There is also interest in lysophosphatidycholine, LPC, a high-affinity ligand for G2A, a lymphocyte-expressed protein-coupled receptor. Genetic deletion of the receptor results in autoimmunity [220]. LPC is reduced in SLE [221] and anti-LPC has been detected [222].

Chronic Infection

In the non-SLE patient, there is great interest in chronic infections, including *Chlamydia pneumoniae*, as potential causes of atherosclerosis [223–233]. Simple antibiotic regimens could conceivably eliminate these infections and reduce later coronary artery disease. Whether these chronic infections lead to accelerated atherosclerosis in SLE is currently unknown.

Coronary Artery Disease Risk Factors

Multiple studies have now proven that the risk of coronary artery disease (CAD) in SLE cannot be solely explained by traditional cardiovascular risk factors. After controlling for common risk factors at baseline, SLE patients have a relative risk of 10.1 for nonfatal MI [234]. In a study with control subjects matched for traditional cardiovascular risk factors, SLE patients had more carotid atherosclerosis (41 vs 9%) and left ventricular hypertrophy (32 vs 5%) [235]. On average, SLE patients with coronary artery disease have one less traditional cardiovascular risk factor than a control patient [236].

Although traditional risk factors cannot explain all atherosclerosis in SLE, they contribute significantly to the process. Our work has found that routine coronary artery disease risk factors are very frequent in SLE patients (Table 11). In fact, the average SLE patient in our cohort study has 3 or more of these routine CAD risk factors [237].

Some of these risk factors could be due to SLE. Hypertension, for example, is more prevalent in SLE patients with renal disease [20, 29]. Hypertension is associated with coronary artery disease in SLE [150], including some [150], but not all, multivariate analyses [238].

Hyperlipidemia in SLE has two major patterns. One pattern occurs in active disease, especially in pediatric patients. These patients have low HDL cholesterol and apoprotein A1 with elevated VLDL cholesterol and triglyceride levels [239]. Lahita and colleagues have found a similar dyslipoproteinemia in SLE patients with anti-cardiolipin antibody [240]. However, one group has found that disease activity, rather than anti-cardiolipin, explains the reduction in HDL [241]. There are likely defects in early cholesterol transport [242] and VLDL metabolism [241] associated with active SLE. The second pattern occurs in SLE patients on corticosteroids, with higher levels of triglyceride, cholesterol, and LDL cholesterol [243]. Sustained hypercholesterolemia, rather than baseline, or intermittent elevation, is the most important predictor [244]. A third problem identified is decreased lipolysis and chylomicron remnant removal [245].

TABLE 11 Prevalence of CAD Risk Factors

Risk factor	Frequency (%)
Family history	41
Hypertension	48
Hypercholesterolemia	56
Obesity (major)	38
Smoking—ever	56
Smoking—current	35
Sedentary lifestyle	70
Diabetes	7
Homocysteine	15

Lipoprotein(a) has been identified as a risk factor for atherosclerosis in SLE [168, 169]. SLE patients can make anti-lp(a) [246]. Lp(a) may rise with disease flares and be reduced by corticosteroids [247]. SLE patients with higher lp(a) levels also have more immune complexes containing β_2 glycoprotein I [248].

The major cause of death in lupus nephritis patients is cardiovascular disease [249, 250]. Traditional cardiovascular risk factors, especially hypertension and hyperlipidemia, are increased [251]. Tubulointerstitial lipid deposits can be found [252]. In juvenile-onset SLE, nephrotic range proteinuria is the strongest risk factor for atherosclerosis [253].

In our longitudinal study, we found that three CAD risk factors, weight, cholesterol, and mean arterial pressure, were worsened by prednisone therapy. In the regression model, a 10-mg increase in prednisone led to a 5.5-lb increase in weight and a 8.9-mg% increase in total cholesterol, adjusting for all other factors known to affect these risk factors. Thus, even if the development of these CAD risk factors is directly due to SLE, prednisone treatment increases their levels.

Our more recent work has focused on a newly identified risk factor for cardiovascular disease, homocysteine. Homocysteine is an amino acid that has a direct toxic effect on endothelium [254] and indirect effects, including induction of a vascular endothelial cell activator [255], promotion of vascular smooth muscle proliferation, and an inhibitory effect on endothelial cell growth [256].

Hyperhomocysteinemia has been shown to increase the risk of coronary artery disease, stroke, and carotid artery stenosis in the Physicians' Health Study [257] and the Framingham Heart Study [258]. In the Hopkins Lupus Cohort Study, 15% of the 337 SLE patients had elevated homocysteine. Raised homocysteine levels were significantly associated with stroke and arterial thrombosis [259]. A retrospective study has comfirmed this association [260].

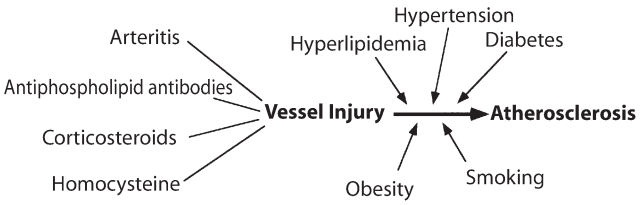

FIGURE 1 Legend—Atherosclerosis precipitation via vascular injury.

Inflammation plays a major role in the pathogenesis of atherosclerosis and myocardial infarction in the general population. The benefit of statins, for example, is mediated not just by their lipid-lowering effect, but by an anti-inflammatory effect (demonstrated by reduction in C-reactive protein) that likely stabilizes plaques. In the general population, C-reactive protein, IL-6, fibrinogen, and other markers of inflammation are predictive of atherosclerosis [261]. In SLE, C-reactive protein was not predictive in a multivariate model [167] nor in univariate analyses in our lupus cohort. However, in one case-control study, C-reactive protein was increased in SLE cases vs SLE controls [169]. We did not find fibrinogen to be predictive of atherosclerosis. In one study, fibrinogen increased with duration of disease regardless of disease activity, and was increased in SLE patients with thrombosis [262].

Prolonged corticosteroid therapy could precipitate atherosclerosis indirectly, by increasing the levels of CAD risk factors (hypertension, hypercholesterolemia, hypertriglyceridemia, diabetes mellitus, obesity, and homocysteinemia) [150, 179, 259] or directly, via vascular injury (Fig. 1). Accelerated atherosclerosis has occurred in SLE patients without corticosteroid use, but such cases are very rare [263]. In a 1986 review, Nashel made a strong case that the latter occurs [264]. In animals, corticosteroids and ACTH produce vascular injury [265, 266], alter vascular connective tissue [267], and worsen experimentally induced atherosclerosis [268]. Patients with Cushing's syndrome, before effective treatment was available, commonly developed accelerated atherosclerosis [269].

Treatment

Primary prevention of CAD is the goal, although there are no long-term studies proving that reduction of CAD risk factors reduces CAD in SLE. Most of the CAD risk factors increased by prednisone are amenable to lifestyle or pharmacologic therapy. However, a more recent study found that, other than hypertension, management of traditional cardiovascular risk factors was suboptimal [270].

Obestiy

Obesity is the most common and costly nutritional problem in the United States [271]. Over 38% of SLE patients have morbid obesity. There has been a 30% increase in obesity in the United States over the past decade, some of which is explained by a preference to calorically dense foods and a sedentary lifestyle. Corticosteroid therapy, by increasing appetite, leads to increased caloric intake. Coupled with the sedentary lifestyle so common in SLE patients, because of fatigue, arthritis, and orthopedic complications such as osteonecrosis, it is not surprising that obesity is such a problem among SLE patients.

Treatment of obesity has been discouraging, because two-thirds of people who lose weight will regain it within 1 year, and nearly all within 5 years [272]. Lifestyle modification emphasizes the role of dietary composition and exercise. Low-fat diets enhance short-term weight loss [273] and maintenance of the lowered body weight [274]. Low-fat diets will, in addition, reduce the hyperlipidemia so common in SLE. Exercise increases caloric expenditure and promotes dietary compliance. It reduces the desire for foods that are high in fat [275]. Exercise is not contraindicated in SLE and does not cause SLE flares [276]. Appetite-suppressant drugs should be avoided because of their risk of pulmonary hypertension and valvular heart disease [141]. Potentially useful drugs include a lipase inhibitor, tetrahydrolipstatin, that prevents the digestion and absorption of ingested fats [271]. Surgical therapy is limited for those with severe obesity (body-mass index >40) or to those with body-mass index between 35 to 40 who have life-threatening morbidity. Gastroplasty with or without intestinal bypass can be considered.

Diabetes Mellitus

Although only 7% of our cohort patients have diabetes mellitus requiring insulin or oral drug therapy, oral glucose tolerance testing shows the prevalence of diabetes is much higher [277]. Our work has found that hydroxychloroquine use reduces glucose levels significantly in SLE patients, thereby contributing to the protective effect of hydroxychloroquine [277]. In addition, we have found that diabetes mellitus is a risk factor for the accelerated atherosclerosis of SLE (Table 12). Lifestyle modification to reduce the risk of diabetes mellitus in SLE patients with hyperglycemia is essential, and should include dietary modification, weight loss, and exercise. The modern treatment of diabetes mellitus should include combinations of insulin and oral agents that improve glycemic control and improve insulin sensitivity [278]. The five classes of drugs to be considered are insulin, sulfonylurea, metformen,

TABLE 12 Predictors of Coronary Artery Disease in the Hopkins Lupus Cohort

Variable	OR (95% CI)	P-value
Age	1.08 (1.05–1.09)	0.001
Female sex	0.31 (0.19–0.55)	0.04
Homocysteine	1.05 (1.01–1.10)	0.02
Obesity	2.78 (1.61–4.76)	0.06
Hypertension	5.69 (3.35–9.18)	0.001
Diabetes mellitus	4.63 (2.75–7.82)	0.004
Renal insufficiency	2.77 (1.79–4.27)	0.02
Lupus anticoagulant	3.79 (2.51–5.72)	0.002

acarbose, and troglitazone. Troglitazone, for example, can reduce insulin resistance and improve glucose tolerance [279].

Hyperlipidemia

Hypercholesterolemia and elevated levels of LDL-cholesterol are very common in SLE patients (Table 11) and are risk factors for the development of accelerated atherosclerosis [151].

Lifestyle modification, with low-fat, low-cholesterol diet [183, 280], exercise, and weight loss would be the ideal primary prevention program. Many SLE patients, however, are unsuccessful in lifestyle modification and should be candidates for pharmacologic therapy. We have found that SLE patients are at increased risk for elevated liver function tests and CPK elevation with the use of lovastatin and gemfibrozil [281] and recommend that these be monitored in treated patients. SLE patients who do not respond adequately can be considered for the use of more potent statins [282, 283]. Atorvastatin has also been associated with hepatitis in an SLE patient [284].

Antimalarial therapy has a protective effect against hyperlipidemia in SLE. We showed the effectiveness of hydroxychloroquine in a longitudinal model that adjusted for other factors affecting cholesterol [150, 277]. Hydroxychloroquine exerts a beneficial effect on lipids even in corticosteroid-treated patients [285]. Antimalarial therapy reduces total cholesterol, VLDL, and LDL [286]. Chloroquine reverses the increased hepatic synthesis of lipoproteins [287]. There are, however, rare cases of chloroquine cardiomyopathy [288].

Hypertension

Hypertension is very prevalent in SLE patients (Table 8) and is aggravated by corticosteroid therapy [150]. Many SLE patients with nephropathy may have hypertension that requires three or four drugs for control. Hypertension is an independent risk factor for the development of coronary artery disease (Table 12) and renal insufficiency/failure [152].

Treatment of hypertension requires lifestyle modification with dietary factors, including lower sodium, exercise, and weight loss. Pharmacologic treatment should include the use of ACE-inhibitors because of their favorable effect in reducing renal scarring [155] and left ventricular hypertrophy [289, 290], and lack of adverse effect on the lipid profile [155]. Beta-blockers and thiazides increase insulin resistance [291] and increase the risk of diabetes [292]. In addition, beta-blockers might worsen Raynaud's phenomenon, felt to be a risk factor for pulmonary hypertension in SLE.

Estrogen Replacement Therapy

In the postmenopausal woman with SLE, estrogen replacement therapy has the potential benefit of reducing hyperlipidemia and possibly atherosclerotic risk [293, 294], osteoporosis, senility [295], and tooth loss, in addition to quality-of-life concerns, In studies in the general female population, hormone replacement therapy has increased, rather than decreased, the early risk of myocardial infarction [296]. Estrogen replacement therapy has not been given routinely in SLE because of concerns of increasing hypercoagulability [297] (especially in those patients with anti-phospholipid antibodies) or causing SLE flares. In one cohort study, postmenopausal nurses who took hormonal replacement therapy were more likely to develop new lupus [298]. These issues will not be definitively addressed until the current SELENA trial, a randomized double-blind, placebo-controlled clinical trial of hormonal replacement therapy, is completed. Many women continue to have fears of the increased risk of breast carcinoma with estrogen replacement therapy [299]. Raloxifene, a designer estrogen, may exert its estrogen-like effects on bone without stimulating the endometrium or increasing breast cancer risk, but whether it will be protective against cardiovascular disease is unknown [300].

Management of Myocardial Infarction

The acute management of an SLE patient with myocardial infarction is similar to that of a non-SLE patient. SLE patients are candidates for thrombolytic therapy (especially if they have anti-phospholipid antibodies), angioplasty, and coronary artery bypass graft surgery. The difficulty is in determining acutely whether the myocardial infarction is due to atherosclerosis, arteritis, or thrombosis secondary to anti-phospholipid antibody syndrome. Early coronary angiography can be helpful. Serial coronary angiograms may provide evi-

dence of rapid changes in vessels that is consistent with arteritis rather than atherosclerosis. High-dose corticosteroid therapy should only be given at the time of myocardial infarction if there is proof of arteritis by angiogram or a very high suspicion based on extracardiac active lupus, because of the possible adverse effect it may have in causing marked scar thinning [301].

Anti-phospholipid Antibodies

Systemic lupus erythematosus patients who have anti-phospholipid antibody syndrome will be treated with long-term high-intensity warfarin [302]. A more recent retrospective study strongly suggests that low-dose aspirin may be a useful prophylactic therapy [303]. Antimalarial therapy may have an antithrombotic benefit [277]. In an *in vitro* study, statins blocked the binding of anti-phospholipid antibodies to endothelial cells [304].

Other Treatments

The presence of macrophages and activated T cells in atherosclerotic plaques suggest that immunity plays a role in atherosclerotic progression. CD40–CD40 ligand interactions may be important in the development of atherosclerosis. In endarterectomy specimens, CD40 is expressed by macrophages and possibly other cell types. In early atherosclerosis, monocytes adhere to the endothelium and then enter the intima. Macrophages accumulate cholesterol, become foam cells, and smooth muscle proliferates. T cells, two-thirds of which are $CD4^+$, are found in these atherosclerotic lesions. CD40–CD40 ligand interactions mediate the signaling that leads to the activation of both antigen-presenting cells and T cells. Thus, it is hypothesized that, in atherosclerotic plaques, triggering of CD40L on T cells leads to regulation of T-cell expansion and cytokine production [305]. Anti-CD40 ligand therapy was examined in two multicenter studies in SLE; one trial was halted because of unexpected thrombosis and the other showed no benefit [306]. Other immune-based therapies may be considered in the future.

Cardiovascular Mortality

Urowitz and colleagues first drew attention to the bimodal pattern of mortality in SLE, with early deaths due to active disease and infection and later deaths due to cardiovascular disease [184]. With better survival from SLE, both the morbidity and mortality from accelerated atherosclerosis can be expected to increase (Table 13) [29, 43, 151, 180, 181, 184, 186, 307–312].

Ward *et al*., 1995 [309]	16

In the study of causes of death in 144 SLE patients in an inception cohort, cardiovascular disease was the third leading cause of death (after SLE and infection) with 13 deaths from myocardial infarction, 7 from congestive heart failure, 2 from valvular heart disease, and 1 sudden death. Five cardiovascular deaths occurred in women under the age of 50. Surprisingly, African-Americans were less likely to die of cardiovascular disease [309].

Cardiovascular Surgery

Systemic lupus erythematosus patients are at greater risk of complications from cardiovascular surgery, [313, 314]. In one study, acute renal failure and wound complications were identified [313]. Reinforcement of suture lines has been recommended [314].

SUMMARY

Pericarditis is the most common form of cardiovascular lupus clinically detected. Other forms of cardiac lupus are rare, or are subclinical. The major challenge to clinicians is accelerated atherosclerosis, one of the major causes of mortality.

SYSTEMIC LUPUS ERYTHEMATOSUS AND THE CARDIOVASCULAR SYSTEM: VASCULITIS

Barri J. Fessler
Karen E. Rendt
Gary S. Hoffman

Clinical manifestations of vascular injury in systemic lupus erythematosus (SLE) may develop due to vasculitis and/or noninflammatory vasocclusive disease [1]. The expression of vasculitis may take several forms: isolated cutaneous lesions, single visceral organ involvement, or a multiorgan system disease [2]. Our current understanding of vasculitis in SLE patients is based on case reports or small case series. Determination of the true incidence of vasculitis in SLE is complicated by the fact that the diagnosis of vasculitis is often a clinical diagnosis, lacking histologic or arteriographic confirmation. Many of the more extensive SLE series [3–6] fail to document the incidence of vasculitis, and those that do provide proof of vasculitis indicate that it is an infrequent complication of SLE (Table 1). In view of its uncommon occurrence, it is difficult to accumulate significant numbers of SLE patients who have vasculitis, for either pathophysiologic studies or prospective trials of therapeutic agents. In addition, noninflammatory vasculopathies are confounding variables as they may mimic or rarely coexist with vasculitis [7–10].

A variety of noninflammatory vasculopathies may be observed in SLE [1]. Endothelial cell injury and/or activation resulting in intimal proliferation may lead to thickening of the walls of small blood vessels. Such changes are often widely distributed and may be associated with "micro-" or small visible infarcts that may or may not contribute to organ dysfunction [11, 12]. Activation of neutrophils and upregulation of endothelial cell adhesion molecules following exposure to complement split products and other chemoattractants may lead to leukoaggregation within the vasculature, causing transient or permanent end organ damage [13–15]. Occlusion of vessels by platelet-fibrin thrombi associated with clinical features of thrombotic thrombocytopenic purpura has also been observed in a small number of SLE patients [16–18]. Lastly, the most common and clinically significant vasculopathy in SLE is associated with the presence of anti-phospholipid antibodies (See Chapters 39–43). These different forms of vasculopathies are generally not inflammatory and are not regarded as true vasculitis. However, vasculitis may rarely occur concomitant with the anti-phospholipid antibody syndrome [8–10, 19].

PATHOGENESIS OF VASCULITIS IN SYSTEMIC LUPUS ERYTHEMATOSUS

Many immunologic mechanisms are involved in the pathogenesis of vascular injury in SLE. As a consequence of complex interactions between endothelium,

TABLE 1 Incidence of Vasculitis by Organ System in SLE

Organ	Estimated frequency based on clinical diagnosis	Reported frequency based on histologic proof of vasculitis[a]
Skin [5,7,46,48,49,99,166,167]	15–50%	NA[b]
Lung [94,95,168]	1–2%	18-20%
		8/44 autopsy cases [94]
		4/20 autopsy cases [95]
Gastrointestinal tract [47,99,100,129,168–172]	1–3%	24%
		6/25 autopsy cases [172]
Central nervous system [69,70,75]	Uncommon	7–12%
		3/24 autopsy cases [69]
		4/57 autopsy cases [70]
Heart [132,133]	Rare	3–37%
		1/30 autopsy cases [132]
		6/16 autopsy cases [133]
Genitourinary tract [143,147,148–151]	Case reports	NA
Large vessels [7,152-155,158,159]	Case reports small series	NA

[a] May overestimate frequency due to sampling bias, that is, autopsy studies represent patients with fulminant/treatment resistant vasculitis.
[b] NA, not available.

inflammatory cells, autoantibodies, and immune complexes, necrotizing inflammation of blood vessel walls ensues. The trigger that initiates the cascade of interactions between cells and factors that determine the location of vascular inflammation is unknown. Upregulation of adhesion molecules on vascular endothelium and leukocytes is an important determinant of localized inflammation and has been implicated in the development of vasculitis [20]. In one *in vitro* model it has been shown that antigenic fragments of DNA (which can be found in the circulation of some lupus patients) induce human umbilical vein endothelial cells (HUVEC) to express intercellular adhesion molecule-1 (ICAM-1) on their surfaces [21]. Activation of endothelial adhesion molecules would allow adherence to the endothelium by polymorphonuclear cells (PMNs) and lymphocytes and facilitate their entry through the vessel wall into the tissue. Blocking the interaction between adhesion molecules, ICAM-1 and CD18/CD11b, located on the endothelial cell and neutrophil, respectively, prevents the development of vasculitis in an experimental model [15]. In addition, the demonstration of upregulated expression of adhesion molecules CD11a/CD18 and VLA-4 on lymphocytes from SLE patients with vasculitis further supports a role for adhesion molecules in the pathogenesis of vasculitis [22]. However, upregulation of adhesion molecules is also observed in many types of tissue inflammation, including those in which the vessel is not injured.

Immune complex deposition is thought to play a pivotal role in the development of SLE vasculitis. It is not the mere presence of circulating immune complexes that cause disease, but the inflammatory events that occur after their deposition in tissue. Factors that enhance immune complex deposition include (1) moderate antibody production with antigen excess resulting in intermediate-sized immune complexes that are not efficiently cleared; (2) antibody production against a limited number of antigenic determinants or a complex antigen, producing smaller immune complexes that are slowly eliminated; (3) the type of antibody produced, for example, immunoglobulin M (IgM) complexes are larger at all ratios of antigen, unless there is extreme antigen excess, and are more readily eliminated; (4) blockade or overload of the reticuloendothelial system, which may occur from large amounts of immune complexes [23–25]; (5) alteration in vascular permeability (the release of vasoactive amines from platelets and mast cells may cause endothelial cell retraction, allowing immune complexes to enter the vessel wall) [26]; and (6) regional differences in hydrostatic pressures, such as occurs in the glomeruli [27].

Deposition of immune complexes in the vessel wall is followed by activation of the complement cascade. Complement fragments, such as C5a desarg, promote chemotaxis of polymorphonuclear cells and expression of endothelial adhesion molecules [28, 29]. The release of polymorphonuclear enzymes and oxygen radicals

produces tissue injury. One animal study utilizing male albino New Zealand rabbits has indicated the essential role of polymorphonuclear cells in the production of vasculitis in that model system. Serum sickness was produced with bovine serum albumin (BSA) and the immune response being enhanced with either pooled rabbit anti-BSA or *Escherichia coli* endotoxin with the BSA. One group was neutrophil-depleted by pretreatment with anti-polymorphonuclear globulin at a dose sufficient to cause circulating polymorphonuclear counts of <300/mm^3. In this group necrotizing vasculitis was absent [30].

The role, if any, that autoantibodies play in the pathogenesis of vasculitis is unclear. Some have speculated that anti-endothelial antibodies may play a role in triggering the development of vasculitis. Anti-endothelial antibodies obtained from patients with lupus have been studied *in vitro* and found to upregulate endothelial cell expression of VCAM-1, ICAM-1, and E-selectin, as well as enhance leukocyte adhesion to endothelial cells [31, 31a] (Fig. 1). In addition, experimental evidence suggests the existence of cross-reactive epitopes in endothelial cells, lysophosphatidylcholine (LPC) and oxidized LDL. LPC is formed during oxida-

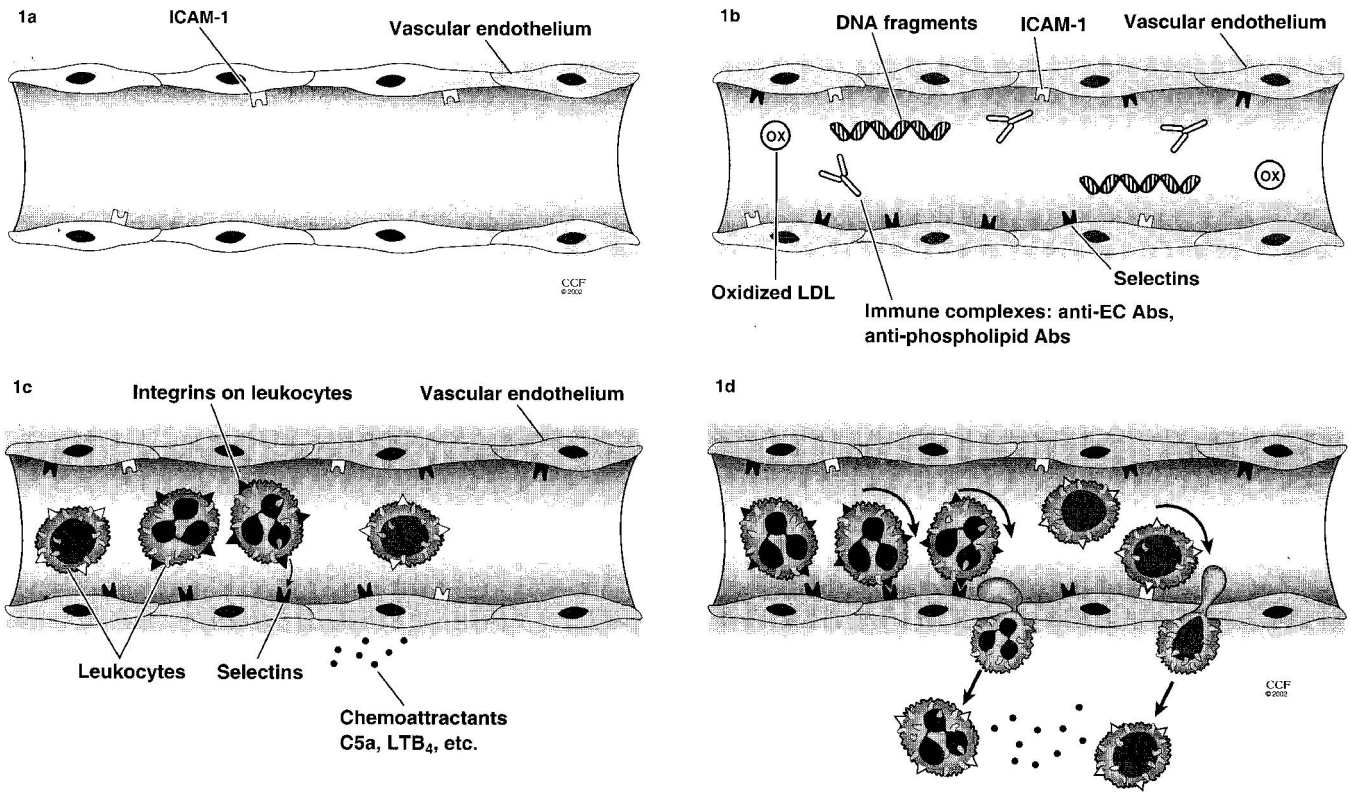

FIGURE 1 Possible mechanisms of vascular injury in SLE. In addition to soluble factors (e.g., complement, leukotrienes, immune complexes) and inflammatory cells (PMNs, lymphocytes), the endothelium itself plays an active role in vascular injury. (a) In the resting state, endothelial cells (EC) exhibit a low level of expression of surface ligands (ICAM-1, and others). (b) Appearance of adhesion melecules (selectins) on the surface of endothelial cells induced by circulating factors (fragments of DNA, anti-endothelial cell antibodies, IL-1, TNF α, lipopolysaccharide, anti-phospholipid antibodies, oxidized LDL, and others). (c) Interaction of activated lymphocytes and PMNs from the circulation with endothelial cells: binding of selectins on EC with their carbohydrate ligands on leukocytes mediates initial tethering and rolling. Chemoattractants promote directed migration of the rolling leukocytes toward the source of the chemoattractant. Binding of the chemoattractant (e.g., C5a, LTB4, PAF, IL-8, and others) to the chemoattractant receptor on the leukocyte triggers integrin expression. (d) The interaction of integrins (LFA-1, VLA-4, and others) on leukocytes with EC surface molecules from the immunoglobulin gene superfamily (ICAM-1, ICAM-2, ICAM-3, VCAM-1, and others) results in tight adhesion of the leukocytes to the ECs, thus permitting diapedesis (migration through the wall and into the tissue beyond). Activation of complement by immune complexes, and release of oxygen radicals by PMNs can contribute to local vascular injury.

tion of LDL or as a result of the action of phospholipase A2 on phosphatidylcholine; it is an important antigen in oxidized LDL. An immune reaction to LPC leading to endothelial attack culminating in vasculitis, thrombosis, or atherosclerosis, is suggested by significantly larger amounts of antibodies to LPC in patients with SLE compared with normal controls [32]. Other proposed mechanisms by which anti-endothelial antibodies may induce vascular injury include: complement fixation [33], recruitment of neutrophils, and antibody-dependent cellular cytotoxicity [34]. Anti-neutrophil cytoplasmic antibodies (ANCA), a heterogeneous group of autoantibodies directed against a variety of antigens within the neutrophil and monocyte, have been associated with certain systemic vasculitides, such as Wegener's granulomatosis [35]. The role that ANCAs play in the pathogenesis of vasculitis is unproven [36]. ANCAs have been isolated in the sera from SLE patients with varying frequency (0–93%) [37–44]. However, the presence of ANCAs in SLE does not correlate with major organ involvement, disease activity, or the presence of vasculitis [38, 40, 42]. False-positive ANCAs in lupus patients may be due to the binding of myeloperoxidase (one of the substrate antigens in ANCA immunoassays) to DNA contained within the antigen binding site of anti-DNA antibodies [45].

As there is heterogeneity in the clinical manifestations of SLE vasculitis, as will be discussed in the next section, it is reasonable to hypothesize that different mechanisms of vascular injury may be operant in different patients, or even in the same patient in different vascular beds. Thus, for example, different factors may be responsible for the development of leukocytoclastic vasculitis in the skin as compared to inflammatory aortic aneurysms. Much has yet to be learned about the determinants of vascular attack by the immune system, both from the standpoint of understanding what activates the circulating leukocyte population, as well as identifying the unique features of specific vascular beds that lead to targeting and attack by the immune system.

THE SPECTRUM OF VASCULITIS IN SYSTEMIC LUPUS ERYTHEMATOSUS

Cutaneous Vasculitis

Cutaneous vasculitis is the most common form of vasculitis in SLE, occurring in 19–50% of patients [4, 5, 46–49]. Its recognition, in some instances, has correlated significantly with severity of disease and organ involvement [48–52]. Cutaneous vasculitis typically occurs as an early manifestation of SLE, developing within 5 years of disease onset [49]. Non-Caucasian patients have a higher incidence of cutaneous vasculitis than Caucasian patients [49, 53–55]. Clinical expression of vasculitis includes petechiae, palpable purpura (Fig. 2), urticaria, nodules, bullae, nail-fold (Fig. 3), and splinter hemorrhages, ulcerations, gangrene, and livedo reticularis [56]. In the early stages of evolution, cutaneous vasculitis

FIGURE 2 Palpable purpura of the lower extremity of a patient with active lupus who also had arthritis and pericarditis.

FIGURE 3 Nail-fold infarcts. There are pinpoint lesions in the nail beds, most prominent in the second, third, and fifth fingers of the left hand. There is also Raynaud's vasospasm involving the second and third fingers of the same hand.

may be flat and only later become palpable. Severe vasculitic involvement may lead to bullae formation, ulceration, or skin necrosis (Fig. 4). Purpuric lesions, palpable or nonpalpable, are the most frequently observed manifestation of inflammatory vascular disease in SLE, occurring more often in patients with anti-SSA antibodies and Sjögren's syndrome/SLE overlap [57, 58]. In addition, patients with cryoglobulins are more than twice as likely to develop cutaneous vasculitis than those without cryoglobulins [59]. Severe small-vessel vasculitis may cause small microinfarcts of the tips of the digits, which heal with "ice pick" scars (Fig. 5). Infrequently, vasculitis may manifest as urticaria (5–10%) [60–62] and requires differentiation from allergic urticaria. The lesions may be hyperpathic to light touch, persist for more than 24 h, and may display stippled petechiae that heal with hyperpigmentation.

Vasospasm may be a primary event or may occur secondary to vasculitis, embolic phenomena, vasoactive drugs, vasculopathy, or toxins. Arteritis of medium-sized vessels of the skin may cause vasospasm of the ascending dermal arterioles with pooling of blood in the superficial horizontal venous plexus and give rise to mottling (livedo reticularis). Alternatively, livedo reticularis may be associated with the vasculopathy of the antiphospholipid antibody syndrome. This finding may be generalized and/or accentuated about the outer arms, thighs, and over large joints. Livedo reticularis occurs in approximately 20% of SLE patients [51]. Punch biopsies of the skin are usually unrewarding because the deep dermal vessels are not accessible by this technique [56]. Anti-cardiolipin antibodies are found in 80% of patients with SLE and livedo reticularis [51]. Severe vasculitis of medium-sized vessels may also cause digital gangrene [4, 63], but fortunately this is rare (1–5%) [4, 5]. Cutaneous ulceration and gangrene may also develop as part of the vasculopathy associated with the anti-phospholipid antibody syndrome [64–66].

Histologically, most lupus vasculitic skin lesions demonstrate leukocytoclastic vasculitis with preferential involvement of arterioles, capillaries, and venules (Fig. 6). This is the most common form of vasculitis in SLE. In addition, small arterioles and postcapillary venules of other organs may be simultaneously affected. Infiltration and destruction of the vessel walls by polymorphonuclear cells is accompanied by polymorphonuclear fragmentation. The nuclear "debris" denotes leukocytoclasis [67]. Some cases primarily demonstrate vascular and/or perivascular infiltrate with mononuclear cells. Whether this merely represents a later stage of leukocytoclastic vasculitis is uncertain. Direct immunofluorescence of the skin lesion typically demonstrates granular IgG, complement, and fibrinogen in and/or around blood vessels [68].

FIGURE 4 Severe palpable purpura with ulcerations affecting the lower extremity of a patient with active lupus manifested by glomerulonephritis, arthritis, serositis, and central nervous system disease.

FIGURE 5 Healed microinfarcts of the fingertips. Often referred to as "ice pick" scars, they appear as ischemic ulcers surrounded by areas of hyperemia.

Central Nervous Systems and Peripheral Nervous System Vasculitis

Neuropsychiatric manifestations may be seen in up to 75% of SLE patients [3–5, 69, 70]. Central nervous system (CNS) abnormalities are more common than peripheral neuropathy (3–18%). CNS vasculitis may rarely be the sole presenting symptom of lupus [71]. Several studies have noted a correlation of cutaneous vasculitis with CNS disease [49–52, 72]. Feinglass *et al.* [50] observed that of a total of 140 cases, 52 had neuropsychiatric manifestations, among whom a clinical diagnosis of cutaneous vasculitis was made in 46%. In contrast, of the 88 without neuropsychiatric disease, cutaneous vasculitis was clinically recognized in only 17%.

Although CNS symptoms are usually attributed to vasculitis, demonstration of CNS vasculitis on postmortem examination of SLE patients is infrequent [69, 70, 73, 74]. Rather, an occlusive vasculopathy

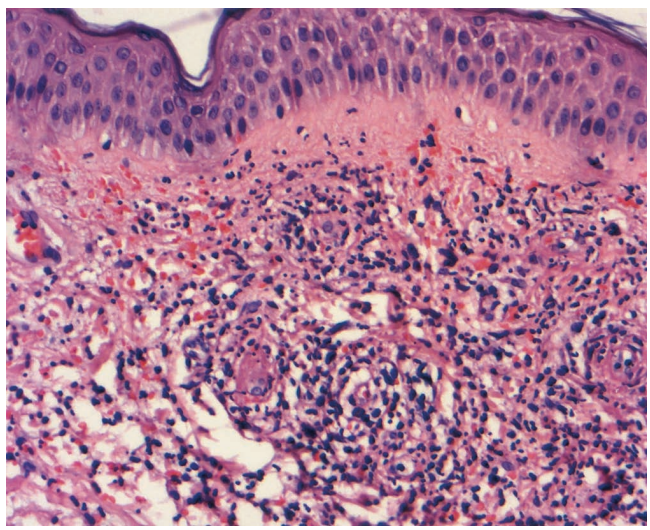

FIGURE 6 Skin biopsy demonstrating leukocytoclastic vasculitis involving postcapillary venules with fibrinoid necrosis within vessels and a perivascular mixed inflammatory infiltrate with nuclear dust. (Photo courtesy of Kathleen J. Smith, M.D.)

characterized by intimal proliferation of arterioles and capillaries and vascular hyalinization, associated with infarcts and hemorrhage, is observed. Johnson and Richardson [69] found vasculitic lesions in only 3 of 24 (12%) autopsy cases and Ellis and Verity [70] recorded arteritis in 7% of 57 cases.

Central nervous system vascular disease usually affects small vessels (diameter ≤2 mm). The result is multiple microinfarcts that may vary in age from region to region. This feature allows distinction from hypertensive encephalopathy and the CNS lesion of thrombotic thrombocytopenic purpura. The former has the additional feature of hypertrophy and hyalinization of the media of larger vessels, and thrombocytopenic purpura is distinguished by its microangiopathic peripheral blood smear, as well as the paucity of CNS parenchymal disease. When parenchymal vascular lesions are present in thrombocytopenic purpura, they are usually of the same age. The CNS lesions of SLE are most common in the cerebral cortex and brain stem and correlate with generalized seizures and cranial nerve deficits, respectively. Large-vessel vasculitis of the CNS is distinctly rare, with less than a dozen cases described in the literature [75]. Subarachnoid hemorrhage is an uncommon complication of SLE and may result from a ruptured intracerebral aneurysm [76–80]. Pathology specimens have revealed medium-sized vessel vasculitis.

If vasculitis affects the retina, it is usually bilateral. One eye is usually more severely affected than the other. Lesions tend to be focal and characterized by intraretinal hemorrhage and local retinal infarction with variable adjacent retinal exudation (Figs. 7 and 8). Fluorescein angiography may be useful in identifying the extent of disease and response to treatment (Fig. 9). Papillitis may result from vascular disease of nutrient vessels to the optic nerve [81, 82]. Only a few postmortem ocular specimens have been studied. Findings have included vasculitis in the choroidal circulation [83, 84]. Retinopathy may be a marker of disease activity and CNS involvement [85, 86].

Spinal cord vascular lesions may manifest as transverse myelopathy [87]. In one series, 2 of 12 cases had histopathologic evidence of vasculitis. Perivascular round cell infiltrates, collagen proliferation, thrombotic occlusion of small arteries and arterioles, and micro-

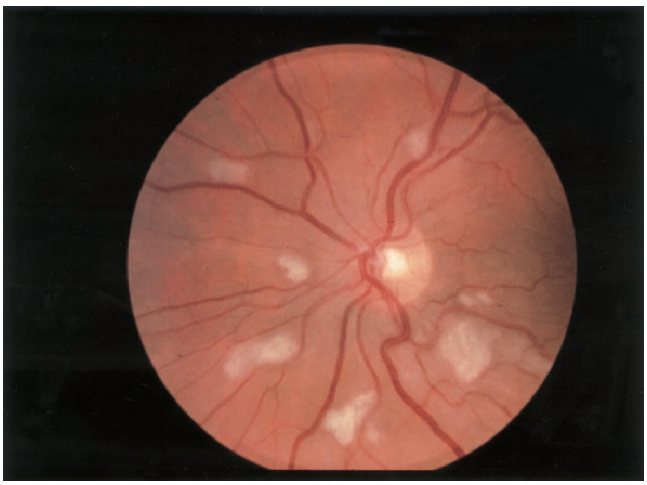

FIGURE 7 Fundus photograph reveals cotton wool spots or nerve fiber layer infarcts in a patient with SLE. (Photo courtesy of Careen Lowder, M.D.)

FIGURE 8 Fundus photograph of the right eye reveals flame shaped hemorrhages and cotton wool spots, the two most frequently reported ocular findings in SLE. (Photo courtesy of Careen Lowder, M.D.)

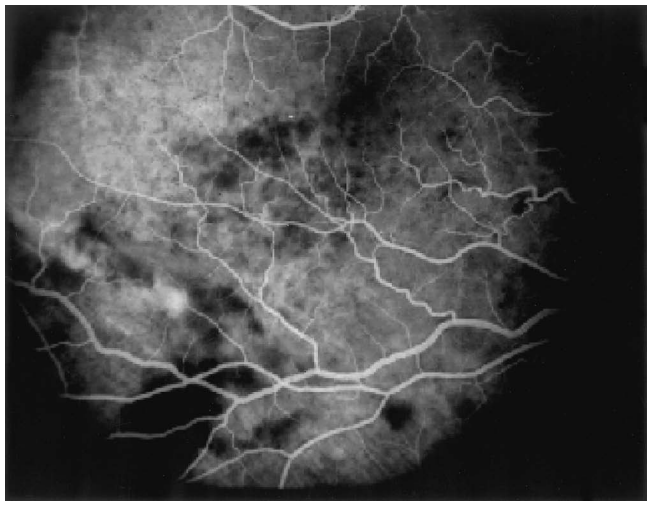

FIGURE 9 Fluorescein angiogram reveals focal areas of choroidal nonperfusion as seen in patients with choroidal ischemia. (Photo courtesy of Careen Lowder, M.D.)

scopic hemorrhage in the cord parenchyma were noted in all cases. Whether more extensive sampling of tissue would have demonstrated frank vasculitis in all cases is a matter of speculation.

Peripheral neuropathy in SLE may be due to vasculitis of the vasa nervorum that may result in multifocal sensorimotor neuropathy with prominent sensory symptoms [88, 89]. Mononeuritis multiplex has also been reported [88, 90, 91]. Nerve biopsy may show evidence of necrotizing vasculitis with perivascular inflammatory infiltrates and intimal thickening [92, 93].

Pulmonary Vasculitis

The contribution of vasculitis to pulmonary pathology in SLE has been reported to range from 0 to 40% [94–98]. Fayemi [94] reported 20 autopsy cases, of which 6 had pulmonary symptoms. Four had vasculitis involving the muscular and elastic arteries, which contrasts with more commonly recognized predilection for small vessels noted in other organs. Gross *et al.* [95] reported abnormalities of the pulmonary vasculature in 8 of 43 cases, including involvement of small arteries and arterioles. Radiographically, lesions may appear as areas of atelectasis, infiltrates, or, rarely, nodules or cavities caused by ischemic necrosis. Despite the extensive vascular changes that can occur, cor pulmonale or right ventricular hypertrophy have been uncommon. This may reflect rapid evolution of vascular pathology.

Gastrointestinal Vasculitis

Vasculitis within the abdomen is uncommon [7, 47, 99] and associated with a high mortality rate (Table 2) [100]. Vasculitis may affect the vessels within the mesentery [101], (Fig. 10), pancreas [102–104], peritoneum (Fig. 11), and, rarely, liver [105–108] and gall bladder [109, 110].

Mesenteric vasculitis is estimated to occur in approximately 1–2% of SLE patients [47, 99, 101] and may affect the vessels supplying the stomach, small, intestine, or large intestine [111–114]. Clinically, gastrointestinal symptoms may range from nausea, bloating, vomiting, diarrhea, postprandial pain and/or fullness, to frank hemorrhage and acute abdominal pain. The less acute gastrointestinal symptoms might erroneously be attributed to side effects of commonly prescribed medications such as corticosteroids, NSAIDs, hydroxychloroquine, and azathioprine. Physical exam findings of guarding and rebound may be absent or appear only late in the disease course in the patient taking corticosteroids or other immunosuppressive agents. Unexplained acidosis, a falling hematocrit, and hypotension are worrisome clues to a possible intra-abdominal crisis [115]. X rays may be normal or reveal thumbprinting, ileus, or pseudo-obstruction [110]. Computed tomography (CT) scan may reveal bowel-wall thickening [116] and prominence of mesenteric vessels [117]. Vasculitis involving the intestinal tract is typically a small-vessel vasculitis affecting arterioles and venules [118] that are beyond the resolution of arteriography. Rarely, periarteritis nodosa-like aneurysmal lesions in medium-sized vessels may occur. When present, aneurysms may thrombose or rupture, causing hemorrhage and death [118, 119]. Intestinal vasculitis may lead to mucosal ischemia, resulting in ulceration, hemorrhage, infarction, or perforation [118, 120, 121]. Exploratory laparoscopy or laparotomy should be considered early, as a delay in diagnosis of ruptured or infarcted bowel has a very high mortality rate. Medina *et al.* [122] found that among 44 SLE patients with acute abdomen requiring surgery, none of 33 died who were operated on within 48 h of presentation, whereas 10 of 11 died who were operated on >48 h after presentation. In most but not all [123] series, patients with mesenteric vasculitis have evidence of lupus activity affecting other organs. Pneumatosis cystoides intestinalis, although more frequently associated with other connective tissue diseases such as scleroderma or rheumatoid arthritis, may be a benign finding [124] or may be associated

TABLE 2 Gastrointestinal Involvement and Morbidity

Series	No. of patients	Gastrointestinal involvement (%)	Histologic proof (%)[a]	Death (%)
Matolo and Albo [171]	51	27.5	Unclear	43

[c] Patient selection emphasized acute surgical presentations.

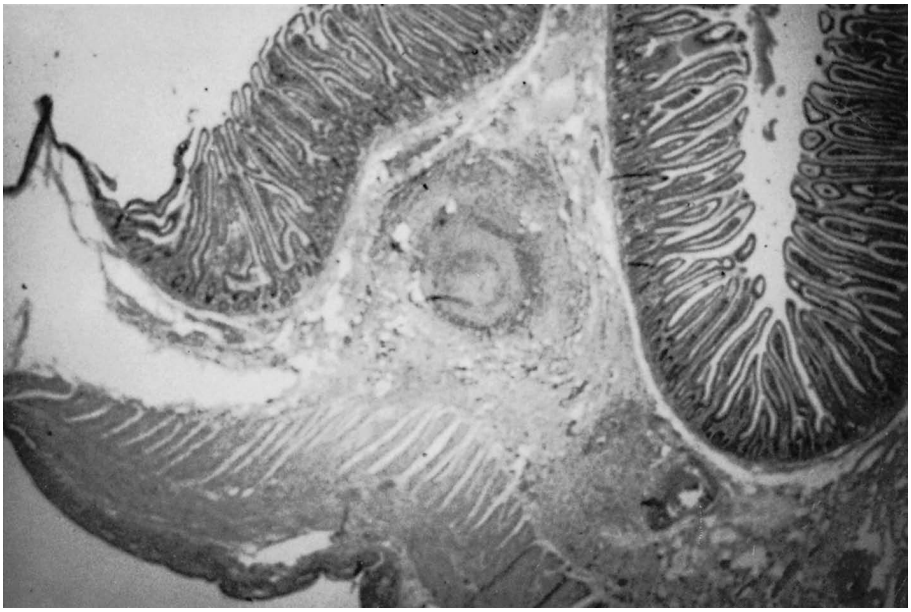

FIGURE 10 Gastrointestinal vasculitis. Transmural intestinal segment demonstrating a medium-sized vessel with thrombosis and whose wall is infiltrated with inflammatory cells.

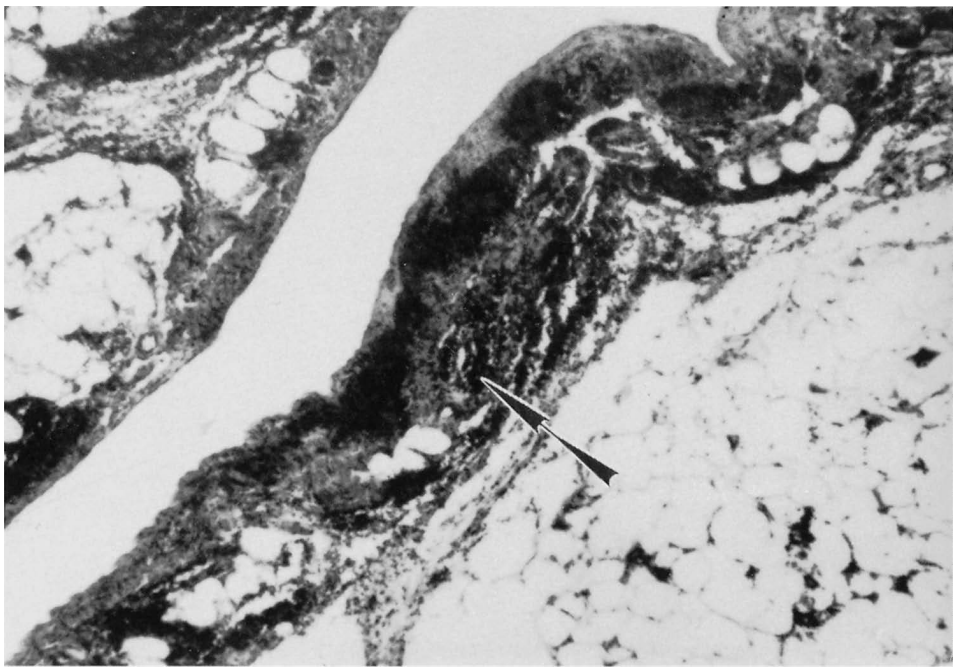

FIGURE 11 Vasculitis of the peritoneum. This patient presented with massive ascites. At laparotomy, no abnormal viscus was found but a peritoneal biopsy demonstrated extensive small-vessel vasculitis.

with intestinal vasculitis in SLE patients [101, 125, 126]. Inflammatory vascular disease affecting venules supplying the intestines has also been implicated in the etiology of protein losing enteropathy in SLE [127, 128].

Vasculitis may also affect other organs within the abdominal cavity. Histologic evidence of necrotizing arteritis of the liver has been reported in 18–20% of postmortem cases [107, 129]. Spontaneous hepatic rupture caused by small- and medium-sized vessel vasculitis is a

rare complication [105, 130]. Acute acalculous cholecystitis due to vasculitis may occur in isolation or may be associated with widespread disease activity [109, 110]. Vasculitis has been implicated as a cause of pancreatitis in a subset of SLE patients [102, 103].

Because of the rarity of the condition, there is no standardized approach to the treatment of gastrointestinal vasculitis. Controlled trials of treatment regimens do not exist. High-dose corticosteroids (1–2 mg/kg IV methylprednisolone) and bowel rest are generally effective in treating those patients whose vasculitic manifestations include abdominal pain, ileus, even ulceration and hemorrhage, but obviously one must carefully rule out bowel infarction, perforation, or obstruction before settling on nonsurgical management strategies. Case reports exist describing concomitant use of cytotoxic agents, most commonly cyclophosphamide, in management of lupus gastrointestinal vasculitis [115, 131].

Vasculitis of the Heart

Coronary artery vasculitis is exceedingly rare in SLE and has been documented primarily in case reports [132–140]. Vasculitis affecting the coronary arteries may occur in the absence of extracardiac lupus activity, thereby making the diagnosis especially challenging. Diagnosis is usually made by serial coronary angiographic studies. However, the sensitivity and specificity of angiography is unknown. Angiographic findings suggestive of vasculitis include arterial aneurysms without concomitant distal stenoses, smooth focal tapering stenoses, and/or rapidly developing arterial occlusions on repeated studies. Both the mainstem and its branches including the sinus node artery have been involved [137]. Vessels that are no longer the site of active vasculitis may have persistent aneurysms or stenoses that may thrombose and cause myocardial infarction. In some cases, vasculitic changes have been accompanied by fibrosis of the conduction system [140]. Rare examples of cardiac valve dysfunction caused by small-vessel vasculitis have also been documented [137].

Vasculitis of the Genitourinary System

True vasculitis of the kidney is the least frequent manifestation of vascular disease within the kidney, occurring in less than 5% of SLE nephritis patients [141, 142] (Fig. 12). Vascular immune deposits, noninflammatory necrotizing vasculopathy (Fig. 13), and thrombotic microangiopathy are other forms of vascular disease implicated in the pathogenesis of SLE-associated renal disease [12, 143, 144]. In renal vasculitis, the vessels affected are usually small- and medium-sized arteries, most commonly intralobular arteries. It is most frequently associated with diffuse proliferative glomerulonephritis. The presence of vasculitis on renal biopsy is believed to be an independent indicator of adverse renal prognosis [145, 146].

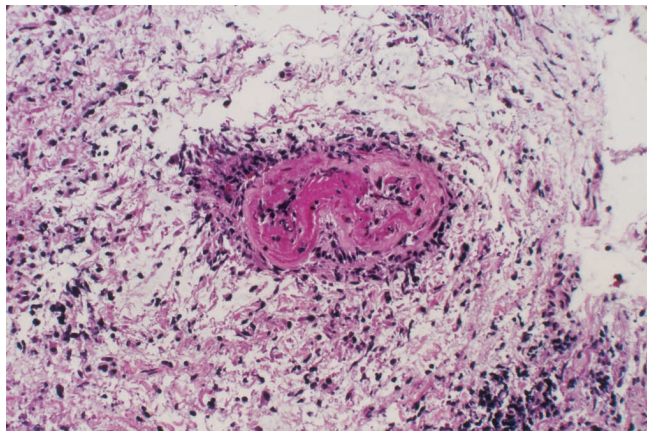

FIGURE 12 Acute vasculitis: necrotizing vasculitis with transmural infiltration by neutrophils and lymphocytes. (Photo courtesy of William J. Cook, M.D.)

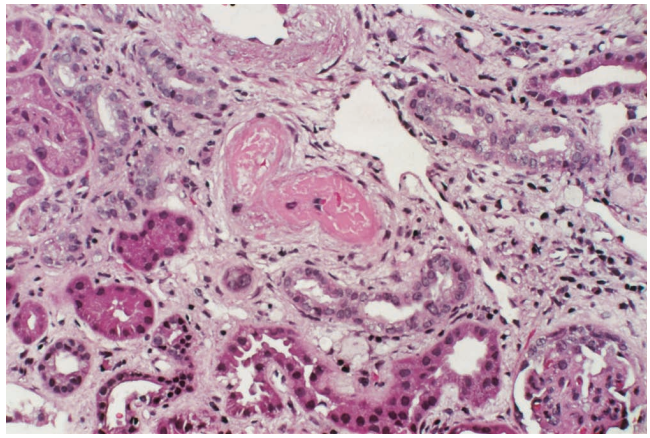

FIGURE 13 Lupus vasculopathy: The arteriole on this renal biopsy is narrowed by intimal deposits of eosinophilic material which likely represents a mixture of fibrin and immune deposits. Although the endothelium is necrotic, there is no inflammation. (Photo courtesy of William J. Cook, M.D.)

Case reports of lower genitourinary tract involvement include examples of hydronephrosis, hydroureter, and acute renal failure in the absence of cytotoxic therapy [147, 148]. Histologic examination of the bladder has demonstrated interstitial cystitis. In rare instances, ureteral vessels have been affected, and displayed necrotizing vasculitis with extensive fibrinoid changes. Such lower genitourinary tract disease should be considered in an SLE patient with deteriorating

TABLE 3 Vasculitis of the Placenta

Series	No. of patients	No. of placentas	Fetal outcome (live births)	Types of vascular lesions studied			
				Vasculitis	Thrombosis	Intimal proliferation	Tortuosity
Abramowsky *et al*. [162]	10	10	4	5	2	Reported[a]	Reported

[a] Not quantitated.
[b] NR, not reported.

renal function in the absence of red blood cell casts and in whom calculi and extrinsic causes of compression have been excluded. In the cases reported, obstruction was relieved by corticosteroid therapy [147, 148]. In addition, rare cases of necrotizing vasculitis of the penis [149] ovaries [150], and uterus [151] have been reported in lupus patients.

Large-Vessel Disease

Large-vessel vasculitis of the aorta and its branches is exceedingly rare in SLE. Cases of Takayasu's arteritis associated with SLE have been described [152–155]. However, the coexistence of these two diseases may merely be an issue of semantics, that is reconciled when one recognizes that in fact aortitis or disease of aortic branch vessels may rarely be a part of SLE [156, 157].

Large-vessel involvement has been reported to affect the abdominal aorta, subclavian, carotid, coronary, and lower-limb arteries [138, 158–160]. Large-vessel vasculitis of the extremities resulting in gangrene is very uncommon in SLE patients. In a literature review of all reported English-language cases of limb-threatening vascular occlusion, 12 cases were identified, of which 4 were due to vasculitis [161]. Pathologic specimens demonstrated full-thickness necrotizing arteritis with polymorphonuclear cell infiltration [159, 161]. Immune complexes were not identified. Sympathectomy and streptokinase have not proven to be useful in these cases. Corticosteroids have allegedly provided relief of intermittent claudication and limited the damage caused by large-vessel vasculitis [158, 160].

Vasculitis of the Placenta

The contribution of placental vasculitis to fetal mortality has been subject to preliminary evaluation that has led to conflicting observations (Table 3). Abramowsky *et al.* [162] have studied the placentas of 10 women with SLE. Five of 10 specimens demonstrated vascular fibrinoid necrosis and mononuclear and/or polymorphonuclear inflammatory infiltrates. Some vessels were tortuous and others aneurysmal. These changes were seen in the 5 multiparous patients who suffered fetal loss after the first trimester, but were noticeably absent in the primagravids. Hanly *et al.* in a prospective study of 11 cases could not document any distinct form of placental pathology. They found no evidence of vasculitis [163]. Demonstration of immune complexes in diseased as well as in normal placentas raises questions as to what role immune complexes play in placental insufficiency and abortion [164]. The correlation of fetal outcome with placental thrombosis, phospholipid antibodies, vasculopathy, or vasculitis is not yet clear. In addition, many of the histologic features described in placentas of SLE patients are very similar to those in preeclampsia and may be present to a lesser degree in the placentas of normal nonlupus patients [165].

Differential Diagnosis of SLE Vasculitis

Immune responses in SLE are inherently abnormal and further compromised by immunosuppressive therapy. Deterioration in clinical status must take into account the possibilities of infection, drug toxicity, disease progression, thrombosis from anti-phospholipid antibodies, and less commonly, disseminated intravascular coagulation or thrombotic thrombocytopenic purpura. Any of these multisystem processes can mimic vasculitis or, conversely, be complicated by vasculitis.

Management

Because (1) the diagnosis of lupus vasculitis is often uncertain, (2) large numbers of similarly affected patients are not available for prospective studies, and (3) vasculitis usually does not occur in the absence of a

variety of other pathologic events, it is difficult to perform controlled therapeutic trials for lupus vasculitis. For life-threatening major organ involvement with vasculitis, aggressive therapy with corticosteroids, cyclophosphamide, intravenous immunoglobulin, and/or plasmapheresis has proven useful in selected patients. Treatment must remain a matter of clinical judgement; one must consider the patient's global illness, of which vasculitis may be only one factor and not necessarily the dominant consideration.

SYSTEMIC LUPUS ERYTHEMATOSUS AND THE LUNG

E. Clinton Lawrence

Systemic lupus erythematosus (SLE) is a systemic disease with protean manifestations affecting virtually every organ either directly or indirectly. Involvement of the lung and pleura in SLE may be as common as the renal involvement and more common than involvement of the central nervous system [1]. Fortunately, pulmonary derangements in SLE are not usually as life threatening as may be the renal or central nervous system complications. Nevertheless, pulmonary dysfunction does occur in SLE and may be a significant cause of morbidity and occasionally of mortality.

The reported frequency of pulmonary involvement in SLE varies greatly among published series, depending on the population studied and the referral patterns of the institution [2]. For example, parenchymal lung involvement attributed to SLE has ranged from as low as 0.9% [1] to a high of 98% [3]. Most series indicate that pulmonary involvement occurs 50% or more of the time in SLE [4], with autopsy series reporting even greater frequencies of involvement [5]. However, clinically inapparent pulmonary impairment may occur in the majority of cases, since abnormalities of pulmonary testing have been reported in 88% of unselected cases in one series [6]. The most frequently noted abnormality was the diffusing capacity for carbon monoxide, which was reduced in 72% of cases [6]. However, there was no correlation between the pulmonary abnormalities and other measures of lupus activity [6]. Additionally, one prospective study has shown only a low rate of pulmonary function deterioration over time [7].

In addition to primary pulmonary disorders attributed to SLE, secondary pulmonary complications, especially infections [1, 2], may occur as a consequence of disease in other organs or of treatment. Clearly, then, pulmonary derangements in SLE may frequently challenge the diagnostic and therapeutic acumen of physicians from a variety of disciplines.

PRIMARY PULMONARY INVOLVEMENT IN SYSTEMIC LUPUS ERYTHEMATOSUS

The term pulmonary involvement in SLE, as used in this chapter, refers to abnormalities not only of the lungs themselves but also of contiguous structures involved in normal respiration. In this context, distinct clinical entities have been described that correlate with anatomic disease of the diaphragm, the pleura, the lung parenchyma (including interstitium, bronchioles, and alveoli), and vasculature. Each of these disease processes is discussed in greater detail.

Diaphragmatic Involvement

It has long been recognized and shown radiographically that certain patients with SLE may exhibit progressive loss of lung volumes because of insidious and progressive basilar atelectasis accompanied by elevation of both hemidiaphragms [8]. Whether this syndrome of so-called shrinking or vanishing lungs was due

to abnormalities within the lungs (i.e., atelectasis) or to abnormalities of the diaphragms was not clear until Gibson *et al.* [9] measured diaphragmatic function in unselected patients with SLE. Abnormalities of maximal transdiaphragmatic pressures during maximal inspiratory effort were present in four of the five individuals who had elevation of the diaphragms. These and other findings [10–13] indicated that weakness of respiratory muscles, possibly as part of a more generalized myopathy or mysositis or even diaphragmatic fibrosis [12], might explain the syndrome of vanishing lungs.

However, incrimination of diaphragmatic weakness as the primary factor in the pathogenesis of shrinking lungs has been challenged by Laroche *et al.* [13], who found decreases in maximal transdiaphragmatic pressure caused by incomplete activation of the diaphragm during a maximal voluntary effort in only 3 of 12 patients with SLE. These observations led them to invoke a restriction in chest-wall compliance to explain the syndrome.

Although the role of the diaphragm in the shrinking lungs syndrome remains controversial, the clinical picture is characteristic. Patients thus afflicted often complain of dyspnea that is out of proportion to objective impairment of pulmonary function. The sensation of dyspnea may be exacerbated by the recumbent position when the diaphragm pushes further into the chest cavity. Such patients may find at least partial alleviation of their discomfort by sleeping with the head of their bed elevated. Rarely, patients may suffer from muscle weakness resulting from an association of myasthenia gravis and SLE; such patients may respond to anticholinesterase drugs such as edrophonium-chloride (Tensilon). It is not clear from the literature whether corticosteroid and immunosuppressive therapy improve diaphragmatic performance in affected patients. Fortunately, such treatments may not be needed for diaphragmatic disease per se, because Gibson *et al.* [9] reported that three of their five patients remained stable over 4–6 years.

Pleural Involvement

Involvement of the pleura may occur in as many as 50% of SLE patients [1, 2, 5] either as pleuritis with chest pain or as frank effusion. The pathogenesis of the pleuritis appears to be lymphocyte and plasma cell infiltration of the pleura [2] although granulomas have also been described in biopsy specimens [14]. In patients with known SLE, pleural effusion in the presence of disease activity elsewhere may be due to lupus involvement of the pleura, particularly when the effusion is bilateral, as is often the case. The other major diagnostic consideration in established SLE is infection, particularly in patients who have been receiving immunosuppressive drugs. Thoracentesis with examination of the pleural fluid is essential to clarify the diagnosis [15].

Although effusions related to SLE or infection may share certain characteristics, other differences may be appreciated (see Table 1). With infected pleural effusions, bacteria may be seen with Gram stain or grown from culture. The white blood cell (WBC) count is usually much higher in bacterially infected effusions than in effusions caused by SLE and shows a predominance of neutrophils [16], whereas either a lymphocytic or a neutrophilic predominance has been described with SLE [17]. Tuberculous effusions may be similar to SLE effusions, with a lower total white blood cell count and a lymphocytic predominance [16, 18]. With grossly infected fluids (empyemas), the glucose and pH levels are typically low [19, 20], whereas these values are characteristically normal in SLE effusions [21]. The features that most readily distinguish SLE effusions from infected effusions are immunologic, such as reduced levels of complement and the presence of immune complexes, anti-DNA antibodies, and occasionally lupus erythematosus (LE) cells [22–25]. The same characteristics serve to differentiate pleural effusions in SLE from effusions seen with pulmonary embolus with infarction and from malignant effusions. Pleural fluid findings that may be considered diagnostic of SLE include (1) LE cells, (2) pleural fluid ANA titer greater than or equal to 1:160, and (3) a pleural fluid/serum ANA ratio of greater than 1 [26].

Early in the course of the disease process, it is sometimes difficult to differentiate SLE from rheumatoid arthritis (RA). Pathologically, evidence of pleural involvement is present in the majority of patients with either disease process [4]. Clinically, however, the two disorders vary a great deal. For example, the majority of patients with SLE complain of pleuritic chest pain and dyspnea, whereas the pleural disease in patients with RA is often asymptomatic [4]. Effusions in RA more often affect men and are associated with subcutaneous rheumatoid nodules, high-titer rheumatoid factor, and parenchymal lung disease [27–31].

Analysis of the pleural fluid is helpful in distinguishing between the two processes. Thus the glucose is normal in SLE but is almost always decreased in RA [30, 31], so that the finding of a pleural fluid glucose level of less than 30 mg/dl in the absence of infection or malignancy is virtually diagnostic of RA [30, 32, 33]. Complement levels, both total hemolytic complement (CH100) and C3 and C4, may be decreased in either disease and thus are helpful in differentiating effusions

TABLE 1 Differential between SLE and Other Causes of Pleural Effusions

	SLE	RA	Pulmonary infection	Pulmonary embolus[a]	Malignancy
Symptoms	Chest pain Dyspnea	May be asymptomatic	Fever Chest pain	Chest pain Dyspnea	Varies
Pleural fluid character	Usually clear (may be hemorrhagic)	Clear	Clear to cloudy	Clear to bloody	Clear to bloody
Protein	Increased	Increased	Increased	Increased (usually)	Increased
Glucose	Normal	Decreased (often)	Decreased (often)	Normal	May be decreased
pH	Normal	Normal	Decreased (empyema)	Normal	May be decreased
WBC	Increased (<10,000/mm^3)	Increased (<10,000/mm^3)	Increased (>10,000/mm^3)	Increased	Increased
Cell predom	PMN[b] or lymph	PMN or lymph	PMN (lymph with Tb)	PMN (usually)	Varies
Complement					
C_3	Decreased	Decreased	Normal	Normal	Normal
C_4	Decreased	Decreased	Normal	Normal	Normal
Total	Decreased	Decreased	Normal	Normal	Normal
Immune complex					
C_1q	Often positive	Always positive	Negative	Negative	Negative
RFm[c]	Rarely positive	Usually positive	Negative	Negative	Negative
Raji	Often positive	Usually positive	Negative	Negative	Negative
Anti-DNA	Often positive	Negative	Negative	Negative	Negative
LE[d] cells	Occasionally positive	Negative	Negative	Negative	Negative

[b] PMN, polymorphonuclear.
[c] RFm, monoclonal antirheumatoid factor by radioimmunoassay [22].
[d] LE, lupus erythematosus.

caused by connective tissue disease from those resulting from other causes of pleural effusions, but they are of no value in separating SLE from rheumatoid arthritis. Immune complexes may be present in either disease with enough overlap so that it would be difficult to establish a diagnosis firmly solely by the presence of immune complexes in the pleural space regardless of the assay employed [22]. The presence of either anti-DNA antibodies or LE cells in the pleural fluid is diagnostic of SLE [22, 23]; LE cells may also be seen in the pleural fluid with drug-induced SLE [34].

Once infection and other causes of the effusions have been excluded, treatment may be directed at the lupus effusion. In the absence of systemic disease activity, treatment with nonsteroidal anti-inflammatory drugs such as indomethacin or corticosteroids may be tried. Other immunosuppressive agents such as cyclophosphamide or azathioprine are rarely indicated for SLE pleuritis alone, but may be considered for systemic involvement such as renal disease. Pleural effusions caused by SLE usually respond to therapy or resolve spontaneously. Occasionally, however, chronic pleuritis ensues and may require pleurectomy to achieve symptomatic relief [35, 36].

Parenchymal Lung Involvement

Acute Lupus Pneumonitis

Involvement of the lung parenchyma in SLE has been appreciated since the time of Osler [37]. Subsequently, a variety of reports have documented cases of pneumonitis in the absence of detectable infection in patients with SLE [38–41]. The term *acute lupus pneumonitis* has been applied to individuals with an abrupt febrile pneumonitic process in whom infection has been excluded (see Fig. la).

Matthay and co-workers [41] reported 12 such cases from a pool of 102 SLE patients over a 6-year period (11.7% incidence). The clinical presentation was suggestive of bacterial pneumonia with fever, pleuritic chest pain, cough with hemoptysis, and dyspnea as prominent features. However, cultures for pathogens were negative, and LE preparations or ANA studies were positive. Only 50% of these cases were diagnosed as having SLE before admission. Despite treatment with corticosteroids either alone or in combination with azathioprine, 50% were left with persistent infiltrates with pulmonary function studies severely restricted in one patient.

The pathologic changes in acute lupus pneumonitis are generally nonspecific, with evidence of acute alveolar wall injury, alveolar hemorrhage, alveolar edema, and hyaline membrane formation (see Fig. 1b) [38–42]. A small vessel vasculitis has been suggested to be distinctive for SLE [43]; diffuse interstitial lymphoid infiltrates suggestive of lymphocytic interstitial pneumonitis have also been described [41]; depositions within the lung of immune complexes of IgG, C3, and DNA have been reported [44, 45].

Acute lupus pneumonitis may respond to treatment with corticosteroids alone [46] or to azathioprine when corticosteroids are ineffective [47]. The addition of plasmapheresis to immunosuppressive therapy may be warranted for refractory cases of fulminant acute lupus pneumonitis [48–50]. Nonetheless, the mortality and morbidity of acute lupus pneumonitis are extremely high [41].

Donald Greenberg, M.D.)

Chronic (Fibrotic) Lupus Pneumonitis

In addition to the acute pulmonary disease associated with SLE, some patients may develop a more chronic syndrome characterized by progressive dyspnea and diffuse interstitial infiltrates (see Fig. 2) [46]. The incidence of interstitial disease in SLE varies from 0 to 9% in reported series [51, 52], indicating this to be an uncommon feature of SLE. In a series of 18 cases with diffuse interstitial lung disease and SLE reported by Eisenberg *et al.* [53], 7 (39%) initially presented with pulmonary symptoms, but other cases developed at various stages of SLE. As might be expected, pulmonary function studies showed a restrictive pattern with reduction in lung volumes and in the diffusion capacity for carbon monoxide. All patients in their series exhibited positive LE preparations, and most had ANAs as well. In addition, most suffered from other stigmata of SLE, including arthritic complaints and skin, renal, or central nervous system involvement. An association of interstitial pneumonitis in SLE with anti-Ro (SSA) antibodies has been described [54, 55]. A trend toward an increased occurrence of other autoantibodies may also be present [56].

The differential diagnosis of diffuse pulmonary infiltrates developing in patients with established SLE is limited mainly to infection (particularly when immunosuppressive therapy has been employed) and to SLE-associated fibrosis of the lungs. However, the diagnostic possibilities are more numerous in patients with interstitial infiltrates before the onset of the more classic features of SLE. When challenged with such cases physicians try to limit the diagnostic possibilities through clinical exclusion of such conditions as cardiogenic and noncardiogenic pulmonary edema (i.e., congestive heart failure and the adult respiratory distress syndrome, respectively).

To distinguish between the various causes of interstitial lung diseases, specialized procedures are required. As indicated in Figure 3, bronchoscopy with bronchoalveolar lavage to exclude infection is the diagnostic procedure of choice; lung tissue may also be obtained with transbronchial lung biopsy. Major diagnoses that may be established include (1) infection, particularly opportunistic ones; (2) cancer, particularly lymphangitic carcinomatosis or bronchioalveolar cell carcinoma; (3) sarcoidosis (defined *clinically* as the finding of characteristic noncaseating granulomas in a patient with a compatible clinical presentation in whom other causes of granulomas have been excluded); (4) interstitial fibrosis; and (5) no pathologic diagnosis [57]. When either of the latter two results from transbronchial lung biopsy are encountered, the clinician is faced with deciding whether to act on the available

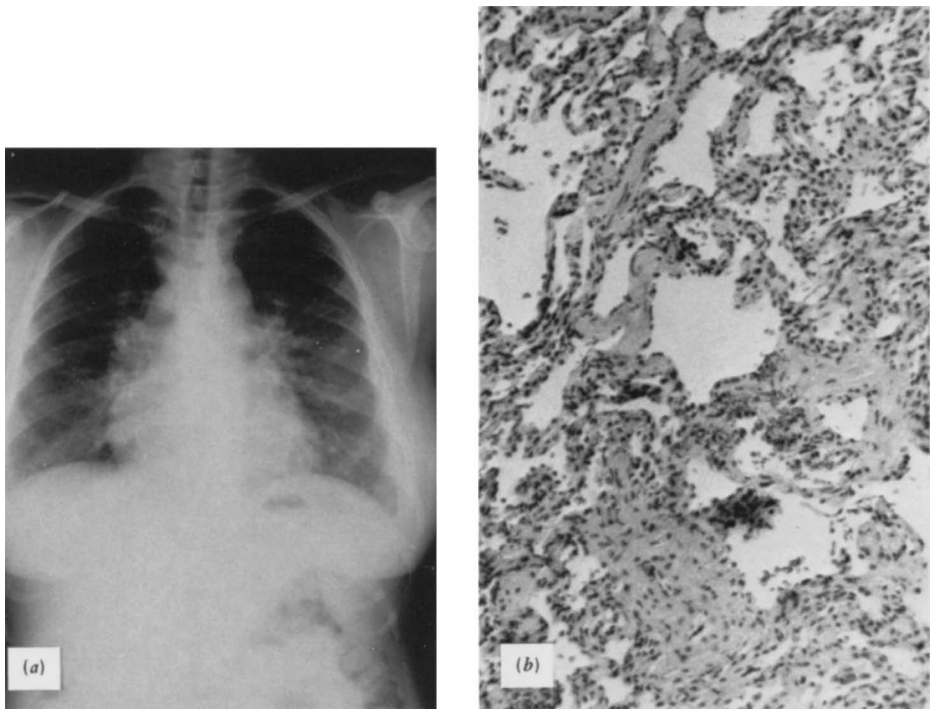

FIGURE 2 Interstitial lung disease associated with SLE. (*a*) Chest *x* ray showing diffuse interstitial infiltrates in a woman with established SLE. (*b*) Transbronchial biopsy specimen shows mild interstitial fibrosis (H&E, × 250.) (Courtesy of Carlox A. Mattioli, M.D.)

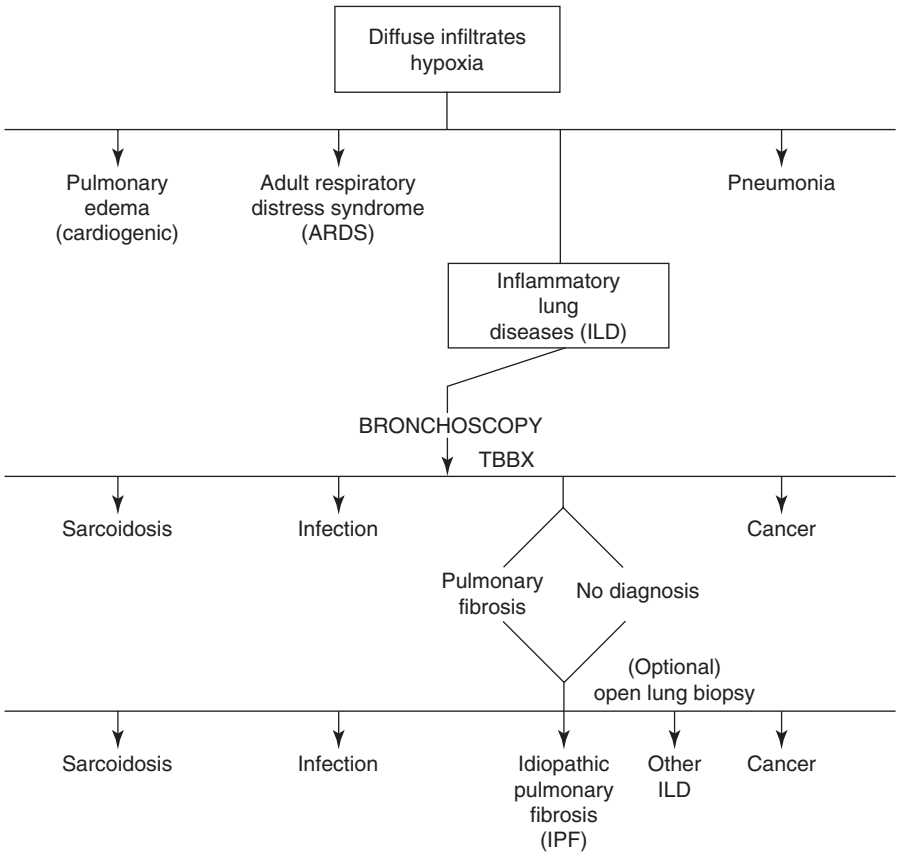

FIGURE 3 Clinical approach to the patient with pulmonary infiltrates and hypoxia. TBBX, Transbronchial lung biopsy.

information or to proceed to lung biopsy via either thoracotomy or video-assisted thoracoscopy (VAT). Some would advocate proceeding directly to thoracotomy or VAT whereas others rarely send patients to open lung biopsy, arguing that the risk relative to transbronchial lung biopsy is higher and the additional information to be gained is small. The type of patient involved should influence the approach taken. Thus, in nonimmunocompromised individuals, the additional yield from open lung biopsies compared with transbronchial biopsies may be low [58]. Others have argued for open lung biopsy in critically ill immunocompromised patients [59, 60]. Because of the many variables involved, the invasive diagnostic approach to any given patient must be carefully individualized. In SLE, the main value of either transbronchial or open lung biopsies is to exclude other diagnostic possibilities, particularly infections, since the histological features of chronic lung involvement in SLE are nonspecific (see Fig. 2b) [42].

When the more classic features of SLE precede the pulmonary involvement, differentiation from infection rather than other causes of neutrophilic alveolitis becomes the critical issue [61]. In cases in which the pulmonary involvement is the presenting feature, however, it may be difficult to implicate SLE initially. For example, the clinical, radiographic, laboratory, and immunologic features of idiopathic pulmonary fibrosis and SLE-associated chronic fibrosis are very similar [62, 63]. Indeed, idiopathic pulmonary fibrosis is usually distinguished from SLE by the absence of extrapulmonary manifestations [63]. Perhaps the most dramatic illustration of how difficult it may be to diagnose SLE when the initial abnormalities are limited to the lungs was a patient who was initially reported as having idiopathic pulmonary hemosiderosis with immune complex deposition in the lungs [64] who later exhibited more classic features of SLE [65].

The chronic interstitial lung disease of SLE, while infrequent, may have a poor prognosis [66]. The response to corticosteroids may be disappointingly poor, similar to the response of idiopathic pulmonary fibrosis [67, 68], which resembles SLE in its pulmonary manifestations. There are insufficient data with which to

access the possible usefulness of cytotoxic therapy or of plasmapheresis singly or in combination for the treatment of SLE-associated pulmonary fibrosis. One attempted heart–lung transplant in a 16-year-old male with SLE and chronic pulmonary fibrosis was unsuccessful [69]. However, the patient also suffered from multisystem disease and was moribund at the time of transplantation.

New therapeutic modalities being used for idiopathic pulmonary fibrosis could potentially be useful for SLE-associated pulmonary fibrosis. For example, α-interferon was effective in halting disease progression in a small series of European patients with idiopathic pulmonary fibrosis [70]; additional studies are underway in the United States.

Pulmonary Vascular Involvement

Diffuse Alveolar Hemorrhage

Diffuse alveolar hemorrhage may be considered as a manifestation of acute lupus pneumonitis, but because of its distinctive features is herein treated as a separate clinical entity. A report of 19 cases and review of the literature [71] demonstrated that diffuse alveolar hemorrhage affects predominantly young women (median age 27) and can be the initial manifestation of SLE in from 11 to 20% of patients. Hemoptysis eventually appeared in all 19 cases but was present on admission in only 42% of the cases vs 66% of cases previously reported. Pulmonary capillaritis was found in 8 of 10 lung tissue samples, representing a far higher percentage of capillaritis than noted in previous series. Concurrent lupus nephritis was found in the majority of cases (14/15) and associated infections were present in more than half of patients with diffuse alveolar hemorrhage. The overall mortality rate is approximately 50%, with increased mortality associated with the presence of infection, the requirement for mechanical ventilation, and usage of cyclophosphamide for acute diffuse alveolar hemorrhage episodes.

The diagnosis of diffuse alveolar hemorrhage may be suspected during bronchoscopy with bronchoalveolar lavage, as the aspirated fluids become progressively more bloody. Microscopically, bronchoalveolar lavage may demonstrate red blood cells, either free or within alveolar macrophages [72]; hemosiderin-laden macrophages indicate bleeding of 48 h or greater duration [73]. The appropriate treatment of diffuse alveolar hemorrhage is high-dose intravenous methylprednisolone in the range of 15 mg/kg daily for 3 days. Plasmapheresis appears to not improve survival whereas cyclophosphamide treatment is associated with a worsened outcome.

Pulmonary Hypertension

Severe pulmonary artery hypertension with resultant cor pulmonale may occur as an isolated disease (primary pulmonary hypertension) [74–77] or in association with the connective tissue diseases [78–84]. In the latter category, pulmonary hypertension is more commonly associated with scleroderma [78, 79] and the mixed connective diseases than with either RA [81] or SLE [82, 83]. However, several reports have documented the development of pulmonary hypertension in patients with either established or quiescent SLE [82–87]. Despite the sensation of breathlessness, patients are not profoundly hypoxemic, and the chest X ray is characteristically clear; pulmonary function studies show a restricted pattern with a reduced diffusion capacity for carbon monoxide [87]. Interestingly, Raynaud's phenomenon, which occurs in both primary pulmonary hypertension [75–77] and the pulmonary hypertension associated with scleroderma, is also common in SLE patients with pulmonary hypertension [82–85]. Thus, pulmonary vascular hyperresponsiveness with vasoconstriction, rather than vasculitis, is likely involved in the pulmonary hypertension of SLE. Indeed, vasculitis is rarely seen in lung biopsy specimens or autopsy lung tissues from SLE patients with pulmonary hypertension.

The prognosis for severe pulmonary hypertension, whether primary or associated with SLE or other forms of connective tissue disease, is poor [74–88]. Until more recently, the medical treatment for both primary pulmonary hypertension and pulmonary hypertension associated with connective tissue diseases had been unsatisfactory. However, continuous infusion epoprostenol (Prostacyclin) has been shown to prolong survival and improve performance status and hemodynamics in primary pulmonary hypertension [89] and to improve performance and hemodynamic parameters in pulmonary hypertension associated with connective tissue diseases, especially scleroderma [90] and SLE [91]. Endothelin receptor antagonists, oral agents that are effective in patients with both primary and scleroderma-associated pulmonary hypertension [92], hold promise for SLE-associated pulmonary hypertension as well.

One successful treatment for primary pulmonary hypertension, as well as pulmonary hypertension secondary to congenital heart disease (Eisenmenger's complex), has been heart–lung or lung transplantation [93, 94]. Indeed, one of two patients initially reported from Papworth Hospital at Cambridge, United Kingdom, survived heart–lung transplantation for SLE-associated pulmonary hypertension [88], but a subsequent report from this center cautioned against lung

transplantation in SLE patients, especially those with anti-cardiolipin antibodies [95]. Long-term survival has been reported following heart–lung transplantation in another SLE patient transplanted for pulmonary hypertension [96]. Thus, while systemic diseases have in general been considered contraindications for lung or heart–lung transplantation, selected patients with SLE may be considered for some form of lung transplantation on a case-by-case basis.

Thromboembolic Disease

The occurrence of anti-phospholipid antibodies in patients with SLE may predispose them to recurrent thromboses of both the arterial and venous systems, along with thrombocytopenia and increased fetal loss [97–99]. The presence of lupus anticoagulant increases the risk for deep venous thrombosis with or without pulmonary embolism by sixfold, while anti-cardiolipin antibodies increases the risk twofold [100]. The incidence of anti-phospholipid antibodies in SLE patients may be as high as 41% [101]. Deep venous thrombosis occurred in 10/24 patients (41%) and pulmonary embolism in one patient [101]. Thus, thromboembolic disease should be considered in all SLE patients with appropriate presentation, especially those with anti-phospholipid antibodies. Treatment may require anticoagulation with placement of an inferior vena cava filter because of the ongoing risk of recurrent thromboembolism. Additionally, chronic thromboembolic disease, with or without anti-phospholipid antibodies, is one cause of pulmonary hypertension in SLE [88]; therefore, all SLE patients with pulmonary hypertension should be evaluated for this possibility.

Pulmonary Disorders Associated with SLE

Infections

Infections, particularly pulmonary ones, are extremely common in immunocompromised patients [102]. Immunocompromised people are susceptible to common and uncommon bacterial organisms as well as to unusual (opportunistic) infections with fungi, viruses, and protozoa [102]. Patients with SLE are similarly at risk for a variety of infections [103, 104].

Treatment with corticosteroids and other immunosuppressive drugs is certainly implicated in many of these infectious problems, but some evidence exists for abnormalities of immune defense in SLE in the absence of immunosuppressive therapy [105–108]. For example, neutrophils are defective in both chemotaxis [105] and phagocytosis [106]. A serum inhibitor of complement-derived chemotactic factor activity may also contribute to increased susceptibility to infection in SLE [108]. Alveolar macrophage function is also impaired [109]. For all these reasons, SLE patients may be at risk of severe infections with common organisms, such as *streptococcus pneumoniae* [110].

In an effort to reduce the incidence of pneumococcal infections, investigators at the National Institutes of Health have shown that SLE patients can be successfully immunized against pneumococci, although with less of an antibody response than seem with controls [110]. SLE patients may also be safely and successfully immunized against influenza [111]. However, the efficacy of either pneumococcal or influenzal vaccines in preventing infection is unproven. For this reason, the decision of whether to immunize SLE patients with either or both vaccines must be determined on an individual basis. Certainly, annual influenzal vaccination is recommended for immunocompromised individuals unless contraindications to vaccination exist.

The presentation of pulmonary infections in SLE may be dramatic or more subtle, especially when corticosteroids mask the febrile response. Although primary (noninfectious) acute lupus pneumonitis may be indistinguishable clinically from bacterial pneumonia (i.e., fever, chest pain, hemoptysis, and pulmonary infiltrates), the presumption of infection *must* always prevail until evidence for the lack of infection has accumulated. As discussed earlier, procedures such as bronchoscopy with bronchoalveolar lavage and/or transbronchial lung biopsy or even lung biopsy via thoracotomy or video-assisted thoracoscopy may be needed to determine whether the process is infectious. The use of sheathed-brush sterile catheters [112, 113] or quantitative cultures of bronchoalveolar lavage fluids [112] may allow non-contaminated sampling of lower respiratory secretions for stains and cultures. It must be emphasized that empiric therapy with broad-spectrum antibiotics is indicated *immediately* in such cases, even if appropriate cultures cannot be obtained initially.

Other Associated Conditions

Uremic Pulmonary Edema

Systemic lupus erythematosus patients may present with clinical and radiographic signs of pulmonary edema, including bilateral pleural effusions and confluent fluffy perihilar infiltrates. This usually occurs in the setting of fluid overload and uremia from progressive renal failure [4]. The anatomic findings of pulmonary edema have also been ascribed to infection, aspiration, increased intracranial pressure, or congestive heart failure [42]. Obviously, many of these conditions may coexist in critically ill patients with SLE.

Postpartum Pneumonitis

Systemic lupus erythematosus is primarily a disease affecting young women of childbearing age. Many of these women with established SLE become pregnant and have uneventful pregnancies, while others may have exacerbations of their disease process [114]. However, as many as one-half of SLE patients suffer a major flare during the postpartum period [115]. This can occur up to 8 weeks after delivery, with worsening lupus as the most common abnormality seen [115]. Cases of acute lupus pneumonitis developing in the postpartum period have been described [115, 116]. The clinical presentation and high mortality are similar to cases unrelated to pregnancy [41]. Anti-phospholipid antibodies may be involved in some cases of postpartum pneumonitis [99].

Bronchiolitis/Bronchiolitis Obliterans with Organizing Pneumonia (BOOP)

Although a restricted pattern of pulmonary function is characteristically associated with SLE [6, 117, 118], obstruction to airflow has also been described [119] and attributed to bronchiolitis found in open lung biopsy materials. Bronchiolitis was also described in 1 of 12 of the Matthay *et al.* [41] cases and has been reported in both RA [120] and in scleroderma [121]. Clinically, patients experience cough, dyspnea, and wheezing [122]. The response to corticosteroid therapy is variable, with five of six RA patients dying [120] despite such measures. The SLE patient reported by Kinney and Angelillo [119], however, is said to have improved with corticosteroids. Bronchiolitis obliterans with organizing pneumonia (BOOP) has rarely been reported in SLE [123] and is usually responsive to corticosteroids.

Sarcoidosis

Sarcoidosis and SLE are dissimilar clinically, yet they share certain impairments of immunologic function. For example, humoral immune function is augmented in both diseases with hyperglobulinemia and circulating immune complexes, while T-cell activity is impaired [124, 125]. Several cases of the concurrence of SLE and sarcoidosis have been reported [125–130]. It is unclear whether these two disease processes occur in the same individual by coincidence or through some common mechanisms related to immune complex deposition or defective T-cell function [127].

Lymphocytic Interstitial Pneumonia

The usual form of interstitial lung disease in SLE is nonspecific [42] and is similar to Liebow's usual interstitial pneumonia [131]. However, cases have been reported in which the histological appearance has been consistent with lymphocytic interstitial pneumonia [132, 133], which represents another subset of the interstitial pneumonias as classified by Liebow [131]. The lung's interstitium in lymphocytic interstitial pneumonia is diffusely infiltrated by mature lymphocytes and plasma cells. Patients with lymphocytic interstitial pneumonia are characteristically ill with fever, cough, and dyspnea.

Lymphoma and Pseudolymphoma

Patients with SLE have an increased incidence of lymphomas [134–137] and Kaposi's sarcoma has been reported [138]. Additionally, focal masslike accumulations of lymphocytes and plasma cells in the lungs are termed *pseudolymphomas* when the process is localized to the lungs [139, 140]. A case of pseudolymphoma occurring in SLE has been reported [141]. Thus lymphocytic interstitial pneumonia and pseudolymphoma may represent variations in the spectrum of a premalignant but benign process.

Management

The overall approach to the various pulmonary aspects of SLE has been discussed in the preceding sections. To reiterate, the basic tenets of the management of SLE-related pulmonary problems are as follows:

1. Assume infection to be present until proven otherwise.
2. Establish a definitive diagnosis whenever possible.
3. Treat with broad-spectrum antibodies until infection is excluded.
4. Move quickly to immunosuppressive therapy when infection is excluded or in patients not responding to antimicrobial therapy.
5. Consider the anti-phospholipid syndrome in patients with thromboembolic disease.
6. Consider vasodilator therapies including prostacyclins and endothelin receptor antagonists for the treatment of pulmonary hypertension.

Although immunosuppressive therapy or plasmapheresis [142, 143] alone may improve many of the manifestations of SLE, even more impressive results are obtained when immunosuppressive therapy is coupled with plasmapheresis [144]. There are little published data on the efficacy of such combined therapy on the pulmonary complications of SLE, except for reports of dramatic improvement in patients with fulminant acute lupus pneumonitis [48–50]. Because this pulmonary complication has an inordinately high mortality rate [41] further consideration of cytotoxic therapy com-

bined with plasmapheresis in acute lupus pneumonitis seems warranted. Lung transplantation may be a therapeutic option for highly selected SLE patients with pulmonary fibrosis or pulmonary hypertension.

NONHEPATIC GASTROINTESTINAL MANIFESTATIONS OF SYSTEMIC LUPUS ERYTHEMATOSUS

Iris Dotan
Lloyd Mayer

When considering the "systemic" nature of lupus erythematosus, the gastrointestinal (GI) tract tends to be overlooked, not by the disease itself but by the primary physician. William Osler's description [1] in 1895 of significant gastrointestinal crises in "erythema exudativum multiforme" illustrates that the GI tract can overshadow many of the other aspects of systemic lupus erythematosus (SLE). In general, the major GI complications of SLE are less frequently seen than the skin rash, arthritis, and nephritis that commonly bring patients to clinical attention. However, if we look at various series of patients with SLE [2–15], we find that there are quite a number of listed signs and symptoms related to the GI tract (Table 1). For example, in the largest such series, by Dubois and Tuffanelli [5], of 520 patients studied, 53% had nausea or vomiting, 49% complained of anorexia, and 19% had abdominal pain. Although many of these symptoms are nonspecific and may relate to other systemic manifestations of SLE (e.g., nausea and vomiting secondary to uremia) or may be side effects of drug therapy, some may represent inapparent GI tract disease.

As just suggested, a major problem in recognizing GI tract disease as a complication of SLE is that much of the same GI pathology can be induced by the various medications used in SLE treatment. For example, there are controversies about lupus pancreatitis and about liver disease caused directly by SLE vs aspirin-induced focal necrosis or steroid-induced fatty liver or pancreatitis. Another problem is that many of the symptoms related to the GI tract are not as severe as the more pressing arthritis or nephritis and thus tend to be glossed over. In this chapter, a review of the diverse GI disorders seen as sequelae of SLE is presented, beginning at the beginning: the oral cavity. GI ailments related to therapy for SLE and SLE induced by drugs prescribed for GI disorders are considered in a separate section.

ORAL CAVITY

Clinical Features

The GI tract extends from the mouth to the anus, so involvement of the oral cavity in SLE should be considered a GI manifestation. Oral lesions are so central and common a sign in SLE that presence of oral ulceration is one of the criteria in the diagnosis of SLE [16]. They tend to precede severe systemic disease flares [17]. Involvement of the oral cavity is reported to occur in 7–57% of SLE patients [2, 6, 8–12, 14, 18]. Oral lesions are in general of three types: erythematous, discoid, and ulcerative. According to one study [12] erythematous

lesions occur most often (35%), followed by discoid (16%) and ulcerative (6%) lesions. Another study [9] found 9% of patients to have more than one lesion at a time. The lesions may merge into one another and may be associated with edema and petechiae [11].

Discoid Lesions

Discoid lesions may be painful. They are characterized by a central area of erythema with white dots surrounded by rays of white striae and telangiectasia, are firm on palpation, and have a well-defined elevated border [11–19]. They are found in decreasing frequency in the buccal mucosa, gingiva, labial mucosa, and vermilion border [9, 11, 19] and are generally seen in patients with active disease [11]. They may be ulcerated and are infected by yeast in about 50% of cases [19].

Ulcers

Ulcers are usually shallow, 1–2 cm in diameter, tend to occur in crops, and are most commonly found on the hard palate (89% of cases) [9]. They may also be found on the buccal mucosa and extend into the pharynx in about one-third of patients [9]. Involvement of the nasal and laryngeal mucosa has also been described [20–22]. Oral ulcers often present with pain, a burning sensation, soreness, dry mouth, and when extending into the pharynx, with odynophagia and even dysphagia [7]. These lesions may persist for years [11, 23, 24] or may be intermittent, displaying cyclical remissions and exacerbations [7]. As with discoid lesions, oral ulcers tend to occur with disease flares [11, 17, 24]. The presence of oral ulcers has been considered by some to be a poor prognostic sign. One study [7] reported patients with oral ulcers to have a higher mortality than patients without oral ulcers. This has not been corroborated by a second study [9].

Erythematous Lesions

Erythematous lesions are typically painless, flat, red lesions with poorly defined borders. They are occasionally accompanied by edema and petechiae. They most commonly occur on the hard palate [11].

Pathology–Pathophysiology

The histopathology and immunopathology of the discoid lesions in SLE are similar to those of discoid lupus erythematosus (DLE) except that the inflammatory infiltrate found deep in the connective tissue is more diffuse and less intense in SLE [11, 19, 24, 25]. Keratotic plugging, pseudoepitheliomatous hyperplasia, and epithelial cell islands within the connective tissue are also found. The inflammatory infiltrate found in the connective tissue is typically lymphohistiocytic with an occasional plasma cell, and the inflammatory infiltrate is typically separated from the epithelium by an eosinophilic free zone. The infiltrating cells are predominantly $CD4^+$ and $CD8^+$ T cells distributed in the lamina propria, submucosa, and occasionally in the epithelium. Less than 5% of the infiltrating inflammatory cells express interleukin-2 receptors or transferrin receptors [26]. Epithelial cell changes are seen and include the presence of colloid bodies, multinucleated cells, occasional nuclear hyperchromatism, and rarely dysplasia. Some epithelial cells express major histocompatibility class II antigens with HLA-DR being more commonly present than HLA-DP. No HLA-DQ is seen. Liquefaction degeneration of the basal epithelial cell layers is also noted [26]. Hyalinization of the subepithelial connective tissue may occur, as can edema of the lamina propria [11, 19, 24, 25]. Immunoglobulin and complement as well as fibrinogen is deposited in the basement membrane zone and is found in both discoid lesions and in clinically normal mucosa of SLE patients [11, 19, 27–32].

Ultrastructurally, the lesions show cytomorphologic features peculiar to keratinizing epithelium. Dyskeratotic cells and filamentous bodies, which probably correspond to the colloid bodies seen on light microscopy, are present [19, 33–37].

As is suggested by the occasional presence of dysplastic epithelial cells in discoid lesions (see earlier), it is important to be aware that cancer can develop in long-standing discoid lesions of the lip at the vermilion border [11].

Erythematous and ulcerative lesions show nonspecific changes, including liquefaction degeneration of the basal layer and a diffuse subepithelial inflammatory infiltrate [11, 19, 24]. Erythematous lesions also show subepithelial and epithelial inflammation, disturbed epithelial maturation, and acanthosis [11]. On immunopathology, IgM deposits are noted in the basement membrane [11].

Diagnosis

As a significant proportion of oral lesions may be asymptomatic, careful examination of the oral cavity is mandatory in all lupus patients. Besides the difficulty in distinguishing discoid lesions from lichen planus and leukoplakia, there may be difficulty in distinguishing SLE oral lesions from monilia, erythema multiforme, pemphigus, and herpetic lesions [38–40]. Bacterial, fungal, and viral cultures, as well as detailed drug

history, can help in these cases. In addition, the finding of immunoglobulin and complement deposition in the basement membrane in discoid lesions (see earlier) may be useful as a distinguishing feature, as immunoglobulin deposition is rare in lichen planus and leukoplakia [19]. Schiodt [25] described five features that may distinguish discoid lesions from the similar appearing lesions of lichen planus and leukoplakia: (1) hyperkeratosis with keratotic plugs; (2) atrophy of the rete processes; (3) edema of the lamina propria; (4) deep inflammatory infiltrate; and (5) thick, patchy, or continuous periodic acid Schiff positive deposits in the basement membrane zone. Presence of two or more of these criteria was specific and sensitive for the diagnosis of SLE discoid lesions.

Therapy

There are no well-controlled trials demonstrating efficacy of therapy of any of these lesions [19]. Treatments that have been recommended for oral ulcerations include oral and topical steroids [19]. For discoid lesions, antimalarials [9, 21, 39, 41] have been tried, as have oral and topical steroids [41, 42] and dapsone [43, 44]. Treatment directed at controlling the SLE flare itself may often prove helpful in ameliorating the oral lesions. Antimicrobial, antiviral, or antifungal therapy should be used where infection is suspected or proven. Drug withdrawal, such as the withdrawal of hydralazine (shown to resolve oral ulcerations in at least one patient with SLE) [45], may, on occasion, prove useful.

SLE and Sjögren's Syndrome

Sjögren's syndrome has been associated with SLE in 13–20% of patients [46–48]. A higher percentage of sicca symptoms associated with SLE has been reported, but as the criteria for Sjögren's syndrome classification ***were not met*** this probably is an overestimation [49, 50]. Though Sjögren's syndrome usually appears in later stages of the disease, it may precede the diagnosis of SLE [51]. Compared to patients with SLE alone, those with secondary Sjögren's syndrome tend to exhibit fewer systemic manifestations, especially renal involvement [52].

Other Oral Lesions

Other oral lesions have been seen in lupus patients. Acute necrotizing ulcerative gingivitis has been associated with SLE [24, 53]. It is manifested by ulceration, bleeding, facial swelling, dysphagia, halitosis, and even sloughing of the gingival tissue with loss of teeth. Steroids may contribute to the severity of the disease. Treatment includes (1) reduction in steroid dose; (2) oral, topical, and if severe, intravenous antibiotics against usual mouth flora or against a specific organism if one is identified; and (3) topical gentian violet. Jaworski *et al*. [53] suggested that altered host immune mechanisms, such as decreased chemotaxis of polymorphonuclear cells, in addition to further suppression of the immune system by immunosuppressive agents used in the treatment of SLE, probably contribute to tip the host–organism balance in favor of the symbiotic organism. All SLE patients especially those taking steroids or other immunosuppressive drugs, should be instructed to maintain excellent oral hygiene, and dentists should be alerted to the greater risks of postoperative bleeding and infection in this group [54].

Other rare lesions include Raynaud's phenomenon of the tip of the tongue [55] and tense bullae of the oral cavity [56]. The bullae resolve with steroid therapy. A case of oral hairy leukoplakia has also been documented [57]. SLE patients may also get yeast infections or oral herpes simplex virus, especially during exacerbations or steroid therapy [7, 11, 21]. In addition, drugs used in the treatment of SLE may cause oral lesions. For example, antimalarials have been reported to produce brown or blue–gray pigmentation of the oral mucosa [58].

ESOPHAGUS

The incidence of esophageal disease is difficult to ascertain. The reports on the incidence of symptomatic esophageal disease vary widely (1.5–22%) [3, 5, 7, 8, 13]. One problem is the fact that no correlation between symptomatology and pathology exists [15]. Compounding this problem is the possibility that some patients with mixed connective tissue disease, with known esophageal pathology, may have been misclassified as SLE in the earlier literature.

Clinical Features

Patients with SLE may present with dysphagia, heartburn typical of acid reflux, as well as atypical chest pain. Esophagitis with ulcerations may be seen in about 3.5% of patients [3, 8], rarely with perforation [13]. Mucosal bridging, a finding occasionally seen in patients with a history of peptic esophagitis, has also been reported [59]. In addition, corticosteroids or immunosuppressive therapy can predispose patients to *Candida* esophagitis, and patients may present with oral candidiasis and odynophagia.

Pathology–Pathophysiology

Controversy exists as to the etiology of the esophagitis and chest pain seen in lupus patients. Some consider these findings to be peptic in origin. Evidence for this comes from the findings of abnormal esophageal motility, specifically hypoperistalsis and aperistalsis in as many as 72% of lupus patients [15, 60–65], that might result in decreased clearance of refluxed acid. Others have found a high incidence of gastroesophageal reflux [15]. The type of dysmotility seen varies. In one study of unselected SLE patients studied by manometry, X-ray, and history, 14% had aperistalsis in the lower two-thirds of the esophagus, lower esophageal sphincter, or both (i.e., the smooth muscle portion of the esophagus) consistent with a progressive systemic sclerosis picture; 14% had a motility disorder of the upper one-third of the esophagus (i.e., the skeletal muscle portion of the esophagus) consistent with a dermatomyositis picture; and two had involvement of the entire esophagus [61].

This has led other authors to suggest that the pathologic findings in the lupus esophagus are vasculitic rather than peptic in origin. Castrucci *et al*. [15] hypothesized that the hypoperistalsis or aperistalsis found in the esophagus of SLE patients may be due to an inflammatory reaction in the esophageal muscle or to ischemic vasculitic damage of the Auerbach plexus. Harvey *et al*. [3] noted arteritis in the esophagus of four SLE patients in association with esophageal ulcers. A large proportion of patients with esophageal ulcers in these studies had been taking steroids, which suggests that these may have been stress ulcers.

More recently, a lesser incidence of involvement of the lower esophageal sphincter (LES) in SLE has been reported [66]. In contrast to systemic sclerosis patients, 81.8% of whom had LES abnormalities, 30% classified as severe, none of the SLE patients evaluated had severe involvement of the LES. This may explain the interesting observation that the complications of acid reflux so pronounced in other collagen vascular diseases such as progressive systemic sclerosis are not noted in SLE.

Despite manometric and histologic evidence of esophageal disease, the lack of correlation of abnormalities to symptoms makes one wonder about the significance of these findings. With the exception of the occasional esophageal ulcer [5, 6, 8, 13], which only rarely has been reported to perforate, esophageal symptoms are generally not severe.

Diagnosis

Esophagitis and esophageal ulcer may be diagnosed by esophagogastroduodenoscopy or by barium esophagram. Esophageal dysmotility may be detected by manometric studies or occasionally on barium esophagogram.

Therapy

As it is not clear whether the esophagitis and ulcerations found are vasculitic in origin, peptic in origin, or a complication of steroid therapy, it is difficult to determine the appropriate mode of therapy. Empiric proton-pump inhibitors, H_2 blockers, or other antacid therapy in patients taking steroids is controversial. A controlled trial of antireflux therapy in patients with SLE would greatly help determine whether such esophageal lesions truly are peptic in nature and help to decide whether antiacid and antireflux therapy should be routinely recommended to SLE patients. Treatment of the lupus itself may help if in fact the esophageal lesions are vasculitic in origin. A trial of calcium channel blockers for esophageal dysmotility may be of benefit. Patients with *Candida* esophagitis will require appropriate antifungal therapy, including nystatin or clotrimazole troches for mild infections and fluconazole for more severe cases.

STOMACH AND DUODENUM

Clinical Features

Lupus patients with intestinal complications referable to the stomach or duodenum may have gastric or duodenal ulcer disease. Abdominal pain is the most common symptom, often described as burning, boring, or nagging. Pain is usually epigastric and relieved by food or antacids. Nausea and vomiting may occur with gastric ulcer or duodenal ulcer complicated by gastric outlet obstruction. A small proportion of patients may present with bleeding or perforation. On physical examination, abdominal tenderness or fecal occult blood may be found, but the exam is often nonspecific. Corticosteroid use may mask the signs and symptoms of disease.

Pathology–Pathophysiology

The actual incidence of ulcer disease in SLE has never been directly addressed. In Brown *et al*.'s review [4], it is mentioned that 5% (4 of 85) of patients had ulcer disease unrelated to therapy, while Ropes [8] quotes a figure of 20% (7 of 35). Dubois and Tuffanelli [5] cite a 1.5% incidence of ulcer perforation, which resulted in death in one patient taking steroids. While the role of *Helicobacter pylori* and nonsteroidal anti-inflammatory agents in the etiology of gastroduodenal ulcers is now well established [67, 68], in SLE patients

the possibility still exists that such ulcers are a direct consequence of lupus. One group reported a case of giant gastric ulceration associated with the anti-phospholipid antibody syndrome, which resolved on treatment with anticoagulants and corticosteroids [69]. In a review of the digestive tract findings in connective tissue disorders, Siurala *et al*. [70] performed gastric biopsies on 17 patients with SLE. Four showed superficial gastritis, and an additional 8 showed varying degrees of atrophic gastritis. There appeared to be no correlation to therapy, and of note was the presence of similar histologic findings in 8 of 20 control patients with celiac disease. No data were available as to the presence of anti-parietal cell antibodies, which have been seen in these patients [71] and may relate to the atrophic gastritis. Nadorra *et al*. [13] found heterotopic calcification of the superficial gastric mucosa in 3 of 36 autopsies of patients with childhood-onset SLE, albeit 2 of the 3 had been on hemodialysis. Thus there does not appear to be sufficient data to determine whether SLE is causative in the development of peptic ulcer disease.

Okayasu *et al*. [72] performed an autopsy study in Japan examining the risk of cancer in patients with connective tissue disorders. Although it was found that dermatomyositis was strongly associated with the development of gastric carcinoma, no such association was found for SLE either in the stomach or elsewhere. Thus there appears to be no link between SLE and the development of gastric malignancy.

Diagnosis

The diagnosis of gastric or duodenal ulcer may be made on clinical grounds or by esophagogastroduodenoscopy or upper GI series. *Helicobacter pylori* infection may be detected through serology for IgG and IgA anti-*Helicobacter* antibodies, by [^{13}C] or [^{14}C]-urea breath test following an oral urea load, or with endoscopic biopsy using urease or histologic examination.

Therapy

It is reasonable to treat all documented benign gastric and duodenal ulcers with proton-pump inhibitors, H_2 blockers, or other antiacid therapy, and it has been argued that it is reasonable to give prophylactic therapy to those patients taking steroids, aspirin, or nonsteroidal anti-inflammatory drugs. Misoprostol may also be considered for prophylaxis, although the complication of misoprostol-induced diarrhea (up to 40% of patients) may be worse than the symptoms of peptic ulcer disease. Special consideration should be given to bleeding peptic ulcers in SLE patients. Hiraishi *et al*. [73] reported a patient with SLE who presented with severe upper gastrointestinal bleeding as a result of gastric ulcer. The bleeding did not stop with conventional antiulcer therapy or by surgery in which an antral ulcer penetrating into the ileum with histologic stigmata of vasculitis was found. The bleeding was controlled only after pulse methylprednisolone therapy was initiated, stressing the issue of etiology-oriented therapy.

Other Gastric Manifestations

Watermelon Stomach

A case of iron deficiency anemia due to chronic blood loss attributed to watermelon-stomach in an SLE patient with anti-cardiolipin antibodies was reported by Archimandritids *et al*. [74]. This rare condition of gastric antral vascular ectasia is associated with connective tissue disorders in 62% of cases. Treatment with methylprednisolone and subsequently hydroxychloroquine in addition to iron supplements was effective in controlling the anemia.

SMALL AND LARGE INTESTINE

Some of the more relevant and potentially dangerous GI complications of SLE occur in the small and large intestines. Although some complications described earlier (such as aspirin-induced gastritis or ulcer) may be related to therapy, complications seen in the small and large intestines (such as vasculitis of the bowel with concomitant bleeding perforation) are clearly lupus related.

Vasculitis

Clinical Features

Patients with vasculitis may present with any of a variety of abdominal pain syndromes. They may present with nondescript bloating, nausea, and diarrhea or may have abrupt and massive GI hemorrhage or acute abdominal pain. Lupus-related symptoms referable to the intestine may be insidious or acute, localized or diffuse, benign or catastrophic. Steroid use may cloak symptoms. One must maintain a high index of suspicion when the lupus patient reports abdominal complaints in order to avert disaster.

Vasculitis of the small or large intestine is the most serious GI complication of SLE [21]. It may present as GI hemorrhage, occurring in 46% of cases in the Nadorra *et al*. [13] study and resulting in death in one-half of these cases, therefore accounting for about 25% of the deaths in their series. It may also present as an acute abdomen secondary to intestinal ischemia or infarction with perforation [75–80]. In the Zizic *et al*. study [77], for example, 5 of 107 SLE patients seen in

their clinic died from intestinal perforation, making it the major cause of death in their series. In general, the outcome with perforation is dismal, resulting in death in more than two-thirds of cases [81] when the outcome was known.

Patients with intestinal vasculitis may present with less severe symptoms such as nausea, vomiting, bloating, diarrhea, and fever on the basis of intestinal ischemia with or without ileus, infection, obstruction, or malabsorption [75, 79, 82, 83]. These symptoms are often insidious, may be masked by corticosteroids, often precede the more serious complications of perforation and hemorrhage, and should alert the clinician to the possibility of an approaching disaster. Unexplained acidosis, hypotension, abdominal distention, or bowel dilation on X-ray should alert the clinician to the possibility of a perforated viscus. Absence of bowel sounds and presence of guarding are not reliably found [84].

Additionally, those SLE patients with peripheral vasculitis, circulating rheumatoid factor, central nervous system involvement, and thrombocytopenia appear to be more at risk for developing an acute abdominal event according to one study [77], although others dispute this [84].

Pathology–Pathophysiology

Grossly, the appearance of the bowel ranges from segmental edema [4, 21, 82, 85] to discrete ulceration [86–88] to gangrene [88] and perforation [75–80]. Histologically both small vessel arteritis [13, 76, 79, 80, 89] and venulitis [79, 88, 90] have been seen, although larger vessels may be involved as in polyarteritis nodosa [21] (Fig. 1). Lesions of the larger vessels tend to produce more necrosis and gangrene. Associated histologic findings include atrophy and degeneration of the media of small arteries, fibrinoid necrosis of vessel walls, old thrombosis, phlebitis, and monocyte infiltrate in the lamina propria. Acute and chronic inflammatory infiltrate is seen, often confined to the mucosa but occasionally transmural [13].

Pneumatosis cystoides intestinalis, a usually benign entity that consists of intramural air in the intestine, has multiple etiologies and may be seen in SLE [91] as a possible result of vasculitis. In one case this finding was associated with a cecal perforation [78] whereas it was benign in others [91, 92].

Diagnosis

In those patients with the more insidious onset of symptoms, appropriate studies can be obtained, such as barium studies (or gastrografin when perforation is suspected) or endoscopy looking for signs of ischemia secondary to vasculitis (such as thumbprinting, ulcerations, and pallor) (Fig. 2). Computed tomography (CT) may reveal nonspecific findings such as bowel wall thickening and ascites [93, 94]. Arteriography may play a role in the diagnosis of ischemia secondary to vasculitis as reported in one case [89], whereas a second report [95] describes the use of an [111] indium granulocyte scan to identify 4 of 5 lupus patients with gastrointestinal symp-

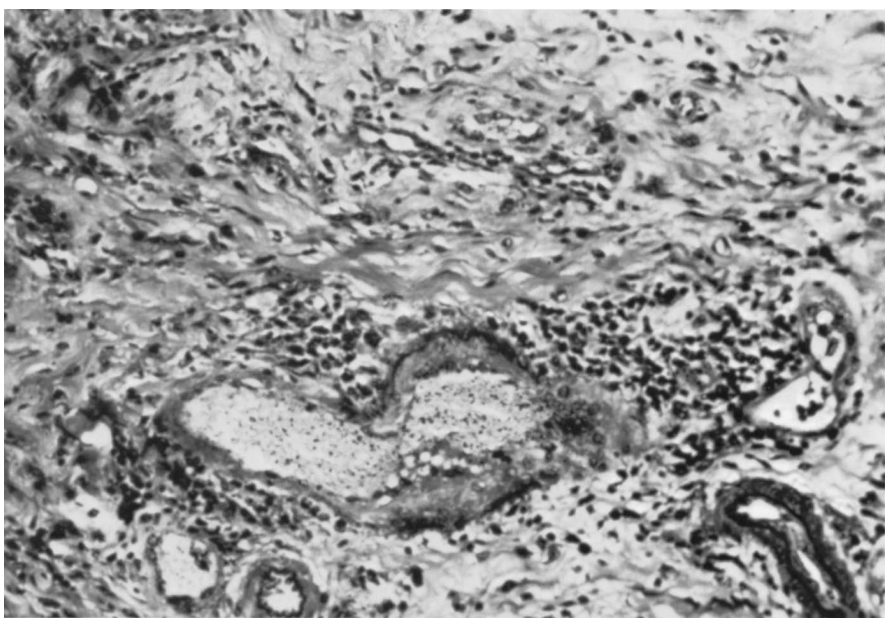

FIGURE 1 A cut section of a sigmoid biopsy from the patient whose X ray is depicted in Fig. 2. Note the perivascular lymphocytic infiltrate and destruction of a large artery wall. (Courtesy of Dr. David Sachar.)

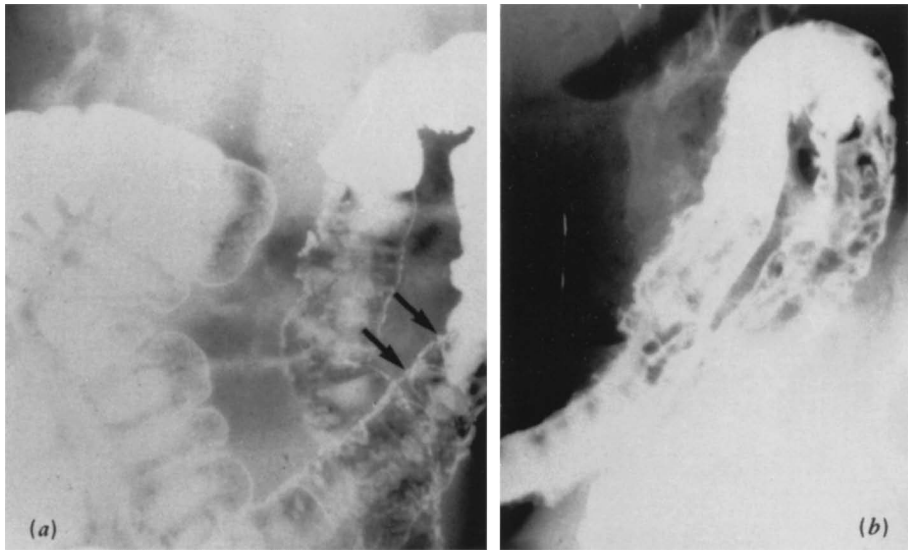

FIGURE 2 Barium enema X ray presentation of a patient with acute lupus vasculitis of the bowel. There are discrete ulcers (collar button ulcers—arrows (*a*)) seen as well as increased secretions ("graying" of the barium (*b*)). (Courtesy of Dr. David Sachar.)

toms who were then determined to have vasculitis. These latter tests have not been generally used. In those patients presenting with acute abdominal pain, CT findings may assist in the diagnosis of mesenteric ischemia. Byun *et al*. [96] retrospectively examined 39 CT examinations performed on 33 patients with acute abdominal pain and report that 31 (79%) had signs of ischemic bowel disease, defined by at least three of the following: bowel wall thickening, target sign (thickened bowel wall with peripheral rim enhancement or an enhancing inner and outer rim with hypoattenuation in the center), dilatation of intestinal segments, engorgement of mesenteric vessels, and increased attenuation of mesenteric fat. This suggests that CT may be useful for detecting the primary cause of gastrointestinal symptoms, particularly in the patient presenting with acute abdominal pain. In those patients presenting with an acute abdomen, emergency exploratory laparotomy is in order.

Therapy

Intestinal perforation or infarction as well as small bowel ischemia requires emergency surgery for resection of the involved area, as mortality is high in untreated cases. Early laparotomy has been shown to improve survival [97]. High-dose intravenous steroids are commonly used, and in patients who do not rapidly improve, cyclophosphamide can be added [98]. Large bowel ischemia may be treated expectantly with blood products, fluids, and antibiotics when appropriate. As with small bowel ischemia, high-dose prednisone is the most common and recommended treatment and was reported to resolve one case of pneumatosis cystoides intestinalis in a lupus patient with vasculitis [88]. In case this fails, high-dose cyclophosphamide was successful in the treatment of one patient with peritonitis and colitis due to intestinal vasculitis [100].

Other SLE-Related Intestinal Diseases

Intestinal Thrombosis

In addition to vasculitis-associated intestinal ischemia and infarction, infarction and ischemia have also been seen in the lupus intestine in association with thrombosis. Lupus patients with the anti-phospholipid antibody syndrome seem to be especially at risk. Asherson *et al*. [101] describe a case of bowel infarction necessitating colectomy. Histologic examination of the specimen revealed the presence of thrombus in branches of the inferior mesenteric artery with the total absence of any vasculitis. The patient's serum demonstrated antibodies to phospholipid (the lupus anticoagulant) and to cardiolipin, leading the authors to theorize that a thrombotic diathesis, on the basis of the presence of these antibodies, precipitated the bowel infarction. Another group has reported a case of repeated intestinal ulcerations secondary to thrombosis in a patient with lupus and high serum anti-phospholipid antibody levels [102]. Diagnosis and therapy are similar to those for intestinal vasculitis, and include appropriate

anticoagulation or antithrombotic medication. Plasmapheresis for patients with anti-phospholipid antibody syndrome may be of some benefit [98].

Inflammatory Bowel Disease

An association between SLE and both ulcerative colitis [86, 103, 104] and Crohn's disease [105, 106] has been suggested. Although this may imply that some lupus patients may have intestinal findings secondary to inflammatory bowel disease rather than vasculitis, there is no convincing proof. In most disputed cases, the pathology seemed most likely to be vasculitic and the association with inflammatory bowel disease, when seen, to be coincidental [104]. Diagnosis is made by clinical history in addition to typical barium X-ray findings or colonoscopic or histologic appearance, or both. Treatment includes sulfasalazine, 5-aminosalicylate derivatives, steroids, and azathioprine/6-mercaptopurine.

Drug-Related Disease

As with the other parts of the GI tract, drug therapy may contribute to intestinal disease in SLE. For example, Khoury [108] describes a case of an SLE patient who developed ulcerative proctitis twice, each time after starting ibuprofen, which remitted when the ibuprofen was stopped. NSAIDs have been shown to trigger the onset of UC in predisposed patients so this may be the unmasking of an underlying disease. One must always be aware that patients with inflammatory bowel disease may develop drug-induced SLE from drug therapy such as rafliximab (anti-TNF) and sulfasalazine [109]. Diagnosis may be suggested by history. Treatment includes withdrawal of the offending drug.

Protein-Losing Enteropathy

There are 24 reported cases of protein-losing enteropathy in association with SLE [110–116]. It is defined as excessive transintestinal mucosal loss of plasma proteins. It typically occurs in young women. Clinically, one may see diarrhea and typical manifestations of hypoproteinemia such as peripheral edema. It is characterized by coarse, thickened folds in the stomach and small bowel with or without ulcerations. The diagnosis is suspected in patients with hypoproteinemia and no other obvious source of protein loss and may be confirmed by radioisotopic studies or 24-h stool α_1-anti-trypsin clearance [115]. In some cases [110, 116–119] the enteropathy preceded the diagnosis of SLE. The reported cases responded to low-dose steroid therapy, and it was postulated that immune complex deposition led to increased permeability of intestinal capillaries and subsequently of the epithelial lining cells [111], analogous to glomerular basement membrane deposition in lupus nephritis.

Fat Malabsorption

Malabsorption of fat, with or without carbohydrate malabsorption, has also been described [69, 83, 120–124]. Clinically it is manifest by the presence of voluminous oily, foul smelling stools and weight loss in a patient with adequate oral intake. Diagnosis is suggested by a positive staining of stool sample with Sudan black and may be confirmed by elevated levels of fat in a 72-h stool collection or by ^{14}C-Triolein breath test. Pathologically, Weisman *et al*. [121] reported widening and blunting of the villi and immune complex deposition in their case of fat malabsorption. This lesion responded dramatically to steroids with reversal of the histologic picture.

In another report [124] two cases of fat malabsorption in SLE patients are described that are attributed to lupus-induced gut hypomotility with subsequent bacterial overgrowth. One would expect antibiotics to improve fat malabsorption in this case.

It is also theoretically possible, though unproven, that serositis leading to adhesions and partial bowel obstruction as described by Miller *et al*. [125] might lead to stasis and bacterial overgrowth with subsequent fat malabsorption and that lupus- or drug-induced pancreatitis [21, 83, 126–131] might lead to pancreatic insufficiency with concomitant fat malabsorption. Treatment of antibiotic- and steroid-unresponsive cases would include low-fat diet, lipid-soluble vitamin (A, E, D, K) supplements, cholestyramine, and judicious use of antidiarrheal agents.

Gluten-Sensitive Enteropathy (Celiac Sprue)

The coexistence of lupus and celiac sprue has been rarely reported [132]. Siurula *et al*. [70] noted nonspecific inflammatory changes in villus blunting on random small bowel biopsy specimens and likened these to celiac sprue. Davies and Marks [133] reported the case of a patient with SLE who developed dermatitis herpetiformis, a dermatologic disease with a known association to celiac sprue. This suggests the possibility of an association between SLE and celiac disease in these patients. In fact, several patients with collagen vascular disease and protein malabsorption with diarrhea, including one patient with SLE, have reportedly responded to a gluten-free diet [69, 122]. Classically, the diagnosis of celiac sprue is made by the presence of flattened small intestinal villi on biopsy that normalize on gluten-free diet and recur with reintroduction of

gluten into the diet. However, many lupus patients with celiac-like changes on intestinal biopsy do not respond to a gluten-free diet. Immunohistologic studies reveal deposition of C3 in the capillary walls of the small intestine [134]. Steroids may prove effective in resistant cases.

Chronic Intestinal Pseudo-Obstruction

Several small case-series reported the association of chronic intestinal pseudo-obstruction (CIPO) with lupus [135–138]. This complication, characterized by ineffective intestinal propulsion and manifested by abdominal pain and distention, bloating, vomiting, and constipation reflects a dysfunction of the visceral smooth muscle or the enteric nervous system. Out of 19 cases reported, 9 had CIPO as the initial presentation of SLE. Interestingly, in 12/19 there was bilateral ureterohydronephrosis [138], suggesting a central smooth muscle motility problem of neuropathic or myogenic origin. The diagnosis is made by radiographic studies showing fluid levels and dilated bowel, without an organic cause for obstruction, and by manometric studies. Treatment is with high-dose steroids, parenteral nutrition, promotility agents, and maintenance immunosuppression. Perlemuter *et al*. [139] used octreotide, 50 μg twice daily, when the previous measures failed, with no recurrence of CIPO. Even with aggressive therapy, CIPO remains a serious complication of SLE associated with a mortality of 26% (5/19 patients).

Amyloidosis

Amyloidosis in association with lupus has very rarely been reported [140, 141]. Patients may present with recurrent diarrhea and GI bleeding.

PERITONEAL CAVITY

Clinical Features

The presence of peritoneal inflammation has been well documented in autopsy and surgical studies as well as in several case reports [7, 8, 83, 125, 131, 142–147] in as many as 63% of patients [7]. Peritoneal inflammation may present in a number of ways, ranging from an acute abdomen to painless ascites. Overt signs may not be present due to the masking effect of steroids.

Pathology–Pathophysiology

The inflammatory change in the peritoneum is presumably due to deposition of immune complexes in mesenteric vessels [148–150] and can result in abdominal pain compatible with an acute abdomen [83, 151] or can be painless [129, 142, 143]. Patchy serosal and peritoneal plaques have been observed [144]. Peritoneal inflammation can also result in ascites, which in various series is present in 8–88% of cases [5, 8, 13]. Paracentesis usually reveals an exudative effusion with white blood cells [152] that is sterile when cultured. Lupus erythematosus (LE) cells were found in about one-third of the patients in one study [153]. Interestingly, the ascitic fluid has been shown to have high DNA-binding activity and low total complement, supporting a role for immune complexes in the development of ascites. Ascites can also be due to the nephrotic syndrome or constrictive pericarditis, both of which should be considered first before ascribing the ascites to peritoneal inflammation. Lastly, Budd-Chiari syndrome (thrombosis of the portal vein and potentially the inferior vena cava) as a consequence of clotting diathesis in SLE patients with lupus anticoagulant has also been reported to produce ascites [154] and should be considered in the differential diagnosis.

The presence of ascites increases the patient's susceptibility to spontaneous bacterial peritonitis. This complication has been reported in SLE [155, 156]. Conn [157] suggests that it is relatively more common in patients with "disseminated" SLE than in patients with alcoholic cirrhosis. The great majority of cases of spontaneous bacterial peritonitis develop in the hospital, usually more than 1 week after admission [157]. In one of the SLE patients reported to have developed spontaneous bacterial peritonitis, *Streptococcus pneumoniae* was the causative organism [151].

Lupus patients with renal failure on continuous ambulatory peritoneal dialysis are obviously at risk for bacterial peritonitis. For example, Allais *et al*. [142] reported a case of *Listera monocytogenes* in a lupus patient on continuous ambulatory peritoneal dialysis. Abdominal abscesses have also been found [13, 91]. Perforation of the intestine in a patient with SLE can also lead to peritonitis [77].

Hemoperitoneum has also occurred in SLE [158]. In this case, the patient had a ruptured gastroepiploic aneurysm, which showed evidence of vasculitis (fibrinoid necrosis with destruction of muscle and elastic fibers in the vasa vasorum as well as disintegration of the connective tissue layer of the tunica media). A fall prior to the development of the hemoperitoneum was probably the precipitating event. McCollum *et al*. [159] have also reported on the development of a ruptured aneurysm in a patient with SLE, in this case the hepatic artery.

Diagnosis

The value of paracentesis is obvious in the lupus patient with ascites or signs of peritonitis. Zizic *et al*. [77] emphasized the urgency in evaluation and diagnosis of such patients, maintaining a high index of suspicion, because many of the gross signs of peritonitis such as rebound tenderness and guarding may be masked by the high steroid doses that these patients are often taking.

Therapy

Once a diagnosis is made, appropriate therapy should be initiated. In the case of SLE-induced peritonitis, increasing the dose of steroids has been shown to be effective [152]. In the presence of ascites, steroids alone appear to be less effective and some have suggested that the addition of cyclophosphamide improves outcome [149]. For bacterial peritonitis, antibiotics should be instituted, and for bowel perforation or aneurysm rupture, emergency surgery is imperative.

Serositis may also lead to other complications. For example, as noted earlier, Miller *et al*. [125] described a case of small bowel obstruction secondary to extensive small bowel adhesions in a patient with SLE serositis.

PANCREAS

Clinical Features

Pancreatitis in association with SLE has been recognized for some time [72, 83, 127, 130, 131, 158, 160, 161] although the incidence is variable, ranging from 1% to 23% [6, 8, 13]. In most reported cases, it occurs in the setting of SLE with multiorgan involvement. Clinically, the presenting symptoms of acute pancreatitis in SLE are no different than those found in non-SLE patients: severe abdominal pain, often radiating to the back; nausea; and vomiting. X rays frequently reveal a localized ileus of either the small bowel or colon (sentinel loop). The activity of the underlying SLE appears to be greater in those patients with pancreatitis than in those without [126, 162].

Complications of pancreatitis are not common. Fistulae and abscess have not been noted. Pseudocyst formation [91, 162] and resolution [163] have been reported. Three-fourths of the patients in the Pollak *et al*. [84] series with pancreatitis died. The signs and symptoms of chronic pancreatitis are more subtle and may include evidence of diabetes and fat malabsorption.

Pathology–Pathophysiology

Because steroids as well as other drugs used in SLE such as azathioprine have been implicated in pancreatitis [131, 164–167] there have been some questions as to whether SLE in and of itself can cause pancreatitis. The weight of evidence points toward an actual vasculitic lesion as etiologic in some cases of lupus pancreatitis [127]. Several cases occurred in the presteroid era [83, 130] and in patients not taking steroids or immunosuppressives [126, 162]. Furthermore, in some patients the pancreatitis resolved while either maintaining or increasing their steroid dose [162]. Four of 20 patients in the Reynolds *et al*. [162] review had no predisposing factor for their pancreatitis other than SLE, and histologically, steroid-induced pancreatitis differs from the vasculitic picture of pancreatitis seen in the available animal models thus far [168, 169]. A role for antiphospholipid and anti-cardiolipin antibodies, seen in some patients with lupus, has been suggested [170, 171].

Ropes [8] described the pancreas in three lupus patients as containing, respectively, (1) moderate fibrosis and lymphocytic infiltration; (2) ectasia of the acini; and (3) acute and chronic inflammatory changes in the vessels with fibrinoid necrosis. The absence of clinically evident pancreatitis in Ropes' study [8] concurrent with the finding of pancreatitis in 6% of his autopsied cases, suggests the possibility of subclinical pancreatitis in lupus patients. Further evidence for this comes from the Tsianos *et al*. [12] study in which 30.5% (11 of 36) of SLE patients who had no abdominal pain or other gastrointestinal symptoms while at the time of blood drawing had hyperamylasemia. The authors suggest that asymptomatic pancreatic damage in SLE may occur frequently and that the hyperamylasemia in these patients probably reflects a slow, subclinical, inflammatory process of the pancreas. Another possibility is hyperamylasemia from small bowel perforation.

Diagnosis

Acute pancreatitis may be diagnosed by typical symptoms and blood work. The serum amylase level is elevated, but amylase isoenzymes, serum lipase, and amylase/creatinine clearance ratio (>5.5) are suggested to differentiate pancreatic from salivary hyperamylasemia and the hyperamylasemia seen in renal disease [172]. In addition, an inflamed, edematous pancreas on sonogram or computed tomographic scan can confirm the diagnosis.

Therapy

If steroids or azathioprine are suspected to be the inciting agent, they should be withdrawn. Treatment of

uncomplicated acute pancreatitis should include fluid support, analgesics, and placing the pancreas at rest by allowing no food by mouth.

GALLBLADDER

Gallbladder disease is distinctly uncommon in SLE patients. Four cases have been reported [13, 173–175] and in one of these cases [173] occurred in a patient with increased activity of disease and high levels of circulating immune complexes. Histologically, the gallbladder in this case revealed an acute arteritis with periarterial fibrosis, consistent with SLE vasculitis. These changes are similar to those seen in other vasculitic syndromes such as polyarteritis nodosa, in which gallbladder disease is more common [176]. It is interesting that the gallbladder is often involved in polyarteritis nodosa but rarely in SLE. This may suggest differences in the type of immune complexes generated in these two diseases.

SPLEEN

Splenomegaly, usually asymptomatic, has been reported in various series of SLE with a frequency of 9–67% [2, 5, 6, 9, 10]. Symptomatic disease of the spleen in association with SLE may also occur. Asherson *et al*. [101] reported a patient with lupus anticoagulant whose clotting diathesis led to splenic artery thrombosis with subsequent splenic infarction, requiring splenectomy. One case of spontaneous splenic rupture and hemoperitoneum in a girl who was later diagnosed with lupus has also been described [177]. Ropes' examination [8] of autopsy specimens from patients with SLE revealed the spleen to contain fibrosis, hemosiderosis, congestion, acute and chronic inflammation, onion skin thickening of the arterioles, splenic infarcts, and, in one case a caseating granuloma consistent with tuberculosis. Rare cases of asplenism have also been reported [178].

DRUG-RELATED PATHOLOGY

Corticosteroids and aspirin are two therapeutic agents used in SLE that are fraught with significant side effects. As has been discussed, they can be implicated in many pathologic findings in the GI tract. Steroids may cause pancreatitis, fatty liver, possibly peptic ulcer disease, and may increase the risk of diverticular perforation [19]. Aspirin and nonsteroidal anti-inflammatory drugs are equally implicated in a variety of disorders such as gastritis, gastric ulcer, and liver disease. *However, there are no lupus-specific data on nonhepatic gastrointestinal side effects of either nonsteroidal anti-inflammatory drugs or the selective Cox-2 inhibitors* [179]. Antihypertensives, such as methyldopa, have been implicated in chronic active hepatitis, and thiazides are etiologic in some cases of pancreatitis. Azathioprine, used in the treatment of SLE, can cause pancreatitis, typically presenting within the first 3 weeks of therapy. Ibuprofen has been implicated in a case of colitis in a patient with SLE [107]. Also of interest is a reported case of procainamide-induced lupus with pancreatitis [180]. It is unclear whether the pancreatitis was caused by the drug itself or by the lupus syndrome. Antimalarials, also used in the treatment of SLE, may cause blue, gray, or brown pigmentation of the buccal mucosa [51]. Cyclophosphamide can cause stomatitis. In general, as has been suggested by Hoffman and Katz [81], if any GI complication arises one should think of a drug-related event before proceeding to a more extensive workup.

In addition to various lupus drugs causing GI symptoms, there are various drugs used in GI diseases that may cause drug-induced SLE. Infliximab therapy has been associated with the development of ANAs and anteds DNA antibodies. In some patients, a lupus like illness was described. Trimethoprim-sulfa and tetracycline, both used in patients with infectious diarrhea and in Crohn's disease [181] may do this. Sulfasalazine and olsalazine have also been implicated, and IgG against the (H2A H2B)–DNA complex has been documented in two cases [182–184]. It may be difficult to determine which is the primary disease. The symptoms usually resolve on cessation of the offending agents.

CONCLUSIONS

Approach to SLE Patients Presenting with Abdominal Pain

From this overview, several conclusions can be drawn that we hope can guide therapeutic decisions in the future. The most serious GI complications of SLE are those associated with abdominal pain. As noted previously, medication effects should always be considered first, since they are probably more common than the serious GI complications. If a drug-related effect is ruled out, the appropriate laboratory evaluation (including CBC, ESR, serum amylase and lipase levels, serous lactate urinalysis and stool guaiac in addition to disease activity-related serologies) should be initiated. Abdominal X rays, looking for a paralytic ileus or free air secondary to perforation, should be followed by a diagnostic paracentesis, if warranted. Ascites should always be tapped to rule out the possibility of concomitant spontaneous bacterial peritonitis or the much

rarer hemoperitoneum. Computed tomography is valuable in assessing both lupus-related as well as unrelated abdominal events, as it should be kept in mind that SLE patients presenting with abdominal pain syndromes may have conventional gastrointestinal illnesses [184]. Quick surgical intervention is mandatory if there is evidence of perforation or gangrene, as it appears that earlier surgery, even in sicker patients, yields a better prognosis. If paracentesis and X rays are negative, then these patients fall into Dubois' category [21] of potentially reversible ischemia and should be treated with increasing doses of steroids. These patients should respond rapidly.

As more studies are performed, we should gain a better knowledge of subcategories of patients and their responses to various treatment protocols. Until then it would be prudent to be more aggressive in treating these patients, since current knowledge supports this course.

HEPATIC DISEASE AND SYSTEMIC LUPUS ERYTHEMATOSUS: COINCIDENCE OR CONVERGENCE

Ian R. Mackay

ABSTRACT

The chapter is introduced with the problem nomenclature of diseases for which the nature is not fully understood, well exemplified by autoimmune hepatitis and systemic lupuns erythematosus. Autoimmune hepatitis was initially called chronic active hepatitis and lupoid hepatitis, and was seen in the 1960s as being akin to systemic lupus erythematosus (SLE) by reason of shared features indicative of an autoimmune pathogenesis. Later, promulgations of Criteria Committees on both diseases defined distinctions rather clearly. Estimated coexistences in cases primarily designated as SLE would be about 1%, and in cases primarily designated as autoimmune hepatitis about 5% but with some multisystem features in a higher proportion of cases. In autoimmune hepatitis, the clinical presentation can extend from organ (liver)-specific to multisystem features, but differences from SLE are seen in hepatic histopathology and autoimmune serologic reactions. Among the latter, distinguishing markers include the much higher frequency and persistence of anti-double-stranded (ds)DNA in SLE and the occurrence of particular autoantibodies, to F-actin (SMA), microsomal cytochrome P450 species (anti-LKM (liver–kidney microsomes)), and neutrophil cytoplasm (anti-neutrophil cytoplasmic antibody (ANCA)), in autoimmune hepatitis but not in SLE. The immunogenetic (including HLA-based) predisposition to autoimmune hepatitis and SLE has shared as well as disease specific components, consistent with degrees of clinical overlap sufficient in some cases for criteria for both diseases to be fulfilled.

INTRODUCTION

Liver Disease and Lupus Erythematosus

Systemic lupus erythematosus (SLE) is a multisystem autoimmune disorder with varying major involvement of diverse organs and tissues. Hence definition and diagnosis raise striking challenges to nosologists, clinicians, epidemiologists, geneticists, and others. This challenge of defining SLE has been met twice by committees of the American Rheumatism Association, in 1971 [1] and 1982 [2], and useful criteria for SLE have emanated. However, given that lupus is by definition "systemic," there is a nosologic dilemma when disease affects only one organ or system (kidneys, skin, synovium, or central nervous system (CNS)), but there is a positive anti-nuclear antibody (ANA) reaction and autoimmune-type histopathology. A particular example is provided by the varied neuropsychiatric syndromes of

SLE, when present in isolation [3]. The liver is another example yet, despite the usual "organ-specific" nature of autoimmune hepatitis, some otherwise typical cases show multisystemic features akin to SLE; this in fact prompted the initial designation of autoimmune hepatitis as lupoid hepatitis [4].

Additionally, there have been two expectations raised by the striking advances in autoimmune serologic diagnosis over the past 30 years [5]. One, partly realized, is that serologic specificities would correlate sufficiently well with particular clinical features to provide for accurate classification of multisystem autoimmune diseases. The other, as yet unrealized, is that serologic specificities would provide key insights into etiology and pathogenesis, by elucidation of the origin and nature of the initial provocation of the disease. It will be evident that the liver is not a usual target organ for the "lupus process." The rationale for this chapter is that there is a definable type of chronic hepatitis that has in common with SLE an autoimmune background, some shared serologic features and, occasionally, overlapping clinical expressions. We therefore seek to analyze the various points of convergence and divergence for the two diseases.

The Logic of Naming and Diagnosis of Disease and Establishing Causality

We endorse a claim that scant attention has been paid to defining disease in clinical medicine [7]. Problems of nosology must arise frequently in a volume on a disease such as SLE, for which many of the various components of etiology and pathogenesis are still unknown; thus some comment is needed on the logic of diagnosis and disease terminology. Scadding [8] in 1996 and Temple *et al.* [7] in 2001 distinguished two schools, *essentialist* (reductionist) and *nominalist*, as providing alternative approaches to the definition or description of disease. Essentialists have the expectation of an ideal form behind every affect or concept, expressed in medicine by the hankering for a unified concept of disease that can be related to an identifiable class of agents causing illness. In other words, there is an underlying pathological etiology and the disease state should be defined by the essential lesion [7]. Thus essentialists, in the case of autoimmune hepatitis as well as SLE, would seek to define these in terms of the immunologic abnormalities that are demonstrable in the laboratory or, with advances in genetics and genomics, in terms of a genetic abnormality. Unfortunately, for most of the presumed autoimmune disorders, this is still not sustainable. Nominalists on the other hand hold that the purpose of definition is simply to state the features by which the members of the class might be recognized, and designate diseases by criteria which require no presumption of any particular underlying cause, autoimmune or other. In practice autoimmune hepatitis is now specified in terms of an aggregate of features, inclusive and exclusive, that have received a consensus endorsement by the International Autoimmune Hepatitis Group (IAIHG) [9, 10]. Hence the adjectival use of "autoimmune" is, in the present state of knowledge, simply a convenient way of emphasising particular characteristics that are lacking in other types of chronic hepatitis, and is at best only presumptive of pathogenetic (autoimmune) mechanisms unique to the disease. Thus for the present, for both autoimmune hepatitis and SLE, the nominalists hold sway.

CHRONIC ACTIVE AND LUPOID HEPATITIS: EARLY DESCRIPTIONS

Semantic problems started early on [11]. Thus the term *chronic active hepatitis* (CAH) was first introduced in the mid-1940s to describe a relatively benign albeit protracted type of epidemic (presumably viral) hepatitis affecting soldiers in World War II [12]. In the 1950s the term (or a variant, active chronic hepatitis) became applied, in fact more aptly, to a new and striking syndrome particularly affecting young women. This was recognized in several centers much at the same time, and marked by a progressive and often fatal hepatitis with superadded immunologic and endocrine abnormalities [13–16]. The reported occurrence in one patient with CAH of a positive lupus erythematosus (LE) cell test [17], and an association in several cases of CAH with features seen in SLE, including positive LE cell tests, prompted the term lupoid hepatitis [4]. Thereafter, the recognition of the immunologic basis of the LE cell test and evolving ideas on the autoimmune pathogenesis of SLE, together with the detection of anticytoplasmic antibodies [18], led to autoimmunity being nominated in the pathogenesis of CAH [19].

A review of the literature from the 1960s illustrates that authors frequently observed a "spill over" of features of CAH into those of SLE and, in more recent years, there has been a shift in the clinical presentation of CAH from younger-aged women with more severe and progressive disease to older-aged women with a milder disease [20, 21]. Our description in 1956 of seven subjects with lupoid hepatitis specified various features that are included among the revised criteria for SLE: malar rash, nonerosive arthritis, serositis, renal disorder, hematologic disorder with cytopenias, and immunologic disorder [4], and other contemporary reports on CAH in young women were in keeping with this experience. These included 26 cases of which a "surprising number" had either arthralgia or actual arthritis which, together with serositis, pneumonia, or erythema multiforme,

prompting a suspicion of collagen disease [16]; nine cases with liver cirrhosis in whom a diagnosis of a "lupus erythematosus-like syndrome" could be made, with five having Sjögren's syndrome [22]; two cases "with probable DLE with cirrhosis or severe hepatitis" [23]; and one case with chronic hepatitis and a classic syndrome of SLE with pericarditis, pleurisy, and joint pains [24]. In a later study [25], there were tabulated 81 cases of "active juvenile cirrhosis" with accompanying diseases that included rashes, arthralgia, "lupus kidney," autoimmune thyroid disease, and ulcerative colitis, although the authors considered that "this form of chronic liver disease cannot be equated with systemic lupus erythematosus." Another study [26] described four cases of "progressive hyperglobulinemic hepatitis" with extrahepatic features, but again, the syndrome differed from the authors' experience with typical SLE. Two case studies in the 1960s further illustrate the uncertainties. In one [27], there were 15 patients of whom 13 were considered to have lupoid hepatitis and two SLE with a coexisting liver disease, viral hepatitis and alcoholic cirrhosis; of the former 13, the systemic features were minor and not reflective of SLE (arthralgia, 8; fever, 1; a weakly reactive VDRL test, 3). In the other [28], there were 20 patients with CAH of whom most had a positive test for ANA and prominent systemic features (arthritis or arthralgia, 16; pleurisy, 4; rashes, 5; ulcerative colitis, 3; convulsions, 2; cytopenias, 11) and a high frequency of familial stigmata of autoimmunity such that the disease expressions "were remarkably similar to those encountered in systemic lupus erythematosus."

A large case experience with CAH has accrued at the Mayo Clinic, Rochester, MN since the 1960s. Of 88 cases reported in 1975 [29], and 126 cases in 1983 [30], that were seronegative for HBsAg and with known etiologies excluded, and hence deemed suitable for corticosteroid treatment, an associated autoimmune disease was recorded in 37 of 88 in the first series, and in 21 of 126 in the second. While the frequency of a positive test for ANA was 55%, the authors rejected a relationship of the disease to SLE, and also the notion that "lupoid" features defined a subset of cases distinguishable from others; the opinion was that "the autoimmune markers associated with CAH may reflect dysglobulinemia associated with the severity of hepatocellular inflammation and necrosis" [29].

DIAGNOSTIC CRITERIA: SYSTEMIC LUPUS ERYTHEMATOSUS AND AUTOIMMUNE HEPATITIS

This section examines the possible connection between SLE and autoimmune hepatitis from the standpoint of the clinical and laboratory criteria used to define these diseases.

Criteria for Systemic Lupus Erythematosus

Systemic lupus erythematasus is a disease with a pleomorphic expression and widely varying severity. In 1971 the American Rheumatism Association (ARA) selected a set of 14 major manifestations (criteria) that included 21 items considered to characterize SLE, and recommended that SLE could be diagnosed if four or more of these criteria were present, serially or simultaneously, during a period of observation [1]. These criteria were evaluated in 1974 for early SLE by Trimble *et al.* [31]. Application of the initial criteria was claimed to give a 90% sensitivity and 98% specificity, but the criteria were criticized. In 1982 an ARA subcommittee published revised criteria in which defining terms were clarified, some items were eliminated, and recently recognised serologic markers were included [2]. The 11 criteria, in abbreviated form, included the following. 1: malar rash; 2: discoid rash; 3: photosensitivity; 4: oral ulcers; 5: nonerosive arthritis; 6: serositis; 7: renal disorder; 8: neurologic disorder; 9: hematologic disorder, either hemolytic anemia or reduced numbers of cellular elements in the blood; 10: immunologic disorder on serologic testing, including LE cells, anti-DNA, anti-Sm; and 11: ANA to an abnormal titer at any point in time. A diagnosis of SLE required four of these criteria and, when fulfilled, provided a sensitivity and specificity of 96%. Notably, liver dysfunction of any type does not appear among these criteria.

Criteria for Autoimmune Hepatitis

IASL Criteria Committee, 1976

The first definition of "generic" CAH was presented by a Criteria Committee of the International Association for Study of the Liver (IASL) in 1976 [32], but the definition reflected the prevailing uncertainty over diseases that should be included under the rubric of CAH. However, even in 1971, heterogeneity of CAH was well recognized [33], since cases with autoimmune serologic markers seemed separable from cases positive for the recently recognized marker for hepatitis B virus (HBV) infection, the HB surface antigen (HBsAg). Subsequently "chronic active hepatitis" was seen as a spectrum of diseases [34] which could include, in addition to autoimmune and viral hepatitis, hepatic expressions that occur in drug sensitivity, alpha$_1$-antitrypsin deficiency, Wilson's disease, or ethanol abuse. At that time, posttransfusion non A, non B virus infection, now attributable to hepatitis C virus (HCV), was not the major

contributor to the chronic hepatitis case load that it is today.

Nominated Attributes, 1980s

The autoimmune type of chronic hepatitis became better defined during the 1980s with the specification of the following attributes that were characteristic albeit not exclusive markers for diagnosis [35]: 1: female gender; 2: age at onset 10 to 30 years or after 50 years; 3: Eurocaucasian racial background; 4: multisystem disease expression; 5: histologic features of periportal piecemeal necrosis; 6: seronegativity for HBsAg and anti-HCV, and lack of other evident etiologies; 7: hypergammaglobulinemia during disease relapses, more than 30 g/liter; 8: autoantibodies to nuclei, smooth muscle (SMA) or liver–kidney microsomes (LKM), to "acceptable" titer (see later); 9: HLA-B8, DR3 by histocompatability typing; 10: responsiveness to treatment with corticosteroid drugs; and 11: sparing from hepatocellular carcinoma that tends to supervene on most other types of chronic hepatitis or cirrhosis.

International Autoimmune Hepatitis Group (IAIHG): Brighton Report, 1992

The International Autoimmune Hepatitis Group [9] was convened in 1992 in Brighton, United Kingdom, to "review all the features of autoimmune hepatitis (AIH) and determine whether a consensus could be reached on criteria" The ensuing Brighton Report presented diagnostic criteria for definite and probable autoimmune hepatitis, based on features generally similar to those cited in other reports, but with the innovation that the inclusive or exclusive criteria, clinical, biochemical, histologic and serologic, could be given positive or negative scores or weightings according to their estimated contribution to the diagnosis. The prototype of this scoring system was developed from retrospective analysis of 145 patients attending one center with classic features of autoimmune hepatitis, and 250 with other liver disorders. The system was then modified through three subsequent revisions based on panellists' experience with their own case material.

IASL Criteria Committee, 1994

A Criteria Committee of the IASL [36] revised their 1976 Manual in 1994 in which autoimmune chronic hepatitis was distinguished from other types of chronic hepatitis according to "the presence of significant titers of circulating tissue antibodies and the absence of other causes of chronic hepatitis," namely viruses, drugs, toxins, and metabolic abnormalities. The required titer for antibodies to nuclei, and/or to smooth muscle with specificity for actin, was 40 or greater, but laboratory conditions including test substrates and appropriate standards for performance of tests were not nominated. This committee also presented indicative rather than diagnostic histologic criteria, including plasmacytosis, bridging necrosis, and pseudo-glandular rosettes of liver cells (see later). A quick response of the disease to low-dose corticosteroid treatment was accorded diagnostic significance.

World Congress of Gastroenterology (WCG) Working Party, 1994

An international working party [37] was organized and funded by the WCG of 1994 to report on the Terminology of Chronic Hepatitis. The term autoimmune hepatitis was recommended in preference to earlier synonyms including chronic active hepatitis, lupoid hepatitis, and plasma cell hepatitis. The concise definition of autoimmune hepatitis used by this group was "unresolving predominantly periportal hepatitis, usually with hypergammaglobulinemia and tissue autoantibodies, which is responsive to immunosuppressive therapy in most cases." The laboratory descriptors included a five-fold selective increase in serum immunoglobulin (Ig)G concentration, and titers of autoantibodies, either ANA, SMA, or anti-LKM, of 1:40 on tissues, or 1:160 for ANA on the HEp2 cell substrate. Almost all patients (Eurocaucasoid) would carry the HLA class II alleles DR3 or DR4. Patients with markers of virus infections should not be considered to have autoimmune hepatitis. An indicative significance was accorded to biopsy features of bridging necrosis, plasmacytosis, and formation of liver cell rosettes.

International Autoimmune Hepatitis Group, Revised Criteria, 1999

The IAIHG Brighton Report of 1992 (see International Autoimmune Hepatitis Group (IAIHG): Brighton Report, 1992, see earlier) has been assessed and reevaluated in several studies in recent years, with modifications to accommodate newer diagnostic methods, histopathologic appearances on liver biopsy, and ascertained imprecisions in the original scoring system. The revised criteria and scoring system [10], with scores for "definite" and "probable" autoimmune hepatitis provide a sensitivity for diagnosis of 97–100%. However, specificity is much lower, in the range of 45–92%, by reason of liver diseases other than autoimmune hepatitis, fulfilling criteria for a "probable" diagnosis. This shortfall should be overcome in the

future by improved and more stringent application of autoimmune serologic testing.

AUTOIMMUNE HEPATITIS: CONTEMPORARY CLINICAL APPRAISAL

Description of the Disease

Autoimmune hepatitis can present through a spectrum from asymptomatic disease recognized only by biochemical abnormalities of liver function to an acute hepatitis in some 25% of cases [38], and is progressively cirrhotogenic [39–41]. It is predominantly a disease of women (F : M, 8 : 1), and the age incidence is bimodal with peaks in early adult life and after 40. The disease usually has a long asymptomatic preclinical course which is a feature of many other autoimmune disorders, and may be disclosed by extrahepatic expressions including amenorrhoea in women, or by incidentally detected abnormalities in biochemical tests of liver function. Symptomatic cases have evidence of hepatocellular dysfunction, with symptoms of nausea, anorexia, and jaundice, and signs that include hepatosplenomegaly as well as features of multisystem immune disease. The subset referred to as type 2 autoimmune hepatitis (see later) is often expressed as severe hepatitis in early childhood. The biochemical features on serum analysis are high levels of transminase enzymes and modest elevations in levels of alkaline phosphatase and gamma glutamyl transpeptidase. A highly elevated level up to 100 g/liter of IgG of polyclonal type is seen resulting in a marked overall increase in serum globulins, with "marker status" accorded to a level above 30 g/liter; this greatly exceeds the minimal to modest increase in SLE. Other autoimmune diseases in which there is pronounced hypergammaglobulinemia are those that are localized to parenchymal tissues, primary Sjögren's syndrome and thyroiditis. Treatment with prednisolone induces such characteristic improvement in all clinical and biochemical indices and in histologic changes that this has diagnostic utility. As mentioned earlier, the diseases identified as CAH and lupoid hepatitis in the 1950–1960s that predominantly affected young women now appear less prevalent than the more indolent versions that affect middle-aged to elderly females [20, 21]. This has connotations for therapy which was based mainly on studies of the prototype disease of earlier years.

Extrahepatic Manifestations of Autoimmune Hepatitis

The earlier descriptions of clinical features of autoimmune hepatitis (see earlier) included features simulating those seen in SLE, facial rash, arthralgia, hemolytic anemia, thrombocytopenic purpura, and mild nephropathy. In a study of 108 older subjects with CAH [42] there were prominent frequencies (26–35%) of features of Sjögren's syndrome, renal tubular acidosis, or fibrosing alveolitis as well arthropathy, rashes, and thyroid disease. Coexistence with ulcerative colitis was cited in many of the earlier reports [19, 28, 39, 42]. However, while there is clear overlap between autoimmune hepatitis and other autoimmune disorders, in terms of clinical expression or morphological features such as lymphoid infiltrations, the clinical terrain of autoimmune hepatitis and SLE differs in several respects. These include the usual absence in autoimmune hepatitis of the renal lesions characteristic of lupus nephritis and cerebral involvement, and the presence of coexistences that are infrequent accompaniments of SLE, notably ulcerative colitis. In particular, the type 2 variant of autoimmune hepatitis has no co-associations with SLE.

Subtypes of Autoimmune Hepatitis

Serologic reactants are a cornerstone of diagnosis of autoimmune hepatitis. In addition to the earlier classic markers of CAH, ANA, and SMA (see later), there was described in 1973 a novel reactant enriched in microsomes of liver and kidney (LKM) [43]. Subsequent reports of anti-LKM-associated CAH suggested a predominance of cases in children presenting with a particularly severe type of hepatitis [44, 45]. In 1987, Homberg and colleagues [46] formalized the description of CAH with anti-LKM and considered that this was a sufficiently distinct variant to be identified as type 2. The utility of separating types 1 and 2 is debatable [9]. The rationale for this (Table 1) is based on the childhood predominance in type 2, disease associations that are more "multisystem" in type 1 and "organ-specific" in type 2, the greater and so far unexplained geographical prevalences for type 2 in middle and southern European countries vs those for type 1 the United States [47], Australia [48], Sweden [49], Japan [50], and the United Kingdom except among children [51], and the polarized serologic reactivities. Suggestions for subclassification of autoimmune hepatitis into yet further types based on other serologic reactivities have not been endorsed.

Autoimmune Overlap Syndromes Involving the Liver

It is well known that multiple autoimmune diseases may aggregate in one patient or related family members; in fact this clustering is a defining marker for

TABLE 1 Revised Scoring System for Diagnosis of Autoimmune Hepatitis [10]

Parameters/features[a]	Score	Notes[b]	Parameters/features[a]	Score	Notes[b]
Female sex	+2		Liver histology		
ALP : AST (or ALT) ratio			Interface hepatitis	+3	
<1.5	+2	1	Predominantly lymphoplasmacytic infiltrate	+1	
1.5–3.0	0		Roasting of liver cells	+1	
>3.0	–2		None of the above	–5	
Serum globulins *or* IgG above normal			Biliary changes	–3	5
>2.0	+3		Other changes	–3	6
1.5–2.0	+2		Other autoimmune disease(s)	+2	7
1.0–1.5	+1		Optional additional parameters:		8
<1.0	0		Seropositivity for other *defined* autoantibodies	+2	9
ANA, SMA, or LKM-1			HLA DR3 or DR4	+1	10
>1 : 80	+3	2	Response to therapy		
1 : 80	+2		Completes	+2	11
1 : 40	+1		Relapse	+3	
<1 : 40	0		Interpretation of aggregate scores		
AMA positive	–4		Pretreatment:		
Hepatitis viral markers			Definite AIH	>15	
Positive	–3	3	Probable AIH	10–15	
Negative	+3		Postreatment:		
Drug history			Definite AIH	>17	12
Positive	–4	4	Probable AIH	12–17	
Negative	+				
Average alcohol intake					
<25 g/day	+2				
>60 g/day	–2				

[a] ALP, alkaline phosphatase; AST, aspartate aminotransferase; ALT, alanine aminotransferase; ANA, antinuclear antibodies; SMA, smooth muscle antibodies; LKM-1, type 1 liver–kidney microsomal antibodies.

[b] Explanatory notes: 1, The ALP : AST (or ALT) ratio relates to the degree of *elevation above upper normal limits* (unl) of these enzymes, i.e. = (IU/I ALP ÷ unl ALP) ÷ (IU/I AST ÷ unl AST); 2, Titers determined by indirect immunofluorescence on rodent tissues or, for ANA, on HEp-2 cells. Lower titers (especially of LKM-1) are significant in children and should be scored at least +1; 3, Score for markers of hepatitis A, B, and C viruses (i.e., positive/negative for IgM anti-HAV, HAsAg, IgM anti-HBc, anti-HCV, and HCV-RNA). If a viral etiology is suspected despite seronegativity for these markers, tests for other potentially hepatotropic viruses such as CMV and EBV may be relevant; 4, History of recent or current use of known or suspected hepatotoxic drugs; 5, "Biliary changes" refers to bile duct changes typical of PBC or PSC (i.e., granulomatous cholangitis, or severe concentric periductal fibrosis, with ductopenia, established in an *adequate* biopsy specimen) and/or a substantial periportal ductular reaction (so-called marginal bile duct proliferation with a cholangiolitis) with copper/copper-associated protein accumulation; 6, Any other *prominent* feature or combination of features suggestive of a different etiology; 7, Score for history of any other autoimmune disorder(s) in patient or first-degree relatives; 8, The additional points for other defined autoantibodies and HLA DR3 or DR4 (if results for these parameters are available) should be allocated *only* in patients who are seronegative for ANA, SMA and LKM-1; 9, Other "defined" autoantibodies are those for which there are published data relating to methodology of detection and relevance to AIH. These include pANCA, anti-LC1, anti-SLA, anti-ASGPR, anti-LP and anti-sulfatide (see text); 10, HLA DR3 and DR4 are mainly of relevance to Northern European caucasoid and Japanese populations. One point may be allocated for other HLA Class II antigens for which there is published evidence of their association with AIH in other populations; 11, Assessment of response to therapy may be made at any time. Points should be added to those accrued for features *at initial presentation*.

an autoimmune basis for a given disease, and SLE is a particular example. A distinction can be made between "coexistence" when two distinct disease entities (albeit both autoimmune in nature) occur together in the one individual, and "overlap" when there is coexpression of two usually distinct entities within a single organ, for example, the liver, such that it is difficult to establish a primary diagnosis of one or the other.

Autoimmune Hepatitis–Systemic Lupus Erythematosus

The overlap between features of chronic active hepatitis and SLE was the initial prompt for the diagnosis of lupoid hepatitis (see Chronic Active and Lupoid Hepatitis: Early Descriptions). However, as experience with autoimmune hepatitis has accrued, the general

viewpoint would be this is a disease with characteristics independent of those of SLE and that when features of both are expressed in the one individual, the use of coexistence rather than overlap is preferable.

Autoimmune Hepatitis–Primary Biliary Cirrhosis

This overlap between two autoimmune diseases of the liver that are usually quite distinct histologically and serologically, autoimmune hepatitis and primary biliary cirrhosis (PBC), has received considerable attention in the more recent hepatological literature [52, 53]. Overlap specifies the coexistence in one individual of features specific for either disease, including clinical presentation, biochemical abnormalities of liver function, histologic lesions, and marker autoantibodies; the disease expression involves both periportal hepatocytes as in autoimmune hepatitis, and small intrahepatic bile ducts, as in PBC.

According to publications, the perception of overlap depends on the perspective of the observer. Thus, among 162 cases with the primary diagnosis as autoimmune hepatitis [54], there was PBC overlap in 8 (5%) whereas among 130 cases with a primary diagnoses of PBC [55], there was an autoimmune hepatitis overlap in 12 (9%); thus a "mid figure" for the frequency of overlap could be about 7%. However, the "basic" disease among such overlap cases may well be PBC according to observations by Lohse *et al.* [56], since their cases were intrinsic PBC on an immunogenetic background (permissive HLA alleles, B8 and DR3) of autoimmune hepatitis.

An aspect of interest is the high frequency, up to 50%, of antinuclear serologic reactions in PBC of particular specificities, anti-centromere, anti-Sp100 which is directed against a transcriptional regulatory protein that aggregates in nuclear dots, and anti-gp210 and anti-p62 that are components of the nuclear pore complex [57]. Anti-dsDNA and anti-chromatin are not expressed and hence the rarity of coexisting PBC and SLE is not surprising. We can, however, note the presence in PBC of anti-centromere reactivity which is often accompanied by the clinical features of the CREST variant of systemic sclerosis, which itself coexists in about 10% of cases of PBC [58]. This coexistence of disease and serologic reactivity is provocative, since mitochondrial autoantigens of PBC and the centromeric autoantigens of CREST exist in separate organelles of the cell, and there is no demonstrable cross-reactivity between them [59].

Autoimmune (Immuno) Cholangitis (AIC)

As originally described [60], AIC is a syndrome expressed clinically by a chronic cholestatic liver disease and histologically by periductular lymphoid aggregates in the liver, in these respects serologically simulating PBC, but tests for the antimitochondrial antibody are negative, whereas tests for ANA are positive. At one stage, AIC was aligned with autoimmune hepatitis but the ANA specificities are inconsistent with this. Since, opinion has veered toward the idea that AIC is a serologic variant of PBC [61]. Notably the specificity of the ANA reactions is identical with that of those seen in PBC, namely, anti-centromere (ACA), anti-Sp100, and antibodies to the nuclear pore complex [62]. The viewpoint of Czaja *et al.* [63], was that AIC cannot be assimilated into any single diagnostic category, but instead represented either a variant form of diverse conditions, a transition stage of another disease such as PBC, or a single entity with varying manifestations; it was recommended that its status be "protected" pending further knowledge.

THE LIVER IN SYSTEMIC LUPUS ERYTHEMATOSUS: CLINICAL ANALYSIS

The liver is not spared in SLE, as judged by the exemplary 570 cases reported by Pestina *et al*. [64]. There is hepatomegaly in 50% of cases attributed mainly to fatty liver or congestion, and an increase in aminotransferase levels or other biochemical functional abnormalities in 30% to 60% of cases, reflecting nonspecific reactive hepatitis, a term used to describe mild hepatic abnormalities accompanying inflammatory lesions elsewhere in the body [65]. Some case studies have been particularly directed to the question whether the "lupus process" can involve the liver in the same way as other vulnerable tissues. The study by Runyon *et al.* [66] comprised 238 cases in which the diagnosis of SLE was based on fulfilment of four or more of the initial ARA criteria; liver function tests were performed in 206. There was at least one abnormal liver function test result in 124 cases, and the authors' criteria for "liver disease" were met in 43 (21%), among which disease was drug-related in 7. Liver biopsy findings in 33 of the cases are described later. In another study on 81 cases of SLE, hepatomegaly was present in 42% and biochemical abnormalities of liver function in 44%, with 14 of the latter cases being drug-related [67]. In a third study on 264 cases of SLE surveyed prospectively, in which clinical and laboratory indices were derived over a 12-month period of observation, there was evidence of liver disease in 67 (25%), but this was drug-related in 29 and attributed to causes unrelated to SLE, including alcohol abuse in 13 [68].

There is an infrequent liver syndrome that has become recognized as a "lupus variant," this being an

SLE-like disease with antibodies against phospholipids (anti-phospholipid syndrome) associated with vascular occlusive disease of the liver and/or nodular regenerative hyperplasia [69–72]. The presence of the lupus anticoagulant, whether occurring in the primary anti-phospholipid syndrome, or that accompanying SLE, has been observed in several instances with hepatic venous thrombosis and Budd-Chiari syndrome [69], or with hepatic arterial occlusion. Notably, the presence of anti-phospholipid (anti-cardiolipin/lupus anticoagulant) is not a reported feature of autoimmune hepatitis [70]. Moreover the lupus anticoagulant has been associated with liver infarction due to hepatic arterial occlusion, without ensuing portal hypertension [71]. Hepatic veno-occlusive disease, as seen in cases of SLE, or subjects with anti-phospholipid antibody, is related to the Budd-Chiari syndrome but the occlusive lesion affects central or sublobular veins rather that larger hepatic veins. Nodular regenerative hyperplasia of the liver is now an acknowledged hepatic complication of SLE, when the latter is accompanied by anti-phospholipid antibody [65, 67]. A literature survey by Sekiya *et al.* [72] covered 46 patients with nodular regenerative hyperplasia of the liver with accompanying rheumatic disorders that included SLE in 15, Felty syndrome in 12, rheumatoid arthritis in 5, systemic sclerosis in 2, Sjögren's syndrome in 1, and primary anti-phospholipid syndrome in 2. On the other hand, the overall frequency of nodular regenerative hyperplasia among Japanese cases of SLE was quite low, 0.3% [72].

AUTOIMMUNE HEPATITIS: THE VISION OF THE HISTOPATHOLOGIST

Histopathology: The Deviation of Hepatitis and Lupus

Histopathology is the point at which autoimmune hepatitis moves closer to the realm of hepatology and organ-specific autoimmunity, and away from the multisystem autoimmune diseases. As indicated earlier (Chronic Active and Lupoid Hepatitis: Early Descriptions), the earlier clinical and histologic descriptions of "chronic active hepatitis" were virtually generic for all types of chronic hepatitis and only in the 1970s was it realized that quite different liver diseases were encompassed within the ICD9 rubric 570.71, chronic active hepatitis. The availability of liver biopsy samples led to numerous descriptions of the histopathology of chronic active hepatitis, and these became formalized by reports from an International Group of Pathologists, 1969 and 1977 [73–74]; their recommendations provide the basis for current morphological criteria.

The Histopathology of Autoimmune Hepatitis

The earliest descriptions of CAH emphasized the inflammatory cellular infiltrates in portal tracts of the liver and within lobules, with plasma cells particularly prominent [16, 75, 76], and with fibrosis, nodule formation, and cirrhosis as sequential lesions (Fig. 1). An early lesion to be recorded was bridging necrosis, denoting the confluence of areas of hepatocellular necrosis between adjacent portal tracts, considered to be a precursor to nodule formation and cirrhosis [77]. The most characteristic feature was that first described as "piecemeal necrosis" [76], and now as interface hepatitis, representing destruction of liver cells at an interface between the parenchyma and connective tissue in portal tracts, with accompanying dense lymphoid infiltrations including lymphocytes and plasma cells. Interface hepatitis is evident at the edge of portal tracts and septa from where lymphoid cells invade the limiting plate of the hepatic lobule, and where hepatocellular injury is most intense, shown by hydropic swelling or apoptosis of hepatocytes. Lymphocytes can be seen in close contact with hepatocytes—peripolesis—and within them—emperipolesis, as effectors of hepatocellular destruction. Other morphological features include intralobular aggregates of lymphocytes contiguous with damaged hepatocytes (lobular hepatitis) and formation by hepatocytes of pseudo-glandular structures (rosettes). Hepatocellular damage in autoimmune hepatitis is typically expressed as apoptosis, seen as shrunken acidophilic remnants of hepatocytes equivalent to the Councilman or acidophilic bodies long familiar to hepatic histopathologists [78], and now seen as indicative of immunologically mediated cellular damage.

There are particular aspects to the histopathology of autoimmune hepatitis. *First*, many of the changes described above are seen in all types of chronic hepatitis, whether attributable to virus infection, autoimmunity, or allergic drug reactions, and are generic to immune-mediated damage to hepatocytes. This type of tissue parenchymal lesion is not a noted feature of the pathology of SLE (*vide infra*). *Second*, histopathologists in their earlier descriptions distinguished lesions with interface hepatitis, chronic aggressive (active) hepatitis, from lesions marked only by hepatic portal infiltrates without interface hepatitis, chronic persistent hepatitis, in which progression toward cirrhosis was deemed unlikely [73, 74], but there is now less emphasis on this distinction [9]. *Third*, morphological appearances as described above do not inform on the immune mechanisms of hepatocellular injury, whether cytolytic T cells, cytokines, or antibody-dependent cellular cytotoxicity

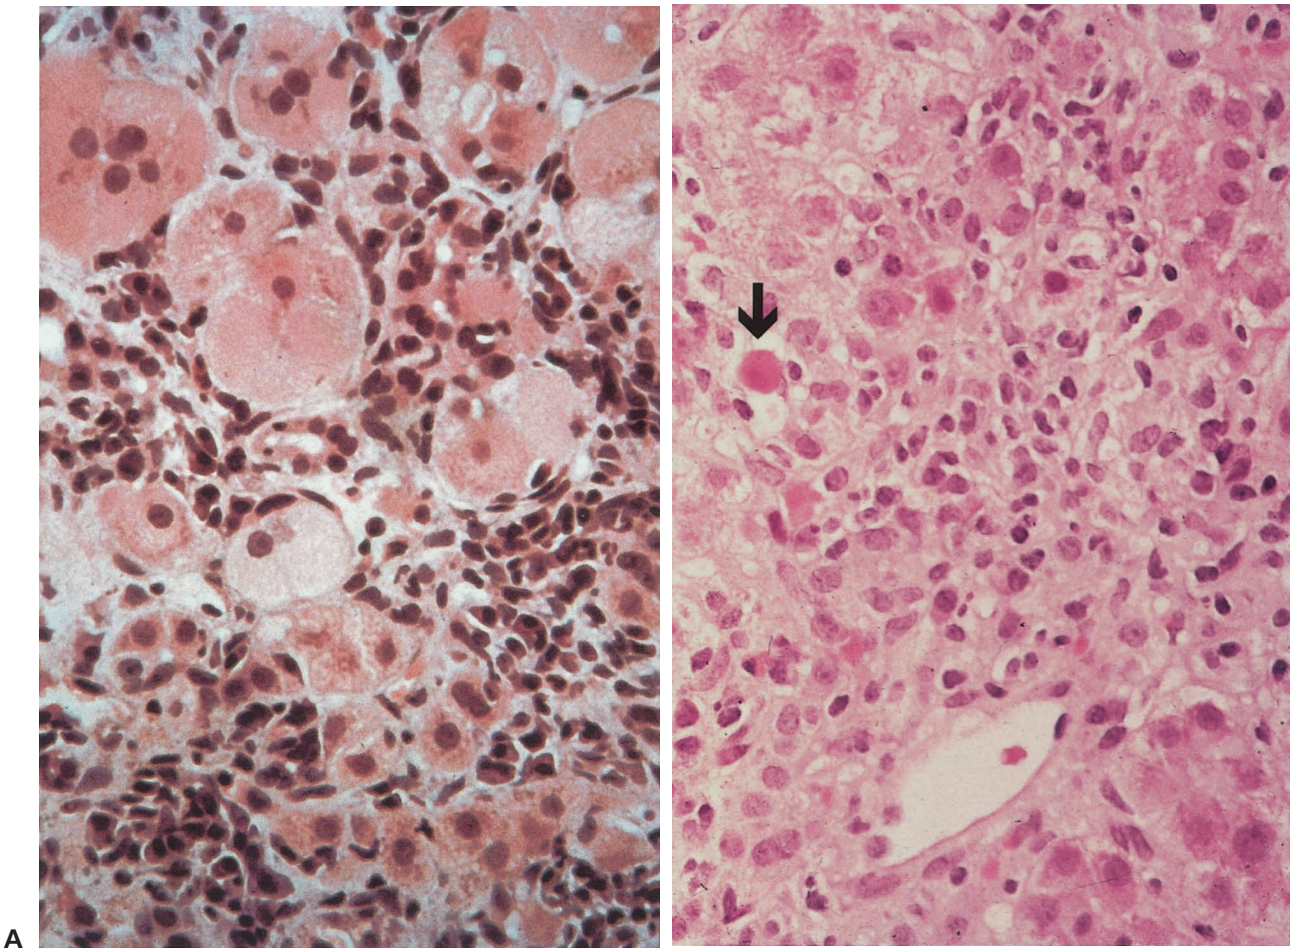

FIGURE 1 Histologic appearances in liver biopsy samples from autoimmune hepatitis. Intralobular lesions illustrating (**A**) cytolysis with ballooned hepatocytes with contiguous infiltrating lymphoid cells (left), and (**B**) apoptotic body, among damaged hepatocytes, arrowed (right) (hematoxylin eosin, ×550 and ×400, respectively). (Fig. 1A, kindly provided by Dr. Nigel Swanston.)

(ADCC). Plasmacytosis is a feature of autoimmune hepatitis that is widely recognized (although not by all [79]); intrahepatic plasmacytosis and local antibody formation would facilitate the occurrence of ADCC, but demonstration of a membrane-located autoantigen is needed to uphold ADCC as a basis for hepatocellular injury.

Histopathology of the Liver in SLE

The relevant studies are those in which there was an established diagnosis of SLE and histologic data on the liver were available. A report by the author in 1959 [80] included 19 cases with the following findings: normal liver or entirely nonspecific lesions including venous congestion, 6; portal fibrosis and/or minor lymphoid infiltrates interpreted as nonspecific reactive hepatitis, 11; inactive cirrhosis, 1; and hepatitis 1 with the diagnosis revised to chronic active hepatitis. In the study by Runyon *et al.* [66] on 238 cases a histologic diagnosis was available in 33 and included cirrhosis in 4, chronic hepatitis in 4, and miscellaneous entities in 25. They separated SLE and CAH by concluding that "patients who satisfy the ARA criteria for SLE and have clinical and histologic evidence of chronic active hepatitis as well should be considered as having both diseases." The study in 1981 by Gibson and Myers [67] included 81 cases with biopsies obtained in 7, showing a portal inflammatory infiltrate in 5 and CAH in 1. Finally the report of Miller *et al.* [68] in 1984 included liver biopsy data in 14 of 264 cases, with none showing any serious or unusual lesion. The rare association of nodular regeneration hyperplasia of the liver with SLE is discussed earlier. The upshot is that histologic examination of the liver in the "standard" case of SLE will show either normal findings, lesions attributable to drug toxicity, or

nonspecific changes, and that no lupus-specific pathology will be evident. Some cases that fulfill clinical and histologic criteria for autoimmune hepatitis may have sufficient multisystem features and serologic characteristics to justify a diagnosis of SLE. However, such cases appear to be minor "contaminants" in collected series of cases of SLE.

AUTOIMMUNE HEPATITIS: THE VISION OF THE SEROLOGIST

Refinements in serologic testing in autoimmune diseases have led to the reasonable expectation that profiles of autoantibody reactions would align with diagnostic specificity and even signify the pathogenetic origins of syndromes or diseases [6]. The recognition of positivity for anti-nuclear antibodies in chronic hepatitis initially suggested a pathogenetic relationship between autoimmune hepatitis and SLE, but the serologic profiles for these diseases were found to show clear distinctions, particularly for autoimmune hepatitis the much lower frequency of autoantibodies to dsDNA and RNPs and singular reactivities such as reactivity to F-actin in type 1 disease and to cytochrome P450 (LKM antigen) in type 2 disease. In this section, the serologic reactions in type 1 and type 2 autoimmune hepatitis will be considered separately, since these are nonoverlapping, notwithstanding the fact that the histologic evolution and outcome, and perhaps even the basic pathogenesis, are similar for the two types. In particular, there are no lupoid features in type 2 AIH, and serologic expressions tend to align more with the organ-specific than the multisystem autoimmune diseases (see later).

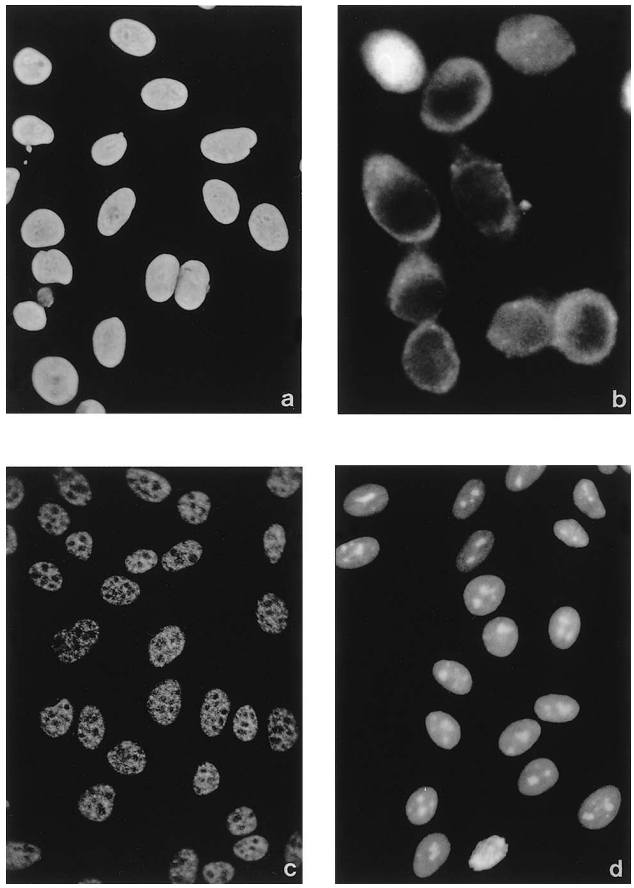

FIGURE 2 Antinuclear staining patterns by immunofluorescence displayed by autoimmune hepatitis sera. (**A**) diffuse homogeneous (anti-histone); (**B**) peripheral (anti-nuclear membrane); (**C**) speckled (anti-RNP); (**D**) anti-nucleolar and diffuse staining. (Fig. 2 kindly provided by Dr. Josefa Wesierska-Gadek)

Serologic Reactions in Type 1 Autoimmune Hepatitis

Anti-nuclear Autoantibodies

Entire Nucleus—Immunofluorescence ANA

Positive results for ANA in autoimmune hepatitis were initially recognized by the LE cell test and later by immunofluorescence on tissue substrates (Fig. 2). Specific patterns of immunofluorescence reactivity on nuclei were first described in 1961, [81] and these became better defined with the use of cultured cell substrates (HEp-2 cells), suggesting that a variety of nuclear antigens may contribute to ANA reactivity in autoimmune hepatitis. A representative frequency of a positive ANA test in autoimmune hepatitis is about 70% [19, 82]. A homogeneous pattern of staining appears more frequently in active disease but, overall, the frequencies of homogeneous (34%) and speckled patterns (38%) may be equivalent [82], reflecting multiple nuclear reactants. However, better data based on standardized techniques under international workshop conditions, as has pertained for diabetes-related autoantibodies [83], would be helpful. An informative multicenter study was conducted under the aegis of the IUIS Standardization committee in which frequencies were cited for ANA positivity on HEp-2 cells according to serum dilution [84]; the respective frequencies for normal subjects at 1:40, 1:80, 1:160, and 1:320 were 32, 13, 5, and 3, which clearly illustrates the sensitivity–specificity "trade-off." Interpretations on the frequency of ANA in autoimmune hepatitis should be made in the light of this study, together with the recognition that the level of ANA reactivity will depend on disease activity, and that any given serum can have multiple ANA specificities at different levels. Particular specificities of ANA

in autoimmune hepatitis do not appear to correlate with particular clinical features.

Nucleosome—Chromatin and Histones

The nucleosome comprises an octamer of histones enwrapped by two coils of DNA (146 base pairs). Histones are small conserved nuclear proteins that bind to DNA in chromatin, and exist as five main classes, H1, H2A, H2B, H3, and H4, which have particular structural features [85]. The octamer is constituted by two H2A–H2B dimers and an H3–H4 tetramer stabilized by noncovalent bonds, and completing the structure is an H1 linker molecule that connects separate nucleosomes; a linear array of nucleosomes forms a primary chromatin fiber of 100 Å diameter. The chromatin fiber supercoils into increasingly larger fibers based on histone-dependent internucleosomal interactions. The condensation of chromatin into a quaternary protein structure is believed to constitute an epitope, if not *the* epitope, for both autoimmune T and B cells that generates anti-nuclear antibodies, whether in SLE or autoimmune hepatitis [85]. Other nuclear structures including individual histones may then be drawn in due to intermolecular epitope spreading. A quaternary protein structure as a primary autoimmune B-cell epitope is exemplified by various other nuclear autoantigens including Ku, U1-RNP, and the proliferating cell nuclear antigen (PCNA), and perhaps also by other autoantigens such as the $\beta_2$glycoprotein–phospholipid complex of the anti-phospholipid syndrome [86].

Antibodies to histones occur typically in spontaneous and drug-induced SLE, with all subtypes recognized as autoantigens in differing configurations. It has been assumed that antihistone is the predominant antinuclear reactivity in autoimmune hepatitis, although a frequency by ELISA of only 25% of 20 sera has been cited [87], and in another study by ELISA on 65 cases previously screened by immunofluorescence for a range of ANA reactivities, the frequency was 23 of 65 (35%) [88]; 11 of these 23 sera were reactive also with other nuclear autoantigens and 12 only with histones.

dsDNA

Anti-double-stranded (ds) DNA is the hallmark reactivity in SLE and is seldom lacking in active disease. The numerous studies to ascertain the frequency of anti-dsDNA in autoimmune hepatitis have given divergent results attributable to technical aspects of the assays used. Studies in the 1970s using liquid or solid phase immunoassays and commercial sources of DNA reactant indicated a high frequency of positivity but similarly positive results were obtained in other types of chronic liver disease indicating low specificity [89, 90], likely attributable to contaminant single-stranded (ss)DNA to which there is nonspecific reactivity in various chronic inflammatory disorders. Smeenk *et al.* [91] in 1982 used a more specific immunoassay for anti-dsDNA based on precipitation of immune complexes by polyethylene glycol, and obtained a positivity rate of 10%. Gurian *et al.* [92] in 1985 reported on assays (in 8 cases of lupoid hepatitis) based on Farr-type immunoprecipitation, a nitrocellulose membrane filtration method, and *Crithidia luciliae* immunofluorescence; there were positive results by the Farr-type assay but negative results in all cases by the other more specific assays. Leggett *et al.* [93] in 1987 studied 25 cases by immunofluorescence with *Crithidia luciliae* and a reliable immunoprecipitation assay for anti-dsDNA with 4 patients giving positive tests, 2 transiently and 2 persistently. The report of Wood *et al.* [94] in 1986 on 91 cases of CAH using an ELISA of claimed high sensitivity and specificity for anti-dsDNA, according to calibration against *Crithidia luciliae* immunofluorescence, cited a positivity rate of over 50%, and with no significant differences in positivity according to either ANA positivity or other disease characteristics; since this is not in line with other studies, the ELISA may have been detecting low affinity anti-dsDNA.

A conspectus of the various studies on anti-dsDNA in autoimmune hepatitis prompts comment on assay format and disease activity. As mentioned earlier, rigorous standardization of most autoimmune serologic tests is still an unmet need, and minimal requirements include availability of standard reference antisera and serum-exchange to derive an optimal assay format, and the convening of international workshops for uniform results between laboratories. A study underscored the tendency of ELISAs to show greater variability than other assay formats [95]. In terms of the disease itself, good case definition is important and, whatever the reactivity is that is being tested for, the general experience is that the stage of disease has a marked influence on the degree of positivity, this being much greater in active than in inactive disease. In regard to anti-dsDNA, a reasonable consensus is that this frequency is low (about 10% of cases) and positivity is transient so that, in this respect, autoimmune hepatitis differs serologically from SLE.

Centromere Proteins

The anti-centromeric pattern of ANA by immunofluorescence represents reactivity to centromere proteins (Cenp) A, B, and C. These reactivities have been defined by immunoblotting, and ELISA using recombinant centromere proteins, and are characteristically associated with the CREST variant of scleroderma [95]. Autoantibodies to centromere (ACA) were identified by immunofluorescence (ACA) and/or ELISA in as

many as 42% of 65 cases of AIH [88]. However, in our experience (I. R. Mackay, unpublished) and that of others (J. Wesierska-Gadek and E. Penner, personal communication), the frequency and serum titer of ACA in autoimmune hepatitis are low and, notably, recorded coexistences of CREST and autoimmune hepatitis are scarce, in contrast to what pertains for PBC [58, 59].

Ribonucleoproteins

Ribonucleoproteins (RNP) include a family of proteins present in the nucleus and cytoplasm that are complexed with, and influence the processing of different low molecular weight ribonucleic acids. The various RNP antigens that are reactants for ANAs present in SLE and Sjögren's syndrome are recognized by a characteristic speckled pattern by immunofluorescence, and reactivities with specific epitopes have been studied using recombinant proteins. In SLE and related multisystem autoimmune diseases, antibodies to various RNP antigens tend to align with a particular clinical syndrome or disease subset [6].

In general, autoantibodies to the well-defined RNP molecules are reported at moderate frequency in autoimmune hepatitis sera [96–98]. In one study on 30 cases, there was reactivity to the 70-kDa U1-RNP in 8, and to the Ro/La (SS-A/SS-B) antigens in 3 (97), and in another report on cases from North America and Asia, 95 and 47, respectively, the frequencies for the North American cases were 43% for snRNPs and 38% for Ro/La, and frequencies for the Asian cases were generally higher [98]. One reactivity described was to an unidentified 52-kDa RNP, in 23% of 65 cases of AIH [82], but there has been no follow-up on this.

Nucleoli

Anti-nucleolar antibodies (ANoA) occur in SLE and related multisystem diseases, and particularly in primary systemic sclerosis (PSS). ANoA were identified by immunofluorescence on monolayers of human fibroblasts in autoimmune hepatitis, as well as in SLE and PSS (99). Major reactants for ANoA are fibrillarin [6] and a 113-kDa molecule with three functional domains characterized as poly (ADP-ribosyl) transferase (pADPRT) [86]. Anti-pADRPT were detected in 7 of 50 cases of autoimmune hepatitis, but reactive sera differed from those in other rheumatic diseases in not inhibiting the catalytic activity of the enzyme, indicating differences in the nature of the autoepitope(s) [86].

Nuclear Envelope

The nuclear envelope is a complex porous assembly of proteins that separates the nucleus from the cytoplasm. The three structural components are (a) the inner and outer nuclear membranes, (b) the nuclear pore complex that serves as a conduit for proteins between nucleus and cytoplasm, and (c) the nuclear lamina that provides part of the architectural framework of the nucleus [86]. Each of these components has autoantigenic reactivity for sera in various of the multisystem rheumatic diseases and in autoimmune liver diseases. Autoantibodies to the lamina occur more particularly in autoimmune hepatitis [86], and to the nuclear membrane and pore complex more particularly in PBC [57]. The nuclear lamina, depending on the cell type and differentiation state, contains 1–6 immunologically related polypeptides, the lamins. The three major members are lamins A, B, C present in equimolar amounts, and three minor members are B2, D, and E. The lamin polypeptides have similar molecular masses of 60–75 kDa, but are readily separated by two-dimensional gel electrophoresis, so allowing for identification of different reactants in disease sera. Wesierska-Gadek *et al.* [100] detected and characterized antibodies to lamins by Western blotting in 12 (24%) of 51 autoimmune hepatitis sera, with zero reactivity for normal control sera. Lamins A and C were reactants at greatest frequency; all 12 of the reactive sera were from the 16 "active" cases in the series, whereas the 35 remission sera were nonreactive. This high frequency (75%) of antilamin reactivity in active autoimmune hepatitis is in contrast with quite low frequencies in SLE and other rheumatic diseases, and in PBC.

Anti-cytoplasmic Autoantibodies

Entire Cytoplasm

Numerous cytoplasmic structures act as autoantigens in SLE and other multisystem autoimmune (rheumatic) disease, and also in autoimmune hepatitis as illustrated by the complement-fixing autoantibodies to cell homogenates described in the 1950s [18]. Certain of these cytoplasmic reactions that have been characterized at the molecular level in autoimmune hepatitis polarize uniquely with either type 1 or type 2 disease, and do not occur in SLE (see later).

Neutrophil Specific Cytoplasmic Antibodies (ANCA)

Considerable interest developed in the 1960s in what were termed granulocyte-specific anti-nuclear antibodies. These were seen particularly in rheumatoid arthritis and in autoimmune hepatitis in which titers by immunofluorescence were considerably greater, by several logs, than those for conventional ANA [101]. The likelihood is that a good proportion at least of these granulocyte-specific ANA described earlier represented what is now recognized as anti-neutrophil cytoplasmic antibody

(ANCA) in which the cytoplasmic reactants clump in a perinuclear distribution. There are two discrete species of ANCA, cytoplasmic (c)ANCA and perinuclear (p)ANCA that have different disease associations and different substrate reactivities. cANCA occur in Wegener's disease and vasculitides in which the major antigens are found in azurophilic granules, particularly a 29-kDa protein triplet, proteinase 3. There are different species of pANCA, with that detected in systemic necrotizing vasculitis being identified as myeloperoxidase. In a study from Italy, the frequency of pANCA in type 1 autoimmune hepatitis was 65% (but 0% in type 2), and in chronic hepatitis C infection with autoimmune features, 13% [102]. ANCA of various specificities are reported in SLE but their presence does not correspond to any particular subtype and their frequency and titer are low relative to type 1 autoimmune hepatitis [103]. The reactant for pANCA in autoimmune hepatitis and other gastrointestinal diseases is not the usual myeloperoxidase. One study reported this as lactoferrin or elastase, another as a 50-kDa nuclear envelope protein that is restricted to neutrophils and myeloid cell lines, and yet another as high mobility group (HMG) proteins 1 and 2 [104].

LP Antigen, SLA

A liver pancreas (LP) antigen was described in 1981 by Berg *et al.* [105] by complement fixation, and this has been coidentified with the reactant described in 1987 as soluble liver antigen (SLA) by Manns *et al.* [106] by radioimmunoassay; SLA sometimes occurred in type 1 autoimmune hepatitis in the absence of all other serologic markers. The reactant for SLA has been successively attributed to cytokeratins 8, 18, [107] glutathione *S*-transferase [108], and most recently as the UGA-serine transfer RNA–protein complex or tRNA-associated protein (tRAP) [109, 110]. Structural considerations placed this protein in the family of serine hydroxymethyl transferases [111]. Reactivity with SLA is not reported in SLE.

Ribosomal P Proteins

Ribosomal P proteins are a set of three ribosomal phosphoproteins of 38 kDa (P_O), 19 kDa, (P_1), and 17 kDa, (P_2) that contain 22 carboxy terminal residues constituting a main immunodominant region or autoepitope [112]. Autoantibodies to ribosomal P proteins occur in some 16% of patients with SLE, and are a marker of active disease and, possibly, cerebral lupus (see Chapters 26 and 27). Autoantibodies to ribosomal P proteins have been described in type 1 autoimmune hepatitis, and this is a reactivity that could link autoimmune hepatitis with SLE; thus there is described a patient with SLE who, after 4 years follow-up, lost ANA with the appearance of anti-Po followed by anti-P_1 and anti-P_2, and this coincided with the development of an autoimmune hepatitis [113]. The temporal relationship of anti-P and liver dysfunction suggested a pathogenic (hepatocytotoxic) effect of anti-P, noting that an epitope similar to that at the carboxy terminus of ribosomal P proteins is present on the surface of cultured hepatoma cells [114]. Moreover, antibody to ribosomal P (anti-38kD, P_O) was shown to penetrate living hepatoma cells and induce cellular dysfunction [115]. This same protein is demonstrable on the surface of intact T lymphocytes [116]. The significance of anti-P for liver disease specifically associated with SLE was assessed in 131 patients with SLE among whom 4 (3%) had liver disease with histologic features similar to those of classic CAH [117]; in all 4, together with 2 additional referred cases, antiribosomal P was demonstrable whereas in cases of autoimmune hepatitis without evidence of SLE, antiribosomal P was not detectable. Moreover, in a case-control study on 20 subjects with SLE in whom anti-ribosomal P was, or was not detectable, the former group had significantly greater liver involvement [118]. Perhaps there is a subset of cases of autoimmune hepatitis in which there are lupus features characterized by and possibly even caused by circulating anti-ribosomal P; however, this possibility does not appear to have received recent attention.

Asialoglycoprotein Receptor

The asialoglycoprotein receptor (ASGPR) was identified in 1984 as a component of liver membrane protein preparations used as antigenic reactants with autoimmune hepatitis sera [119, 120]. The ASGPR, itself a glycoprotein, effects the binding and endocytosis of serum glycoproteins for disposal by the liver. It is a well-conserved protein but with differing numbers of subunits according to species; there are two subunits in humans. The properties and isolation of ASGPR and detection of antibodies by radioimmunoassay are described by McFarlane [120], subsequent studies have been limited because ASGPR is cumbersome to purify biochemically and difficult to express to high yield as a recombinant protein from a cDNA. A multinational study on reactivity of ASGPR, showed a 76% positively rate in autoimmune hepatitis, but positive results in 7–19% of cases in various other categories of liver disease indicated limited specificity [121]. ASGPR is not cited as an autoantigen in SLE.

Anti-cytoskeletal Autoantibodies

The cytoskeleton comprises structural proteins of the cell that support subcellular organization, cellular contractility, and locomotion [122]. The three types of

filaments and fibers include actin microfilaments (6 nm), intermediate sized filaments (15 nm), and microtubules (30 nm). Autoantibodies are revealed by immunofluorescence on substrates such as smooth muscle rich in these components [123]; the smooth muscle layer in mouse gastric mucosal preparations has proved to be a convenient substrate to demonstrate these [124].

Smooth Muscle Antibody (SMA)

It was found in the 1960s that SMA was a reliable marker for autoimmune hepatitis, with numerous studies affirming the high frequency of reactivity, about 70% [125]. While the diagnostic specificity of SMA is tempered by its presence in other destructive liver diseases including PBC, chronic viral hepatitis, and even alcoholic hepatitis, frequencies and titers are substantially lower than in autoimmune hepatitis [122]. It is relevant to the theme of this chapter that the presence of SMA, more than any other reactivity, segregates autoimmune hepatitis from SLE, meaning that SMA is in some way associated with hepatocellular destruction of a type that does not occur in SLE. Technical procedures for optimal testing for SMA are described by Fusconi *et al.* [126], and by Cançado *et al.* [127, 128] who emphasize the need for prior heat inactivation of sera. Ascertaining the subspecificity of the SMA reaction is critically important, as described later.

F-Actin

Actin is a globular protein of 46 kDa that is present in all cells as a constituent of microfilaments, and it is this cytoskeletal reactant that has diagnostic specificity for autoimmune hepatitis. Actin can exist as G-actin which is a monomer, or as F-actin which is polymerized into filaments; the antigenic reactivity depends on the conformation in the native molecule of epitopes which can be destroyed under conditions such as immunoblotting. Unfixed or lightly fixed tissues, for example, vinblastin-treated cultured cells prepared as monolayers for immunofluorescence, are a favored substrate [125]. Antibody to F-actin to high titer is demonstrable in some 70–90% of cases of autoimmune hepatitis in acute or active phases, but frequencies and titers are reduced in remission phases [125]. A report on 99 patients with type 1 autoimmune hepatitis cited a positivity rate of 74%, with this correlating with younger age, progressive disease, and the HLA alleles B8 and DR3 [129]. Reactivity to F-actin has a much higher diagnostic specificity than does generic SMA, a point deemed worthy of reemphasis in a more recent article [130], since SMA reactions in viral infections and other miscellaneous diseases are mostly attributable to antibodies to other cytoskeletal elements, often intermediate filaments (vimentin) [123]. Anti-F actin autoantibodies give additional staining of the mesangium of renal glomeruli, brush borders and peri-tubular fibrils of renal tubules (this used to be called SMA-T) and, with strong reactions, a "polygonal" pattern of staining on liver sections due to the abundant submembranous distribution of actin in liver cells [104, 130, 131] (Fig. 3).

Antibody to F-actin may well have immunopathogenic significance in autoimmune hepatitis, since liver destruction from any cause could result in release of actin that would then behave as an autoantigen in individuals genetically predisposed (see later), and the copious submembranous actin of hepatocytes could serve as a target for an ongoing damaging immune response. However, despite the possible importance of F-actin as autoantigen for diagnosis and pathogenesis, studies on epitope analysis and T-cell responses have not been pursued to the same degree as for many other autoantigens.

Non-actin Cytoskeletal Filaments

Cytoskeletal filaments other than actin (vimentin, tubulin) account for SMA reactions, particularly low titer reactions in nonautoimmune liver diseases and viral infections [104, 123]. Autoantibodies to the intermediate filament desmin are reported in myocarditis, and to tubulin in infectious mononucleosis [125].

Unidentified Anti-liver Membrane Antibodies

The possibility of a specific reactant located in the liver cell membrane has prompted several immunoblotting studies using purified liver membrane preparations. While these consistently show multiple reactants at differing molecular weights, none has yet been identified as a true liver membrane-specific autoantigen. Many of these reactants decrease markedly in intensity of signal after increases in serum dilution beyond 1:1000 and also during immunosuppression-induced remission of disease, and may simply be consequential to hepatocellular damage [131].

Serologic Reactions in Type 2 Autoimmune Hepatitis

Anti-microsomal Autoantibodies

LKM-1 (P450 2D6)

Autoantibodies were detected in CAH in 1973 that reacted by immunofluorescence with cytoplasm of liver cells and the P3 segment of proximal renal tubular cells [45], and their microsomal location led to the designation of liver–kidney microsomal (LKM) antigen. Anti-LKM associated-CAH occurred predominantly in children with rapid progression to cirrhosis. A

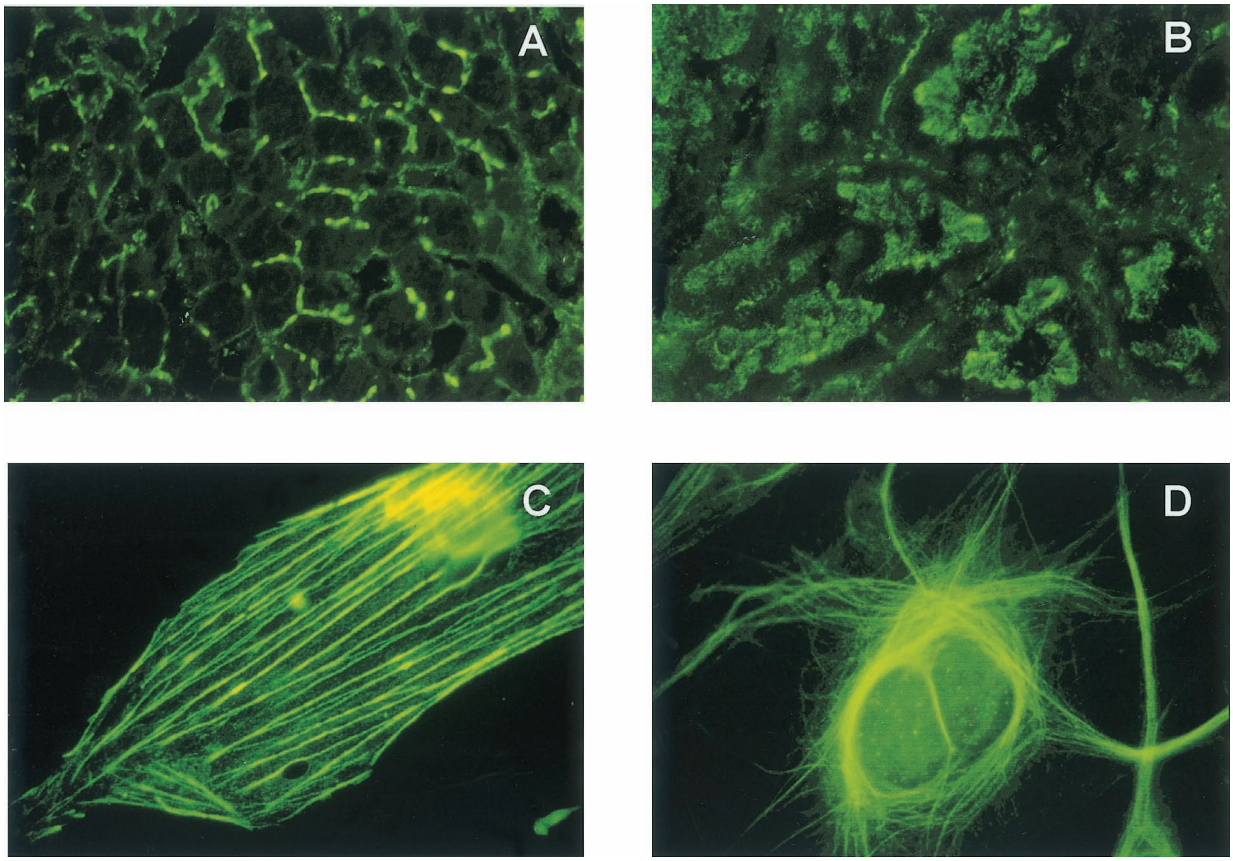

FIGURE 3 Anti-actin specific patterns by immunofluorescence of smooth muscle antibody that differentiate autoimmune hepatitis (**A**–**C**) from other disease sera (**D**). (**A**) Liver showing polygonal staining pattern of submembranous actin; (**B**) kidney showing actin-specific staining of brush borders of renal tubules and peritubular fibrils; (**C** and **D**) cultured fibroblasts showing actin microfilaments ("cables") (**C**), and vimentin intermediate filaments (**D**). (Reproduced by kind permission of publishers of *Autoimmunity* [104].)

dichotomy between the lupoid and anti-LKM types of chronic hepatitis seemed evident from the earliest descriptions [45], and was substantiated in 1987 by analysis of 87 cases [46]. In particular there is a serologic polarization, in that there was no overlap among cases of autoimmune hepatitis of ANA/SMA and anti-LKM reactions. Accordingly, despite similar histopathology and outcome (cirrhosis), there is general recognition of two distinct types, 1 and 2, of autoimmune hepatitis [46, 132] (Table 2). Subsequently different types of anti-LKM were nominated according to the disease background, with the LKM autoantigen associated with spontaneous type 2 disease being LKM-1, and other microsomal reactants being LKM-2 and LKM-3 (see later).

Molecular identification of LKM antigens was achieved during the 1980s, based initially on immunoblotting [133], and later by screening with sera of gene expression libraries [134]. The LKM-1 reactant was revealed as an isoform of the cytochrome oxidase P450 enzyme family, P450 2D6. The P450 2D6 autoantigen contains three linear epitopes of which the most reactive has the sequence DPAQPPRD within the region of residues 257–269 [135]. The molecular identification of the specific reactant for type 2 autoimmune hepatitis is in contrast to the still uncharacterized specific reactant(s) for type 1.

LKM-2 (P450 2C9) and LM (P450 1A2)

An anti-microsomal reactivity of serum, for which the reactant was termed LKM-2, was recognized in 1984 in cases of acute and chronic hepatitis induced occasionally by exposure to medicinal drugs, particularly tienilic acid [136]; the reactant was subsequently identified as another CYP450 isoform, 2C9 [137]. In cases of drug-induced hepatitis provoked by dihydralazine, sera react by immunofluorescence with microsomes only of liver cells; this liver microsomal (LM) reactant was identified

TABLE 2 Comparisons and Contrasts for Type 1 and Type 2 Autoimmune Hepatitis

	Type 1	Type 2[a]
Female	8:1	8:1
Age	Bimodal	Bimodal, peak in early childhood
Course	Progressive, but steroid-responsive	Progressive, but steroid-responsive
Associated clinical features[b]	Arthritis, serositis, cytopenias, colitis, thyroiditis	Thyroiditis, gastritis, diabetes, vitiligo
Genetics, HLA	DR4,B8,DR3,C4AQO haplotype	More data needed
Trigger factors	EBV? HAV? drugs, rarely	None described[c]
Models	See Ref. 104	None described
Autoantibodies to	Various nuclear antigens, esp. chromatin; smooth muscle (actin)	Microsomal cytochrome P450 2D6 (LKM-1), thyrogastric antigens

[a] Data on type 2 from Homberg *et al.* [46].
[b] Type 1 with systemic features can resemble SLE; type 2 does not.
[c] Chronic hepatitis with anti-LKM occurs with HCV infection or hepatic drug reactions, but these cases are diffentiated from spontaneous type 2.

as yet another isoform, CYP450 1A2 [138]. Further still, other drugs can induce immune-mediated hepatitis, each associated with antibodies to a particular CYP450 isoform involved in its hydroxylation [104,139].

A theoretically interesting disease is the LKM-associated type 2 autoimmune hepatitis that occurs in some 10–20% of cases of juveniles with the autoimmune polyendocrine syndrome type 1 (APS-1). This syndrome results from defective function of the nuclear transcriptional protein encoded by the autoimmune regulator (*AIRE*) gene. APS-1 is a complex autoimmune–immunodeficiency syndrome resulting from homozygous inheritance of a mutant *AIRE* gene, and the autoantibody expressions include reactivity to two CYP450 isoforms 1A2 and 2A6 among others [139]. The *AIRE* protein expressed in dendritic cells in various sites is in some way involved in the establishment of immune tolerance, but clinical expressions are limited to organ-specific rather than multisystem disease type autoantigens.

LKM3 (Anti-UDP Glucuronosyl Transferase)

An anti-LKM reactivity was recognized in 1983 in cases of hepatitis associated with delta (D) hepatitis virus infection and became known as anti-LKM-3 [140]. This microsomal autoantigen has been identified not as a CYP450 isoform but instead as the bilirubin conjugating enzyme uridine 5′-diphosphate glucuronosyl transferase (UGT) 1.6 [141]. A rare spontaneously occurring type 2 autoimmune hepatitis has been identified with anti-UGT (LKM-3) reactivity of serum [142]. More recently autoantibodies reacting with various UGT isoforms were detected in 3 of 18 cases of type 2 autoimmune hepatitis, most strongly against UGT1A1 which is the main isoform involved in the glucuronidation and disposal of bilirubin [143].

Liver Cytosol Type 1 (LC-1)

Autoantibodies were recognized in 1988 to a soluble liver cytosolic antigen in children with type 2 autoimmune hepatitis [144], and this reactivity was further characterized in 1992 [145]. Anti-LC1 reactivity is of interest. because it is organ (liver) specific, and also disease-specific for type 2 autoimmune hepatitis in that, unlike LKM-1, it is not demonstrable in chronic hepatitis C virus infection (see later); however, anti-LC1 may occur in children with type 1 autoimmune hepatitis [146]. The LC-1 antigen can be eluted from liver cytosol as a protein of 240–290 kDa and, since the signal by immunoblot under reducing conditions is at 62 kDa, it may exist as a tetramer [147]. By immunofluorescence, anti-LC1 shows a characteristically decreased homogeneous staining of hepatocytes toward the central vein, usually obscured by accompanying anti-LKM-1 reactivity, and is demonstrable also by immunodiffusion, immunoblot, or counterimmunoelectrophoresis [147]. Anti-LC-1 has more recently been identified as formiminotransferase cyclodeaminase (FTCA) or argininosuccinate lysase [131], but FTCA is more likely according to molecular weight [148]. The FTCA molecule has two domains, a globular FT domain joined by a short linker to the CA domain; autoantibodies mainly recognize a conformational structure associated with the FT domain [149].

Hepatitis C Virus and Autoimmune Serologic Reactions

There are many literature citations on the association between HCV infection of the liver and serum reactivities characteristic of autoimmune hepatitis, particularly anti-LKM-1. These raise provocative questions on

etiopathogenesis and therapy, but there are no indications that HCV is an initiator of multisystem autoimmunity [150]. In a study from France on 83 patients with HCV infection, the frequency of anti-LKM (anti CYP450 2D6) was as high as 77% [151]; in common with other studies on HCV–associated anti-LKM-1, titers were relatively low and males were overrepresented. Also, compared with spontaneous type 2 autoimmune hepatitis, there is a selection for an antibody epitope other than that within residues 257–269 of CYP450 2D6 [152]. In regard to autoantibodies associated with type 1 autoimmune hepatitis, HCV infection was reported to be associated with rheumatoid factor, with SMA although actin-specificity was not stated, and with ANA at low frequency, but with AMA very rarely [153]. The predominance of type 1 autoimmune hepatitis in geographic areas of the world where HCV is least endemic, and the absence of markers of HCV infection in typical type 2 in children, argues against HCV being an important antecedent of autoimmune hepatitis. However, the association of LKM-1 reactions with HCV infection and (weak) sequence homologies between envelope proteins of HCV and CYP450 molecules have led to speculation that HCV might, in some instances at least, provide a molecular mimic that could initiate autoimmune hepatitis [154].

How Close Is the Serologic Overlap for Autoimmune Hepatitis and SLE?

With multiple variable disease expressions in autoimmune hepatitis and SLE, some degree of serologic overlap is to be expected. The major overlaps are the presence in both diseases of antibodies to chromatin-histones as the major ANA reactant, anti-DNA albeit weakly expressed in autoimmune hepatitis, and anti-ribosomal P proteins as a low frequency contributor. On the other hand, there are serologic reactions in autoimmune hepatitis that do not occur in SLE, including, in type 1, antibodies to F-actin, to the molecule originally described as soluble liver antigen and now identified as tRNA-associated protein (see earlier), and to various microsomal (CYP450) enzyme antigens and the liver-specified molecule FTCA (LC-1) in type 2 disease. Thus the contrasts outweigh the similarities.

T-Cell Reactivity in Autoimmune Hepatitis

T cells are important in the induction and effector phases of all autoimmune responses, and currently functional assays are based either on cell proliferation or lymphokine release on exposure of T cells to autoantigen. A new technique with future potential based on binding of antigenic peptides (when indentified) to MHC tetramers, should indicate the level of representation in blood or tissues of autoantigen-specific CD8 or CD4 T cells [104]. However, more knowledge is needed on the moieties of autoantigens that are relevant to autoimmune induction, and effector activities of T cells in autoimmune hepatitis as well as in SLE.

IMMUNOGENETICS PREDISPOSITION

General Comments

In Chapter 5 of the previous edition, Reveille optimistically commented "by the time the next edition of this book is published the genetic contribution to SLE will be almost completely defined." The actual progress in the genetics of SLE is discussed herein in Chapter 4, and a 2001 benchmark is struck by the review of Wakeland *et al.* [155]. The latter reviews the genetic contributions of alleles of HLA, Fcγ receptors, and null alleles at complement loci, and results of linkage studies based on genome-wide screens in SLE families that reveal several chromosomal regions of interest. Of note, some regions associated with susceptibility in humans are syntenic with genome segments identified in one or another of the various mouse strains with susceptibility to lupus. Emerging technologies for identification of loci of interest are expected to advance knowledge of SLE very rapidly, but less so for autoimmune hepatitis by reason of the lower population prevalence and level of clinical interest, and absence of a spontaneous disease in animal models [131]. However, when data from genome wide screens do become available from autoimmune hepatitis families, the forecast is for some sharing with SLE of susceptibility loci.

MHC (HLA) Alleles

An association was first recognized in 1971 between type 1 autoimmune hepatitis and the class 1 alleles A1, B8, with B8 as the primary risk allele [156]. Later, a DR3 association was defined, and family studies identified association with the HLA A1-B8-DR3 haplotype with DR3 as the likely risk allele, with linkage disequilibrium explaining the earlier associations [157]. The association with HLA DR3 was widely confirmed and this was calculated to confer a relative risk for disease of 6 to 7 [158]. The DR3 allele was shown to be part of an extended haplotype which included C4A gene deletions [159, 160], providing a genetic basis for low levels of the C4 component of complement in autoimmune hepatitis. An association with DR4 was subsequently recognized [161]. There may exist two nonexclusive immunogenetic subsets of type 1 autoimmune hepatitis, the HLA DR3 subset with a younger age of onset, more

progressive disease, a greater tendency to relapse despite corticosteroid therapy, and a higher requirement for liver transplantation, and an HLA DR4 subset with an older age of onset and more benign disease [162]. Advances in molecular genotyping have further characterized the immunogenetic background of type 1 disease [163, 164]. There is a high representation of the HLA DRB1*0301-DRB3*0101-DQA1*0501-DQB1*0201 haplotype, 52 vs 19% of controls, and a strong secondary association with the DR4 allele DRB1*0401, 54% of DRB3*0101 negative patients compared with 23% of DRB3*0101 negative controls. Among cases from North America, a lysine residue at position 71 of the HLA DRβ polypeptide ($lysine_{71}$) is central to a proposed "disease susceptibility motif" that may bind the still unknown disease initiating autoantigen for type 1 autoimmune hepatitis. There are different HLA risk alleles among populations of non Eurocaucasian background, but these mostly, but not exclusively, express the DRβ1 $lysine_{71}$ disease susceptibility motif [164]. Notably, type 2 autoimmune hepatitis is serologically distinct from type 1, and immunogenetically distinct as well, although susceptibility alleles are yet to be determined [164].

Comparing autoimmune hepatitis with SLE, HLA DR3 is a risk allele for both diseases although the level of risk is lower for SLE (2–3 vs 6–7), whereas DR2 is a risk allele only for SLE, and DR4 only for type 1 autoimmune hepatitis [164, 165]. Complement loci, particularly C4QA null, confer risk for both diseases.

Non-MHC Alleles

Non-MHC (low) risk alleles for type 1 autoimmune hepatitis include the TNG-A gene that results in high constitutive and induced levels of TNF-α, and the G allele of the CTLA-4 molecule that mediates down regulation of the T-cell responses [164]. Inheritance of two copies of mutant autoimmune regulator (*AIRE*) gene leads to a remarkable phenotype of disordered immunity (autoimmune polyendocrine syndrome type 1) that can include a type 2-like autoimmune hepatitis with antibodies to CYP450 isoforms [104], but not SLE. The *sle*1 gene region identified in murine models of SLE, that has a likely ortholog (1q 22–24) in humans according to genome wide scans [155], includes genes that determine nuclear (chromatin) antigen targeting; this region could be implicated as well in type 1 autoimmune hepatitis. Other than the *sle*1 region there are various other suspected loci involved in the pathogenesis of SLE [155, 166] (and see Chapters 3 and 14), with functional effects via clearance of antigen/immune complexes, lymphoid signaling, apoptosis, and epitope modification. The degree of sharing of such genes in autoimmune hepatitis and SLE will be an intriguing question for the future.

In broad outline, genetic determinants of autoimmunity can be collected loosely into four groups. The first group, probably shared among most autoimmune diseases, comprises genes that confer global immunologic hyperresponsiveness, with genes particular to female sex a clear example, or genes that interfere with processes of tolerance including apoptosis, since there is characteristic clustering of similar or different autoimmune expressions within affected patients and related family members. Curiously, however, reported coexistences within autoimmune hepatitis families of cases of SLE [167], are less frequent than would be expected. The second group comprises genes responsible for immunogenetic targeting of immune responses to particular autoantigens, and/or diseases to particular tissues, and includes MHC alleles that encode products with a high binding capacity for a tissue-specific molecule, genes in the *sle*1 region (see earlier), and perhaps genes that influence the assembly and structure for T- and B-cell receptors. The third group of genes includes those that influence events after immune activation, for example, polymorphisms of cytotoxic lymphocyte antigen (CTLA)-4, or genes that encode inflammatory cytokines including tumor necrosis factor. The fourth group, "end organ" genes, influences susceptibility to immune attack of a particular target tissue, for example, the genetic defect in thyroid cells that predisposes to thyroiditis of obese chickens [167]; such genes could confer predisposition to autoimmune damage to the kidney in lupus [155], or in some way confer end-organ susceptibility in autoimmune hepatitis.

ENVIRONMENTAL AGENTS

The understanding of the genetic–environmental interactions that precipitate or perpetuate autoimmune diseases remains sketchy, even for the model diseases in inbred mice that are susceptible to reductionist analysis. Environment contributes 50% of the risk or usually more for autoimmunity, with the simplest explanation being that a source of injury, usually an infectious agent, causes release of intracellular antigens to which tolerance has not been established, with induction of self-reactive lymphocytes that maintains an autoimmune reaction. Additionally, the infectious agent may contain sequences which sufficiently resemble a critical host molecule such that autoimmune induction is potentiated; this molecular mimicry hypothesis is the subject of much contemporary discussion in relation to autoimmunity [168].

Suspected environmental determinants of SLE, including the Epstein-Barr virus (EBV), are discussed in Chapters 3, 44, 45. In autoimmune hepatitis, suspected viruses have included EBV [169] and measles (now considered unlikely) and the hepatitis viruses, particularly A and C (HAV, HCV). Type 1 autoimmune hepatitis is occasionally preceded by HAV infection [40] and the frequent reporting of cases in young women in the 1960s coincided at that time with a wave of endemicity of HAV infection. Type 2 autoimmune hepatitis in adults, but not in children, is associated with markers of HCV infection in some geographical regions [132], and mimicry sequences have been identified between the HCV polyprotein and sequences of cytochrome P450 autoantigen [170]. At present, however, there appears to be insufficient evidence to incriminate virus infection as a trigger for either autoimmune hepatitis or SLE. Therapeutic drugs, although quite infrequent instigators of either autoimmune hepatitis or SLE, raise interesting considerations. A drug-related hepatitis with antibodies to CYP450 can occur after use of drugs disposed of by this pathway [171], but without concomitant expressions of SLE. However, there are some drugs, particularly α-methyl dopa and minocycline, that can induce by unknown means a clinical replica of autoimmune hepatitis, or a syndrome resembling SLE; these conditions are essentially drug-dependant and, unlike the spontaneously occurring counterparts, recede when the offending drug is withdrawn [171].

CONCLUSIONS

This chapter has considered issues raised by the nosologic problems of autoimmune (organ-specific) hepatitis and lupus affecting the liver. Accordingly the chapter included brief comment on the nomenclature of diseases, particularly those for which causes are either unknown or multifactorial and/or which have retained traditional and sometimes illogical names. Three propositions provided the infrastructure to the chapter. First, there is a disease (autoimmune hepatitis, previously CAH) intrinsic to the liver and in the domain of hepatology, that, by reason of its autoimmune causation, can on occasions exhibit sufficient criteria for SLE for it to become coidentified with that disease. Second, SLE itself is a disease with such widespread inflammatory expressions, including "toxic" effects from tissue breakdown, that there will be secondary damage to the liver equivalent to that seen in conditions such as severe infections. Third, there could be a very broad recruitment of immune effector processes, the "lupus process" that might cause damage to the liver of a type similar to that occurring in other tissues, kidney, brain, skin, etc. that are usually affected in lupus. The arguments for convergence include the autoimmune basis for both diseases, the shared serologic feature of anti-nuclear (anti-chromatin) antibody, and some sharing of immunogenetic determinants.

Acknowledgments

Appreciation is expressed to Drs. Josefa Wesierska-Gadek and Nigel Swanston for illustrative material, and Ms. Elaine Pearson for her expert preparation of the manuscript.

THE CELLULAR HEMATOLOGY OF SYSTEMIC LUPUS ERYTHEMATOSUS

Ronit Simantov
Jeffrey Laurence
Ralph L. Nachman

Hematologic abnormalities are common in systemic lupus erythematosus (SLE); nearly every patient will manifest some hematologic disturbance at one point in the disease. If this association is not recognized, such changes can lead to the spurious diagnosis of a primary blood disorder.

The American College of Rheumatology revised criteria for the classification of SLE established hematologic parameters for the diagnosis of SLE (Table 1) [1, 2]. The four attributes emphasized (hemolytic anemia, leukopenia, lymphopenia, and thrombocytopenia) are the most common hematologic abnormalities seen in SLE patients, and are discussed in this chapter, as are some other aspects of cellular hematologic disturbances in SLE.

Hematologic abnormalities are often an initial manifestation of SLE, and are among a variety of important prognostic variables which predict the course of the disease. In a study of 464 patients with SLE, autoimmune hemolytic anemia (AIHA) and immune thrombocytopenic purpura (ITP) represented a serious or life-threatening complication in 8 and 16% of cases, respectively [3]. Similarly, in a prospective study of 126 patients in the Netherlands, hemolytic anemia was found in 13%, neutropenia in 47%, lymphopenia in 20%, and thrombocytopenia, which was also found to be associated with decreased survival, was found in 27% [4]. In a study of familial lupus in French Caucasian patients, thrombocytopenia was found in 21% and hemolytic anemia in 6.6%, a rate similar to that seen in a matched group of patients with sporadic SLE. Although other manifestations of SLE such as renal disease and discoid rash were significantly different in sporadic and familial SLE, the rate of hematologic disase was constant [5].

In general, hematologic abnormalities represent a marker for disease severity in SLE, reflecting the effects of the inflammatory disease on bone marrow function and on peripheral blood cell survival [6]. Characteristics of hematologic abnormalities may predict the course of disease. Therefore, recognition and proper management of hematologic complications in patients with SLE is critical because of differences with respect to prognosis, therapy, and survival.

ANEMIA

Anemia, defined as a hemoglobin <12 g/dl for women and 13.5 g/dl for men, is common in patients with SLE. Multiple pathogenic mechanisms have been recognized, including impaired erythropoieisis, metabolic anemias, and immune-mediated peripheral destruction of red cells. The causes of anemia in SLE are outlined in Table 2.

Anemias Due to Decreased Red Cell Production

The majority of SLE patients with moderate decrements in hemoglobin concentration (8–11 g/dl) and a

TABLE 1 Hematologic Criteria for the Diagnosis of SLE[a]

Hemolytic anemia: hematocrit <35% with an increased reticulocyte index
Leukopenia: <4000/mm^3 on two or more determinations
Lymphopenia: <1500/mm^3 on two or more determinations
Thrombocytopenia: <100,000/mm^3, in the absence of drug therapy known to be associated with a decreased platelet count

Anti-erythropoietin antibodies

normal peripheral blood smear are diagnosed as having anemia of chronic disease (ACD). By definition, ACD excludes anemia due to bleeding, hemolysis, or bone marrow infiltration, and is characterized by hypoferremia with normal or increased serum ferritin; normal or elevated serum total iron binding capacity; increased red cell protoporphyrins; reduced or absent marrow sideroblasts in the presence of adequate iron stores; and a normal bone marrow myeloid to erythroid ratio. The pathogenesis of ACD is related to ineffective iron incorporation into the erythron despite normal iron stores. This may be due to trapping of iron in cytokine-activated macrophages, effectively reducing the amount of circulating iron available to developing erythrons [7].

In patients with ACD, the plasma level of erythropoietin is often low in relation to hemoglobin concentration. Patients with SLE have been found to have high levels of inflammatory cytokines which may be related to the pathogenesis of ACD [8]. *In vitro*, IL-1 and TNF-α, as well as interferon α and interferon β, inhibit erythropoietin mRNA levels and erythropoietin synthesis in cell cultures and perfused rat kidney models [9]. Inflammation-associated cytokines, such as TNF-α, IL-1, and TGF-β, have an inhibitory effect on erythroid colony formation *in vitro* [10]. It is likely, therefore, that the pathophysiology of ACD in patients with SLE involves the inhibition of erythropoietin production by inflammatory cytokines, and impaired response of the bone marrow to erythropoietin.

The ACD in SLE complicated by renal failure represents a distinct subset of patients with normochromic, normocytic anemias. The most important pathophysiologic mechanism in the anemia of renal failure is bone marrow hypoproliferation due to a decrease in erythropoietin production by the diseased kidney. Recombinant erythropoietin therapy has been shown to be safe and effective in the treatment of anemia of chronic renal disease [11, 12]. In addition, it is essential that iron stores be adequate in all SLE patients with anemia.

There is evidence that recombinant erythropoietin can improve the hematocrit in patients with impaired erythropoiesis due to inflammatory disease. Erythropoietin therapy has been used in patients with ACD related to rheumatoid arthritis, malignancies, AIDS, and inflammatory bowel disease, with improvement in hematocrit by several percentage points, a decrease in red cell transfusion requirements, and an improvement in quality of life parameters [13]. A randomized, placebo-controlled trial of erythropoietin therapy in rheumatoid arthritis patients showed a significant improvement in hemoglobin concentration and an overall decrease in disease activity [14]. In a study of recombinant erythropoietin therapy in five patients with SLE without renal failure, at doses of 400 units once a week to 3000 units three times a week for 3–7 months, all patients experienced a rise in the hematocrit (mean increase from 32 ± 2 to 42.2 ± 3), with decrease to baseline values 1 to 2 months after erythropoietin was discontinued. SLE activity measured by serum C3, creatinine, and urinalysis was not affected, and therapy was tolerated well, although one patient with anticardiolipin antibodies had an episode of thrombophlebitis while on erythropoietin therapy [15].

Although recombinant erythropoietin therapy may be appropriate for certain subsets of patients, including those who have severe anemia requiring transfusion [16], more recent studies have shown resistance to erythropoietin activity in SLE due to autoantibodies directed against erythropoietin [17]. In a series of 100 SLE patients with anemia, anti-erythropoietin antibodies were detected in 21, although the presence of these antibodies did not correlate directly with the level of anemia [18]. Anti-erythropoietin antibodies have also been demonstrated in pure red cell aplasia (PRCA), an immune-mediated anemia characterized by normochromic, normocytic anemia, reticulocytopenia, and marrow erythroid hypoplasia [19]. Antibodies in PRCA, a rare cause of anemia in SLE [20], have been reported to inhibit proliferation of erythroid precursors as demonstrated by decreased colony-forming units of

erythropoiesis (CFU-E) in bone marrow cultures [21, 22].

Erythropoietin therapy has been used with some success in patients with PRCA [23], even in patients with high endogenous erythropoietin levels [24, 25]. It has been proposed that pharmacologic doses of erythropoietin may overcome the interaction of autoantibodies with erythropoietin receptors on red cell precursors.

Other treatment modalities for presumed immune causes of PRCA have included high-dose cyclophosphamide, cyclosporin A, danazol, azathioprine, antilymphocyte globulin, and intravenous gamma globulin [26, 27]. An important etiology to exclude as a cause of aplasia is infection with human parvovirus B19, which may clinically mimic SLE, and is generally treated with intravenous gamma globulin [28, 29].

Iron deficiency anemia due to blood loss or malabsorption may occur in SLE, alone or in combination with other anemias. In a series of 132 SLE patients with anemia, iron deficiency anemia was as common as ACD (35.6 and 37.1%, respectively) [21]. The peripheral blood smear in iron deficiency reveals microcytic, hypochromic erythrocytes with anisocytosis and poikylocytosis. Thrombocytosis is a common finding. Iron studies reveal hypoferremia, elevated total iron binding capacity, and low transferrin saturation. Serum ferritin generally correlates well with storage iron levels but may appear normal in the setting of inflammatory processes. Bone marrow examination shows low or absent stainable iron.

Menstrual losses and/or pregnancy may explain iron deficiency in younger women with SLE, however, the finding of iron deficiency warrants a search for an underlying cause if there is no obvious source of bleeding. Patients with SLE may be particularly susceptible to gastrointestinal loss of iron due to the use of non-steroidal anti-inflammatory drugs, aspirin, and steroids. Therapy includes oral or parenteral iron supplementation.

Autoimmune Hemolytic Anemia

Increased erythrocyte destruction by autoantibodies, known as autoimmune hemolytic anemia (AIHA), can be an initial manifestation of SLE and occurs in approximately 10% of patients with SLE [4, 30]. Laboratory findings include anemia with reticulocytosis and a positive direct antiglobulin test (DAT, direct Coombs test), which detects IgG or C3b bound to the red blood cell membrane. A positive DAT may be found in SLE without concomitant hemolysis. Occasionally, the indirect antiglobulin test is also positive, indicating circulating autoantibodies to erythrocytes [31].

Additional laboratory testing includes indirect bilirubin and serum lactate dehydrogenase, which are elevated in hemolytic anemia, serum haptoglobin, which may be decreased. Review of the peripheral blood smear may reveal anisocytosis, spherocytosis, polychromasia, and nucleated red blood cells.

Erythrocyte autoantibodies are classified into two main groups based on their thermal requirements: "warm" antibodies of IgG or IgA isotype that associate with red cells optimally at 37°C; and IgM "cold" antibodies, which characteristically bind at 20°–25°C and dissociate when the temperature is raised to 35°C but coat the cell with complement. The most common form of AIHA is "warm" antibody AIHA, mediated by the binding of IgG (most often IgG1 or IgG3) and/or complement to antigens on the erythrocyte. The autoantibody is often directed toward an antigen in the Rh system. After binding to the erythrocyte, the Fc portion of the antibody then mediates binding to Fc receptors on splenic macrophages, resulting in destruction of the erythrocyte and clearance from the circulation.

Detailed serologic examination is indicated in actively hemolyzing patients with AIHA. Detection of antibodies may occasionally be complicated by the presence of circulating autoantibodies in patients with SLE. Serologic testing initially involves the DAT and ABO/Rh phenotyping. If the DAT is positive, a red cell eluate is made and tested for antibody reactivity, then titrated for quantitation and tested for specificity against a panel of red blood cells. If the DAT is negative but AIHA is strongly suspected, the more sensitive polybrene method is used. The serum is initially screened at 20° and 37°C, and tested for cold agglutinin. Further testing is done to determine thermal range and specificity, and antibodies are titrated against standard red cell panels for quantitation and specificity determination. In recently transfused patients, testing for alloantibodies is also done.

The cellular basis for AIHA in SLE can be divided into three areas: (1) cells responsible for autoantibody formation; (2) cells responsible for regulation of antibody-producing cells including T lymphocytes, monocytes, and idiotypic networks; and (3) cells which mediate the destruction of antibody-coated erythrocytes. The ultimate resolution of AIHA lies in the capacity to reestablish normal immunologic control mechanisms.

Several experimental models have helped to elucidate the mechanism of AIHA. The New Zealand Black (NZB) strain of mice spontaneously develops AIHA, and has been an important tool in studying the disease. Specific autoantibodies generated from these mice have been useful in characterizing red blood cell epitopes recognized by autoantibodies in AIHA [32, 33]. Studies

have shown the importance of genes regulating apoptosis in the development of autoreactive B cell clones. In particular, the expression of the bcl-2 gene can inhibit the autoantigen-induced apoptosis of B cells in the periphery, but not of immature B cells in the bone marrow, suggesting that regulation of autoreactive B cells occurs by a different mechanism in the bone marrow [34]. Transgenic models of autoimmune disease have also been useful in the study of AIHA. The anti-red blood cell Ig H + L (HL) mice were generated by introducing the heavy and light chain genes from an NZB-derived anti-red blood cell autoantibody producing hybridoma into fertilized mouse ova. The HL mice demonstrate hemolytic anemia despite clonal deletion of autoreactive B cells in the bone marrow and peripheral lymph nodes. In these mice, peritoneal cavity lymphocytes are sequestered without exposure to "self" red blood cell antigens and expand, subsequently undergoing activation by environmental antigens resulting in AIHA [35].

The importance of T helper cells in the expansion and activation of autoreactive B cells in the development of AIHA was supported by studies of RAG-2–/– mice, which lack mature B and T cells, crossed with HL mice. The RAG-2–/– × HL mice did not develop AIHA, indicating that the presence of T helper cells was required for the manifestations of the disease [36]. When the bcl-2 gene was introduced into HL mice, autoreactive B cells in the peritoneal cavity showed prolonged survival due to decreased apoptosis, and AIHA was potentiated. The cytokine network and genetic control leading to the generation and survival of B cells with specificity to erythrocytes remains to be elucidated.

Other mechanisms may also be involved in the pathophysiology of SLE-linked AIHA. In a prospective study of 500 consecutive patients with SLE, Alarcon-Segovia *et al.* showed that there was a significant association between the presence of hemolytic anemia and antiphospholipid antibodies (APLA) [37]. This relationship has been confirmed in other studies and suggests that the generation of APLA is not secondary to the hemolytic process, but rather may have some pathogenic significance in certain cases of AIHA [38, 39].

Therapy of AIHA is generally indicated in the presence of progressive hemolytic anemia with hemoglobin falling below 7 g/dl. Corticosteroids are the treatment of choice in IgG-mediated AIHA, with an initial daily dose of 1 mg/kg prednisone or its equivalent. Supplementary folic acid should be given to all patients with hemolytic anemia, due to increased requirements in the setting of rapid cell turnover. Response to therapy, indicated by increasing hematocrit and decreased reticulocyte count, is usually seen within 2 to 3 weeks. For responders, the prednisone is slowly tapered by about 5 mg daily every week. Approximately 75% of SLE patients have a serologic and clinical response to this therapy, although a positive DAT may persist following treatment.

The mechanism of corticosteroid activity is thought to be through the inhibition of binding of opsonized erythrocytes by Fc-receptors on mononuclear phagocytes. Corticosteroids decrease the number of Fc receptors expressed on monocytes, and can block the Fc receptor directly by competitive binding. In addition, corticosteroids inhibit the synthesis of autoantibodies by B cells [40].

Red blood cell transfusions may be indicated in the presence life-threatening anemia. Alternate forms of immunosuppressive therapy, including cyclosporin, cyclophosphamide, and azathioprine, are used to treat steroid-resistant AIHA. Because the spleen is the site of destruction of opsonized erythrocytes, splenectomy has long been used as a treatment of AIHA. Remission in response to splenectomy has been reported to be 50–75% [41]. Attempts have been made to predict response to splenectomy, which has been reported to be less successful in SLE patients than in non-SLE related AIHA. A valid predictor of response to splenectomy includes antibody type, as "warm" AIHA is more responsive than cold agglutinin–related hemolysis. Patients showing an initial prompt response to steroids are often reported to respond favorably to splenectomy compared to patients who require prolonged treatment; however, satisfactory remission rates in response to splenectomy have also been reported in patients who failed corticosteroid therapy [42]. Some patients will continue to require steroids to maintain a remission even after splenectomy [43].

Danazol, 600–800 mg per day, also appears a useful adjunct to glucocorticoid therapy in severe AIHA or in cases of steroid treatment failure [44]. Other therapeutic modalities include immunosuppressive therapy such as azathioprine and cyclophosphamide, which have been shown in uncontrolled trials to benefit patients who were unresponsive to steroids, splenectomy, or both. Antilymphocyte sera has been employed with variable and usually short-lived benefit. Plasmapheresis and plasma exchange has also been used, followed by maintenance therapy with an immunosuppressive agent [45]. Intravenous gamma globulin has also had positive results in patients with refractory AIHA [46]. Alternative therapy directed against autoantibody-producing cells includes Rituximab, an anti-CD20 monoclonal antibody which specifically depletes B lymphocyte and is approved for the treatment of lymphomas. Rituximab should be considered for treatment of refractory, life-threatening AIHA given several positive reports in patients with and without SLE [47].

Autoimmune hemolytic anemia occurring together with immune thrombocytopenia (ITP) is known as

Evans' syndrome. Patients usually have isolated episodes of thrombocytopenia and hemolytic anemia, which may also be accompanied by neutropenia. Autoantibodies against erythrocytes, platelets, and neutrophils have been demonstrated, and are directed against distinct, non-cross-reactive epitopes on red cells and platelets [48]. Evans' syndrome is seen in lupus patients and may be associated with a syndrome of immune dysregulation characterized by generalized lymphadenopathy and abnormal serum immunoglobulins, as well as with primary immunodeficiencies, lymphoproliferative disorders, and autoimmune lymphoproliferative syndrome [49, 50]. Treatment includes corticosteroids, cyclosporin, and intravenous immune globulin, although patients typically have a chronic and relapsing course with significant morbidity and mortality [51].

Other Causes of Anemia

Porphyria

Subsequent to the association of SLE with porphyria, first recognized in 1952, there have been numerous case reports of SLE associated with porphyria cutanea tarda, acute intermittent porphyria, and porphyria variegata [52].

Systemic lupus erythematosus and the hepatic porphyrias share a number of features, including rash, fever, photosensitivity, mucous membrane lesions, gastrointestinal symptoms, neuropathy, and psychosis. Both diseases may also be precipitated by sun exposure, fatigue, and drugs. Shared pathophysiologic mechanisms are suggested by findings of similar patterns of immunoglobulin and complement deposition in the epidermal basement membrane and dermal blood vessels. Case reports have emphasized the similarities in dermatologic and pathophysiologic features of SLE and porphyria cutanea tarda, other clinical SLE manifestations are often absent [53, 54]. Similarly, in a series of 15 patients with acute intermittent porphyria, 8 (53%) had a positive ANA, although only 1 had clinical evidence of SLE [55]. Indeed, the clinical and serologic data suggestive of a connective tissue disorder, when arising in an individual with porphyria cutanea tarda, may be secondary to hepatic dysfunction or to hepatitis C infection [56, 57].

THROMBOCYTOPENIA

Platelets are essential for normal hemostasis, acting to form an occlusive platelet plug at the site of injury and to accelerate the localized activation of circulating plasma procoagulants. Normal platelet counts range from 150,000–450,000/μl and the normal life span of circulating platelets is 7–10 days. Thrombocytopenia has been found to be present in 15–25% of SLE patients and is associated with increased mortality. In a single-institution study of 665 patients with SLE followed prospectively for 20 years, thrombocytopenia ($<100{,}000/mm^3$) was found to be an independent predictor for mortality, along with renal disease, lung involvement, disease activity, and age [58]. In a study of 389 patients with SLE, thrombocytopenia was found to be the only independent risk factor of poor prognosis [59]. Thrombocytopenia was also found to be one of several independent predictors of 6-month mortality in a series of 806 patients followed at the University of Toronto [60]. Interestingly, however, hemorrhagic complications of thrombocytopenia were a rare cause of death in these series. In a cohort of 300 lupus patients in the United Kingdom, 5% had hemolytic anemia and 17% had thrombocytopenia. In the 41 patients who died, the most common cause of death was malignancy (20%), and thrombocytopenia was not associated with an increased risk of death [61]. Acute thrombocytopenia occurring during SLE flares is particularly associated with complications and increased mortality [62].

The major causes of thrombocytopenia in SLE patients with platelet counts below $100{,}000/mm^3$ include (1) hypoproliferative thrombocytopenias; (2) peripheral destruction of platelets; and (3) abnormal platelet distribution due to congestive splenomegaly. The most common cause of thrombocytopenias is likely drug effect, and hundreds of different medications have been implicated. Medications causing peripheral destruction of platelets include quinine, quinidine, aspirin, heparin, sulfonamides, and non-steroidal anti-inflammatory drugs. Other agents, including thiazides, ethanol, and chemotherapeutic agents lead to depressed megakaryopoiesis. In this context, all drugs or chemicals should be suspected in patients with thrombocytopenia.

A study to determine the strength of clinical evidence for individual drugs as a cause of thrombocytopenia reviewed 515 patient case reports on patients with drug-induced thrombocytopenia (excluding heparin). In 247 patient case reports (48%), the drug appeared to be the causal agent of thrombocytopenia. Although a number of the reports reviewed in this study did not provide direct evidence for drug-related thrombocytopenia, over 98 drugs were implicated in thrombocytopenia, most frequently quinidine, trimethoprim-sulfamethoxazole, and gold [63].

An important, often underrecognized cause of thrombocytopenia in hospitalized patients is heparin-induced thrombocytopenia. This syndrome is characterized by a decrease in the platelet count typically 4 or more days after the onset of heparin exposure, and may

be accompanied by serious venous or arterial thrombosis. It is important to consider this diagnosis in SLE patients who are being treated with heparin, as the syndrome may mimic catastrophic antiphospholipid syndrome or vasculitis flare. The etiology involves the production of heparin-dependent anti-platelet factor 4 (PF4) antibodies which bind to platelets and endothelial cells and lead to immunologic destruction of platelets and a high risk of thromboembolic disease. Heparin is absolutely contraindicated in this condition and treatment should be initiated with a direct thrombin inhibitor such as lepirudin or argatroban [64].

In immune-mediated thrombocytopenias, the mechanism of platelet destruction involves the coating of platelets with IgG autoantibodies and clearance from the circulation by the phagocytic cells of the reticuloendothelial system. The platelet autoantibodies frequently are directed toward glycoprotein IIb/IIIa or GPIb/IX, the major adhesive protein receptors on the platelet surface. Circulating immune complexes are observed in some patients. In patients with chronic ITP, T cells reactive with altered GPIIb/IIIa complexes or with peptide fragments of GPIIb/IIIa have been detected. These reactive T cells were $CD4^+$ and HLA-DR restricted, and were involved in production of anti-GPIIb/IIIa antibodies in peripheral blood mixed lymphocyte cultures from ITP patients [65]. Attempts have been made to differentiate immune-mediated thrombocytopenia in SLE patients from "classic" ITP. Similar levels of platelet-associated IgG have been observed, but differences in T-cell responses have been noted [66].

Several studies have documented an association between the development of thrombocytopenia in patient with SLE and the presence of anti-phospholipid antibodies. Patients with a circulating lupus anti-coagulant or anti-cardiolipin antibody were three times more likely to have a history of a moderate to severe thrombocytopenia than were antibody-negative patients [67]. The presence of anti-phospholipid antibodies is associated with more severe thrombocytopenia in patients with SLE, but is also associated with endothelial cell activation and incurs a greater risk of thrombosis rather than clinical bleeding [68, 69]. The frequency of thrombocytopenia in SLE patients with anti-phospholipid antibodies has been shown to be 13–40% according to several series [70]. Conversely, a study of 109 patients with ITP showed that 69 (46%) had a positive lupus anti-coagulant or anti-cardiolipin antibody [71].

The diagnosis of ITP is made by excluding secondary causes of thrombocytopenia due to medications or associated with other illnesses [72]. Patients generally present with purpura, petechiae, gingival bleeding, and, in more severe cases, hemorrhagic bullae. Splenomegaly is evidence against ITP [73]. Typical characteristics of the history in ITP patients and findings on physical examination are described in Table 3.

TABLE 3 Diagnosis of ITP in SLE Patients[a]

History
Bleeding symptoms
Type of bleeding
Severity of bleeding
Systemic symptoms
Weight loss
Fevers
SLE disease activity
HIV risk factors
Pregnancy status
Medications
Alcohol use
Transfusion history
Comorbid conditions
Liver disease—may cause thrombocytopenia
Acute renal or neurologic dysfunction—suggest thrombotic thrombocytopenic purpura (TTP)
Physical examination
Skin: petechiae, ecchymoses
Mucosal signs of bleeding
Spleen—lack of splenomegaly
Evidence for thrombosis—consistent with anti-phospholipid antibody syndrome
Lymph nodes—enlargement consistent with SLE, or may suggest lymphoproliferative disease

[a] Adapted from Practice Guidelines in ITP developed by the American Society of Hematology [75].

The peripheral blood smear in ITP reveals a decrease in the number of platelets and an increase in megathrombocytes, and the bone marrow contains an increased number of megakaryocytes [74]. Laboratory studies for the diagnosis of ITP in SLE patients are outlined in Table 4. In order to standardize diagnosis and management of ITP, the American Society of Hematology convened a panel to establish specific practice guidelines for ITP. This guideline, which was published in 1996, is based on review of scientific evidence where available, and, for areas in diagnosis and management of ITP where only case series or no evidence was available, based on the consensus opinion of the expert panel [75].

The strategy of treatment of ITP associated with SLE is the same as for the idiopathic cases, with consideration of immediate need for intervention, long-term benefits, and long-term hazards of each therapeutic option. The benefits of steroid therapy for ITP have been known since the introduction of glucocorticoids into clinical practice in the early 1950s, and corticosteroids remain mainstay of therapy. Prednisone 1–2 mg/kg per day is the initial therapy of choice in ITP patients with

TABLE 4 Laboratory Studies in SLE Patients with Suspected ITP

Complete blood count
Peripheral blood smear
Findings consistent with ITP
Thrombocytopenia, some large platelets
Normal red blood cell morphology
Normal white blood cell morphology
Lupus anti-coagulant/anti-cardiolipin antibody
Bone marrow aspirate/biopsy
Findings consistent with ITP
Increased number of megakaryocyte
Normal myeloid and erythroid maturation
Consider
Biochemistry profile: BUN/creatinine, LDH
Direct antiglobulin test
HIV test
Thyroid function tests
Coagulation studies

platelet counts <30,000/mm^3 and/or purpura or other bleeding. If there is a response with a normalization of the platelet count over 1 to 2 weeks, prednisone is tapered by 5–10 mg/week. Although there are no randomized controlled trials comparing glucocorticoids to no treatment, or any studies showing an effect of glucocorticoids on overall morbidity or mortality, retrospective studies have reported complete response rates to steroids in adults to be 30–38%, overall response rates of platelet counts greater than 50,000/mm^3 of 65–80%, and prolonged remissions to steroids of 15–20% [76]. The proposed mechanism of corticosteroid action is decreased Fc-mediated clearance by antibody-coated platelets, and decreased production of autoantibodies. Corticosteroids may also reverse the bleeding diathesis prior to a rise in platelet count, by inhibition of vascular endothelial cell activation with resultant decrease in vascular permeability and vasoconstriction of the capillary bed.

Splenectomy is the oldest form of therapy for ITP. Platelets reside in the intravascular compartment and are destroyed by macrophages in the splenic sinusoids. The spleen provides an optimal microenvironment for the interaction of antibody- or immune-complex-coated platelets with phagocytes. Splenectomy is recommended for patients with persistent platelet counts <10,000/mm^3 for 6 weeks and little or no response to therapy. Splenectomy has been shown to lead to increase in platelet counts; however, a number of patients will relapse years after splenectomy. Response to splenectomy has been reported to be 50–80% in different case series, with 60–80% of patients achieving durable responses; half of relapses occur in the first 6 months [77, 78]. Laparoscopic splenectomy has been demonstrated to be effective in patients with ITP [79]. It is important to note that splenectomy is associated with a risk of infection with bacterial organisms, and patients should be vaccinated with pneumococcal, meningococcal, and *Haemophilus influenzae* vaccines prior to splenectomy.

IVIG, 1–2 gm/kg over 2 to 5 days, may be used in patients who are refractory to treatment with glucocorticoids, preoperatively prior to splenectomy, or in initial treatment for patients with severe bleeding. Anti-Rho (D), 50 µg/kg, should be considered in patients who are blood group Rh (+) and have not been splenectomized or for those in whom splenectomy is not feasible. In a study of 272 patients with ITP, a hemostatic platelet increase was found in greater than 70% of the Rh+ non-splenectomized patients. Response in splenectomized patients was minimal [80]. The proposed mechanism of action is blockade of the reticuloendothelial system with antibody–red cell antigen complexes. An advantage over intravenous immunoglobulin is the lower cost. Hemolysis may be seen, although it is generally moderate and self-limited.

Patients who relapse after splenectomy may be treated with prednisone at the lowest doses possible to maintain a safe platelet count. However, some patients will not respond to corticosteroids or will need doses higher than 10–15 mg/day, which might lead to unacceptable side effects and necessitate treatment with other agents. There is no single established algorithm for treatment of refractory ITP and pharmacologic treatment should be based on individual patient needs and the side effect profiles for the medications. If corticosteroids have failed, the next recommended agents are danazol 200 mg four times a day, vincristine 1–2 mg/week, colchicine, 0.6 mg three times per day, dapsone 75–100 mg per day, or vincristine 1–2 mg per week (IV). More potent immunosuppressive agents, including azathioprine 150 mg per day, oral cyclophosphamide (2 mg/kg per day), or high-dose intravenous cyclophosphamide (1–1.5 mg/m^2 every 4 weeks), may also be considered. Cyclosporin A is associated with a 40–50% response rate [81]. Pulsed high-dose dexamethasone (40 mg per day for 4 days) and high-dose intravenous methylprednisolone (15 mg/kg/day for 3 days) therapy [82] have also been used with some success in patients with refractory ITP [83]. Vincristine- and vinblastine-loaded allogeneic platelets have been used with some success in patients with refractory ITP (as well as refractory AIHA) as a method of delivering targeted vinca alkaloid to the reticuloendothelial system [84]. Some patients who do not respond to other pharmacologic

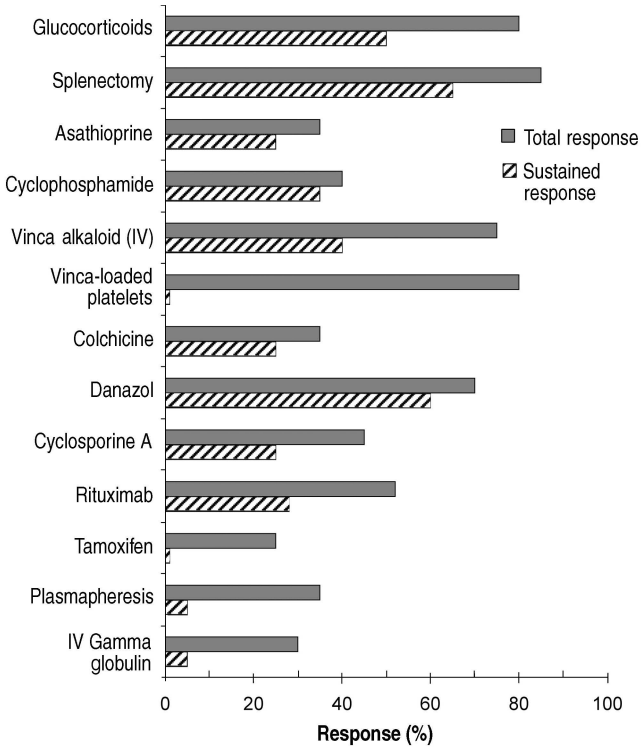

FIGURE 1 Rates of response (total or sustained) achieved with various therapeutic modalities for ITP are shown.

therapy continue to respond to intravenous gamma globulin at doses of 0.5–1.0 g/kg, although responses are always transient, lasting a few weeks, and the therapy is expensive. Reports have demonstrated the effectiveness of Rituximab, a chimeric monoclonal antibody directed against the CD20 antigen on B lymphocytes leading to B-cell depletion, in treatment of patients with chronic ITP [85]. Rates of response to various therapies for ITP are shown in Fig. 1.

A retrospective analysis of 59 patients with SLE and ITP showed that 80% of the 50 patients who were treated with prednisone alone responded initially but only 12% of these patients had a sustained remission. More favorable sustained responses were seen in patients treated with a combination of prednisone and either danazol or hydroxychloroquine (50 and 64%, respectively). Splenectomy was performed in 17 patients, 10 of whom had a sustained long-term response (65%) [86].

Thrombotic thrombocytopenic purpura (TTP) is comprised of a pentad of symptoms: thrombocytopenia, microangiopathic hemolytic anemia, fever, renal dysfunction, and neurologic manifestations. TTP has been described in patients with SLE, but strict criteria for an association are difficult to define as manifestations of SLE mimic many of the features of TTP [87]. In children, unlike in adults, TTP is associated with the development of SLE within the subsequent 4 years [88]. More recent discoveries have shed light on the pathogenesis of TTP. Plasma from patients with TTP has been found to contain unusually high molecular weight multimers of von Willebrand's factor (VWF). Levy *et al.* showed that patients with a rare familial form of TTP have inherited mutations in ADAMTS13, a member of the ADAMTS (a disintegrin-like domain, a metalloproteinase domain, and thrombospondin motifs) family of protein-cleaving proteases [89]. Simultaneously, three other groups reported the identification of ADAMTS13 as a protease that can cleave plasma VWF [90, 91]. Patients with TTP have been shown to contain an antibody against the protease [92]. SLE patients have been shown to contain an antibody against the von Willebrand factor protease and demonstrate reduced protease activity even in the absence of TTP. The significance of these findings in SLE remains to be explored [93].

The pathophysiology of TTP may also be related to the effect of plasma factors in TTP patients on microvascular endothelial cells (EC). Exposure of microvascular EC to diluted TTP plasma leads to the induction of apoptosis of EC [94]. Untreated TTP is fatal in over 80% of cases. Treatment of TTP includes emergent plasma infusion, plasmapheresis, steroids, and vincristine [95, 96].

Qualitative Platelet Defects

At sites of vascular injury, platelets adhere to the endothelium, display receptors for binding of fibrinogen and other coagulant factors, aggregate to form a hemostatic plug, and catalyze the rapid, localized production of thrombin. Within seconds, activated platelets release preformed vasoactive substances that contract vessels and accelerate blood clotting. They rapidly synthesize and release lipid mediators such as thromboxane A2 (TXA2), a potent vasoconstrictor and platelet activator.

Drug-induced platelet dysfunctions are the most frequent platelet disorders, and impaired platelet aggregation due to aspirin is by far the most common platelet dysfunction. Aspirin specifically blocks TXA2 formation in platelets by irreversibly inactivating platelet cyclooxygenase, a key enzyme in synthesis of TXA2. Platelets do not contain the inducible enzyme, cyclooxygenase-2 (COX-2), but only the constitutive form, cyclooxygenase-1, so that the new specific inhibitors of COX-2 developed for anti-inflammatory effects do not inhibit platelet function and thus do not induce a bleeding tendency. The thienopyridines such as clopidogrel block ADP binding to its receptors on platelets and therefore decrease platelet activation by

ADP but do not block the TXA2 pathway. Clopidogrel is used in prevention of thrombosis in vascular stents and for prevention of stroke and myocardial infarction.

Systemic lupus erythematosus patients also manifest autoimmune-mediated qualitative platelet defects. Antibodies directed against GPIIb/IIIa, the glycoprotein membrane receptor for fibrinogen, have been reported in SLE and can induce a thrombasthenia-like syndrome if they interact with or block functional sites on the GPIIb/IIIa complex. SLE patients with acquired storage pool deficiencies have also been reported.

Platelet adhesion requires interaction of membrane GPIb receptors with collagen or von Willebrand's factor (vWF) Acquired von Willebrand's disease is a rare complication of SLE [97]. In acquired von Willebrand's disease, the pathogenic mechanisms responsible include binding of anti-vWF IgG antibodies to vWF on endothelial cells and platelets leading to early removal of the vWF and a diminished level of large multimeric vWF, as well as the inactivation of vWF function by circulating anti-vWF antibodies [98]. Treatment of acquired VWD is similar to that of congenital disease, with replacement of factor or use of desmopressin to augment release of vWF, in conjunction with immunosuppressive agents [99].

LEUKOPENIA

Leukopenia, defined as a total peripheral blood count of less than 4500/mm^3 is common in SLE patients. Occasionally the leukocyte count will transiently fall to as low as 1000/mm^3; however, such a profound decrement should not be ascribed to SLE without a thorough search for other etiologies including drugs (e.g., antimalarials and immunosuppressive agents).

Although it might be anticipated that the leukopenia would be associated with an increased incidence of infection, in the absence of other factors this appears not to be the case. This was established by a prospective study of the clinical course of 223 SLE patients followed for 655 patient-years [100]. In this study, the frequency of infection increased progressively with increasing corticosteroid dose; however, leukopenia did not predispose to infection. These observations were confirmed by other studies which showed that bacterial infections were more frequent in SLE patients than in matched controls; however, no correlation was seen with levels of leukopenia [101]. The potential causes of leukopenia, related to peripheral destruction by immune- and non-immune-mediated mechanisms, sequestration, and drugs, are listed in Table 5 and discussed later.

Leukocytosis, in contrast, is rare in SLE in the absence of infection or corticosteroid therapy, though elevations in the leukocyte count may be seen during an acute exacerbation of SLE. During corticosteroid administration, leukocytosis with a relative lymphopenia is common because of granulocytosis.

TABLE 5 Mechanisms of Leukopenia in SLE

Anti-neutrophil antibodies
Anti-lymphocyte antibodies
Cross-reactive antibodies (e.g., anti-Ro)
Drug-induced
Bone marrow dysfunction
Decreased progenitor pool
Inadequate mobilization response
Peripheral destruction
Hypersplenism
Immune complexes
Circulating apoptotic neutrophils

Neutropenia

In a study of 126 patients with SLE, neutropenia occurred in 47%; however, there was no association of neutropenia with infections or overall mortality. The mechanisms of neutropenia in SLE include neutrophil-reactive autoantibodies, bone marrow suppression, and increased neutrophil apoptosis. Qualitative abnormalities of a range of granulocyte functions (adherence to vascular endothelium, chemotaxis, phagocytosis, and microbial killing) have been reported in SLE as well.

Anti-neutrophil antibodies have been described in patients with SLE in several series [102, 103]. Circulating neutrophils in SLE commonly bear increased amounts of membrane immunoglobulin, related to both immune-complex deposition and anti-neutrophil antibody. Evidence for antibody-mediated peripheral destruction in the autoimmune neutropenias is well documented [104]. Antigen specificity has been described but its significance is not known; anti-neutrophil cytoplasmic antibodies from a series of pediatric patients with SLE were directed toward a number of neutrophil antigens, including myeloperoxidase, cathepsin G, and elastase. These specificities, however, did not correlate with disease activity or with target organ involvement [105]. Specific autoantibodies to ribonucleoprotein particles (anti-Ro) have been shown to bind to a cross-reactive neutrophil membrane protein [106].

Arenas *et al.* found that the number of myeloid CFU-C is lower in SLE patients with severe neutropenia, suggesting an inhibition of myeloid development in patients with SLE [107]. Whether this inhibition is medi-

ated by cellular immunity, autoantibody effects, or bone marrow microenvironment is not known, although IgG autoantibodies from patients with SLE have been shown to bind to CD34 positive hematopoietic precursor cells [108]. Finally, SLE patients have been found to have increased numbers of apoptotic neutrophils, which correlate with increased disease activity [109]. One proposed mechanism is decreased expression of monocyte CD44 in SLE, leading to decreased binding and clearance of apoptotic neutrophils by monocyte-derived macrophages [110].

Recombinant human granulocyte colony stimulating factor (GCSF) has been used in combination with antibiotics to treat SLE patients with impaired wound healing, with a subsequent rise in their neutrophil counts [111]. Neutrophil counts have been shown to increase, with a decrease in the number of serious infections [112, 113]. Patients with SLE and neutropenia have also been treated with GCSF. GCSF has also been combined with high-dose corticosteroids in neutropenic patients with SLE [114]. GCSF and GM-CSF are generally well-tolerated, with the primary side effect being bone pain, although arthritis flares and leukocytoplasmic vasculitis have been reported in patients receiving GCSF [115]. The use of colony-stimulating factors remains a reasonable treatment option in selected patients with SLE whose neutrophil counts are below 1000/mm^3; however, studies of optimal use and cost–benefit analyses have yet to be performed [116].

Lymphocytes

Lymphopenia in SLE patients generally occurs during acute phases of the disease, with lymphocyte counts rising following effective therapy. Of 361 patients examined for 24 clinical and laboratory variables, lymphopenia was the only factor that occurred more frequently with increased age [117]. Lymphocytopenia is strongly associated with the presence of anti-Ro (SSA0 antibodies and with anti-ssDNA [118]. There is considerable evidence that anti-lymphocyte antibodies (ALA) may have a significant influence on the number and function of lymphocytes in SLE. These antibodies have been shown to react with T cells and disrupt T-cell functions such as interferon production. Another suggested mechanism of ALA-induced lymphopenia is the induction of cytokines which may in turn lead to reduced lymphocyte number [119]. Various specificities of SLE ALA have been related to lymphocyte membrane antigens as well as neural, nuclear, spermatozoan, and trophoblatic determinants. ALA have also been implicated in the pathogenesis of neuropsychiatric manifestations of SLE [120].

A proposed mechanism of lymphopenia associated with SLE is the regulation of apoptosis, involving Fas antigen and Fas ligand interactions. Fas antigen, a cell-surface molecule found in lymphocytes, mediates the transduction of apoptotic signals induced by activation [121, 122]. Fas antigen is also expressed on hematopoietic progenitor cells and may be involved in the regulation of hematopoiesis [123]. Lymphopoiesis has been explored in two murine models of SLE, the MRL-lpr/lpr mouse, which is defective in Fas antigen, and the C3H-gld/gld mouse, which has a defective Fas ligand. These studies showed that Fas/Fas ligand interactions caused apoptosis of T lymphocytes. In addition, overexpression of Fas antigen directly suppressed lymphopoiesis [124].

Monocytes

The percentage of monocytes in SLE is often greater than in normal controls, although absolute monocytosis (>800/mm^3) is unusual. Monocyte function such as generation of respiratory burst induced by phagocytosis has been shown to be decreased in monocytes isolated from patients with SLE [125]. Dysregulation of monocyte differentiation has also been observed in patients with SLE. Monocytes isolated from SLE patients were found to function as antigen-presenting cells *in vitro*, and serum from SLE patients induced normal monocytes to differentiate into antigen-presenting dendritic cells, which can induce T-cell activation and B-cell growth and differentiation, and may be involved in the induction of autoimmune responses [126]. Dysregulation of the production of cytokines such as IL-1 receptor antagonist [127], IL-10 [128], and IL-6 [129] by monocytes in SLE patients, may also play a role in the immunologic processes in this disease. These interactions are discussed in greater detail in other chapters.

Natural Killer Cells

Natural killer cells (NK) express the antigen CD56 and represent approximately 5% of circulating and splenic leukocytes. Natural killer cytotoxicity is a distinct arm of the host immune surveillance system and may be important in the elimination of tumors and virus-infected cells. NK bind to susceptible targets and effect rapid lysis, a function which has been reported to be impaired in SLE patients. NK cell cytolytic activity was shown to be greatly reduced in children with SLE, and defective function persisted even during inactive phases of the disease [130]. NK cells are also decreased in number in SLE patients, particularly during active disease [131].

BONE MARROW DISEASE IN SYSTEMIC LUPUS ERYTHEMATOSUS

The role of the bone marrow microenvironment in the maintenance of normal hematopoiesis is a subject of intense study. Cytokines produced by bone marrow stromal cells are essential for the differentiation and development of hematopoietic cells. Emerging characterization of bone marrow in patients with SLE has revealed defects in some of these processes, some of which may be important in the etiology of red cell hypoplastic syndromes in SLE [132]. Similarly, findings such as dyserythropoiesis, megaloblastic changes, or marrow hypoplasia, which suggest impaired erythroid production, may help to explain an impaired reticulocyte response in some SLE patients with AIHA [133]. Bone marrows of patients with lupus and cytopenias have also been reported to have storage and hemophagocytic histiocytes [134].

Myelofibrosis is a myeloproliferative disease characterized by the abnormal growth of erythroid, myeloid, and other hematopoietic precursors; varying degrees of marrow fibrosis; and extramedullary myeloid metaplasia in the spleen and liver. The pathogenesis of the prominent fibrosis is controversial, both in idiopathic cases and in those associated with infection, malignancy, and SLE, but may relate to the release of cytokines which stimulate fibroblast proliferation and collagen and fibronectin production. The onset is usually insidious, with symptoms of anemia or splenomegaly. Several cases have been recorded in association with SLE, and have been generally characterized by anemia and a leukoerythroblastic appearance on peripheral blood smear [135]. In addition, there have been a number of case reports of myelofibrosis as the presenting manifestation of SLE [136, 137]. Treatments that have been used include high-dose steroids as well as intravenous immunoglobulin, which may improve cytopenias but may not have a profound effect on the extent of bone marrow fibrosis [138].

Antimetabolite drugs such as azathioprine are often employed as immunosuppressive agents in SLE. The main hematopoietic toxicity of azathioprine is bone marrow depression with anemia, leukopenia, and thrombocytopenia. Long-term use of alkylating agents such as cyclophosphamide is also associated with an increased risk of myelodysplastic syndrome and secondary acute leukemia, which has been reported in SLE [139]. Close monitoring of hematologic parameters is important in patients receiving myelotoxic therapy.

Primary bone marrow failure, presenting with pancytopenia and a hypocellular bone marrow, also occurs in SLE [140]. Although the pathophysiologic mechanism of the bone marrow suppression is unknown, there is evidence to suggest an immune-mediated suppression of hematopoietic progenitor cell growth and differentiation. Therefore, management consists of immunosuppressive therapy in addition to replacement of blood products and management of infection.

Primary therapy may include withdrawal of myelotoxic drugs, high-dose corticosteroids, and possibly growth factors. Some patients may benefit from antithymocyte globulin (ATG), horse or rabbit antibody raised against human lymphocytes, a mainstay of therapy for aplastic anemia in patients without SLE. Prednisone 1 mg/kg is administered concomitantly to ameliorate the serum sickness associated with ATG. Several centers have incorporated methylprednisolone into combination treatment with ATG, cyclosporin, and/or androgenic steroids [141]. Allogeneic bone marrow transplantation is the treatment of choice for young patients with severe aplastic anemia who have an HLA-identical sibling donor [142].

Lymphadenopathy

Lymph node enlargement occurs in 50% of all SLE patients at some point in their clinical course. The most common nodal groups involved are cervical (43%), mesenteric (21%), axillary (18%), and inguinal (17%). Palpable nodes are typically nontender, soft, discrete, and vary from one to several centimeters. Pathology of lymph nodes is characterized by paracortical foci of necrosis and infiltration by histiocytes, lymphocytes, plasma cells, and immunoblasts [143]. The "hematoxylin bodies" seen in necrotic loci, which may contain aggregates of DNA, immunoglobulin, and polysaccharide, are considered pathognomonic of lupus lymphadenitis, but are not always present [144]. The histiocytic necrotizing lymphadenitis of SLE is pathologically similar to Kikuchi-Fujimoto disease, a self-limited systemic illness seen in young patients and characterized by lymphadenopathy [145].

Myeloid and Lymphoid Malignancies in SLE

Considerable attention has been directed toward the possible association of hematologic or other malignancies with SLE. While several studies have reported an association between SLE and lymphoproliferative malignancies, especially non-Hodgkin's lymphoma, the relationship between SLE and solid tumor malignancies remains controversial [146, 147].

A study of 724 SLE patients in a single center in Toronto identified 23 cancers (3.2%) over 7233 patient-years of follow-up. Three of these patients had non-

Hodgkin's lymphoma, and 3 others had other hematologic malignancies, implying a relative risk of 4.2 for hematologic malignancies. There was no increase in the risk for solid tumors in SLE patients in this study [148]. A Danish study of 1585 patients with SLE followed for an average of 6.8 years revealed 8 cases of non-Hodgkin's lymphoma (relative risk 5.2, 95% confidence interval 2.2–10.3). A significantly increased relative risk of cancer of the lung (15 cases), liver (5 cases), and vulva (3 cases) was also found [149]. Cervical cancer risk was found to be increased in a cohort of 297 SLE patients followed at the University of Saskatchewan [150]. In a British cohort of 276 SLE patients followed between 1978 and 1999, only the incidence of Hodgkin's lymphoma was increased as compared with the general population, and there was no correlation between with cytotoxic therapy and malignancy [151]. A proposed mechanism of the etiology of B-cell malignancies in SLE patients is that clones of self-reacting B cells undergo dramatic expansion in lymph nodes and are sensitive to DNA damage. Other possibilities include infectious etiologies such as Epstein-Barr virus (EBV) or common apoptotic defects in lupus and B-cell malignancies [152]. Further studies will be needed to address the potential pathogenic mechanisms of this association, which may involve immunosuppressive therapy, a common etiologic agent, immunoregulatory phenomena, or genetic factors.

ARTICULAR MANIFESTATIONS OF SYSTEMIC LUPUS ERYTHEMATOSUS

Paul E. Di Cesare
Craig J. Della Valle
Joseph D. Zuckerman

ABSTRACT

Articular manifestations of systemic lupus erythematosus (SLE) include both small and large joints, the spine, and the complications associated with chronic steroid use such as osteonecrosis, osteoporosis, and stress fracture. Of the large joints, the knees, and of the small joints, the proximal interphalangeal joints of the hands are most commonly involved. Less frequently involved joints are the wrists, shoulders, ankles, and elbows. Periarticular symptoms can also be seen in SLE including enthesopathy, tenosynovitis, tendinopathy, and myositis as well as periarticular calcifications and nodules.

Osteonecrosis of the hip, knee, shoulder or talus may affect up to 20% of patients with SLE. Although a given patient may have osteonecrosis at mulitple sites, the femoral head is most commonly affected and bilateral involvement is common. Because of its frequency and the significant disability that can result (particularly in the young lupus population), osteonecrosis is the articular manifestation of SLE with the most morbidity. Although the precise pathogenesis of osteonecrosis is unclear, it is clearly related to the use of corticosteroids. This chapter includes an in-depth discussion of the epidemeology, pathogenesis, diagnosis, and classification of osteonecrosis and reviews both operative and nonoperative treatment options.

INTRODUCTION

Patients with systemic lupus erythematosus (SLE) do not constitute a uniform group due to the great variability in its manifestations, thereby making difficult both the diagnosis and management of this condition. The articular manifestations that are a major symptom of SLE resemble those in other rheumatic diseases and thus are not pathognomonic. The initial presentation of SLE is often insidious, with symmetric arthralgias, and as a result many of these patients are frequently misdiagnosed to have rheumatoid arthritis (RA). A nondeforming, nonerosive arthritis is considered the most characteristic articular manifestation of SLE. Rheumatic complaints can only be attributed to SLE when they occur in a setting of other well-recognized symptoms and laboratory parameters detailed elsewhere in this book. In this chapter, we review the clinical and pathologic features of the articular manifestations of SLE.

Joint pain is one of the most common presentations of SLE, occurring in 76–100% of patients [1–5]. Clinical symptoms can range from obvious arthritis with objective evidence of inflammation (e.g., painful joint motion, tenderness, erythema, or effusion) to a painful joint without any objective evidence of inflammation. Symptomatic joints can often precede the other systemic manifestations of SLE. Morning stiffness is another

common joint complaint. The arthropathy of SLE is usually symmetric, similar to RA; however, the arthritis can be short-lived, resolving within 24 h, or behave as a persistent synovitis lasting longer than 6 months. In all cases, SLE arthropathy is characterized by an inconsistency between the severe rheumatic symptoms that can be present and modest physical and radiographic changes [6, 7].

Articular manifestations of SLE include both small and large joints, the spine, and the complications associated with chronic steroid use such as osteonecrosis, osteoporosis, and stress fracture. Of the large joints, the knees, and of the small joints, the proximal interphalangeal joints of the hands are most commonly involved. Less frequently involved joints are the wrists, shoulders, ankles, and elbows [8]. Clinical symptoms localized to the hip should alert the physician to the possibility of osteonecrosis, since this joint is rarely otherwise affected. The clinician should be alert to the possibility of septic arthritis in patients with SLE. SLE patients may have impaired host immune defenses secondary to either the disease process or immunosuppressive therapy. As a result, all new joint effusions should be promptly evaluated for infection. If an inflammatory fluid is encountered, it is suggested that antibiotics be started while awaiting synovial fluid cultures even if the initial Gram stain is not diagnostic. Septic arthritis caused by *Salmonella*, *Enterococcus*, *Neisseria gonorrhea*, and other organisms have been reported in SLE and may be particularly common in patients with a history of osteonecrosis [9–12].

"LUPUS HAND"

Jaccoud's Arthropathy

As in patients with RA, the hands of the SLE patient may be helpful to the disease diagnosis [13, 14]. In 1962, Zvaifler [15] described the characteristic flexion deformities and ulnar deviation of the metacarpophalangeal (MP) joints commonly observed in SLE patients. What was remarkable about his finding was the absence of any changes in the cartilage or bone (Fig. 1). Bywaters [16] astutely noted the similarity of the hand deformities in SLE to those of the Jaccoud's type. These nonerosive, reducible joint subluxations were thus termed Jaccoud's arthropathy, and as a result alerted clinicians that hand involvement in SLE could be deforming. The important finding in most cases was that the deformity is reducible or correctable. Swelling of the proximal interphalangeal and metacarpophalangeal

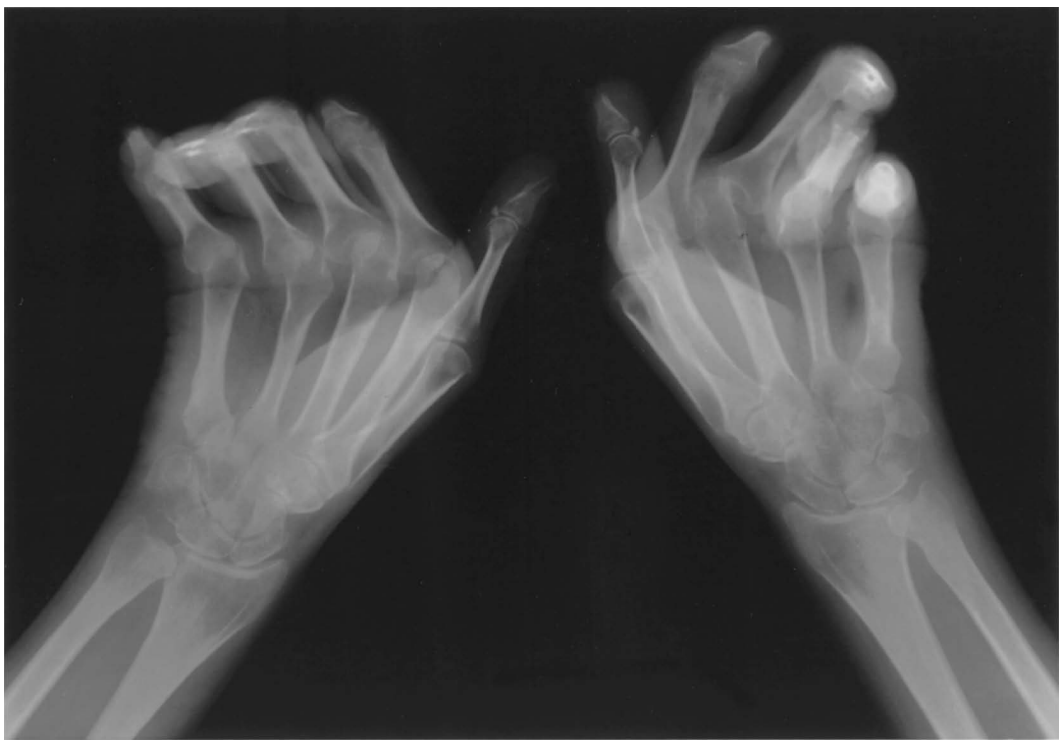

FIGURE 1 Radiographs of the hands of an SLE patient illustrating Jaccoud's arthropathy. Characteristic flexion deformities and ulnar deviation of the metacarpophalangeal joints is seen with the absence of any changes in the cartilage or bone.

joints is the predominant manifestation of SLE in the hand. Hand and wrist deformities include ulnar deviation and subluxation, swan-neck deformities, and thumb interphalangeal (IP) joint subluxations. Figures 2–6 illustrate reducible hand deformities in a patient with long-standing SLE. In SLE patients the presence of Jaccoud's arthropathy occurs more often in patients with a longer disease duration and a longer history of joint involvement [17].

Pathogenesis of Lupus Hand

The hand deformities of SLE patients appear to be secondary to involvement of periarticular tissues (i.e., joint capsule, ligaments, and tendons) resulting in hypermobile digits with reducible deformities. Hand joint deformities can occur without the erosive destruction of articular cartilage that is seen in rheumatoid arthritis. These deformities are usually the result of volar plate and ligamentous laxity as well as tendon subluxation, which lead to joint imbalance [13, 14]. Russell *et al*. [18] reported on the operative findings in several SLE patients with hand deformities. They noted in three patients at surgery (with bilateral palmar subluxation and ulnar deviation at the metacarpophalangeal joints) normal-appearing articular cartilage in all cases, a modest inflammatory synovial membrane in one case, and a marked synovial hyperplasia in another case (histology revealed only a mild mononuclear cell infiltration). These surgical findings further illustrate the differentiation of SLE hand deformities from those seen in the rheumatoid patient. In RA the appearance of joint deformities is consistent with radiographic demonstration of bony erosions and joint degeneration, in contrast to the joint deformities in SLE, which are usually nonerosive and reducible (Jaccoud's arthropathy). Joint erosions or degeneration can occur in SLE patients; however, they are usually nonprogressive and are thought to result from capsular pressure and altered joint mechanics created by joint subluxation.

Clinical Findings of Lupus Hand

In 1973, Bleifeld and Inglis [19] reported on the clinical hand findings in 50 SLE patients. They noted generalized soft tissue laxity in 50% and swan-neck deformities in 38% of patients. Most deformities were symmetric and involved two or more fingers on each hand. The swan-neck deformity was thought to result from laxity of the volar plate with dorsal displacement of the extensor tendon lateral bands. Since they noted no intrinsic muscle contractures and the proximal interphalangeal joints had maintained full flexion, the deformities were easily reducible. Hyperextension of the interphalangeal joint of the thumb was observed in 30% of patients; however, in contrast to thumb deformities seen in the rheumatoid hand, it was not associated with a flexion deformity of the first metacarpophalangeal

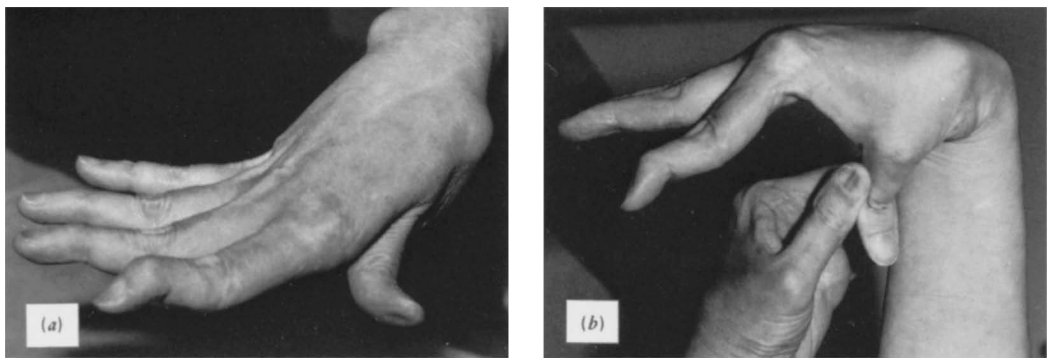

FIGURE 3 (*a*) Swan-neck deformity of the second and third digits. (*b*) Hyperextension of the first interphalangeal joint. (Courtesy of Harry D. Fisher.)

joint. The carpometacarpal joint of the thumb could be subluxated in 16% of patients. Reducible ulnar deviation of the metacarpophalangeal joints occurred in 14% of patients. No cases of metacarpophalangeal joint subluxation were seen. Excessive lateral instability in the distal interphalangeal joints was common. Radiographic examination of these patients' hands revealed no articular destruction except for narrowing of the intercarpal joints in 1 of the 50 patients. The hand deformities noted previously have been since corroborated by Labowitz and Schumacher [2], Esdaile *et al*. [20], Russell *et al*. [18], and Kramer *et al*. [21].

Metacarpophalangeal Joint Abnormalities

The characteristic volar subluxation and ulnar deviation hand deformity of SLE occurs at the metacarpophalangeal (MP) joint. Patients often have full active finger flexion, but a loss of active finger extension. Initially patients can passively extend their finger, but gradually lose this ability with time. The pathologic sequence of deformity that follows includes ulnar subluxation of the extensor tendon, volar subluxation of the proximal phalanx, and intrinsic muscle contracture, while there is still preservation of the articular surface. Surgical treatment of the MP hand deformities includes intrinsic muscle lengthening, release, or transfer, metacarpal "step-cut" osteotomies, and Swanson MP arthroplasties [13].

Interphalangeal Joint Abnormalities

Involvement of the interphalangeal joints (IP) due to laxity of the supporting soft tissue structures can lead to hyperextention, flexion, and lateral deviation deformities. If the deformity remains reducible, then rebalancing surgical procedures can be performed. If the deformity becomes fixed, then fusion of the IP in a functional position is indicated. It is important to emphasize that the restoration of IP joint alignment is essential in order to maintain MP joint realignment [13].

Thumb Abnormalities

The first hand deformity to occur is often that of the thumb, as patients complain of a painless loss of pinching ability [22, 23]. Lateral subluxation of the thumb IP joint is a frequent manifestation, with preservation of the articular surfaces. In order to restore pinching ability, fusion of the thumb IP joint is the surgical treatment of choice. The thumb MP joint can also be the location of deformity as a result of extensor pollicis longus (EPL) subluxation resulting in abnormal thumb flexion. Lateral subluxation may also occur secondary

to collateral ligament laxity. Treatment for this type of thumb deformity may involve EPL rerouting if the IP joint requires fusion or MP fusion when the deformity cannot be passively corrected (13).

Carpometacarpal Joint Abnormalities

Primary subluxation or dislocation can occur at the carpometacarpal (CM) joint. If the thumb MP and IP joints are functioning well and aligned, then a CM fusion with the thumb metacarpal slightly abducted can be performed. An alternative surgical procedure is soft tissue stabilization with rerouting of the flexor carpi radialis as a sling with or without resection arthroplasty [13].

Abnormalities and Treatment of the Wrist

The ligamentous support of the wrist may also be affected, as noneroded carpal bones may sublux or dislocate. Subluxation can occur at either the midcarpal or radiocarpal joints. The most common carpal dislocation involves the lunate [23]; in these cases, surgical treatment of a limited or total wrist fusion may be indicated [13]. Another common wrist problem in SLE patients is dorsal subluxation of the ulna, as patients can present with wrist pain and limited pronation and supination. Much as in RA, untreated dorsal ulna subluxation can lead to extensor tendon rupture by attrition, and surgical treatment may be necessary; Nalebuff recommends a Darrach procedure in these cases [13].

ARTHROPATHY OF THE FEET, SACROILIAC JOINT, AND SPINE

The Foot in SLE

In SLE patients, Jaccoud's arthropathy can occur in the small joints of the foot with approximately the same frequency as in the hands, and in a similar manner [24]. Morley *et al*. [25] reported on 3 patients with bilateral subluxations of the metatarsophalangeal and interphalangeal joints of the toes. In "lupus foot," suggested by Mizutani and Quismorio [26], the most common abnormalities are metatarsophalangeal subluxation, hallux valgus, hammertoes, and forefoot widening without erosions or cystic lesions. Foot deformities were passively correctable in 12 of 14 patients. The patients most frequently affected were those with hand involvement and long-standing disease. Foot deformities can result in painful bunions and callosities, and it is recommended that proper shoe wear and meticulous foot care be instituted to prevent complications [27].

Sacroiliac Joint Abnormalities in SLE

Sacroiliitis, while typically affecting patients with seronegative arthritis, has also been reported in SLE patients [28]. Asymptomatic sacroiliitis has been observed on both radiographs and bone scans of SLE patients [29] with a male predominance [30]. Nassanova *et al*. noted that the male SLE patients with asymptomatic sacroiliitis were negative for HLA B-27 [30]. Symptomatic sacroiliitis, although rare, is seen in some SLE patients [28, 29] presenting as low back pain that is aggravated by movement. As with other acute joint inflammations in SLE patients, infection in the sacroiliac must be ruled out. Treatment with nonsteroidal anti-inflammatory medications (NSAIDs) or steroids may be needed.

Spinal Abnormalities in SLE

The spine in patients with SLE can also be involved. Pathologic lesions may involve the osseous structures, ligamentous complexes, or neural elements of the spine. The majority of spinal involvement in SLE patients occurs in the upper cervical spine, but it can also involve the subaxial spine.

Atlantoaxial Instability

Atlantoaxial instability, most commonly associated with rheumatoid arthritis, also occurs in SLE patients. In a prospective study, Babini *et al*. reported an incidence of atlantoaxial instability in 8.5% of SLE patients based on flexion–extension radiographs [31]. The mechanism by which this instability occurs is unknown, although it has been postulated to be due to generalized laxity of the cervical ligaments similar to that seen in other synovial joints (Jaccoud's arthropathy). None of the patients in this series had associated erosive bony changes. Atlantoaxial instability was associated with longer disease duration, Jaccoud's arthropathy, articular hypermobility, chronic renal failure, and elevated PTH levels. No recommendations or guidelines for the treatment of cervical instability were given, as all these patients were asymptomatic.

LESS FREQUENTLY ENCOUNTERED ARTICULAR AND PERIARTICULAR MANIFESTATIONS OF SYSTEMIC LUPUS ERYTHEMATOSUS

The Shoulder, Hip, and Knee

The shoulders, hips, and knees can be involved in SLE, although they are less frequently involved than are the hands. Jaccoud's arthropathy has been used to

describe large joint involvement and has been reported to occur in shoulders and knees, most cases being symmetrical [32, 33]. Clinical signs of swelling, usually due to soft tissue thickening and joint effusions, are minimal, and joint subluxations or dislocations that are initially reversible can become fixed [27]. Synovitis or Jaccoud's arthropathy of the hip is rare, and therefore any hip or groin pain in an SLE patient should be considered due to osteonecrosis until proven otherwise. One rare and unusual articular manifestation of SLE is erosion of the temporomandibular joint [34, 35]. A diagnostic symptom may be complaint of recurrent earaches.

Periarticular Manifestations

Infrequently, periarticular symptoms can also be seen in SLE.

Enthesopathy and Tenosynovitis

Enthesopathy, defined as inflammation of ligaments, tendons, or joint capsules at their sites of attachment to bone, can also occur. Tenosynovitis has been reported in less than 10% of SLE patients [3]. In a study performed at the Hospital for Joint Diseases, 9 of 70 SLE patients had at least one episode of enthesopathy, including epicondylitis, rotator cuff tendonitis, achilles tendonitis, posterior tibial tendonitis, or plantar fasciitis. Some of these patients also exhibited a concurrent axial arthritis with or without sacroiliitis associated with an asymmetric lower extremity oligoarticular arthritis. Two of seven patients were positive for HLA B27, a proportion similar to the institutional control group. The dominant autoantibody in these patients was anti-nucleoprotein [36].

Tendon Ruptures

Tendon degeneration and rupture has been associated with chronic corticosteroid use, extended disease duration, and presence of other musculoskeletal complications [37]. Several investigators have described infrapatellar tendon rupture [38–40]; in some cases involvement can be bilateral. The clinical presentation is frequently acute, with both physical findings (inability to extend the knee actively, tenderness, and a palpable defect over the area of the rupture) and radiographic findings (a high-riding patella). Although only a few cases have been reported in the literature, it should be noted that there has been a tendency for male predominance in tendon rupture. Histology of ruptured tendons revealed linear hemorrhages, chronic degenerative changes, and vascular infiltration with mononuclear cells. Pritchard and Berney, seeking to identify the frequency of patellar tendon rupture in SLE patients over a 10-year period, reported this phenomenon in 4 of 180 [39]. They noted that all patients with a tendon rupture had been on prednisone for 7–15 years and had other complications associated with chronic steroid use such as osteonecrosis and vertebral compression fractures. Their review of the literature on 17 other cases of patella tendon rupture in SLE patients revealed the same risk factors for development of this complication, including chronic steroid use, extended disease duration, and presence of other musculoskeletal complications. Bilateral achilles tendon rupture has also been reported [41] and is possibly due to a combination of underlying disease and the degenerative changes that result from corticosteroid therapy.

Myositis and Myalgia

Muscle tenderness (40–48% of patients) and generalized myalgia in the proximal limb musculature are common in patients with lupus flares. Inflammatory myositis (5–11% of patients) involving the proximal musculature can be diagnosed by elevated creatinine phosphokinase levels, electromyography (EMG), and muscle biopsy and should be differentiated from proximal weakness due to a drug-induced myopathy secondary to glucocorticoids or antimalarials. There are no cases in the literature of rhabdomyolysis in SLE patients [27]. The EMG findings, which in SLE patients are similar to those observed in dermatomyositis–polymyositis patients, include spontaneous fibrillations, positive potentials, small amplitude, polyphasic potentials, and repetitive high-frequency potentials. Muscle biopsy findings can be normal or show interstitial inflammation, fibrillar necrosis, and degeneration [42].

Nodules and Soft Tissue Calcifications

Subcutaneous Nodules

Subcutaneous nodules have been observed in SLE patients [43, 44]. The histology of SLE nodules may be distinctly different from that of RA nodules. The histology from four nodule biopsies from Larson's series (44) revealed nonspecific inflammation, erythema nodosum, benign mesenchymoma, or fatty necrosis. In another report, Hahn *et al*. [45] described the histology of three biopsied periarticular subcutaneous nodules. In contrast to the observations of Larson, these nodule biopsy specimens revealed deep subcutaneous lesions with central necrosis surrounded by epithelial cells, suggesting that they resembled rheumatoid nodules. Subcutaneous nodules are usually associated with clin-

ically active SLE and may change size in conjunction with disease activity (shrink or disappear with declining disease activity, reappear or increase in size with disease exacerbation). It is speculated that theses nodules result from a common initial event of necrotizing inflammation in the small arteries of the subcutaneous tissue resulting in tissue necrosis distal to the damaged vessels followed by the formation of granulation tissue.

Soft Tissue Calcifications

Soft tissue calcifications that are more prominent in other collagen–vascular diseases (e.g., progressive systemic sclerosis, dermatomyositis, polymyositis) are uncommon in SLE. In most cases, the soft tissue calcification seen in SLE patients is noted as an incidental finding on radiographs, as patients are typically asymptomatic. In SLE, the calcific deposits, if present, are most frequently localized to the lower extremities. Minami *et al*. [46] reported two cases of subcutaneous calcification of the forearm in patients with SLE that were excised surgically. The histology revealed pure calcium phosphate crystals.

Calcinosis Universalis

Calcinosis universalis (deposits of calcium phosphate in muscle, subcutaneous nodules, or periarticular tissues) has been observed in discoid and SLE patients. Weinberger *et al*. reported on an SLE patient with calcinosis universalis who underwent spontaneous remission 1 year after systemic steroid therapy was started [47]. Only approximately 30 cases of calcinosis universalis have been reported in SLE patients [48]. The current recommended nonoperative treatment is diltiazem (a calcium channel blocker) [27].

SYNOVIAL FLUID AND TISSUE IN SYSTEMIC LUPUS ERYTHEMATOSUS

Synovial Fluid

Joint effusions are typically infrequent and of small volume in patients with SLE. Several investigators have reported synovial fluid analysis from SLE patients. Gross description of the SLE synovial fluid is usually a clear to slightly cloudy fluid with good viscosity and mucin clot reflecting a lack of inflammation (suggesting no breakdown of hyaluronic acid by hyaluronidase). Histologic analysis has revealed the presence of lupus erythematosus cells (LE cells), and immunologic analysis has revealed the presence of anti-nuclear antibodies (ANA). Pekin and Zvaifler [49] reported on synovial fluid analysis from 26 SLE patients. In their series, the synovial fluid white blood cell count was less than 2000/mm^3 in 19 of 26 samples and greater than 10,000/mm^3 in only 2 samples. Analysis of the cells revealed that they were predominately mononuclear. Twelve of the specimens of synovial fluid from this study underwent further analysis. Four specimens had the features of a transudate, with an expected high ratio of serum/synovial fluid levels of complement, total protein, and IgG. It was postulated that the noninflammatory transudate resulted from a generalized change in the periarticular vascular permeability, thereby causing a dilution of synovial fluid by edema fluid. The other eight specimens exhibited the features of an exudate. Of these, three had serum/synovial fluid ratios (of complement, total protein, and IgG) approaching 1, indicating a proportional escape of proteins into the joint fluid, which is typical of an exudative effusion; in the other five, the ratio of serum complement to synovial fluid complement was elevated, in contrast to the ratios obtained for either total protein or IgG concentration (i.e., the synovial fluid complement concentration was lower relative to either the protein or IgG concentration), suggesting the local consumption of complement in or just before it entered the synovial fluid. The mechanism of complement consumption, however, is still unknown. The latter five exudative effusions, three of which had the highest white cell counts, with reduced complement content and higher total protein and IgG content, were reminiscent of the synovial fluid seen in RA. A distinguishing feature of SLE joint fluid may be that they typically have fewer polymorphonuclear leukocytes than rheumatoid joint fluid.

Synovial fluid analysis is not pathognomonic for SLE. Many earlier investigators relied only on the LE cell preparation for diagnosis of SLE since they did not have more specific laboratory tests (e.g., kinetoplast of the *Crithidiae luciliae* for detection of antibodies to native DNA and "immunoblot" or Western blot techniques for the detection of soluble RNA–protein conjugate antigens of Sm specificity). The presence of antibodies to both nDNA and Sm from synovial fluid samples is extremely suggestive of SLE [50].

Synovial Tissue

Most investigators have observed that the synovial histopathology in SLE is nonspecific [51–53]. Histologic analysis of synovial tissue has yielded some insights into the pathogenesis of the arthropathy in SLE patients. In 1959, Cruickshank [54], examining histologic specimens obtained from autopsies of 10 SLE patients, observed diminished synovial lining cells, minimal inflammation,

and hematoxylin bodies in the synovial cell layer (thought to be tissue analogs of the LE cell inclusion bodies containing nuclear debris). A thick layer of superficial fibrin-like material deposited along the synovial surface and within the synovium was also observed, with only minimal perivascular inflammation.

Subsequent histologic analyses of needle biopsy synovial fluid specimens have noted greater lining cell proliferation, inflammation, and vascular lesions. Labowitz and Schumacher [2] using light microscopy, observed superficial fibrin-like material on the synovial membrane, focal or diffuse synovial lining cell proliferation, variable inflammation (predominantly of perivascular mononuclear cells), and occasional small vessel wall infiltration suggestive of vasculitis. Many of the vessel lumens were obliterated due to enlarged endothelial cells, inflammatory cells, and organized thrombi. Histologic analysis of specimens from two patients without clinical signs of joint inflammation showed synovial inflammation and vascular lesions. Electron microscopy revealed superficial fibrin-like material in most specimens in the absence of typical fibrin periodicity; lining-cell proliferation consisting of type A (phagocytic), type B (synthesize hyaluronidate), and type C (intermediate and secretory) cells with no clear cellular predominance; necrotic cells and nuclear debris scattered throughout the superficial and deep synovial lining layer; disorganized and multilaminated vascular basement membranes; and enlarged vascular endothelial cells occluding some lumens. Erythrocytes and polymorphonuclear leukocytes were also observed in some specimens in gaps between venular epithelial cells. Aggregates of microtubules reminiscent of paramyxoviruses were seen as vascular endothelial inclusions in some samples. In only one specimen was there a small amount of electron-dense material lying beneath the vascular endothelium similar to that described in the glomerulus of the lupus patient observed. These authors suggested that the small vessel changes contribute to the pathogenesis of the articular disease.

TREATMENT OF SYSTEMIC LUPUS ERYTHEMATOSUS ARTHROPATHY

The arthropathy of SLE tends to be nonaggressive, and thus treatment is generally medical, with either salicylates or nonsteroidal anti-inflammatory drugs (NSAIDs). The goals of medical management include suppression of inflammation, pain relief, and maintenance of normal joint function and muscular strength.

Salicylates

Patients with short-duration arthralgias may not require medication. For patients whose symptoms are more pronounced, initial medical management with salicylates (daily dose of approximately 3 g/day) may be indicated as long as there is no evidence of hepatic inflammation from systemic SLE disease activity. Long-acting salicylate preparations (e.g., zero-order release aspirin) can also be used, allowing for fewer daily doses and longer dosage intervals for medication intake, usually resulting in greater patient compliance. Salicylate levels can be monitored to maintain a therapeutic level of 20–25 mg/100 ml. In the authors' experience, salicylates have been well tolerated in SLE patients; however, the clinician should monitor patients for gastrointestinal intolerance and hepatocellular abnormalities.

Nonsteroidal Anti-inflammatory Drugs

Nonsteroidal anti-inflammatory drugs (NSAIDs) have also been used successfully to treat SLE arthropathy. Cases of aseptic meningitis have been reported with the use of ibuprofen. Results on the use of specific prostaglandin and/or leukotriene inhibitors show promise but still await controlled clinical trials. NSAID selection depends on cost, patient tolerance, drug half-life, and individual patient side effects.

Antimalarial Drugs

Antimalarial drugs—hydroxychloroquine (starting dose of 200–400 mg/day), taken in the evening to reduce gastrointestinal side effects such as nausea—may be a useful adjunct in the management of SLE arthralgias and polyarthritis and can be used in addition to NSAIDs [55, 56]. As antimalarial drugs are slower-acting than salicylates or NSAIDs, the beneficial effects may not be seen during the first month of treatment. Ophthalmologic follow-up is mandatory on all patients treated with antimalarial drugs.

Corticosteroids

Corticosteroids should be used only to treat patients who have failed a trial of other medications (e.g., salicylates, NSAIDs, or antimalarial drugs) and whose activities of daily living are severely impaired. When corticosteroids are prescribed for articular involvement without other accompanying signs or symptoms of SLE disease activity, one should use low doses (equivalent of 10 mg prednisone/day or lower) for as brief duration as is possible.

OSTEONECROSIS AND SYSTEMIC LUPUS ERYTHEMATOSUS

Epidemiology of Osteonecrosis in SLE

Osteonecrosis represents a collection of pathologic conditions of various etiologies that result in impairment of local blood supply to periarticular bone, resulting in bone cellular death. The host response to osteonecrosis can lead to architectural collapse of subchondral bone, joint incongruency, and eventual secondary degenerative arthritis. The reported incidence of osteonecrosis in SLE patients is 4–16%, although it may be higher; the femoral head is involved in 80% of these patients and involvement is often bilateral [57–59]. Because of its frequency and the significant disability that can result (particularly in the young lupus population), osteonecrosis is the articular manifestation of SLE with the most morbidity.

It is interesting to note that there were no reported cases of osteonecrosis in SLE patients prior to 1960; corticosteroid therapy for SLE patients began in the 1950s. Most cases of osteonecrosis in SLE patients are believed to be due in part to steroid treatment, for there is a positive correlation in patients so treated between incidence of osteonecrosis and both dosage and duration of treatment (including pulse steroid therapy) [58–63]. Other possible causes of osteonecrosis include fat emboli, Raynaud's phenomenon, small vessel vasculitis, and the anti-phospholipid antibody syndrome [64–67].

Dubois and Cozen [68] were the first to described osteonecrosis in patients with SLE in 1960. They reported on 11 cases of osteonecrosis in a population of 400 SLE patients who were known to have SLE for a mean of 5.1 years. The mean age of these patients was 36 years old. Eight patients had bilateral and one had unilateral femoral head involvement; the remaining two patients had bilateral knee involvement. These authors noted a different characteristic pattern of clinical symptoms (persistent painful motion localized to a single joint) suggesting osteonecrosis rather than an arthralgia or arthritis due to lupus disease activity. Patients with knee osteonecrosis noted initial clinical symptoms of unilateral swelling and joint effusion (with no increase in local warmth), which were completely relieved by rest. Patients with hip osteonecrosis noted a limp, groin pain, or pain radiating down one side of the thigh, and occasionally thigh muscle spasm. Histology from biopsy of the femoral head of one of these patients revealed osteonecrosis without evidence of vasculitis. There also appeared to be an association between onset of symptoms of osteonecrosis and corticosteroid therapy. In an attempt to determine the incidence of asymptomatic osteonecrosis, these authors examined the hip radiographs of 70 asymptomatic SLE patients, noting only a single case of early osteonecrosis.

Subsequent reports more firmly established the relationship between steroid therapy and osteonecrosis in SLE patients. In 1962, Siemsen *et al*. [69] reported on 3 patients with SLE and osteonecrosis. One male patient with discoid lupus, who never received systemic steroids, had mild membranous glomerulonephritis (positive ANA's were never detected) and osteonecrosis of both femoral heads. Histology of biopsy specimens from this patient revealed evidence of vasculitis in the synovial tissue and muscle but not in bone. Each of the 2 other SLE patients had unilateral femoral head osteonecrosis and had been treated with at least 20 mg prednisone/day for more than 12 months. Leventhal and Dorfman [70] described the cases of 11 women with femoral head osteonecrosis; 10 in patients with SLE and 1 in a patient with discoid lupus. All patients were being treated with or had been treated with steroids. Surgical specimens analyzed by histology from 10 patients (13 femoral heads) failed to demonstrate any evidence of a recent, healed, or chronic vasculitis.

Klipper *et al*. [71] reported on 23 SLE patients with stage 2 osteonecrosis (radiographic changes without evidence of subchondral collapse), and attempted to determine the risk factors for development of osteonecrosis in SLE patients. All but 1 patient was female, and there was no racial predominance. The average interval between diagnosis of SLE and the occurrence of osteonecrosis was 3.4 years (range 0.6–16 years). All patients had received steroids (duration of treatment 40 months, range 7–132 months) with maximum daily dosages of 20–100 mg except for a single patient who was taking 12.5 mg/day. Multiple joints were affected in 83% of patients; femoral head osteonecrosis occurred in 21 patients (15 patients with bilateral involvement), humeral head osteonecrosis in 7 patients, tibial plateau osteonecrosis in 3 patients, and scaphoid osteonecrosis in 1 patient. Eighty-seven percent of SLE patients with osteonecrosis had either Raynaud's phenomenon and/or central nervous system involvement. These authors suggested that osteonecrosis was the result of a generalized vascular pathology. Surgical specimens from 6 patients were analyzed; however, there were no cases of endarteritis within the femoral heads. One histologic specimen did demonstrate the deposition of fibrinoid material in and on the synovial membrane and vessels with fibrous perivascular cuffing (perhaps reflecting a healed vasculitis). These authors concluded that either vasospasm, vasculitis, or both in addition to glucocorticoid therapy might cause occlusion of the microcirculation with resultant bone ischemia.

Dimant *et al*. [72] analyzed 22 patients with osteonecrosis from a cohort of 234 SLE patients. Using life table analysis, they calculated that the projected frequency of osteonecrosis approached 30% in patients who had had SLE for 10–15 years. All the affected patients were women (mean age of onset 30.7 years) who had received steroid treatment; the majority had been diagnosed with osteonecrosis at 4–7 years following the diagnosis of SLE. Osteonecrosis involved the femoral heads in 18 patients and the knees in 4 patients. These authors, however, noted no correlation between the development of osteonecrosis and any particular clinical feature of SLE. Raynaud's phenomenon was present in 36% with evidence of osteonecrosis and in 43% of patients without such evidence. No correlation was found between osteonecrosis and duration, peak dose, cumulative dose, or average monthly dose of corticosteroid therapy; however, a trend toward higher peak and cumulative corticosteroid dose in patients who developed osteonecrosis was observed, possibly reflecting the longer duration of follow-up in these patients. No pathologic specimens were available from patients in this study.

Investigating the possibility of other predisposing factors, Klippel *et al*. [73], who reviewed 31 patients diagnosed with osteonecrosis (confirmed by plain radiographs) from a cohort of 375 SLE patients, noted no differences with regard to sex, racial distribution, age of onset, or select manifestations of SLE between the group that had osteonecrosis and the group that did not. The most commonly affected sites were the large weight-bearing joints of the lower extremities, with a predominance for bilateral involvement. All patients with osteonecrosis had received corticosteroids, and there was a direct correlation between patients with osteonecrosis and treatment with high doses of steroids. An important contribution of this study was the radiographic evaluation of 31 corticosteroid-treated SLE patients without articular complaints. The X rays of bilateral hips, knees, shoulders, ankles, elbows, and wrists revealed radiographic evidence of stage 2 osteonecrosis in 26% of these asymptomatic patients. The authors suggested that the true frequency of osteonecrosis in adult SLE patients might exceed 30% and that as many as 75% of SLE patients with osteonecrosis are asymptomatic.

In a prospective study, Zizic *et al*. [74] studied 54 SLE patients and found that 28 had osteonecrosis. Osteonecrosis was present in multiple sites in 26 of them (93 locations overall); the hips, knees, and shoulders were most commonly affected (in decreasing order of frequency). Demographic characteristics as well as clinical and laboratory findings were similar in patients with and without osteonecrosis, except for cushingoid changes (24 patients [86%] with osteonecrosis vs 4 [15%] patients without). In patients with osteonecrosis, there was a strong correlation between mean steroid dose and number of bony sites involved; mean daily steroid dose for the highest single month (93% of osteonecrosis patients had received greater than 20 mg/day) as well as the greatest number of consecutive 3-, 6-, and 12-month periods of corticosteroid therapy were both significantly higher in patients with osteonecrosis. In patients with Raynaud's phenomenon, even lower mean steroid doses resulted in osteonecrosis. A summary of the literature on osteonecrosis in patients with SLE appears in Table 1.

Pathogenesis of Osteonecrosis

Much of the following discussion is based on studies of osteonecrosis of the femoral head, as this is the site most commonly involved.

Blood Supply of the Femoral and Humeral Head

The frequency of femoral head involvement may be explained, in part, by its vascular supply. The femoral head derives its blood supply from three sources: the intraosseous cervical vessels, retinacular vessels, and the artery of the ligamentum teres. Since each vascular source serves a specific area of the femoral head and there are few vascular anastomoses, disruption of blood supply from one arterial source cannot be compensated for by collateral vasculature. The humeral head has a similarly tenuous blood supply, with the ascending branch of the anterior humeral circumflex artery supplying the largest portion of the articular surface with little collateral overlap.

Vasculitis and Osteonecrosis in SLE

Several pathogenic mechanisms have been proposed to result in osteonecrosis in SLE, including both intrinsic factors due to the underlying disease activity, such as vasculopathy [72], and extrinsic factors such as glucocorticoid treatment. It is possible that a vascular insult, such as vasospasm or inflammation, could interfere with bone microcirculation. This hypothesis is supported by the finding that SLE patients with Raynaud's phenomenon have a higher incidence of osteonecrosis [71, 74]. Vasospasm alone is not a sufficient agent, as there are no reports of osteonecrosis in patients with progressive systemic sclerosis and Raynaud's phenomenon. Klipper *et al*. [71], in a study of 77 patients with progressive systemic sclerosis, and Frayha *et al*. [75], in a retrospective review of 180 such cases, both failed to show osteonecrosis of either the femoral or humeral heads.

TABLE 1 Major Studies on Patients with SLE and Osteonecrosis

Author	Patients with ON[a]/total patients	Presence of Raynaud's and/or CNS involvement	Sites involved[b]	Pathology data	Relationship to corticosteroid therapy
Dubois and Cozen [68]	11/400	NA[c]	Femoral heads, femoral condyles	NA	10/11 had received steroids, dose NA
Leventhal and Dorfman [70]	11/No control group	1 had Raynaud's, 3 had CNS involvement, 1 had vasculitic ulcers	Femoral heads, humeral heads	No evidence of vasculitis or fat emboli	All patients had received steroids: 1 only received steroids for a month, 20 years prior to ON[a]
Klipper *et al*. [71]	23/No control group	87% had Raynaud's and/or CNS involvement	Femoral heads, humeral heads, navicular (scaphoid); tibial plateau	No evidence of vasculitis	All patients had received steroids, maximum dose 20–100 mg/day, except 1, who received 12.5 mg/day. Therapy lasted 9–132 months. One had not received steroids for 13 years prior to ON
Smith *et al*. [142]	7/99—Used control group of 7 patients without ON	3 had Raynaud's and ON vs none in control group; 1 had CNS involvement vs none in control group	Hips, knees, shoulders	NA	All patients with ON had received steroids; no difference from 7 control patients
Delanois *et al*. [155]	14/32 (pediatric group)	No differences between groups with or without ON	Distal femoral condyles, femoral heads, talus, metatarsal, patella, capitulum	NA	All patients with ON had received 54 g (average) compared with 31 g in patients without ON. No difference was found in average annual dose
Dimant *et al*. [72]	22/234	No differences between group with or without ON	Hips, knees	NA	All patients with ON had received steroids. Those with ON received a mean cumulative dose of 43.7 g compared with 30.6 g in patients without ON
Abeles *et al*. [61]	17/365	18% with ON had Raynaud's, 18% without ON had Raynaud's, 2 with ON had CNS involvement	Hips, knees, navicular (scaphoid), capitate	NA	Patients with ON received an average total dose of 32 g steroids compared with 31.8 g for patients without ON. Patients with ON had higher prednisone intake during the initial 6 months of therapy
Klippel *et al*. [73]	31/375	26% with ON had Raynaud's, 35% without ON had Raynaud's, 18% with ON had CNS involvement, 4% without ON had CNS involvement	Femoral head, femoral condyles, talus, humoral head, radial head, metacarpal head, metatarsal head, navicular (scaphoid) lunate	NA	All patients with ON had received steroids. Of those with ON, 32% received higher doses of steroids than those without ON
Zizic *et al*. [74]	28/54	Patients with ON and Raynaud's received less prednisone than those with ON without Raynaud's	Hips, knees, shoulders	NA	Patients with ON received 43.3 g steroids compared with 41.8 g for patients without ON. Patients with ON had higher mean dose of steroids for the higher single month

[a] ON, osteonecrosis.
[b] Anatomic sites are written as they are described by the respective authors.
[c] NA, not available.

Vasculitis is not always seen in pathologic specimens of osteonecrosis in SLE patients; however, it may be undetectable due to its transient presence and possible absence in later stage of the disease [70]. Vasculitis, characterized by inflammation of vessel walls with intravascular activation of polymorphonuclear leukocytes, diapedesis, and release of toxic oxygen species, may stimulate polymorphonuclear leukocytes to self-aggregate (leukoemboli), resulting in intravascular thrombi. Given *et al.* [76] observed leukoaggregating factors such as complement split products in the sera of lupus patients. Increased surface statement of the complement receptor CR3 (involved in cell–cell adhesion) on neutrophils isolated from SLE patients supports the possibility of white cell vascular plugging [77]. Possibly a combination of vasospasm, vasculitis, and white cell vascular thrombi help bring about osteonecrosis in bony sites that lack sufficient collateral circulation (e.g., the femoral head).

Glucocorticoids and Osteonecrosis in SLE

The mechanism of steroid-induced osteonecrosis is still not fully understood. McFarland and Frost [78] suggested that steroids suppress osteoblastic function and therefore interfere with the normal host repair response to microfractures, while other investigators have postulated that the analgesic effect of steroids results in a neuropathic (Charcot-like) arthropathy [79]. Other possible factors include the effects of steroids on fat metabolism, storage (causing fatty liver [80]), and asymptomatic systemic fat emboli. Fisher and Bickel [81, 82], using the oil red O staining technique, were able to identify intravascular fat emboli in patients on corticosteroids who had femoral head osteonecrosis. They concluded that systemic fat emboli (arising from coalescent hepatic fat cysts due to corticosteroid therapy) caused a mechanical vascular obstruction and osteonecrosis. Jones and Sakovich [83] induced osteonecrosis in the femoral heads of rabbits by the infusion of iodized poppy seed oil into their distal aortas. Histologic analysis revealed intraosseous fat emboli and obstructed subchondral arterioles. The presence of steroid-induced fat emboli, however, may be transient, as Leventhal and Dorfman [70] could not detect intravascular fat emboli from multiple human femoral sections stained with oil red O.

Lipid Metabolism and Osteonecrosis

Other investigators have suggested altered lipid metabolism (e.g., increase in fat cell size and/or number) resulting in intramedullary lipocyte proliferation as a cause of osteonecrosis. An increase in the number and/or size of lipocytes could increase intraosseous pressure, reduce sinusoidal circulation, and subsequently infarct the marrow and bone [84, 85]. This theory is supported by the observations of Zizic and co-workers [74, 86], who noted a higher incidence of osteonecrosis in patients with cushingoid features (increased truncal adipose tissue, possibly as a result of increased intramedullary lipocytes). Bluemke *et al.*, using magnetic resonance imaging (MRI) and spectroscopic evaluation in SLE and normal patients, noted a higher marrow fat content in SLE patients in the femoral head and neck, with an inverse relationship to the perfusion of the femoral head [87].

Thrombophilia and Osteonecrosis

A hypercoagulable state may also predispose to osteonecrosis in SLE patients. Asherson *et al.* noted that patients with a hypercoagulable state due to antiphospholipid antibodies had an increased tendency to develop osteonecrosis [88]. Finally, corticosteroid treatment may induce a hypercoagulable state promoting venous stasis and ultimately decreasing oxygenation of affected bone [89, 90].

Conclusions: Pathogenesis of Osteonecrosis

In conclusion, no one pathogenic mechanism can explain the cause of osteonecrosis in SLE. The cause is probably multifactorial and may be either intrinsic or extrinsic causes or both. Certainly, SLE patients are at higher risk for developing osteonecrosis if their mean daily steroid dose for 1 month or more is high [74], if they have evidence of vasospasm (e.g., Raynoud's phenomenon), or have evidence of altered lipid metabolism (e.g., cushingoid features). The reversibility of these risk factors in patients without osteonecrosis, or how long they remain at risk for osteonecrosis, is not known.

Diagnosis Studies

Although many diagnostic radiologic modalities are available (e.g., scintigraphy, computed tomography), magnetic resonance imaging (MRI), because it permits early diagnosis of clinically and radiographically silent cases of osteonecrosis, is the diagnostic tool of choice [91–97]. Magnetic resonance imaging has a diagnostic accuracy rate of 90–99% and a sensitivity and specificity of 80–85%. Computerized tomography and bone scintigraphy are less accurate and may miss early osteonecrotic lesions. Bone scan has an accuracy rate of approximately 85% and sensitivity and specificity of 68–83% [92, 98–100]. Bone biopsy and culture may be necessary to differentiate atypical sites of osteonecrosis

from osteomyelitis [101]. Early recognition of osteonecrosis is important for proper patient counseling, prognosis, and surgery if core decompression with or without structural grafting will be performed. SLE patients who present with osteonecrosis at one anatomic site should undergo a thorough investigation for lesions at other sites including the knee, ankle, and shoulder as many patients eventually develop involvement of multiple joints.

Staging and Classification for Osetonecrosis of the Femoral Head

There have been several classification systems for osteonecrosis. This has led to much confusion in the literature regarding results of treatment and prognosis of early lesions. Although the etiology of osteonecrosis is diverse, the disease process typically progresses through definable stages. Staging of osteonecrosis is based on a combination of pathologic, radiographic, and/or clinical criteria and is important in order to determine prognosis and appropriate treatment [98, 100, 102]. The osteonecrosis staging system proposed by Ficat and Arlet [102], previously in greatest use, has been replaced by a uniform staging system introduced by the Association Research Circulation Osseous (ARCO). In this five-stage system, stage 0 is histology only, stage 1 a positive diagnostic test, stage 2 a positive X ray with no radiographic collapse, stage 3 a positive X ray with collapse, and stage 4 a positive X ray with osteoarthritis. Each stage can be subclassified according to the percentage of head involvement or surface collapse: Subclass A—minimal, with <15% femoral head involvement or <2 mm of surface collapse; Subclass B—moderate, with 15–30% head involvement or with 2–4 mm of surface collapse; Subclass C—extensive, with >30% femoral head involvement or >4 mm of surface collapse. Not all cases of osteonecrosis develop joint degeneration. The critical stage of this new classification system, as of previous ones, is the development of the crescent sign or subchondral collapse. Once this sign is present, the joint will invariably degenerate and orthopedic reconstructive surgery will be necessary (Fig. 7).

Stage 0

This initial stage precedes clinical and radiographic manifestations of the disease. By definition, radiographs, bone scan, and MRI are normal. This stage is usually only diagnosed in the contralateral femoral head in a patient with known osteonecrosis of the opposite hip. Contralateral hip osteonecrosis occurs in 90% of SLE patients [71, 73, 91, 94, 103, 104]. As a result of the disruption of vascular supply to a segment of periarticular bone, cell death occurs [62, 63, 105–108]. Necrotic changes in the marrow elements and empty lacunae representing osteocyte death are the earliest events observed by histology. At this stage, bone maintains its normal trabecular architecture and density.

Stage 1

Stage 1 osteonecrosis usually represents the onset of clinical signs without concomitant radiographic abnormalities. This is referred to as the *silent hip* of osteonecrosis, where histologic changes can be seen and in some cases hemodynamic changes are present [108]. Following cell death, the host repair process begins with a reactive hyperemia to the bone adjacent to the infarcted area, resulting in bone resorption (demineralization and trabecular thinning of the bone). The host repair process continues as new capillaries and granulation tissue invade the area of necrotic bone. The necrotic bone and cellular debris are resorbed by creeping substitution by osteoclasts and phagocytes, respectively. Diagnosis is based on a positive diagnostic test such as a positive bone scan or MRI. Localization of the area of bone involvement may help guide those surgeons who are advocates of core decompression to the precise area of involvement [92, 93].

Symptomatic patients usually complain of intermittent and mild to moderate groin pain. Physical examination at this stage may show a mildly restricted range of motion, particularly in internal rotation [99]. Diagnostic evaluation should start with X rays of the hip, an anteroposterior view (taken with the hip internally rotated 15° for best presentation of the femoral head and neck), and a lateral view. X rays at this stage are by definition normal; however, in some cases subtle changes in the trabecular architecture may be evident when compared with the opposite (normal) side. For patients at risk for osteonecrosis, such as SLE patients, MRI is indicated. Bone scan and biopsy, both of which have been advocated in the past, should be reserved only for those situations in which MRI is not available.

Stage 2

Patients with stage 2 osteonecrosis have a positive X ray finding with no radiographic collapse. These patients most often complain of dull, aching groin pain on weight bearing and occasionally at rest [99]. Physical examination usually reveals a global decrease in range of motion and a slight limp. Radiographic changes are variable; the infarcted area may appear sclerotic in comparison with the surrounding area of the femoral head and neck due to the reactive hyperemia and osteoporosis that occur

FIGURE 7 Anteroposterior radiographs of hips with osteonecrosis demonstrating the various stages: (A) stage 2 osteonecrosis showing areas of sclerosis and cyst formation without evidence of subchondral collapse. (B) stage 3 osteonecrosis reveals the crescent sign. The crescent sign marks the progression from stage 2 to stage 3 osteonecrosis. (C) stage 4 osteonecrosis showing extensive femoral head collapse, joint space narrowing, and secondary degenerative changes.

at the vascularized perimeter of the infarct; the infarcted area may be well delineated by a peripheral rim of increased density due to new bone formation at the periphery of the infarct; or the infarcted area may appear osteoporotic or cystic as the repair process progresses. An important radiographic finding is maintenance of both the joint space and the sphericity of the femoral head. The crescent sign represents the end of stage 2 and the start of stage 3.

Stage 3

Stage 3 osteonecrosis is characterized by a positive X ray with subchondral collapse. As the necrotic subchondral bone is resorbed, the overlying articular cartilage may be left without sufficient structural support for a significant length of time. During this period, either weight-bearing or joint reactive forces may cause the weakened subchondral bone to fracture or collapse, leading to joint incongruity. Radiographically, a crescent-shaped subchondral lucency, termed the *crescent sign*, can be observed. The host response at this point continues to be reparative; however, it is now no longer possible to restore the sphericity of the femoral head and joint congruity.

Patients at this stage usually have an exacerbation of symptoms about the hip, and pain at rest is more common [99]. Many patients will also note a distinct clicking sensation during movement of the hip due to the joint incongruity. On physical examination, the hip range of motion is reduced and a limp is evident. Standard radiographs are pathognomonic; flattening of the femoral head is evident, particularly on the lateral view due to mechanical failure of the osteonecrotic area of the femoral head. The acetabulum is radiographically unaffected.

Stage 4

Stage 4 osteonecrosis, characterized by a positive X ray with secondary degenerative joint disease, represents end-stage disease [99]. With time, due to a combination of joint incongruity and lack of diffusion nutrition to the overlying articular cartilage from the subchondral bone, secondary degenerative joint changes occur.

Patients will complain of increasing joint pain, stiffness, and a deterioration of function. Radiographs reveal flattening of the femoral head, progressive loss of joint space osteophytes, and subchondral cysts on either the femoral or acetabular side or both. These end-stage radiographic changes at times may be indistinguishable from the changes of long-standing osteoarthritis.

Treatment of Osteonecrosis of the Femoral Head

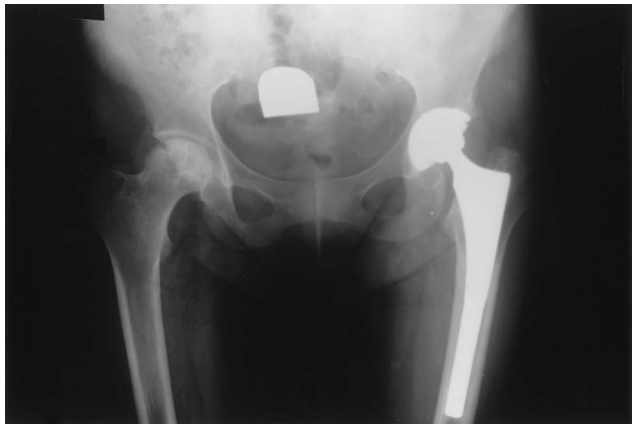
Treatment of femoral head osteonecrosis is based on the stage of presentation, location and percentage of bone involvement, and status of the articular cartilage [100]. Once degenerative joint changes occur, cartilage sacrificing procedures such as joint replacement may be required (Fig. 8) [109, 110]. Since there have been few studies of the management of osteonecrosis of SLE patients, the algorithm of treatment of osteonecrosis from all causes is generally applied. Nevertheless, in the following discussion, results from studies of SLE patients and osteonecrosis will be emphasized where available and appropriate.

The treatment of the early stages of osteonecrosis (stages 0, 1, and 2) is controversial. Prior to the development of the crescent sign (stage 3), treatment options include observation, restriction of weight bearing, electrical stimulation, surgical core decompression with or without structural bone grafting (with either avascular or vascularized fibular graft), and proximal femoral osteotomies. There are two different philosophies of how to treat early femoral head osteonecrosis. One group of physicians believes that the die is cast at the time of the vascular insult and thus that symptomatic management is all that is needed. Prognosis for later subchondral collapse and early degenerative joint disease is based primarily on the percentage and location of bone involvement. The other group of physicians believes in the possibility that surgical treatment can succeed in promoting revascularization, healing the osteonecrotic segment, and preventing collapse. Due to problems in older staging classification systems, it has been difficult to compare outcomes among the various treatment options or to determine the natural history of osteonecrotic lesions. As a result, there have been several nonoperative and operative treatments for osteonecrosis that have had varying results.

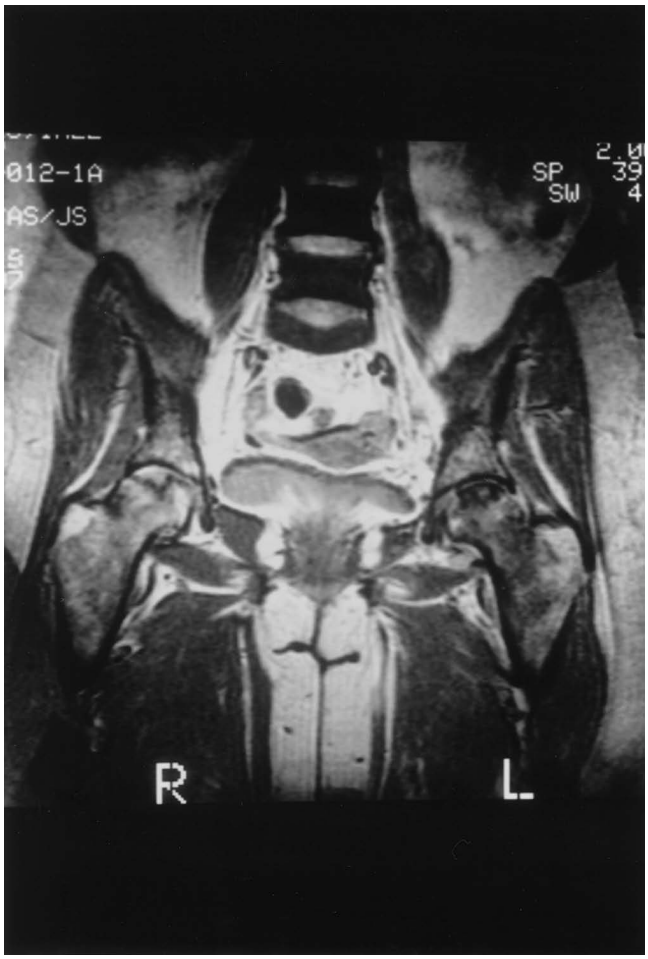
Nonoperative Treatment

Nonoperative treatment with the use of either nonsteroidal anti-inflammatory or analgesic medications can help to decrease symptoms and improve function, but have no known effect on the possible progression to subchondral collapse. Restriction of weight bearing using either a cane or crutches for periods when the joint is more symptomatic can help ameliorate pain; however, such measures have not been shown to affect the ultimate outcome from the osteonecrosis probably due to the high joint reactive forces that cross the hip joint with movement. The results of nonoperative treatment have been variable—again as a result of

A



C



B

FIGURE 8 (A) Anteroposterior radiograph of the hips of a patient with SLE with hip pain localized to the left groin. Marked sclerosis of the femoral head with subchondral collapse is seen consistent with stage 3 osteonecrosis. (B) MRI demonstrates osteonecrosis in both femoral heads compromising more than 30% of the femoral head on the left thereby staging this to 3C osteonecrosis. (C) This patient later went on to stage 4C osteonecrosis and underwent successful treatment with an uncemented total hip arthroplasty.

nonuniform osteonecrosis staging. It is generally believed that patients in whom >50% of the femoral head is osteonecrotic, especially in the weight-bearing area, are likely ultimately to experience subchondral collapse and degenerative arthritis, whereas patients with <15% femoral head involvement will probably heal without collapse. Early reports of poor prognosis for patients with early-stage osteonecrosis did not evaluate the percentage of bone involvement and in some cases reported poor outcomes with this approach, thereby suggesting operative management [98].

Core Decompression

Core decompression is one surgical approach to treating the early stages of osteonecrosis [99,102,

111–113]. In stage 0–2 osteonecrosis, core decompression can be performed; however, its use remains controversial in the orthopedic literature. Ficat and Arlet [102] and Hungerford and Zizic [111] have postulated that elevation of bone marrow pressure within a closed, rigid space such as the femoral neck leads to occlusion of intraosseous blood vessels, resulting in bone ischemia and the clinical symptoms of pain prior to collapse. To diagnose osteonecrosis, these same authors described the "functional exploration of bone" in order to identify pre-radiographic osteonecrosis.

Surgery (core decompression) is performed in order to measure bone marrow pressure, release or decompress elevated bone marrow pressure, and perform a core biopsy for both diagnostic and therapeutic purposes. The surgical procedure for core decompression consists of drilling through the femoral neck into the femoral head with a hollow coring device (6–10 mm in diameter) in order to reduce the elevated intraosseous pressure and improve vascularization. Ficat and Arlet [102] have used this modality extensively with excellent results; however, other authors have not been able to replicate these results [114–116]. Using their own staging system, Ficat and Arlet reported 94% good or excellent clinical results in 82 hips with stage 1 osteonecrosis and 86% good or excellent clinical results in 51 hips with stage 2 osteonecrosis (14% developed radiographic signs of collapse) at an average follow-up of 9.6 years [99,102]. Aaron *et al*. [114], utilizing only clinical criteria, reported only a 44% success rate in patients treated with core decompression. Tooke *et al*. [115] reported a 100% success rate when treating stage 1 hips but only a 58% success rate when treating stage 2 hips with core decompression. Mont *et al*. [117] conducted a cross-sectional study of osteonecrosis in 31 hips in SLE patients and in 48 hips in those who were on steroid medication for other reasons, all treated with core decompression. At an average follow-up of 12 years, only 53% of all core decompression patients had a satisfactory result (68% of SLE patients compared to 33% of other steroid-treated patients had undergone hip replacement surgery). A matched subset of these patients for age, gender, steroid dose, osteonecrosis stage, and length of follow-up showed no statistically significant differences with regard to clinical outcome. The authors noted a worse prognosis for patients who were treated in stage 3 osteonecrosis and who had a greater extent of femoral head involvement. In light of these variable clinical outcomes with core decompression alone, clinicians have sought out other surgical treatments in order to try to preserve articular cartilage and improve outcomes of patients with femoral head osteonecrosis [116].

The issue of cartilage sparing procedures in SLE patients with osteonecrosis who require continued steroid treatment remains unanswered. Some authors note no effect on surgical outcomes in patients who are on steroids [114], whereas others have noted poorer outcomes in patients with continued steroid treatment who have undergone core decompression (with or without concomitant bone grafting) than in similar patients whose steroid treatment had been terminated [115].

Proponents of core decompression cite intraosseous hypertension as a source of joint pain and further bone necrosis, while opponents cite venous hypertension as either an artifact or a result of the necrosis and propose that removal of bone from the femoral head further weakens the subchondral bone, leading to further collapse. Papers citing the success of core decompression can be contrasted to those that show either no difference or worse results as well as both intraoperative and postoperative femoral neck fractures occurring in a small percentage of patients (also reported in SLE patients following the procedure) [118]. Based on these findings, the majority of surgeons believe that core decompression should not be performed for stage 3 or 4 osteonecrosis.

It is probable that the controversy in the literature is at least in part due to the nonuniform staging systems used in the past. It is currently believed that there exists a strong correlation between the size of osteonecrosis of the femoral head and the prognosis for collapse, with significantly better results with smaller-size lesions and sparing of the lateral column. The probability of progression to end-stage (requiring arthroplasty) osteonecrosis has been found to vary between 20 and 60% of cases.

Core Decompression Combined with Structural Bone Grafting

The less-than-desirable outcomes of core decompression alone are believed to be due to a further compromise of the subchondral bone by removal of a core of bone, making it more susceptible to collapse [119]. As a result, some surgeons recommend core decompression with structural bone grafting. The types of grafts used have been either transplanted autografts, allografts, and, more recently, vascularized autograft bone [120–124]. The purpose of a structural bone graft is to act as a mechanical support for the subchondral bone, preventing collapse while enhancing revascularization and healing of the necrotic bone segment. As with the results of core decompression alone, the outcomes of this approach have been quite variable, again probably secondary to the staging criteria used [108,120–125].

More recent results with vascularized fibular strut graft have been encouraging in short-term follow-up and suggest a distinct advantage over core decompression alone for Ficat stage II and III disease [126]; however, as with core decompression alone, if bone grafting is to be performed, a better prognosis is expected for those cases without radiographic evidence of collapse.

Electrical Stimulation and Pulsed Electromagnetic Fields

Adjunctive treatments such as electrical stimulation and capacitative coupling have also been used, with varying results. Electrical stimulation (pulsed electromagnetic fields) is a treatment alternative that is still under investigation and whose approval by the FDA is pending. Tranick and Lanceford [123] reported on the use of electrical stimulation alone in the treatment of osteonecrosis and found that 100% of patients with stage 2 disease had further deterioration of function. Steinberg *et al*. [125], however, noted that electrical stimulation combined with core decompression and bone grafting may improve outcomes of treatment. Aaron *et al*. [114] and Eftekar *et al*. [127], reporting on the use of pulsed electromagnetic fields, were encouraged by a superior success rate to that of core decompression alone. Studies of the use of external capacitative coupling in addition to core decompression and bone grafting report no improvement in treatment outcomes [128].

Proximal Femoral Osteotomy

Proximal femoral osteotomies (cutting and realignment of the proximal femur) have been used in order to replace an osteonecrotic bone segment in the weight-bearing portion of the femoral head with a normal segment of bone [129–131]. In contrast to the previously described procedures, osteotomy may be performed after collapse of the femoral head (stage 3 osteonecrosis)—but before degeneration of the acetabulum occurs (stage 4 osteonecrosis). Two types of osteotomy (angulation and rotational) have been proposed for the treatment of osteonecrosis. A rotational osteotomy, in which the femoral head is rotated 90°, was reported to yield good to excellent results in 80% of 200 hips [129]. However, this procedure is technically demanding, and few centers have been able to repeat these results. An angular osteotomy should is performed to direct a nonnecrotic segment of the femoral head into the weight-bearing portion of the joint; varus osteotomies are used for central or medial head involvement and valgus osteotomies are used for superolateral head defects. Ganz, and Buchler [130] reported that only 8 of 17 patients that had undergone an intertrochanteric osteotomy for osteonecrosis had satisfactory results at 3 years. Gottschalk [131] hypothesized that the poor results observed may be due to continued corticosteroid therapy or metabolic bone abnormalities and concluded that this procedure should be reserved for posttraumatic, idiopathic, or alcohol-induced osteonecrosis. In both applications (rotational or angulation osteotomies) the failure rate increases with the size of the femoral head defect. Beyond 50% involvement, the procedure is contraindicated by virtue of poor outcome (over 70% conversion to total hip arthroplasty at 10 years).

Treatment of Stage 4 Osteonecrosis: Hip Arthroplasty

Treatment of stage 4 osteonecrosis (significant subchondral collapse with secondary degenerative joint changes) is initially aimed at decreasing symptoms (anti-inflammatory drugs, mild analgesics, rest, and assistive devices for ambulation) until pain and disability warrant joint replacement surgery. Because of the high incidence of bilateral osteonecrosis in SLE patients, hip arthrodesis (surgical fusion of the joint) is not a surgical option. Since the femoral head is primarily involved and the acetabulum is relatively spared, some authors have suggested the use of bipolar hemiarthroplasty (replacement of the femoral head and neck with a prosthesis and preservation of the acetabulum). However, results of this approach have been disappointing, and most of these patient need be converted to a total hip arthroplasty as the "normal" acetabulum is typically not normal due to changes that have occurred during the joint deterioration and osteoporosis that occurs secondary to long-term steroid therapy. Surface replacement hemiarthroplasty of the hip (a more limited resurfacing prosthesis) has been proposed as another alternative to total hip arthroplasty; however, conversion rates to total hip arthroplasty approach 40% at 10 years of follow-up [132].

Hanssen *et al*. [133] reported the results of 43 hip reconstructions over a 12-year period in SLE patients. Patients who had undergone total hip arthroplasty had results superior to those who underwent bipolar replacement at a mean follow-up of 57 months. As a result, total hip replacement is the treatment of choice for SLE patients with stage 4 osteonecrosis who have failed nonoperative treatment. It should be noted that the clinical outcomes and survivorship of total hip arthroplasty performed for osteonecrosis (when all etiologies are considered) are worse than those done for other conditions such as osteoarthritis [86]. Although

total hip replacement using cemented femoral and acetabular components has yielded excellent pain relief and a success rate of over 90%, due to the younger age of SLE patients with osteonecrosis, prosthesis inserted without cement (that offer the prospect of biologic fixation) have been used in order to limit the long-term problems of aseptic loosening that have been observed with components inserted with cement.

Hanssen *et al*. [133] reported good to excellent results in 28 of 31 SLE patients who underwent total hip replacement at a mean follow-up of 5.5 years. Although SLE disease activity was quiescent at the time of surgery, complication rates were higher than those for patients undergoing hip replacement without SLE. Twenty-five percent of patients had local wound complications; however, no correlation between corticosteroid use perioperatively and wound complications was noted. Twenty-five percent of the patients in this study had died at final follow-up due to SLE complications unrelated to the total hip arthroplasty. Huo *et al*. [134] reported a survivorship rate of 94.6% at 5 years and 81.8% at 9 years for total hip arthroplasty in SLE patients. The clinical results were good or excellent in all patients at a mean follow-up of 47 months. Other studies have confirmed the effectiveness of total hip replacement for the treatment of stage 3 and 4 osteonecrosis in lupus patients [93,94]. The early results (4- to 8-year follow-up) of total hip arthroplasty performed with porous-coated components inserted without cement in SLE patients have yielded 62.5% good or excellent clinical results—which, however, is still inferior to those in patients so treated for other conditions [135]. Newer total joint component designs and articulating surfaces should improve the long-term outcomes of SLE patients with joint replacements.

Thromboembolic Prophylaxis for SLE Patients Undergoing Total Hip Arthroplasty

All patients who undergo hip replacement surgery are at risk for venous thrombosis, and as a result it is recommended that all such patients receive some form of prophylaxis. In the authors' institution, low-molecular-weight heparin is used for thrombosis prophylaxis. Patients with SLE who have significant serum levels of anti-cardiolipin antibodies (prevalence of 30–40%) and/or lupus anticoagulant are at increased risk for venous thrombosis [88,136–138]. It is still not known whether these patients are at a further increased risk for thrombosis following joint replacement surgery, nor whether our current prophylaxis regimens are adequate. Thrombosis prophylaxis with warfarin may be more appropriate in this subgroup of SLE patients. Patients with a history of embolic phenomena and antiphospholipid antibody have had uncomplicated joint replacement surgery by short-term withdrawal of coumadin and continued aspirin and steroid treatment [139]. SLE patients with lupus anticoagulants have also undergone surgical procedures without complications [140].

Osteonecrosis of Other Sites

Osteonecrosis has been observed in the femoral condyles, talus, humeral head, metatarsal heads, radial head, carpal bones, proximal and distal tibia, and metacarpal heads; it can occur in multiple sites in the same patient, and bilateral involvement is frequent [71,91,101,141–150]. SLE patients who present with osteonecrosis at one anatomic site should undergo a thorough investigation for lesions at other sites including the hip, ankle, and shoulder as many patients eventually develop involvement of multiple joints.

Osteonecrosis About the Knee

Osteonecrosis about the knee may affect one or both femoral condyles, the proximal tibia, or the patella and poses many of the same problems as femoral head involvement. While combined lesions of the distal femur and proximal tibia are common, isolated involvement of the proximal tibia is unusual [144,151–153]. As the knee is a major weight-bearing joint, subchondral collapse, joint incongruity, and progressive joint deterioration can occur. The natural history of osteonecrosis of the knee appears to be poor with the majority of symptomatic patients requiring operative treatment [153]. MRI of the knee in patients without X-ray changes is diagnostic in clinically symptomatic patients and has been found to be more useful than nuclear medicine scans [153]. As in the disease progression for hip osteonecrosis, early radiographic changes include a sclerotic appearance of the involved area, followed by a crescent sign, and later progression to flattening of the condyles, with eventual development of secondary degenerative changes.

Treatment of Osteonecrosis of the Knee

Early treatment of femoral condyle osteonecrosis consists of anti-inflammatory medications, quadriceps-strengthening exercises, and use of a cane or crutches for limited weight bearing in order to decrease symptoms and improve function. As with the hip, the size of the osteonecrotic lesion appears to determine prognosis with larger lesions having a worse prognosis. The combined necrotic angle, as described by Kerboul *et al*. [154], has been shown to be the most useful method for

categorizing the size of the lesion. With this method, a goniometer is used to measure the arc of the angle of the surface involved on both anteroposterior and lateral projections. Lesions with a combined necrotic angle of greater than 250° are categorized as large and have the worst prognosis [153].

Core decompression of the osteonecrotic area to stimulate revascularization has been reported to result in resolution of symptoms in some patients [153]; however, it is not known if it alters the ultimate natural history of the disease. In some cases, the cartilage overlying the osteonecrotic bone may become detached, acting as a loose body within the joint and obstructing knee motion, and should be removed by arthroscopic surgery; an intra-articular injection of lidocaine can be useful in determining whether a given patient's symptoms are related to intra-articular pathology or are related to pain from bone necrosis. If osteonecrosis is localized to only one femoral condyle, a realignment osteotomy designed to shift the weight-bearing forces to the uninvolved condyle may be helpful. If both femoral condyles have osteonecrosis and if secondary degenerative changes or collapse have occurred, then total knee replacement is indicated (Fig. 9). The results of total knee arthroplasty in patients with osteonecrosis of the knee and SLE have not been as good as for patients with osteoarthritis or other inflammatory arthropathies. SLE patients have a reported higher rate of early prosthetic loosening, poorer clinical outcomes, and increased rate of infection [153]. Knee arthrodesis is usually not indicated for SLE patients due to the frequency of polyarticular and bilateral osteonecrosis.

Osteonecrosis of the Talus

Treatment of osteonecrosis of the talus is similar to that of femoral condyle osteonecrosis. If the plain radiographs are normal in a symptomatic patient MRI is diagnostic. Nonoperative treatment includes the use of anti-inflammatory medications and limited weight bearing. Involvement is frequently bilateral and patients may have osteonecrotic lesions of the other bones of the foot and ankle [155]. Arthrotomy or arthroscopic surgery may be required if loose-bodies develop secondary to detachment of a cartilaginous fragment and symptoms develop. Core decompression has been reported by Delanois *et al.* to be useful in patients who do not have subchondral collapse [155]. If subchondral collapse and degenerative joint disease occurs that is resistant to nonsurgical treatment, then tibiotalar arthrodesis is indicated. Total ankle replacement is not an option for these patients, as it has fallen out of general use due to a high incidence of unsatisfactory results compared to the excellent results of ankle arthrodesis [156,157].

Osteonecrosis of the Humeral Head

Osteonecrosis of the humeral head is initially treated with anti-inflammatory medication and exercises designed to maintain shoulder range of motion (Fig. 10) [145]. As the glenohumeral joint is not subjected to the same kind of weight-bearing forces as the large joints of the lower extremity, osteonecrosis of the humeral head seems to have a better prognosis than osteonecrosis of the hip, knee, or ankle. The glenohumeral joint is also less constrained than the large joints of the lower extremity and scapulothoracic motion can in part compensate for lost glenohumeral motion; thus greater amounts of deformity are tolerated before function is severely compromised. Patients with less than 50% involvement of the humeral head have a better prognosis than those who have involvement of more than 75% of the humeral head [158].

Osteonecrosis of the humeral head is relatively uncommon; however, in one series, 25 of 72 patients with humeral head osteonecrosis also had SLE [159]. If significant symptoms persist despite conservative measures and humeral head deformity or degenerative changes occur, humeral head hemiarthroplasty or total shoulder arthroplasty is indicated [158–161]. Core decompression of the humeral head has also been utilized in patients without signs of collapse of the articular surface; however, only moderate success has been demonstrated with this procedure [159, 162]. Patients with symptomatic osteonecrosis of the shoulder should be referred to an orthopedic surgeon early in the course of their disease as severe bone loss can occur which makes total shoulder arthroplasty technically more difficult.

Osteonecrosis of the Metatarsal Head, Radial Head, and Carpal Bones

Osteonecrosis of the metatarsal head is usually treated with medication, limited weight bearing, and shoe modification; however, if these fail, then surgical excision of the metatarsal head may be indicated. Radial head osteonecrosis is also treated with medication and exercises to maintain range of motion, and if these fail then surgical excision of the radial head is the procedure of choice. The carpal bones usually involved with osteonecrosis are the scaphoid, lunate, and capitate; this can be treated with medication and splinting. If symptoms persist and early collapse is evident, surgical treatment by a limited wrist fusion is indicated.

FIGURE 9 (A) Anteroposterior standing knee radiographs of an SLE patient with bilateral knee pain, worse on the left. Osteonecrosis with subchondral collapse is noted in the lateral femoral condyle on the left knee, and in the medial femoral condyle of the right knee. Anteroposterior (B) and lateral (C) radiographic views of the same patient successfully managed with cemented total knee arthroplasty.

FIGURE 10 Anteroposterior shoulder radiograph demonstrated osteonecrosis of the humeral head. A crescent sign seen as a subchondral lucency is present.

OSTEOPOROSIS AND METABOLIC BONE DISEASE IN LUPUS

Oscar Gluck
Michael J. Maricic

OSTEOPOROSIS

Introduction

Osteoporosis is conceptually defined as "a skeletal disorder characterized by compromised bone strength predisposing to an increased risk of fracture. Bone strength reflects the integration of two main features: bone density and bone quality" [1]. Clinically, osteoporosis can be diagnosed without the use of bone density measurements in patients who have had vertebral compression fractures or nonvertebral fragility fractures. The World Health Organization (WHO) has developed criteria for the diagnosis of osteoporosis in postmenopausal Caucasian women based on measurements of bone mineral density (BMD) [2]. The number of standard deviations (SD) below the mean peak adult value at the skeletal site measured is expressed as a "T-score." A T-score of equal or greater than 2.50 SD below peak adult bone mass allows for the diagnosis of osteoporosis without the presence of fragility fractures [2] (Table 1).

The WHO criteria make it possible to assess the prevalence of osteoporosis in patients with lupus and to examine associated risk factors. Several cross-sectional and prospective studies in patients with systemic lupus have suggested a reduction of bone mass and an increased risk for fragility fractures [3, 4]. Therefore, it is advisable to measure bone mineral density in patients with lupus at risk for bone loss.

Factors that play a role in the association between lupus and bone loss include the inflammatory disease itself, disease-related comorbidities and therapy, specifically exposure to glucocorticoids [5]. Recognition of the role of cytokines and other inflammatory mediators in the regulation of bone remodeling has led to a better understanding of the etiology of bone loss in inflammatory diseases, including systemic lupus [6].

EPIDEMIOLOGY OF BONE LOSS AND FRACTURES IN SYSTEMIC LUPUS

The prevalence of patients with lupus having low bone mass varies from 15–46% (osteopenia), to 6–15% (osteoporosis) in different studies [5, 7]. Decreases in both cortical and trabecular bone compared to age matched controls have been reported [8], and low bone mineral density is evidenced in both early and late disease [9, 10]. Thus, the duration of systemic lupus does not seem to be a major factor. Low bone mineral density is seen across multiple skeletal sites, and both the prevalence and incidence of low bone mass reported varies according to the site of measurement (lumbosacral spine, total hip, femoral neck, trochanteric region), gender, and age of the patient studied.

1. Postmenopausal women: Along with other factors, improved survival has increased the population at risk for the development of reduced BMD, osteopenia, and osteoporosis in postmenopausal women with lupus [7].
2. Premenopausal women: In many studies, a higher incidence of osteopenia and osteoporosis by WHO

TABLE 1 World Health Organization Criteria

WHO diagnostic categories	
Diagnosis	**T-score**
Normal	Greater than 1.0 SD below the average value of peak average bone mineral density (BMD)
Osteopenia	More than 1.0 SD below the average value of peak average BMD but not more than 2.5 below
Osteoporosis	More than 2.5 SD below the average value of peak average BMD
Severe osteoporosis	More than 2.5 SD below the average value of peak average BMD and the presence of a fragility fracture

criteria has been noted in premenopausal women with lupus compared to controls [11]. Significant loss of lumbosacral spine bone mass reflecting predominately trabecular bone has been detected in these younger women [5, 7].

3. Males: In men with lupus, the prevalence of low bone density is controversial. A few small studies showed no relationship between low BMD and men with systemic lupus [12]. As in women, glucocorticoid in men seemed to be a major risk factor for low bone mass.

4. Juveniles and children: Patients with juvenile systemic lupus showed a significant loss of bone mass of the lumbosacral spine, specifically while treated with glucocorticoids [13].

In most but not all studies, a higher frequency of osteoporosis at all sites is noted compared to age-matched controls [5]. In one study, equally low bone mineral density values were noted in patients with rheumatoid arthritis or systemic lupus [14].

An association between low bone mineral density and cardiovascular disease (atherosclerosis) in patients with lupus has more recently been described [15], emphasizing the role of inflammatory mediators such as cytokines in both entities.

FRACTURES

There are very few studies that provide data on the incidence of fragility fractures in patients with systemic lupus. In the Baltimore Cohort Study [16], 32 out of 364 SLE patients had fractures, and of those, 24 were defined as atraumatic or fragility fractures. The risk factors for fragility fractures in this study included advanced age, cumulative and highest daily glucocorticoid dose, the presence of previous osteonecrosis of bone, postmenopausal status, and prior identification of osteopenia on X-ray.

Although many anecdotal reports have described multiple vertebral compression fractures in patients with lupus, prospective studies are not yet available. In an extensive retrospective study of 702 women with lupus [17] with a total of 5951 person years, the risk of fracture was noted to be increased (odds ratio = 4.7) in the lupus cohort compared to control women of similar age. Older age at lupus diagnosis and longer duration of glucocorticoid use seemed to be independent determinates of fractures in patients with lupus. In all published recent pharmaceutical trials of patients testing bisphosphonates for glucocorticoid-induced osteoporosis (in which some of these patients were those with systemic lupus), it was noted that most fractures occurred in the postmenopausal female population [18, 19].

PATHOPHYSIOLOGY OF LOW BONE MASS AND OSTEOPOROSIS IN PATIENTS WITH SYSTEMIC LUPUS

Several cytokines, including interleukin 1 (IL1), interleukin 6 (IL6), and tumor necrosis factor-α (TNF-α), play a role in the recruitment, differentiation, activation, and function of osteoclasts *in vivo* [6]. In some experimental models of systemic lupus, levels of IL1, IL6, and TNF-α are increased compared to normal controls [20]. In patients with systemic lupus erythematosus, the spontaneous production of bone resorptive lymphokines (IL1, IL6, and TNF) by B cells has been noted [21].

These cytokines stimulate the release of RANK (receptor for activator of nuclear factor-κB) ligand (RANKL) by vascular endothelium, activated T cells and mesenchymal cells, principally osteoblasts. Synovial fibroblasts may also produce RANKL [22, 23] and thus promote osteoclast activation and differentiation without the participation of other bone cells [24].

RANKL binds to its receptor RANK on preosteoclasts and osteoclasts, thereby inducing osteoclast differentiation and increased activity of mature osteoclasts. A natural soluble inhibitor of RANKL called osteoprotegrin (OPG) (Fig. 1) is a product of osteoblastic/stromal cells [25] and is under cytokine control. The balance between RANKL and OPG production determines the level of osteoclast differentiation and activity. More recently, increased levels of osteoprotegrin have been noted in patients with lupus

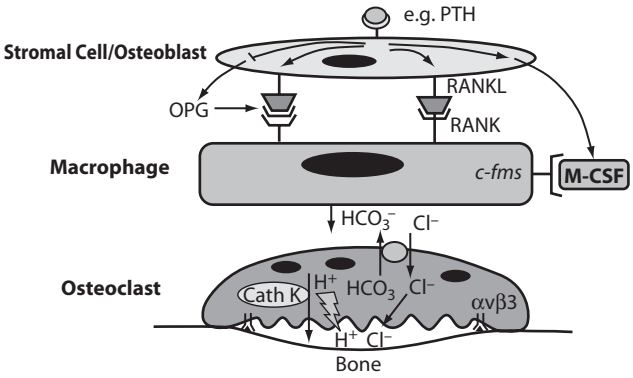

FIGURE 1 Osteoclastogenesis and bone resorption [24].

[26], which could have a protective effect on bone or merely reflect a high turnover state.

Abnormal response of T-helper cells is involved in the pathogenesis of systemic lupus. The release of several TH1 and TH2 derived cytokines may have direct effects on bone resorption. Activation and clonal expansion of CD4 positive autoreactive T cells also release cytokines such as IL6, which play a prominent role in bone reabsorption [6].

The relevance of the observations regarding cytokines in animal models of lupus to human disease is difficult to infer, but the process of bone loss is certainly orchestrated by the vast cocktail of cytokines, secreted both by T and B cells, fibroblasts, osteoblastic cells, and mononuclear cells. The systemic effects of these mediators could explain the relationship between disease activity and osteopenic bone disease in systemic lupus [27].

RISK FACTORS OF OSTEOPOROSIS IN PATIENTS WITH SYSTEMIC LUPUS

Risk factors found to be significantly related to low bone mineral density in patients with lupus include Caucasian race, older age at diagnosis, higher cumulative glucocorticoid dose, higher systemic lupus erythematosus disease activity index (SLEDAI), and postmenopausal status [28]. In most studies, low bone mineral density strongly correlates with cumulative organ damage and high lupus activity index, but not necessarily with duration of disease. Systemic lupus women with osteoporosis, compared to controls, have a history of lower daily calcium intake, are more likely to smoke, and use less oral contraceptives [17]. Glucocorticoid therapy, used in moderate and severe systemic lupus, is usually the pivotal risk factor for bone loss in this patient population [7, 29].

ABNORMAL VITAMIN D METABOLISM

Abnormal vitamin D metabolism has been described in patients with systemic lupus and renal disease [30]. Due to the lack of sun exposure, often required by treatment, patients with lupus are susceptible to vitamin D deficiency. Of course, if there is renal insufficiency, further impairment of vitamin D dihydroxylation and secondary hyperparathyroidism may occur [31].

OVARIAN DYSFUNCTION

Amenorrhea and early menopause have been recognized as risk factors for low bone mass in patients with lupus [5]. Ovarian dysfunction due to the disease activity, or therapy with cytotoxic drugs and/or glucocorticoids has a detrimental effect on bone mineral density. Low estrogen levels lead to increased release of cytokines, such as IL1, TNF, and IL6, and other TH1 linked factors, increased production of RANKL over OPG, and a high turnover bone resorptive state [6].

Patients with lupus may have reduced estrogen exposure due to their concern over estrogen replacement therapy inducing flares of their disease, a controversial issue that is being studied (the Selena trial) but not yet clarified [32]. To date, there are no prospective data demonstrating a deleterious effect of exogenous estrogens on disease activity in human lupus [33]. A more recent case control study [34] found no association between lupus activity and current use or duration of use of hormone replacement therapy or oral contraceptives. In both males and females with lupus, elevated estradiol levels have been described [35], but there have not yet been studies relating this alteration in estrogen metabolism with bone mass in lupus patients.

OTHER HORMONAL FACTORS

Patients with lupus have low DHEA levels [36] and therapy with DHEA may improve bone mass in this population [37]. In addition, increased testosterone oxidation and low plasma androgens have been reported in patients with lupus [38]. The relationship between circulating levels of androgen and bone mass has been addressed in patients with lupus, with women showing a significantly positive relationship between serum dehydroepiandosterone levels (DHEAS) and higher BMD in the lumbar and femoral neck [36]. Low testos-

terone levels have been reported in premenopausal women with lupus, with a high frequency of osteopenia and osteoporosis.

PHYSICAL ACTIVITY AND BONE MASS

In patients with systemic lupus, low bone mass is associated with a lack of physical activity. The presence of arthritis, muscle pain, and weakness reduces mobility and impairs weight-bearing exercises [39]. Studies on physical disability in lupus show a correlation between changes in the disability index, glucocorticoid usage, and the severity of bone mass loss. The disease activity, as measured by the SLICC ACR damage index, can give us information on physical function and disability in patients with lupus. The index score correlates with the physical function scores of the SF36.

LUPUS AND GLUCOCORTICOID-INDUCED OSTEOPOROSIS

One of the most important common causes of low bone mass in systemic lupus is iatrogenic osteoporosis due to chronic glucocorticoid therapy (GIOP). Patients with moderate or severe systemic lupus are commonly exposed to glucocorticoids. There is a rapid initial phase of glucocorticoid induced bone loss (up to 12% of bone mass loss over 6–12 months), followed by a subsequent slower phase of bone loss [40]. Glucocorticoid-induced osteoporosis affects trabecular or cancellous bone (metabolically active bone) more than cortical bone. Alternate day oral therapy with glucocorticoids is also associated with bone loss [41].

Osteoporotic fractures are the most common serious adverse events associated with this therapy [42]. The fragility fracture incidence in the first year of glucocorticoid therapy may be as high as 15% [43]. Cumulative glucocorticoid dose correlates with the risk of fracture in most cross-sectional studies with lupus [5] and prolonged exposure to lower doses also results in bone loss [44]. In the only prospective study to examine this issue, daily rather than cumulative glucocorticoid dose was a strong predictor for vertebral compression fractures [45]. In this study, glucocorticoid users had considerably higher fracture risk than no-users at similar bone density levels. Postmenopausal women on chronic therapy have the highest incidence of fractures because in addition to their systemic lupus and glucocorticoid exposure, estrogen deficiency and aging further contribute to bone loss and microarchitectural deterioration.

PATHOPHYSIOLOGY OF GLUCOCORTICOID-INDUCED OSTEOPOROSIS IN PATIENTS WITH LUPUS

Most forms of osteoporosis result from an increase in the rate of bone reabsorption, coupled by a concomitant decrease in the rate of bone formation. In the case of glucocorticoid therapy, the decrease in rate of bone formation seems to be the predominant mechanism.

The major cytokines controlling bone formation and resorption and their coupling are RANKL (receptor activated nuclear kinase ligand), RANK, and OPG (osteoprotegrin). RANKL is a cytokine produced predominantly by cells of the osteoblast/stromal cell lineage that binds to RANK, its specific receptor on the surface of osteoclasts, leading to osteoclastogenesis and bone reabsorption. OPG, also produced by osteoblasts, acts as a natural decoy inhibitor of RANK. Glucocorticoids inhibit OPG and stimulate the expression of RANKL in human osteoblasts *in vitro* [46]. Thus, during the initial phase of glucocorticoid-induced osteoporosis, osteoclasts may be stimulated. However, osteoclastic function eventually diminishes as demonstrated by inhibition of bone resorption markers [47].

One of the major mechanisms leading to decreased bone mass in GIOP is increased apoptosis or cell death of osteoblasts [48]. Profound suppression of osteoblast numbers and activity subsequently occurs, reflected by significant suppression of markers of bone formation such as bone specific alkaline phosphatase and serum osteocalcin. Histologically, one can demonstrate decreased bone formation rate, decreased trabecular wall thickness, and apoptosis of bone cells.

In addition to their local effects on apoptosis and cytokine production, glucocorticoids also have a number of systemic effects that adversely affect calcium balance [49]. They decrease gastrointestinal calcium absorption and increase urinary calcium excretion, leading to a state of secondary hyperparathyroidism. In addition, glucocorticoids decrease gonadal production of estrogen, testosterone, and adrenal androgens.

DRUG-INDUCED OSTEOPOROSIS IN LUPUS

Cyclophosphamide, methotrexate, and other chemotherapeutic drugs used in lupus have been reported as decreasing bone mineral density or bone mass [50]. Most of these medications are used in lupus concomitantly with glucocorticoid therapy and it is quite difficult to ascertain whether the loss of bone mass

in these patients is due to the chemotherapeutic agent, additional immunosuppressive agents or glucocorticoid therapy. Warfarin impairs the gamma-carboxylation of osteocalcin [51] and thus may have an adverse effect on bone formation. However, clinical decreases in bone density in patients on warfarin have not been demonstrated.

OSTEOMALACIA IN PATIENTS WITH LUPUS

Osteomalacia can be present in patients with lupus. Osteomalacia is a disorder of mineralization of newly formed matrix in adults. Osteomalacia is a syndrome rather than a disease and as such demands a search for the primary etiology. Causes of osteomalacia can be broadly broken down into (1) defective calcium and/or vitamin D absorption and metabolism, (2) calcium or phosphate renal wasting, and (3) inhibitors of mineralization. Insufficient dietary intake of calcium and/or vitamin D, and disorders of malabsorption such as postgastrectomy syndrome or sprue may lead to defective bone mineralization. Patients with lupus often have low sun exposure (as they are often told to avoid the sun) and the dietary intake of vitamin D may also be low (particularly in the elderly). In addition, patients with systemic lupus and/or Sjögren's syndrome with predominant tubulointerstitial disease can develop renal tubular acidosis. Systemic acidosis can contribute to low bone mass by a compensatory enhanced reabsorption of calcium from the skeleton [52].

Anticonvulsants such as phenobarbital, phenytoin, and carbamazepine may cause osteomalacia due to increased hepatic degradation of 25-hydroxyvitamin D [53] through inducement of a metabolizing enzyme that enhances cytochrome P450 liver metabolism. Other anticonvulsants, such as sodium valproate, which do not induce this type of drug metabolizing enzyme, have little or no impact on 25-hydroxyvitamin D levels. Phenytoin and phenobarbital are often utilized in lupus to manage seizures. Patients taking anticonvulsants who are unable to be exposed to sunlight (such as institutionalized patients) are more likely to develop osteomalacia, and usually require an enhanced intake of vitamin D and calcium to achieve positive calcium balance. There is evidence of increased hip fractures in patients on phenytoin [54].

Osteomalacia may also occur in the presence of chronic renal failure due to defective 1α-hydroxylation of 25-hydroxyvitamin D. In the setting of chronic renal failure, osteomalacia is often accompanied by osteitis fibrosa cystica (due to secondary hyperparathyroidism) and osteoporosis. The exact contribution of each disorder to decreased bone density is complex and individual in each patient.

TABLE 2 Laboratory Differential Diagnosis in Osteomalacia

	Calcium	Phosphorus	Alkaline phosphatase
Osteoporosis	Normal	Normal	Normal
Vitamin D deficiency	Low/nl	Low	Elevated
Urinary phosphate wasting disorders	Normal	Low	Normal
Hypophosphatasia	Normal	Normal	Low

Hypophosphatemia most commonly occurs in conditions characterized by defective renal resorption of phosphorus (Fanconi's syndrome, myeloma, lupus, primary Sjögren's syndrome). Hypophosphatemia may occur with or without renal tubular acidosis, which causes osteomalacia by exchanging hydrogen anions with calcium from bone.

Osteomalacia from inhibition of mineralization by etidronate, fluoride, or aluminum is rare, but should be considered in the absence of more obvious etiologies. Adult hypophosphatasia is a rare syndrome characterized by low serum alkaline phosphatase levels which results in abnormal bone mineralization.

Patients with osteomalacia often present with nonspecific bone pain due to insufficiency fractures especially in the areas of the ribs, pubis, or lesser trochanter. An elevated alkaline phosphatase level (due in most cases to secondary hyperparathyroidism) is an important clue that one may be dealing with osteomalacia rather than osteoporosis (Table 2).

BONE MINERAL DENSITY MEASUREMENT

Bone mineral density (BMD) measurements have become an invaluable tool for the assessment of fracture risk in patients and for monitoring response to therapy [55]. There are currently a large number of techniques that permit accurate and precise measurement of bone mass at a variety of skeletal sites. These include central and peripheral densitometry techniques. (Table 3).

Central Techniques

DXA

Dual energy X-ray absorptiometry (DXA) is currently considered to be the gold standard for the assess-

TABLE 3 Methods of Bone Density Measurment

Methods	Major measurement sites	*Short-term precision error (%)	*Accuracy error (%)	Radiation source	Radiation exposure (skin does)
QUS (quantitative ultrasound)	Heel	2–4	3–6	None	None
DXA (pencil-beam and fan-array)	Spine, proximal femur, total body, and forearm	1–2	0–15	X ray	2–5 mrem
PDXA	Peripheral bones	1–2	—	X ray	2–20 mrem
SXA	Forearm and os calcis	1–2	3–5	X ray	1.3 mrem
QCT and PQCT	Spine, forearm	1–3	5–15	X ray or isotopes	100–300 mrem

ment of bone mineral density. The advantages of DXA over other techniques include the vast pool of scientific literature correlating DXA measurements to future fracture risk, low precision errors which make DXA the only device with proven ability to monitor individual response to therapy, and ability to measure multiple sites (usually the spine and the hip) [56]. The ability to measure more than one site helps to negate one of the major limitations of most peripheral devices (the problem of discordance) [57].

Discordance relates to the fact that bone density and T-scores are not the same at all sites. Discordance may be due to differences in peak bone mass, different rates of bone loss after menopause in primarily cortical vs trabecular bones, artifactual elevation of bone density in the spine after age 65, and differences in normative databases between devices and manufacturers. DXA overcomes many of these problems by measuring both cortical (hip) and trabecular (spine) sites and by using a well-established and accepted normative database, the NHANES III total hip database [58].

The majority of cross-sectional data used to establish the diagnosis of osteoporosis in lupus without fragility fractures has been obtained with DXA. The lowest bone mineral density obtained from the lumbosacral spine or any of three sites of the hip (total hip, femoral neck, or trochanteric area), may be used to establish the diagnosis of osteoporosis [59].

Quantitative CT (QCT)

As opposed to the areal bone density obtained with DXA, QCT can take three-dimensional measurements and determine true volumetric bone density [60]. Although techniques are now available for measuring either peripheral (wrist, hip) or central sites, most studies have been performed measuring predominantly cancellous (trabecular) bone of the spine. Since trabecular bone has a greater surface area and thus greater metabolic rate than cortical bone, QCT's major advantage over DXA (which measures a composite of cortical and trabecular bone) has been in assessing the rate of change of trabecular bone mass in patients with high turnover states (e.g., glucocorticoid use, parathyroid therapy) [61].

Peripheral Techniques

Portable peripheral techniques for bone mineral density measurements have been developed. Those include the use of peripheral dual energy X-ray absorptiometry (usually performed at the wrist, heel, or phalanx, single X-ray absorptiometry of the heel, peripheral quantitative computerized tomography of the wrist or hip and quantitative ultrasound (QUS), predominantly performed at the heel [62]. However, in most studies in patients with lupus, these techniques have been used much less than dual energy X-ray absorptiometry in studying patients with lupus [63]. QCT has a special interest in lupus, specifically in patients on corticosteroids, since they are most likely to have involvement of cancellous or trabecular bone.

In summary, in lupus, bone density measurements are used to make a diagnosis of osteoporosis, assess fracture risk, and monitor the effects of therapy. Although both central and peripheral devices are very valuable for fracture risk assessment, at the present time, only DXA has the ability to monitor the effectiveness of therapy.

THERAPY OF OSTEOPOROSIS IN PATIENTS WITH SYSTEMIC LUPUS

As in any at-risk patient, reduction of risk factors and adequate nutrition are important components of intervention in patients with lupus who have low bone mass,

osteoporosis, or other metabolic bone diseases. Physical activity, such as weight-bearing exercises, can enhance muscle mass and strength, coordination, and balance. Education regarding fall prevention and an exercise regimen individualized to the patient's ability are also very useful. Modification of adverse behaviors, such as smoking and inactivity, and prevention of recurrent falls is crucial to avoid fragility fractures.

Calcium and vitamin D in combination have been found to prevent glucocorticoid induced osteoporosis. Multiple studies have shown that dietary calcium with appropriate supplementation is important. The goal is an optimal daily intake of 1000–1500 mg of elemental calcium. Patients with inflammatory diseases, such as lupus, may have impaired calcium intake and decline in gastrointestinal absorption. In patients with lupus, especially if they avoid sun exposure, vitamin D is crucial in the management of low bone mass. Vitamin D increases calcium and phosphorus absorption from the gastrointestinal tract and maintains muscle strength, which is important and plays a role in protection against falls and weakness. At least 400–800 IU of vitamin D a day is appropriate, and in patients with glucocorticoid-induced osteoporosis, this therapy, in addition to calcium, has shown to be protective in a meta-analysis [64].

In patients who are hypogonadal, either postmenopausal women or men with androgen deficiency, hormonal replacement has been suggested [49]. Use of estrogen in patients with lupus, including estrogen replacement therapy, remains controversial. The evidence that estrogens, such as oral contraceptives, can induce anti-nuclear antibodies and the linkage between estrogen exposure with the onset of lupus has been described both in prospective cohort studies and in case reports [65]. Prospective trials of the effects of these hormones on disease activity are not yet available. Thus, estrogen replacement therapy exposes patients to a higher risk of systemic lupus, but there may not be an association with activity of lupus once it is already present.

In postmenopausal women, the long-term benefits vs risks of estrogen replacement therapy are being debated. In July 2002, the hormone replacement therapy (HRT) arm of the Women's Health Initiative (WHI) was stopped prematurely (planned follow-up 8.5 years, actual follow-up 5.2 years) because of an increased risk of breast cancer and an unacceptable rate of the global outcome index [66]. The study did demonstrate fracture risk reduction in hip (34%) and clinical vertebral (34%) fractures for the first time in a prospective study. However, this was offset by the increased relative risk of coronary heart disease (29%) and invasive breast cancer (26%), leading a number of groups including the U.S. Prevention Task Force [67] to recommend caution in prescribing long-term hormone replacement preparations to postmenopausal women for chronic disease prevention (e.g., osteoporosis).

Alendronate

Currently the most widely used therapies in patients with lupus for glucocorticoid-induced osteoporosis and postmenopausal osteoporosis are the bisphosphonates, medications which primarily decrease osteoclastic bone reabsorption. In 1998, Saag and colleagues [18] presented alendronate data from two double-blind trials of 560 patients receiving at least 7.5 mg of prednisone or equivalent daily. The patients had been randomized to three groups: those receiving glucocorticoids for up to 4 months, those receiving them for 4 to 12 months, and those receiving them for more than 12 months. All the data were pooled. As in most trials of osteoporosis, all patients received calcium and appropriate vitamin D. Patients receiving at least 5–10 mg of alendronate per day had significantly increased bone mineral density (BMD) of the lumbosacral spine, trochanter, and femoral neck. Total body BMD was also significantly increased, but only in patients receiving 10 mg of alendronate. In this trial, patients on estrogen were allowed to continue on that therapy.

The second year extension of this trial [68] included 208 patients from the initial cohort receiving 5 or 10 mg of alendronate or placebo. An increase in BMD in the lumbosacral spine and trochanter was demonstrated in patients receiving alendronate, and maintenance of improvement in the femoral neck was also seen. Bone reabsorption markers decreased in the first year, but remained within normal ranges during year 2 for men and premenopausal women. When the alendronate vertebral fracture data was compared to that of controls in this study at 24 months, a significant lowering of vertebral fracture was seen: 0.7% in the alendronate group vs 6.8% in the control group ($P < 0.05$), with 90% reduction of vertebral fractures, year 2, in the pooled data on alendronate. No significant vertebral fracture difference was demonstrated in the first year, but it was seen in the second year [68].

Risedronate

In the prevention trial [69], Risedronate was shown to be efficacious in maintaining BMD in patients initiating glucocorticoid therapy. The study population, including 228 patients, was randomized to 2.5 mg of Risedronate, 5 mg of Risedronate, or placebo. Risedronate was found to be well tolerated, with a distribution of adverse events similar across all groups. In this trial, patients had been receiving glucocorticoid therapy

for less than 3 months. At 12 months of follow-up, BMD in the lumbosacral spine, femoral neck, and trochanter was maintained in patients treated with Risedronate, while patients receiving placebo demonstrated significant progressive bone loss at all sites ($P < 0.05$).

In the treatment trial of Risedronate [70], this agent was proven effective in treating glucocorticoid induced osteoporosis in patients on long-term glucocorticoid therapy, defined as at least 6 months on 7.5 mg of prednisone or prednisone equivalent. The 3-month double-blind multicenter trial studied 290 patients being treated primarily for rheumatic disease. Patients were randomized to either risedronate or vitamin D and calcium. Risedronate significantly increased BMD in both the hip and the spine compared to baseline and compared to placebo (1.76% and 2.9%, respectively. Additionally, assessment of bone turnover markers demonstrated no evidence of oversuppression of bone turnover.

When the data from both the prevention and treatment trials with Risedronate were pooled, there was a 70% reduction in the incidence of vertebral fractures in patients on 5 mg of Risedronate compared to controls within the first year of treatment ($P = 0.016$). The mean incidence of vertebral fractures was 16.3% in the control group and 5.45% in the Risedronate group [70].

Calcitonin

Calcitonin, a 32 amino acid polypeptide hormone that directly suppresses osteoclast activity, is not indicated in glucocorticoid-induced osteoporosis. The Food and Drug Administration (FDA) approved its use in women at least 5 years after the menopause with postmenopausal osteoporosis; however, studies in patients receiving glucocorticoids have been inconclusive.

Meta-analysis of Therapy

A meta-analysis to examine how various drug treatments for glucocorticoid-induced osteoporosis differed by efficacy has been performed [64]. Sixty-one randomized controlled trials lasting at least 6 months in patients using oral glucocorticoids were evaluated. The use of calcium, vitamin D, calcitonin, and bisphosphonates was assessed. BMD was measured in the lumbosacral spine by either QCT, DXA, or DPA. Studies were included in the analysis if changes of BMD from baseline could be determined. Thirty-three studies were eligible for analysis. The data showed that of all the treatments that significantly increased lumbosacral spine BMD, bisphosphonates proved substantially more effective than calcitonin or vitamin D plus calcium ($P < 0.001$). This data, coupled with the data from clinical trials, demonstrated an increase in bone mass and significant reduction of vertebral fractures, providing a strong rationale for the use of bisphosphonate therapy for the treatment and prevention of glucocorticoid-induced osteoporosis.

Parathyroid Hormone Therapy

Parathyroid hormone was utilized in a randomized clinical trial of postmenopausal women (mean age was 63 years) with osteoporosis who were taking glucocorticoids and hormone replacement therapy. Of the 51 patients, 8 had systemic lupus erythematosus. In this study [71], parathyroid administration significantly increased bone mineral density by QCT and by DXA ($P < 0.001$) in comparison to those patients on estrogen plus calcium and vitamin D alone.

During the first 3 months of parathyroid hormone (PTH) therapy, markers of bone formation increased significantly. Parathyroid hormone dramatically increased bone mineral density in the central skeleton of postmenopausal women, some with lupus, with glucocorticoid-induced osteoporosis who were taking hormone replacement therapy.

In glucocorticoid-induced osteoporosis, the addition of parathyroid hormone increased dramatically bone mineral density in the lumbosacral spine and hip over estrogen alone. In the initial study, no patient on parathyroid hormone plus estrogen had any fragility fracture, and those patients, followed for another year, continued to have an increase in bone mineral density. One year after discontinuation of PTH, while the patients continued to receive hormone replacement therapy, lumbar spine bone mineral density remained stable while total hip bone mass increased 5% over baseline levels [61]. Although PTH treatment in postmenopausal osteoporotic women has been shown to reduced incidence in radiographic vertebral fractures, there are no data yet regarding PTH in bisphosphonate treated patients who later receive PTH.

ACR Guidelines

The recommendations for the prevention and treatment of glucocorticoid induced osteoporosis from the American College of Rheumatology [72] include the modification of lifestyle and risk factors for osteoporosis (e.g., smoking cessation or avoidance, reduction of alcohol consumption if excessive, and instruction in weight-bearing physical exercises), initiation of supplementation with calcium and vitamin D, plain or activated form, and the prescription of bisphosphonates,

which should be used with caution in premenopausal women. Patients receiving long-term glucocorticoid therapy (prednisone or equivalent equal to or over 5 mg per day) should be included in these recommendations. The replacement of gonadal hormones, if deficient, needs to be performed with caution, especially in females. The measurement of bone mineral density at the lumbosacral spine and/or hip is required in those patients on chronic glucocorticoid therapy, and if the BMD is not normal, adding a bisphosphonate or a second like agent, including calcitonin, could be considered. In patients on therapy, bone mineral density can be measured as frequently as every 6 months to a year.

Unapproved Therapies for Glucocorticoid-Induced Osteoporosis

Disodium Etidronate

Disodium etidronate, given cyclically, has been shown to be effective in glucocorticoid-induced osteoporosis in a large randomized-controlled double-blind placebo-controlled trial. A 12-month, randomized, placebo-controlled study of intermittent etidronate (400 mg per day for 14 days) followed by calcium (500 mg per day for 76 days), given for four cycles, was performed in 141 men and women (age, 19 to 87 years) who had recently begun high-dose corticosteroid therapy [73]. The mean (+/–SE) bone density of the lumbar spine and trochanter in the etidronate group increased 0.61 +/– 0.54 and 1.46 +/– 0.67%, respectively, as compared with decreases of 3.23 +/– 0.60 and 2.74 +/– 0.66%, respectively, in the placebo group. There was an 85% reduction in the proportion of postmenopausal woman with new vertebral fractures in the etidronate group as compared with the placebo, a secondary endpoint of the trial. Etidronate is not approved in the United States for osteoporosis.

Pamidronate

Intravenous pamidronate has been studied in the prevention of glucocorticoid-induced osteoporosis [74]. A total of 27 patients who required first-time, long-term corticosteroid therapy at a daily dose of at least 10-mg prednisolone were studied. Patients allocated to pamidronate treatment received a baseline intravenous infusion of 90-mg pamidronate at the initiation of their steroid treatment, then received 30-mg pamidronate, intravenously, every 3 months for as long as steroid therapy was continued. The control patients (calcium group) were put on a daily 800-mg elemental calcium supplement given as calcium carbonate. Over 1 year, the pamidronate group showed a significant BMD increase in the lumbar spine (3.6%), and at all sites of the hip (2.2% at the femoral neck). In the calcium group, a significant BMD reduction was registered at the lumbar spine (–5.3%) and at the femoral neck (–5.3%). Differences between the groups were significant at all sites measured. Pamidronate is not approved in the United States for osteoporosis.

DHEA

DHEA, which has not been approved by the FDA as therapy for musculoskeletal symptoms of lupus, has been shown to decrease the glucocorticoid requirement in some patients [37]. It is widely used over-the-counter by patients with lupus.

Hydroxychloroquine

Hydroxychloroquine was found by Lakshminarayanan [75] to be the only factor associated with higher BMD of the hip and spine in patients with systemic lupus, and it remains predictive of higher BMD in a post-hoc analysis. Hydroxychloroquine may be protective against low BMD in glucocorticoid patients with systemic lupus; however, duplicate studies are needed.

THERAPY OF OSTEOMALACIA AND DRUG-INDUCED OSTEOMALACIA

After measuring 25-hydroxy and 1,25-dihydroxyvitamin D, 20–30 μg of 25-hydroxyvitamin D or 0.15–0.5 μg of 1,25-dihydroxyvitamin D were utilized where appropriate. Alternatively, 50,000 units of vitamin D in a pill or 1000 units of vitamin D given intramuscularly could be used. The dose and frequency of administration needs to be adjusted to the serum levels of calcium, phosphorus, alkaline phosphatase, and 25-hydroxyvitamin D level.

RENAL TUBULAR ACIDOSIS

Renal tubular acidosis can be present in patients with lupus and Sjögren's syndrome. In this disorder, the kidney is incapable of conserving bicarbonate and the patients have low serum or plasma bicarbonate concentration and systemic metabolic acidosis.

Patients with renal tubular acidosis can develop osteomalacia, particularly if there is proximal tubular

involvement. Patients with lupus and Sjögren's can have these types of complications. Therapy for renal tubular acidosis includes correction of the systemic disease, the use of oral sodium bicarbonate, and occasionally the use of thiazides to reduce plasma volume and enhance tubular bicarbonate reabsorption.

RENAL OSTEODYSTROPHY

Renal osteodystrophy may occur in patients with lupus and end stage kidney disease. Patients can have high turnover bone disease with secondary hyperparathyroidism or low turnover disease with osteomalacia. Osteitis fibrosis is the most common high turnover lesion of renal osteodystrophy. This represents the response of bone to persistent high levels of PTH. In these patients, there is histological evidence of active bone reabsorption with increases in the number and size of osteoclasts and in the number of reabsorption bays or lacuna within cancellous bone. Fibrous tissue is found immediately adjacent to bone trabecula and may accumulate extensively within the bone marrow space. In contrast, low turnover bone disease with osteomalacia is also seen in patients with renal osteodystrophy.

GLUCOCORTICOID-INDUCED OSTEONECROSIS

See Chapter 37. Osteonecrosis has been reported in 3–30% of patients with systemic lupus erythematosus. This wide range reflects the use of different techniques in defining this condition. Although osteonecrosis has been described in patients exposed to glucocorticoid therapy, in lupus, it occurs even in patients not exposed to glucocorticoids. In osteonecrosis, bone and marrow cells are destroyed, contributing significantly to bone loss, particularly of the femoral head, although the knees, shoulders, and other bones may also be involved. Osteonecrosis in the femoral head has been noted to occur more in subjects taking glucocorticoid therapy for their lupus than in nonusers of this medication. Although it is highly probable that both local and systemic mechanisms are at work, as shown later, in the development of glucocorticoid-induced osteonecrosis, many of these patients may have, in addition to the glucocorticoid exposure and their systemic lupus, smoking, hypercholesterolemia, and hypertriglyceridemia. Symptomatic osteonecrosis occurred in 14.5% of 744 patients with lupus, described in the Baltimore cohort [4], and on many occasions involved multiple joints. Osteonecrosis was not associated with increased mortality, but it was associated with physical disability.

CLINICAL MANIFESTATIONS OF OSTEONECROSIS

The most common presenting symptoms of osteonecrosis include groin, thigh, and buttock pain, and weight-bearing and motion-induced pain. In addition, two-thirds of patients complain of rest pain and night pain. A small group of patients may be asymptomatic.

Other bones involved, in addition to the humeral head, include the femoral condyle, proximal tibia, vertebrae, and small bones of the hands and feet. Many patients have bilateral involvement [76], and some have pain in multiple anatomical areas. Therefore, if a patient presents with osteonecrosis in one hip, the contralateral hip should be assessed for this condition. On physical examination, patients have pain and limitation of motion, particularly with internal rotation and abduction.

Radiographic Evaluation

The plain radiograph may be normal initially in osteonecrosis. Early findings are mild changes in density, followed by sclerosis and cysts. The crescent sign, a subchondral radiolucency, is felt to be pathognomonic [77]. Eventually joint space narrowing and periarticular sclerosis can occur.

Technetium-99 scanning can show decreased uptake in the affected bone. Magnetic resonance imaging is significantly more specific and sensitive than plain radiography or bone scanning. The sensitivity is felt to be up to 91% [78]. Changes can be seen early in the disease, even when other studies are negative. Focal lesions are well demarcated and homogeneous on T1-weighted images, and high intensity line can appear on T2-weighted images, representing hypervascular granulation tissue. This is felt to be a pathognomonic double line sign.

In a study of systemic lupus patients, 23 glucocorticoid-treated patients had no hip pain and negative hip X rays, but a positive MRI. Eight (35%) had evidence of osteonecrosis of the femoral head on MRI, and six, 26%, by bone scanning. Over a 3-year period, only two of the eight patients with initial abnormal MRI had a lesion that could be seen by X-ray. So, overtreatment can occur also in this condition [79].

Staging

There are multiple staging systems for osteonecrosis. The Association of Research Circulation Osseous (ARCO) developed a staging system that attempts to bring conformity to clinical trials and strategies. In stage zero, all diagnostic studies are normal. In stage one, X

rays are normal but MRI imaging is positive or the biopsy is positive for necrosis. The extent of involvement can be less than 15%, 15–30%, or greater than 30%, respectively. In stage two, X rays are positive but there is no collapse, and the extent of involvement remains between 15 and 30% or greater than 30%. In stage three, there is flattening and a crescent sign, indicating subchondral collapse. In stage four, in addition to the flattening of the femoral head with joint space narrowing, there is evidence of early osteoarthritis.

Treatment

Conservative or nonoperative therapy, including bed rest and avoiding weight bearing with crutches has been ineffective. In osteonecrosis of the shoulder, results of conservative therapy may be more efficacious than in the hip.

The results of total hip arthroplasty in osteonecrosis are not as significantly good as with total hip replacement for osteoarthritis [80], which leads to a higher revision rate in patients with osteonecrosis. Nevertheless, arthroplasty is the next best treatment available for this condition. Total arthroplasty is also utilized in osteonecrosis of the knee or shoulder.

The failure of conservative management and relative poor long-term survival of prosthetic devices, total hips, and knees, created the need for other interventions. Core decompression was initially used as a diagnostic tool to measure bone marrow pressure and other biopsy specimens. Small case series in retrospective studies have shown that cord decompression for osteonecrosis of the hip is successful, especially in stage one or stage two hip disease. Core decompression for osteonecrosis of the shoulder or knee has not been properly ascertained. Osteotomy also has been used for this purpose.

In summary, the treatment for osteonecrosis includes conservative therapy, joint replacement, including bed rest and avoiding weight bearing with crutches, core decompression, and osteotomy.

PATHOGENESIS OF GLUCOCORTICOID-INDUCED OSTEONECROSIS

In osteonecrosis, bone and marrow cells are destroyed. Patients with systemic lupus have accompanying small vessel vasculitis and venous endothelial cell changes that lead to stasis, which can increase vascular pressure and eventually cause osteonecrosis. In the earlier medical literature, severe necrosis of the femoral neck was reported to be primarily due to thrombosis and compression of blood vessels, with increased vascular pressure, or to microfractures of bone, or simply to fat and fluid retention [81].

This theory suggested that demineralization and thinning of trabecular bone occurred as a result of interrupted blood flow to the bone, and until more recently, provided the only possible explanation for the profound and rapid necrosis that is sometimes found in patients with osteoporosis of the femoral head.

A more recent theory of pathogenesis suggests that osteonecrosis is a result of a disruption of the complex interplay of osteoblasts and osteoclasts in the bone remodeling cycle. Significant glucocorticoid use leads to the suppression of osteoblastogenesis (the development of mature osteoblasts). Studies in mice given glucocorticoids [82] have shown a threefold increase in apoptosis of osteoblasts compared to normal controls. Osteoblasts that form new bone, once apoptotic, may in turn assimilate into bone matrix or become lining cells of the bone in the process of reabsorption. Histological studies have indicated that only 20–50% of osteoblasts are recovered in glucocorticoid-exposed patients [83], suggesting that programmed cell death of a majority of osteoblasts occurs during each formation reabsorption cycle in osteonecrosis. Apoptosis of osteoclasts are also associated with glucocorticoid use. It appears that part of the function of the osteoclasts may be to signal detection of microdamage and to initiate the bone remodeling process. In glucocorticoid-induced osteonecrosis, the initial signal for remodeling is prevented by apoptosis of the osteoclasts.

Research efforts are now focusing on hormones and cytokines that intervene early in the bone remodeling cycle to prevent apoptosis of osteoblasts and enhance osteoblastogenesis and therefore prevent bone loss from glucocorticoid use. The role of, for example, recombinant PTH on this process is still under study.

CONCLUSION

In patients with lupus, metabolic bone disease can be a significant cause of morbidity. Physicians caring for patients are now able to recognize and intervene to manage these complications. Most notably, dramatic advances in the ability to diagnose low bone mass before the first fracture, together with proven therapies to prevent bone loss are likely to alter fracture occurrence in patients with lupus treated with glucocorticoids.

IMMUNOLOGY OF ANTI-PHOSPHOLIPID ANTIBODIES AND COFACTORS

Tatsuya Atsumi
Eiji Matsuura
Takao Koike

HISTORICAL BACKGROUND

Anti-phospholipid antibodies (aPLs) are present in a wide range of infectious and autoimmune diseases. aPLs, in particular anti-cardiolipin antibodies (aCL) and lupus anticoagulants (LA), are of considerable clinical importance because of the close association with predominant clinical features of venous and arterial thrombosis and pregnancy morbidity. The term antiphospholipid syndrome (APS) has been used to define this set of pathologic features. Recognition of this syndrome is now better understood worldwide as related clinical implications are now more well defined [1–4].

Anti-phospholipid antibodies were first discovered by Wassermann *et al.* [5] as part of the spectrum of antibodies produced in response to syphilitic infection. They found that sera from syphilitic patients could agglutinate a lipoid tissue extract. In the early 1940s, Pangborn [6, 7] identified the antigenic component in tissue extracts used in these tests as a novel anionic phospholipid, named cardiolipin, and the antibodies reactive to cardiolipin were termed reagins. Reagins in serum samples can be detected with the antigen mixture of cardiolipin, cholesterol, and phosphatidylcholine (Venereal Disease Research Laboratory, or VDRL antigen), resulting in a visible flocculation in *in vitro* assays. Although reagins are found predominantly in association with syphilitic infection, they are not specific to antigens of *Treponema palladium*. With the development of tests for treponema-specific antigens (*Treponema palladium* hemagglutination assay; TPHA), in the 1950s, it was observed that individuals with chronically false-positive serologic tests for syphilis (STS), when followed for many years, often developed systemic lupus erythematosus (SLE) [8–11]. These reports were confirmed later in two additional studies [12, 13] and some individuals with SLE and a chronic false-positive STS had recurrent spontaneous fetal loss, thrombocytopenia, and thromboembolic problems, when compared with age-matched SLE patients with a negative STS [8].

False-positive STS results were also noted in early reports of SLE patients with acquired inhibitors of *in vitro* phospholipid-dependent coagulation tests, in particular, the activation of prothrombin [14]. Laurell and Nilsson [11] investigated this association and suggested that the anticoagulant effect and the positive reaction with phospholipid antigen could be ascribed to the same causal factor.

The name lupus anticoagulants, coined by Feinstein and Rapaport [15] represents the first of the major misnomers in this field. These antibodies, which were designated LA because they were originally detected in the plasma of patients with SLE, are now more frequently present in persons who do not have this condition. Although LA prolong coagulation reactions *in vitro*, clinically they can cause thrombotic diseases [16] and individuals with LA do not have a tendency to bleed unless they have a second coagulation defect such as

factor VIII deficiency or thrombocytopenia. Thus, the anticoagulant activity was thought to be linked to an antibody that reacted with a lipid antigen. Against this background, more recent evidence supports that these antibodies are specific for phospholipid complexes with plasma proteins, such as β2-glycoprotein I (β2-GPI).

In the early 1980s, solid phase immunoassays were devised for detection of aPLs and the use of cardiolipin as a solid phase antigen was prompted by observations relating to the presence of the LA to frequent findings of a biological false-positive STS in patients with SLE and other autoimmune disorders. Radioimmunoassay and enzyme-linked immunosorbent assay (ELISA) which directly detect circulating aCL were originally devised by Harris *et al.* [1] and Koike *et al.* [17], respectively. Early studies on the aCL assay demonstrated the requirement of additive bovine serum in the blocking buffer, diluent, or both, to enhance aCL binding to the targeted phospholipid. In 1990, three groups independently reported the requirement of a cofactor (i.e., β2-GPI) for autoimmune aCL binding to the solid phase phospholipid [18–20]. Subsequently, it was shown that the epitope for aCL develops when β2-GPI is adsorbed on polyoxygenated polystyrene plates. It was also shown that β2-GPI interacts with a lipid membrane composed of negatively charged phospholipids [21].

The remarkable range of antigenic specificities of aPLs includes other proteins of protein–phospholipid complexes such as prothrombin, annexin V (placental anticoagulant protein-I), protein S or protein C, and high- and/or low-molecular-weight kininogens [22–25]. In particular, prothrombin has been recognized as the "second" major antigenic target of autoimmune aPLs, and anti-prothrombin antibodies are responsible for LA activity in many cases with APS [22]. The expression of epitopes by at least some of these phospholipid-binding proteins does not depend on the presence of phospholipids. The spectrurm of potential immunogenic targets facilitates subclassification of these heterogeneous antibodies.

In 1998, an international consensus preliminary criteria for the classification of the APS was stated in Sapporo, thus called Sapporo-Criteria (Table 1) [26]. In this criteria, IgG/M β2-GPI dependent aCL and LA detected according to the guidelines of the International Society on Thrombosis and Hemostasis are listed to categorize "definite" APS. As markers of APS, other aPLs are still on discussion.

TABLE 1 Preliminary Criteria for the Classification of the Antiphospholipid Syndrome (Sapporo-Criteria)

Clinical criteria

1. Vascular thrombosis:
   One or more clinical episodes of arterial, venous, or small vessel thrombosis, in any tissue or organ. Thrombosis must be confirmed by imaging or Doppler studies or histopathology, with the exception of superficial venous thrombosis. For histopathologic confirmation, thrombosis should be present without significant evidence of inflammation in the vessel wall.
2. Pregnancy morbidity
   (a) One or more unexplained deaths of a morphologically normal fetus at or beyond the 10th weeks of gestation, with normal fetal morphology documented by ultrasound or by direct examination of the fetus, or
   (b) One or more premature births of a morphologically normal neonate at or before the 34th week of gestation because of severe pre-eclampsia or eclampsia, or severe placental insufficiency, or
   (c) Three more unexplained consecutive spontaneous abortions before the 10th week of gestation, with maternal anatomic, or hormonal abnormalities and paternal and maternal chromosomal causes excluded.

Laboratory criteria

1. Anti-cardiolipin antibody of IgG and/or IgM isotype in blood, present in medium or high titer, on two or more occasions, at least 6 weeks apart, measured by a standard enzyme linked immunosorbent assay for β-glycoprotein 1-dependent anti-cardiolipin antibodies.
2. Lupus anticoagulant present in plasma on two or more occasions at least 6 weeks apart, detected according to the guidelines of the International Society on Thrombosis and Hemostasis.

Definite APS is considered to be present if at least one of the clinical and one of the laboratory criteria are met.

PHOSPHOLIPIDS

Phospholipids are compounds composed of 1, 2-diacylglycerol and a phosphodiester bridge linking the glycerol backbone to the nitrogenous bases of choline, ethanolamine, the inositol derivatives, and glycerol [27]. Cardiolipin is made up of two phospholipid molecules joined by a central glycerol molecule attached to the phosphodiester group. Phospholipids are abundant in the brain, spinal cord, and in body fluids such as plasma, but do occur primarily in various organelle and cellular membranes, including mitochondria, endothelial cells, and aggregated and/or activated platelets. These cells are an essential source of anionic phospholipids such as phosphatidylserine, provide a catalytic surface for proteins, and function as modulators of coagulation pathways. The distribution of phospholipids over the two halves of the cellular membrane bilayer is extremely asymmetric for both phosphatidylserine and sphingomyelin, the first being almost exclusively present in the inner monolayer, whereas sphingomyelin is confined to the outer monolayer [28]. Phosphatidylcholine and phosphatidylethanolamine are distributed more

evenly although phosphatidylcholine seems to have a preference for the outer monolayer and phosphatidylethanolamine for the inner leaflet. The result of this distribution is that the outer surface of cells is in general about 80% composed of phosphatidylcholine, the remainder being occupied by phosphatidylethanolamine. The inner monolayer of the membrane contains virtually all the phosphatidylserine, phosphatidylinositol, phosphatidic acid, and a large fraction of phosphatidylethanolamine, resulting in an almost exclusive location of negatively charged phospholipids in the inner monolayer of the cellular membrane. However, in particular circumstances (i.e., ongoing apoptosis, cell activation, or cell injury) an enhanced loss of phospholipid asymmetry can occur. The phenomenon of scrambling of phospholipids was noted in blood platelets activated by the combined action of the physiologic activators collagen and thrombin.

ANTI-PHOSPHOLIPID ANTIBODIES (aPLs) AND THEIR COFACTORS

Numerous studies have elucidated the specificity of anti-phospholipid antibodies (aPLs). It is clear that the nomenclature of aPLs is a misnomer and that these autoantibodies react with phospholipid-binding plasma proteins (cofactors), such as β2-glycoprotein I (β2-GPI), prothrombin, annexin V, high-molecular-weight kininogen, protein S, and protein C.

Anti-cardiolipin Antibodies (aCLs) and β2-Glycoprotein I (β2-GPI)

Antibodies against β2-GPI

Anti-cardiolipin antibodies (aCLs) present in APS patients can be detected using immunoassays and solid phase cardiolipin as a putative antigen [4, 17]. However, antibodies directed against phospholipid-binding plasma or serum proteins (i.e., cofactors), in particular β2-GPI, are present in serum samples and can be components of a sample diluent and blocking buffer in various types of immunoassay systems. Many studies indicated that one of the predominant antibodies considered to be aCL in APS patients is that against β2-GPI, rather than any of the negatively charged phospholipids such as cardiolipin, phosphatidylserine, phosphatidic acid, and phosphatidylinositol [18–21, 29–35. In contrast, aPLs associated with infectious diseases bind directly to these negatively charged phospholipids [21, 33–35]. Anti-β2-GPI autoantibodies recognize a cryptic epitope on the β2-GPI molecule when β2-GPI interacts with a lipid membrane composed of negatively charged phospholipids or when β2-GPI is adsorbed on a polyoxygenated polystyrene plate treated with γ-irradiation or electrons [21, 29, 30]. With this treatment, oxygen atoms such as C—O and C═O are covalently introduced onto the surface of polystyrene plates, and epitopes recognized by autoimmune anti-β2-GPI antibodies appear [21]. Consistent with this evidence are reports showing that aPLs bind to β2-GPI adsorbed on various commercially available oxidatively modified polystyrene plates [36] or on a nitrocellulose membrane or on an experimentally γ-ray/UV-irradiated polystyrene plates [37] and that an epitope for aPLs is exposed by the β2-GPI molecule modified with glutaraldehyde [38].

Several groups timely reported that anti-β2-GPI autoantibodies in APS patients have a relatively low affinity, which was demonstrated by using IgG Fab′ of the autoantibodies, dimerized β2-GPI molecules which are formed via a disulfide bridge between two mutated domain Vs or between two apple 4 domains fused to the N-terminus of domain I [31, 32, 39].

The epitopic location on β2-GPI for anti-β2-GPI autoantibodies from APS patients is still controversial. In 1996, Igarashi *et al.* first reported that domain IV or I are candidates for epitopic location in the β2-GPI molecule, by using a series of deletion mutant proteins of β2-GPI [30]. Later, George *et al.* [40] demonstrated that domain IV of β2-GPI is one of the major epitopic location for aCL raised in APS patients, using the deletion mutant proteins. In contrast, Iverson *et al.* [41] and McNeeley *et al.* [42] reported that anti-β2-GPI autoantibodies in the major population of APS patients recognized a particular structure in domain I of β2-GPI and antibody binding was diminished by replacement of a related amino acid located in the domain [41, 42]. However, it was also reported that some particular mutations made in domain IV also affected the antibody binding to β2-GPI in anti-β2-GPI ELISA [43].

Nature of a Target Antigen (β2-GPI)

β2-GPI, a 50-kDa protein with a carbohydrate content of 17%, is present in normal human plasma at approximately 200 μg/ml and was first described by Schultze *et al.* in 1961 [44] as a perchloric acid soluble human plasma protein with an unknown function. Northern blots revealed that the polypeptide is mainly synthesized in the liver but also in various cells, as described later. After eliminating sialic acid from the molecule, multiple isoelectric subspecies were identified.

Because β2-GPI is present in the lipoprotein fractions, such as chyromicron, VLDL, and HDL, with ultra-

centrifugation and activated lipoprotein lipase *in vitro*, β2-GPI is also designated apolipoprotein H. β2-GPI binds to various negatively charged substances such as phospholipids, heparin, lipoproteins, and activated platelets and inhibits the intrinsic blood coagulation pathway, prothrombinase activity, and adenosine diphosphate (ADP)-dependent platelet aggregation [45–50].

The complete amino acid sequence of human β2-GPI, as determined by peptide sequencing, reveals a single polypeptide chain composed of 326 amino acid residues with five oligosaccharide attachment sites [51, 52]. The complete nucleotide sequence and the deduced amino acid sequence were defined by cDNA cloning from human liver-originated cells (e.g., a hepatoma cell line (HepG2)), and sequencing [53, 54]. β2-GPI is composed of five homologous motifs of approximately 60 amino acids and which contain highly conserved cysteins, prolines, and tryptophans (Fig. 1). The motif is characterized by a framework of four conserved half-cysteine residues related to the formation of two internal disulfide bridges. These repeating motifs were designated as short consensus repeats (SCR), complement control protein repeats (CCP), or sushi domains. However, the fifth domain (the carboxyl terminus, domain V) of β2-GPI is a modified form that contains 82 amino acid residues and six half cysteines. Table 2 lists proteins of this superfamily together with the number of SCRs units. Proteins listed include β2-GPI, C4 binding protein, complement receptor I (CD35), complement receptor 2 (CD21), decay accelerating factor (CD55), factor H, factor I, factor XIII, and haptoglobin. However, there are no reports as to whether or not β2-GPI is involved in the complement regulation [55].

TABLE 2 Short Consensus Repeat (SCR) Superfamily

Protein	Number of SCR units
β_2-glycoprotein I (apolipoprotein H)	5
C4 binding protein	8
Complement receptor 1 (CD35)	30
Complement receptor 2 (CD21)	16
Decay accelerating factor (CD55)	4
Factor H	20
Factor I	1
Factor XIII	10
Haptoglobin	2

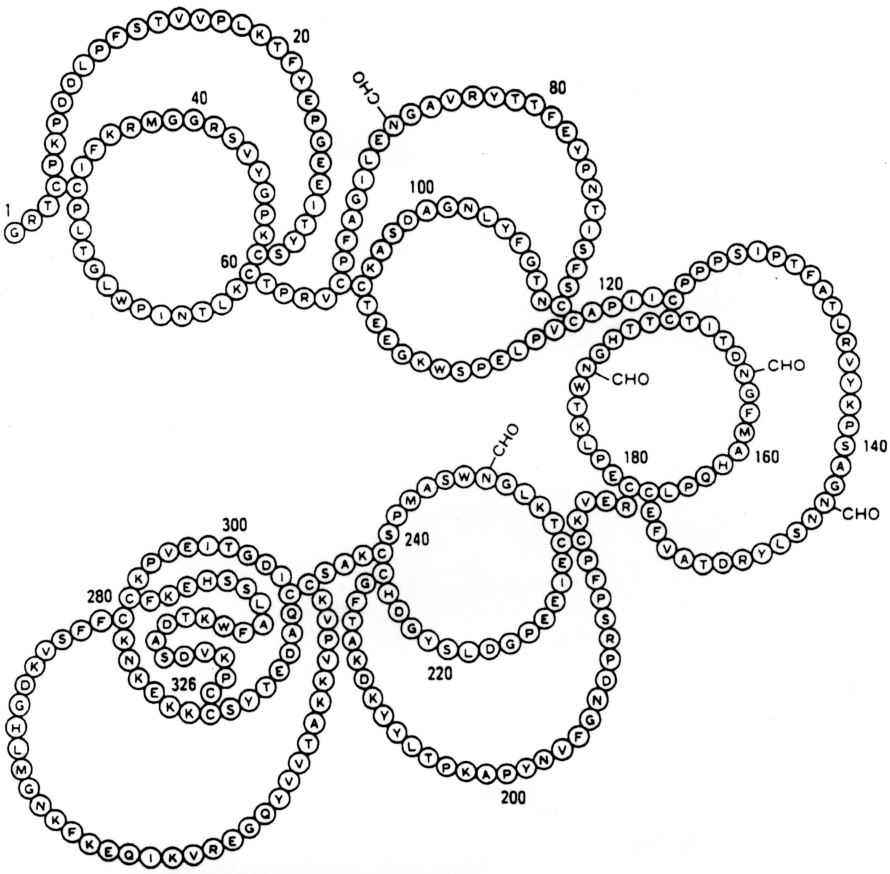

FIGURE 1 Amino acid sequence and location of disulfide bonds in human β2-GPI.

In 1999, two individual groups crystallized human β2-GPI and characterized its tertiary structure [56, 57]. The structure of β2-GPI, which is a highly glycosylated protein, reveals an elongated fishhook-like arrangement of the globular short consensus repeat domains (Figs. 2 and 3). Both of these crystal analyses consistently indicate that half of domain V deviates strongly from the standard fold, as observed in domain I to IV.

β2-GPI binds to solid phase phospholipids through a particular region in the fifth domain, C^{281}KNKEKKC^{288} and the phospholipid binding property is significantly diminished by cleavage of one particular site in the fifth domain of β2-GPI (i.e., K317 and T318) [35, 58–61]. These structural studies on the crystallized β2-GPI indicated that the aberrant half forms a specific phospholipid-binding site. A large patch of 14 positively charged amino acid residues provides electrostatic interactions with anionic phospholipid headgroups and an exposed membrane-insertion loop yields specificity for lipid layers. However, electron density corresponding to the loop, S^{311}-K^{317} is not visible due to high mobility (flexibility) in one of these two studies on the crystallized β2-GPI (Fig. 4) [56]. Further, Hoshino *et al.* [62] determined the tertiary structure of domain V and the result showed that the molecule is composed of well-defined four antiparallel β-strands and two short α-helices, as well as a long highly flexible loop. Thus, the positive charges on the domain interact with anionic phospholipid headgroups and the flexible loop of the sequence, S^{311}-K^{317}, specifically interacts with hydrophobic molecules [63] and putatively inserts into the lipid layer, thereby anchoring the protein molecule to the membrane [56]. Further, it is also known that the interaction of β2-GPI alters the fluidity and polarlization of the target membranes [64].

Hagihara *et al.* [65] reported that the cleavage is weakly produced by factor Xa. Later, the same research group showed that the site-specific cleavage was specifically produced by plasmin treatment [66]. Matsuura *et al*. attempted to predict tertiary structures of intact and nicked (cleaved) domain V of β2-GPI, through protein modeling and analysis on epitopic study on an anti-β2-GPI monoclonal antibody, which is specific to the intact β2-GPI using phage library technology [67]. These data suggested that the two flanking cysteines were important for peptide conformational presentation of the fifth domain, when binding to phospholipids. In contrast, the pathophysiologic implication of plasma/serum levels of the nicked β2-GPI has been discussed. Brighton *et al.* [68] first found that β2-GPI levels are significantly low in patients with thrombosis or disseminated intravascular coagulation syndrome (DIC). Horbach *et al.* [69] reported that plasma β2-GPI levels are lower in patients with DIC as compared with controls and the nicked β2-GPI levels were contrarily high. They suggested that the reduction of β2-GPI levels and the generation of the nicked β2-GPI occurred due to absorption by apoptotic cells and activation of fibrinolysis, respectively. Further, Itoh *et al.* [70] reported highly increased plasma levels of the nicked β2-GPI in patients with leukemia and with lupus anticoagulant. Cleavage of β2-GPI which leads to its reduced antigenicity may play a role in a natural self-defense against autoimmunity and the development of thrombosis in APS; however, the clinical significance of the cleavage should be elucidated in future studies.

β2-GPI is expressed in liver and hepatocyte cell lines, including HepG2 and PLC/PRF/5 [54, 71]. Transcription of β2-GPI apparently does not occur in kidney, liver, or the cell lines HeLa, Molt-4, Raji, and BSM, but the mRNA for β2-GPI has been identified in extracts of villous placental tissue, the choriocarcinoma cell lines, that is, Jeg-3, BeWo, and Jar, endothelial cells, astrocytes, and neurones [54, 72, 73]. β2-GPI has been immunohistochemically localized to the syncytiotrophoblasts and extravillous cytotrophoblasts of both normal term placenta and placenta from pregnancies affected by aPLs [73, 74].

Genetically determined structural variation in the β2-GPI molecule has been identified by isoelectric focusing and by immunoblotting [75]. APOH*2 is the most common allele followed by APOH*1 and APOH*3 alleles in all racial groups [76]. Further, the relationship between β2-GPI polymorphism and its plasma levels were reported [77]. The molecular basis of β2-GPI protein polymorphism (codons at 88, 247, 306, and 316) and its distribution in large U.S. populations, non-Hispanic Whites, Hispanics, Blacks, and/or Japanese has been reported [78–81]. In addition, complete β2-GPI deficient individuals were reported by our group. Analysis of their β2-GPI genes revealed that a thymine corresponding to position 379 of the β2-GPI cDNA was deleted (β2-GPI-Sapporo), hence, a frame shift would occur and this would make the gene code for an amino acid sequence unrelated to β2-GPI beyond this position [82].

Megalin/gp330, is an endocytic receptor that internalizes multiple ligands including apolipoprotein E and B100. Megalin is the main antigenic target in passive Heymann nephritis, where it binds circulating autoantibodies, leading to the formation of subepithelium immune deposits. In 1998, it was reported that megalin is a receptor for a β2-GPI molecule and a β2-GPI–phospholipid complex [83].

Animal Models of APS and β2-GPI-Knockout Mice

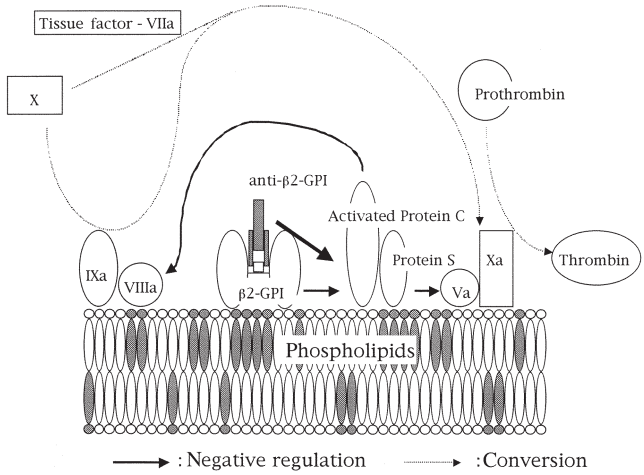

FIGURE 4 Regulation of thrombin generation by protein C system and its inhibition by anti-β2-GPI antibody.

immune complexes, and lupus nephritis are present [84, 85]. Myocardial infarction is the hallmark in the WB F1 male mice [84, 86]. Yoshida *et al.* [87] reported that the incidence of myocardial infarction in these mice increased with age and that over 80% of male WB F1 mice with myocardial infarction had small multiple infarctions in the right ventricular free wall and anterior, posterior, and septal ventricular walls. In the affected coronary arteries the intimate thickening consisted of cellular components with frequent recanalization or an eosinophil thrombus-like substance. Thrombocytopenia is a frequent finding in patients with aPLs. WB F1 mice also develop thrombocytopenia with age, and platelet-associated antibodies and circulating anti-platelet antibodies are present. The mechanism by which thrombocytopenia occurs is unknown.

Hashimoto *et al.* [88] were the first to report that WB F1 male mice produced autoantibodies against cardiolipin and that the titer of aCL increases with age. These antibodies were detected by conventional aCL ELISA [17], and alternatively could be detected by ELISA for anti-β2-GPI antibody detection, using β2-GPI complexed with solid phase cardiolipin [34] or using β2-GPI coated on a polyoxygenated polystyrene plate as an antigen [21].

As another approach to establish the animal model of human APS, active immunization either with aCL, β2-GPI, and a combination of anti-β2-GPI antibodies and β2-GPI were considered. It was suggested that immunization of animals with human β2-GPI induces antibodies that resemble aPLs from APS patients, regarding binding characteristics [89–91] and pathogenic properties [92]. However, the precise β2-GPI specificity of human aPLs requires more intensive investigation.

More recently, by using a homologous recombination approach, β2-GPI-knockout mice were generated [93]. When β2-GPI heterozygotes on a mixed genetic background were intercrossed, only 8.9% of the resulting 336 offspring possessed both disrupted alleles. They possessed an impaired *in vitro* ability to generate thrombin

relative to wild-type mice. Thus, β2-GPI appears to play an important role in thrombin-mediated coagulation.

Monoclonal Antibodies

Five human monoclonal antibodies (IgM) against β2-GPI have also been prepared from peripheral blood lymphocytes of three British patients with APS; sequential Epstein-Barr virus transformation and cell fusion techniques were used [94]. These antibodies bind both to the solid phase complexes of β2-GPI and negatively charged phospholipids and to β2-GPI adsorbed on a polyoxygenated polystyrene surface. All monoclonal antibodies obtained from WB F1 mice (namely, WB-CAL-1) and from APS patients have similar characteristics to those found in sera from APS patients. More recently, it was demonstrated that the WB-CAL-1 antibody or four out of six monoclonal anti-β2-GPI antibodies from patients with APS bind to a deletion mutant of human β2-GPI lacking domain V (DM I-IV) produced in a baculovirus/Sf9 expression system [30, 88, 94, 95]. However, the binding is significantly diminished by further removal of domain IV from DM I–IV. Further, as described previously, particular mutations made in domain IV also affected antibody binding to β2-GPI in anti-β2-GPI ELISA [43]. Thus, domain IV has an important role in expressing the epitope(s) recognized by many (if not most) anti-β2-GPI antibodies from APS patients. A cluster of discontinuous hydrophobic amino acids from domain IV was suggested to be a possible epitope recognized by anti-β2-GPI antibodies present in APS patients. The analyses were made using a phage displayed random peptide library and three-dimensional protein models [43]. In contrast, Iverson *et al.* [41] and McNeeley *et al.* [42] reported that anti-β2-GPI autoantibodies in the major population of APS patients recognized a particular structure in domain I of β2-GPI, and antibody binding was diminished by replacement of a related amino acid located in the domain.

In 1999, a chimeric antibody (namely, HCAL) with the human γ1 constant region as a putative standard for assays to detect IgG anti-β2-GPI antibodies was established [96]. The binding of HCAL was compared with the binding of standards for IgG aCL and anti-β2-GPI antibody assays done in 18 independent laboratories. The reactivity of HCAL is similar to the reactivity to standards for IgG aCL or anti-β2-GPI antibody assays done in collaborative laboratories.

T-Cell Clones Specific for β2-GPI

HLA class II-restricted β2-GPI-reactive $CD4^+$ T cells were identified in the peripheral blood of APS patients [97]. These β2-GPI-reactive T cells possess helper activity that induces the production of antibodies that specifically bind to β2-GPI immobilized on cardiolipin. Further, the same group has established β2-GPI-specific $CD4^+$ T-cell clones and investigated their antigen recognition profiles and helper activity involved in promoting anti-β2-GPI antibody production through IL-6 expression and CD40–CD40 ligand engagement [98]. Interestingly, in the study, the major T-cell clones which responded to a peptide encompassing amino acid residues 276 to 290 of β2-GPI, that contains the phospholipid binding site, were established.

Methodology for Antibody Detection

Detection of anti-β2-GPI antibodies in patients' sera is important for the diagnosis of APS. Such pathogenic anti-β2-GPI autoantibodies recognize an epitope of β2-GPI that appears only when β2-GPI binds to a lipid membrane composed of negatively charged phospholipids or when β2-GPI is adsorbed onto a polyoxygenated polystyrene plate. Anti-β2-GPI antibodies can be routinely detected by ELISA using two types of antigen solid phase: one is β2-GPI associated with a cardiolipin-coated polystyrene plate and the other β2-GPI adsorbed on a polyoxygenated polystyrene plate [21].

In assays using a cardiolipin-coated plate, a control assay without β2-GPI is of particular importance, and antibody binding must be compared in the absence and/or the presence of β2-GPI to evaluate the β2-GPI dependency of antibodies [20, 33, 34, 99, 100]. Antibodies specifically or nonspecifically reactive to phospholipids in sample fluids may directly bind to a cardiolipin-coated plate, even if the plate is first or simultaneously treated with β2-GPI. Direct binding of aPLs to a cardiolipin-coated plate is dose-dependently decreased by the addition of β2-GPI but is not completely diminished even when adding a large excess of β2-GPI [34]. The latter anti-β2-GPI ELISA, with use of a polyoxygenated plate, is much superior, procedures are simple and a false-positive result for aPLs is negligible. Monoclonal anti-β2-GPI antibodies, such as EY2C9 (human IgM) [94] and HCAL [96], have been proposed as international standards of calibration materials by different standardization committees.

Lupus Anticoagulant (LA) and Its Cofactors

History and Definition of LA

Circulating anticoagulants are defined as endogenously produced substances that may interfere with coagulation either *in vivo* or *in vitro* [101]. Most of such

inhibitors are immunoglobulins. Other inhibitors such as elevated levels of fibrin split products are rare. Lupus anticoagulants (LA) are those immunogloblins (IgG, IgM, IgA, or their combination) that interfere with *in vitro* phospholipid-dependent tests of coagulation (prothrombin time (PT), activated partial thromboplastin time (aPTT), kaolin clotting time (KCT), dilute Russell's viper venom time [dRVVT]) [102]. LA was first described (1954) in lupus patients with bleeding tendency [14], thus it was called LUPUS anticoagulant, but this term is a misnomer because the vast majority of patients with LA do not have SLE. The paradoxical relationship between LA and a predisposition to thrombosis was first identified in 1963 [16] and more recent studies clearly identified LA as a factor for both venous and arterial thromboembolic events [103]. In 1980, Thiagarajan *et al.* [104] reported that monoclonal IgM antibody with LA activity cross-reacted with anionic phospholipids, and they proposed that LA binds to anionic but not dipolar ionic phospholipids, thereby limiting the exposed surface required for binding the prothrombinase complex [105]. The *in vitro* action of LA appears to inhibit, albeit at a slow rate, the prothrombinase complex, which consists of factor Xa and Va (Xa/Va complerx) and prothrombin with Ca^{2+} and phospholipids [106].

Cofactors of LA

There are some subtypes of LA classified according to their clotting inhibitory behavior. In 1978, Exner *et al.* [107] reported that there are three types of LA mixing patterns by KCT. In 1990, β2-GPI was identified as a cofactor of solid-phase aCL assay, as described. After the finding, cofactors of LA have been also investigated. Oosting *et al.* [108] and Roubey *et al.* [109] demonstrated that many LA plasmas depended on the presence of β2-GPI in their anticoagulant activity, thus β2-GPI was identified as one of the major cofactors of LA. β2-GPI dependent LA is highly likely to comprise antibodies directed at β2-GPI (anti-β2-GPI antibodies), but many patients with anti-β2-GPI antibodies did not have LA. Takeya *et al.* [110] showed the heterogeneity of LA activity in a series of human/murine monoclonal anti-β2-GPI antibodies. Thus anti-β2-GPI antibodies can be either antibodies with LA activity or those without, and anti-β2-GPI antibodies with LA activity were assumed to be more pathogenic than anti-β2-GPI antibodies without LA [111]. On the other hand, murine monoclonal anti-human β2-GPI antibodies behaved as LA [112], suggesting that not only autoantibodies but also immunized antibodies can have LA activity and that antibody binding to β2-GPI is not necessarily related to the presentation of cryptic/neoepitopes on the molecule.

β2-GPI has only low affinity for phospholipid surfaces, compared with clotting factors [113]. As LA and/or its cofactors compete with coagulation factors for the available catalytic phospholipid surface, it is assumed that anti-β2-GPI antibodies with LA activity enhance the affinity of β2-GPI for phospholipids that have potent competitive reactivity with clotting factors for the catalytic surface. Williams *et al.* [114] reported, using ellipsometry, that high-affinity binding of aCL–β2GPI complex (purified from a single patient's serum) to phospholipids was due to the consequence of bivalent interactions between them and lipid bound β2-GPI. By the solid phase ELISA technique, Takeya *et al.* [110] showed that murine monoclonal anti-β2-GPI antibodies enhanced the β2-GPI binding to fixed phospholipids on ELISA plates. They demonstrated that the Fab′2 fragment of the monoclonal anti-β2-GPI antibody had also promoted the enhancement while the Fab fragment did not, confirming the significance of the bivalency. Using real-time biospecific interaction analysis based on plasmon surface resonance technology, Arnout *et al.* [115] found a high affinity interaction between β2-GPI and phospholipids in the presence of murine monoclonal anti-β2-GPI antibody with LA activity, but not in the presence of monoclonal anti-β2-GPI antibodies without LA activity. Fab' fragments inhibited the formation of stable high affinity complexes on phospholipid surfaces. Arnout *et al.* noted that bivalency may be essential to cross-link two β2-GPI molecules and induce a correct spatial orientation of the phospholipid binding domains of both β2-GPI molecules, thus markedly increasing their affinity for phospholipid surface.

Bevers *et al.* [22] highlighted the importance of prothrombin in causing LA activity when they studied 16 patients with both aCL and LA. After incubation with cardiolipin-containing liposomes and removal of aCL (anti-β2-GPI antibodies), the LA activity remained in the supernatant in 11/16 patients. These 11 samples demonstrated LA activity in a phospholipid-bound prothrombin dependent fashion. Therefore, prothrombin was considered as a second cofactor of LA activity. Unlike β2-GPI, the cofactor effect of prothrombin was highly species-specific and bovine prothrombin failed to support the inhibitory activity of LA [116].

It was suggested that anti-prothrombin antibodies prolong *in vitro* clotting time by inhibiting the conversion from prothrombin into thrombin [117]. One can assume that anti-prothrombin antibodies bind near the cleavage site on the prothrombin molecule by the prothrombinase complex and hamper the thrombin generation. It is not very likely, however, as the phenomena do not explain the correction of the clotting time prolongation by the excess of phospholipids.

Horbach and co-workers [118] reported that purified anti-prothrombin antibodies not only inhibited the prothrombinase activity but also the tenase complex and the inactivation of factor Va by activated protein C. The results may suggest that anti-prothrombin antibodies increase the affinity of prothrombin for phospholipids so that prothrombin–anti-prothrombin antibody complexes compete with the binding of other coagulation factors on phospholipids surface [119], the mechanism being similar to that described for complexes of β2-GPI and anti-β2-GPI antibodies. However, Galli *et al.* [120] demonstrated the dominant inhibitory effect on activated protein C of the anti-β2-GPI antibodies, compared with that of anti-prothrombin antibodies, thus the phenomena may depend on the specificity of antibodies used in the experiments.

Apart from those two major LA cofactors, some other phospholipid binding proteins, such as high- and/or low-molecular-weight kininogen, annexin V, protein C, and protein S, have been proposed as cofactors of LA [121]. However, the roles of these potential cofactors in LA activity are obscure.

Methods for LA Detection

The Scientific and Standardisation Committee of the International Society of Thrombosis and Haemostasis established a subcommittee of lupus anticoagulants/anti-phospholipid antibodies. In 1995, the subcommittee recommended a diagnosis of LA [122] (Table 3). The steps seem relatively simple, but the identification of LA is often difficult because of its highly heterogeneous properties that are due to the difference of isotypes, avidity, or properties of directed antigens. Also there are a number of technical issues which may significantly compromise the diagnosis [123]. Platelets in frozen/thawed samples lead to false-negative LA result, known as platelet neutralization phenomenon [124], thus platelet count in plasma samples should be less than 10,000/μl by double-centrifuging and/or 0.22-μm filtrating [123].

The screening stage of LA detection must be as sensitive as possible. Unfortunately, none of the LA tests have 100% sensitivity, thus a combination of phospholipid-dependent coagulation tests should be performed as the frontline investigation. The choice of the coagulation tests and of the reagents are crucial for sensitivity to detect LA. Lesperance *et al.* [125] ranked tests in order of sensitivity, KCT > tissue thromboplastin inhibition test (TTI) > APTT > dRVVT, whereas Forastiero *et al.* [126] used APTT = dRVVT > KCT. Pengo *et al.* [127] demonstrated that dRVVT was more sensitive, to detect β2-GPI associated LA, than KCT or TTI. These confusing results can be simply attributed to differences in methodology [128]. For the standardization of LA, Arnout *et al.* [112, 129] distributed monoclonal anti-human β2-GPI antibody with LA activity to several laboratories and compared the LA results, showing that LA responsiveness varied largely according to the reagents used. A population of tested samples can also result in the discrepant results found in LA sensitivity. Galli *et al.* [130] showed that KCT is more sensitive for β2-GPI-dependent LA whereas dRVVT is more sensitive for prothrombin-dependent LA. Thus, when LA test sensitivity is investigated using a β2-GPI-dependent LA dominant population, KCT would be more sensitive than dRVVT, and vice versa.

The performance of mixing tests usually provides evidence of an inhibitor. Normal plasma is added to the patient's plasma and will correct coagulation deficiencies so that the prolonged clotting time will return to normal. If an inhibitor is present, the clotting time will remain prolonged or even may be further prolonged. In case of weak or low titer LA, however, the immunoglobulins responsible for LA are diluted in this procedure, leading to the loss of detectable LA activity and a false-negative result. Confirmation of the phospholipid-dependent nature of the inhibitor is obtained using activated platetets, which have negatively charged phospholipids on their surface, or high concentration of phospholipids, demonstrating correction of the coagulation time. A variety of screening tests and correction tests are listed in Table 3 [131].

There currently is no consensus about which test is the "ideal LA test." Scientists need to establish specific LA tests in their laboratories using quality control plasma and an appropriate set of healthy samples to determine the normal limits of clotting time. Some kits for LA determination are now commercially available and they have gained popularity worldwide because of their convenience.

TABLE 3 Diagnosis of Lupus Anticoagulant (SSC of ISTH)

Step 1: Demonstration of a prolonged phospholipid-dependent coagulation screening test(s) (e.g., APTT, KCT);
Step 2: Failure to correct the prolonged screening coagulation test upon mixing with normal platelet poor plasma;
Step 3: Shortening or correction of the prolonged screening test value upon the addition of excess/or reconfigured phospholipid; and
Step 4: Rule out other coagulopathies (such as factor VIII inhibitor, heparin)

Other APS-Related Autoantibodies

Anti-Prothrombin Antibodies

As described earlier, prothrombin was identified as one of the cofactors of LA, thus autoantibodies against prothrombin should be present in patients with APS.

The first techniques used for screening anti-prothrombin antibodies were double diffusion and cross-immunoelectrophoresis [132–135]. Other assays are based on the impairment of prothrombin activation by anti-prothrombin antibodies [24, 136]. However, none of these techniques is suitable for the routine evaluation of large numbers of patients with APS. In 1995, Arvieux *et al.* [137] showed that anti-prothrombin antibodies could be detected using a standard ELISA, prothrombin coated onto irradiated plates (the aPT system). Interestingly, the mode of presentation of prothrombin in solid phase seems to influence its recognition by anti-prothrombin antibodies. Anti-prothrombin antibodies cannot be detected when prothrombin is immobilized onto nonirradiated plates [137] but binding is observed to prothrombin on a suitable anionic surface, adsorbed on γ-irradiated plates or exposed to immobilized anionic phospholipids.

Galli *et al.* [138] showed that prothrombin was recognized more efficiently when the prothrombin was bound to phosphatidylserine-coated ELISA plates using calcium ions, thus anti-prothrombin antibodies could be detected by the phospholipid-bound system in which antibodies were directed against phosphatidylserine–prothrombin complex (the aPS/PT system). Analogy between the behavior of anti-prothrombin antibodies and that of anti-β2-GPI antibodies has been hypothesized. Anti-prothrombin autoantibodies may be directed against cryptic epitopes or neoepitopes that are exposed when prothrombin binds to anionic phospholipds and/or may act as low-affinity antibodies that bind bivalently to immobilized prothrombin. Unlike anti-β2-GPI antibodies or other autoantibodies, however, a high percentage of anti-prothrombin antibodies has species-specificity for the human protein [22] and a minority of anti-prothrombin antibodies reacts with bovine prothrombin [116]. The epitope(s) recognized by anti-prothrombin antibodies have not yet been defined. Some studies suggested that dominant epitopes are likely to be located near the phospholipid-binding site of the prothrombin molecule, although they may have heterogeneous distribution [119, 139].

Studies were done to investigate the clinical significance of anti-prothrombin antibodies detected by ELISA using the aPT system. Some studies have shown their positive correlations with the clinical manifestations of APS [140–142]. In a population of nonautoimmune setting, it has been reported that high levels of anti-prothrombin antibodies confer high risk of myocardial infarction or cardiac death in middle-aged men [143] and thrombotic events [144]. Conversely, other investigators have found no statistically significant correlations between the presence of anti-prothrombin antibodies and manifestations of APS [138, 145–149]. Therefore, the value of anti-prothrombin antibodies as markers of APS has been controversial.

In contrast, anti-prothrombin antibodies detected by the aPS/PT system correlated strongly with the presence of LA and with the clinical manifestations of APS [150]. Most patients with aPS/PT were positive for LA. Many investigators have tested only anti-prothrombin antibodies using the aPT system, presuming that aPT and aPS/PT systems detect the same antibodies. However, no correlation of the titers was found between aPS/PT and anti-prothrombin antibodies in patients with APS or other autoimmune diseases [150]. Thus, aPS/PT represents one of the markers of APS, and testing aPS/PT may help to confirm the presence of LA.

Anti-Annexin V Antibodies

Annexin V (previously known as placental anticoagulant protein I and vascular anticoagulant α) is found in the placenta and in the vascular endothelium, among other tissues [151]. This protein, whose physiologic function remains to be established, has potent anticoagulant properties that are based on its capacity to displace coagulation factors from phospholipid surfaces [152]. It was reported that annexin V is present on the apical surface in placental syncytiotrophoblasts and that levels of this protein are markedly reduced on placental villi in patients with APS [153, 154]. Therefore, it has been thought that annexin V has an antithrombotic role *in vivo* and that the thrombosis in APS patients may be due to reduced levels of the protein at sites where circulating blood contacts cells lining the vasculature. Some reports show the presence of anti-annexin V autoantibodies [23, 155–158], but other aPLs may also affect the annexin-V function via their antigens [159, 160].

Anti-phosphatidylethanolamine Antibodies and Their Cofactors

Phosphatidylethanolamine (PE) is a zwitterionic phospholipid present in the outer leaflet of cell membranes, which has an important role in phospholipid-dependent reactions of protein C system [161]. Although autoantibodies against PE were detectable in some populations of patients [162, 163], their association with thrombosis or LA were not confirmed [164, 165].

Sugi and McIntyre [25, 166] demonstrated that the PE-binding proteins responsible for anti-PE antibodies were high-molecular-weight kininogen (HMWK) and low-molecular-weight kininogen (LMWK) and that anti-PE antibodies recognized HMWK and LMWK

only when presented on PE substrate. Therefore, kininogen was recognized as one of cofactors of aPLs. McIntyre and Wagenknecht [167] stated that fetal and newborn bovine serum should not be used as a blocking agent or in a patient serum diluent because kininogen is present in significantly lower concentration in fetal/new born bovine serum compared with adult bovine serum [168]. More recent studies have shown a preliminary clinical significance of kininogen-dependent anti-PE antibodies [169, 170], in particular, in the obstetric field [155, 171]. However, the clinical utility of anti-PE antibodies is still under discussion.

Other Autoantibodies Associated with APS

Protein C, a vitamin K-dependent plasma glycoprotein, can be activated by the thrombin–thrombomodulin complex. The activated protein C subsequently functions as an anticoagulant, as related to proteolytically inactivating factor Va and VIIa, thereby limiting thrombin generation. Inactivation of these factors is most efficient together with another vitamin K-dependent cofactor protein, protein S. Oosting *et al.* [24] demonstrated that antibodies responsible for inhibiting factor Va degeneration are directed against phospholipid-bound protein C or protein S.

Antibodies against factor XII, which plays a role in initiating intrinsic coagulation and/or intrinsic fibrinolysis, have been reported [172].

Those antibodies may be considered as evidence for established-aPLs negative APS in the future.

PATHOGENESIS OF ANTI-PHOSPHOLIPID ANTIBODIES

Many varieties of pathophysiologic mechanisms have been explored in order to understand the wide spectrum of antigenic specificities of aPLs. Numerous observations will be reviewed here concerning putative mechanisms related to anti-β2-GPI antibodies or other aPLs predisposing to thrombosis and to atherosclerosis.

Platelet Interaction

It is now well appreciated that membranes of activated platelets are an important source of negatively charged phospholipids (e.g., phosphatidylserine, which provides a catalytic surface for blood coagulation). Factor Xa and thrombin are generated by the tenase and prothrombinase complexes, respectively, via the catalytic surface of activated platelets and procoagulant microparticles shed by activation of platelets. Shi *et al.* [173] reported that β2-GPI inhibited the generation of factor Xa by activated platelets and that aCLs (i.e., anti-β2-GPI antibodies) interfered with this inhibition. It was also indicated that β2-GPI affected the generation of factor Xa rather than its binding to platelet-derived microparticles, and that aCLs (i.e., anti-β2-GPI antibodies) interfered with this inhibition [174]. Thus, activated platelets may be a predominant immunotarget of anti-β2-GPI antibodies. Another mechanism by which anti-β2-GPI antibodies may inhibit phospholipid-dependent coagulation reactions has been reported [110, 114]. β2-GPI alone binds weakly to membranes containing physiologic concentrations of anionic phospholipids and does not inhibit the binding of coagulation factors or anticoagulant proteins. Autoantibodies' cross-linking of membrane-bound β2-GPI greatly decreases the rate at which β2-GPI dissociates from the membrane. Thus cross-linked antibody–β2-GPI complexes binding tightly to membranes results in inhibition of binding of other phospholipid-binding proteins.

Endothelial Cell Interaction

Cellular interactions of APS associated autoantibodies have also gained increasing attention. Endothelial cells may be a predominant target leading to a procoagulant state in APS.

Thrombin–thrombomodulin complex activates protein C [175–177], leading to the inhibition of clotting by the proteolytic cleavage of factors Va and VIIIa in the presence of protein S that is synthesized by endothelial cells as a cofactor [178, 179]. Therefore, thrombomodulin, is an anticoagulant receptor that plays a crucial role in the regulation of thrombin generation. Many data have supported the suppressed thrombomodulin–protein C system by aPLs (Fig. 4). The fact that protein C and its cofactor protein S are phospholipid binding plasma proteins, has made this system one of the most likely to be involved in the pathophysiology of thrombosis in APS. APLs might inhibit phospholipid-dependent reactions of the protein C pathway in different ways. First, they can interfere with the activation of protein C by the thrombin–thrombomodulin complex. Thrombin formation inhibited by aPLs could paradoxically cause a prothrombotic tendency due to insufficient protein C activation [180]. It has also been shown that LA positive IgGs inhibit the activation of purified protein C by thrombin on endothelial cells [181, 182] or by thrombin/purified thrombomodulin [183]. Second, the proteolytic effect of activated protein C (APC) on factor Va/factor VIIIa can be inhibited by aPLs. Marciniak and Romond [184] reported that factor

Va degradation was reduced in plasma from patients with LA. Malia *et al.* [185] confirmed the inhibitory effect of IgGs purified from aPL positive patients on factor Va degradation by APC. We [186] showed that human monoclonal anti-β2-GPI antibodies inhibit APC function, definitely confirming the autoimmune aPLs' effect on this system. Finally, the cofactor effect of protein S in the protein C pathway can be affected by aPLs [24, 187, 188].

Bacterial endotoxin or cytokines (tumor necrosis factor or interleukin 1) induce tissue factor (TF), activating the extrinsic clotting cascade [189, 190]. TF is a single chain transmembrane protein composed of 263 amino acid residues [191]. Of the many factors involved in the activation of the intrinsic and extrinsic pathways of coagulation, TF is the only factor that is fully actived in its native form, not dependent on proteolysis, therefore procoagulant activity generation merely requires TF exposure on cell surfaces [192]. Numerous investigators have focused on the upregulation of TF expression by aPLs. We [193] and others [194, 195] showed that aPLs induce TF activity, antigen, or mRNA on endothelial cells as well as on monocytes. As described earlier, TF does not require activation by other enzymes to function, thus its expression per se represents hypercoagulation in patients with aPLs.

Endothelin-1 (ET-1) is the most potent endothelium-derived contracting factor modulating vascular smooth muscle tone [196, 197]. ET-1 is extremely labile, thus the mature peptide is not found within endothelial cells [198]; however, the levels of prepro ET-1 (a precursor of ET-1) mRNA are induced by a range of stimuli, such as thrombin [199] or cytokines. Production and secretion of mature ET-1 peptide occurs within minutes of exposure to these stimuli [200]. Vascular cells are, therefore, able to adjust rapidly ET-1 production as required for the regulation of vasomotor tone [197]. We [201] also showed that markedly increased plasma ET-1 levels were found in APS patients with arterial thrombosis but not in those with venous thrombosis. It is so far the only specific marker for arterial thrombosis in APS. Human monoclonal aCL induced prepro ET-1 mRNA levels, confirming aPLs' direct effect on endothelium regarding ET-1 production. These data suggest that the production of ET-1 induced by aPLs may play an important role in altering arterial tone and contributing to arterial occlusion.

Adhesion receptors are proteins in cell membranes that facilitate the interaction of cells with matrix. Intracellular adhesion molecule-1 (ICAM-1), vascular cell adhesion molecule-1 (VCAM-1), and E-selectin are typical molecules found on activated endothelial cells. Leukocytes stick on endothelial cell via those molecules, further activating endothelium. Some proteases derived from such leukocytes also cause endothelium injury. Cellular interaction of aPLs have attracted great interest. Purified aPLs or monoclonal anti-β2-GPI antibodies induce expression of the adhesion molecules E-selectin, VCAM-1, and ICAM-1. Pierangeli *et al.* [202] showed an *in vivo* model to present the increased leukocyte adhesion by aPLs infusion to mice, in which adhered leukocytes are visualized using scrotum under the microscope.

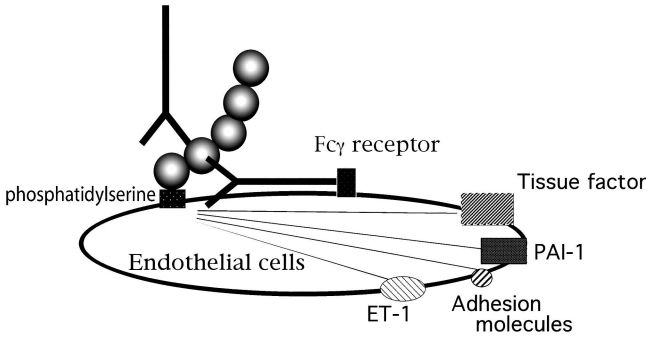

FIGURE 5 Activation of endothelial cells by anti-β2-GPI antibodies. Anti-β2-GPI antibody recognizes β2-GPI bound endothelial cells and induces tissue factor, plasminogen activator inhibitor-1 (PAI-1), adhesion molecules (ICAM-1, VCAM-1, E-selectin), endothelin-1 (ET-1), etc. Consequently, activated endothelial cells express procoagulant activity.

Endothelial cells secrete the inhibitor of plasminogen activator-1 (PAI-1) to depress fibrinolysis by blocking tissue plasminogen activator (t-PA) activity, when activated. Impaired fibrinolysis in APS has been shown in some reports [203–205], but no direct evidence has been reported in the induction of PAI-1 by aPLs.

In any case, aPLs activate endothelium, leading to its perturbation (Fig. 5). The activation may depend on the immune complex formation on cell surface and/or Fcγ receptor stimulation and/or thrombin receptor that delivers a stimulatory signal by thrombin [206].

Gharavi *et al.* reported that monoclonal antibodies against a synthetic peptide consisting of 15 amino acids, which contains a sequence of the phospholipid binding site located in domain V of β2-GPI, enhanced thrombosis and activated endothelial cells [207]. More recently, Dunoyer-Geindre *et al.* demonstrated that β2-GPI localized in late endosomes of human umbilical vein endothelial cells and incubation of anti-β2-GPI antibodies resulted in the antibodies coaccumulation [208]. These findings may lend support to the notion of anti-β2-GPI antibodies inducing thrombotic diathesis but the nature of the β2-GPI receptor on endothelial cells and the mechanism by which antibody binding to β2-GPI on the cell surface transduces a signal have yet to be defined.

Involvement of Apoptosis

Phospholipids are distributed in an asymmetric manner throughout the cell membrane [209]. Induction of apoptosis in murine thymocytes and human neutrophils leads to redistribution of anionic phospholipids to the outer leaflet of cell membranes [210, 211]. It was demonstrated that apoptotic thymocytes are targeted by anti-β2-GPI antibodies in the presence of β2-GPI [212]. Pittoni *et al.* [213] demonstrated that human monoclonal aPL and anti-β2-GPI antibody bind to "early" apoptotic cells. These investigators proposed that apoptotic cells may be a natural immunogen, target, or both for aPLs and the interaction of circulating β2-GPI with redistributed anionic phospholipid may itself generate a novel ligand by which apoptotic cells are recognized directly for phagocytic clearance.

Arterial Diseases and Atherosclerosis

In SLE, myocardial infarction is a major cause of mortality [214–219] and although *in situ* thrombosis in major arteries could be the pathology, coronary atherosclerosis has been demonstrated in a number of postmortem studies despite the relative youth of most of these patients [220]. In 1982, Homcy *et al.* [215] described six cases of ischemic heart disease in patients with SLE aged 15 to 29 years. Of these, 3 patients had atherosclerotic lesions. Doherty and Siegel [220] analyzed the features of 33 patients younger than 35 years of age with SLE and coronary artery disease. The vessel lesion was atherosclerosis in 12 patients, arteritis in 7, and stenosis in 6. It is unclear whether the latter resulted from atherosclerosis or vasculitis.

Epidemiological studies have established that an elevated plasma level of low-density lipoprotein (LDL) represents one of the most important risk factors for the development of atherosclerosis [221]. A subset of chemically modified LDLs such as oxidized LDL (oxLDL) has attracted the interest of researchers as one of the causative factors underlying atherosclerosis [222, 223]. The *in vivo* oxidative modification of LDL has been proposed to play a central role in atherosclerosis [224] as suggested by the presence of oxLDL particles in the early phase of atherosclerotic plaque formation.

It was reported that antibodies against epitopes of oxLDL recognize materials in atherosclerotic lesions but not in normal arteries, and the major antigenic epitopes are induced in apolipoprotein B (apoB) during oxidative modification of LDL [225]. Malondialdehyde (MDA) is an end-product of lipid peroxidation, and conjugation to the lysine residues of apoB induces the epitope for antibodies from human sera [226]. However, autoantibodies induced to oxidative modified lipoproteins occur not only in apoB but also in phospholipids composing of LDL [227].

Vaarala *et al.* [228] reported that aCL raised in SLE patients might cross-react with MDA-modified LDL. Later, others failed to show any cross-reaction between anti-β2-GPI antibodies and antibodies against ox-LDL (anti-oxLDL) in APS patients [229, 230]. It was also shown that anti-β2-GPI antibodies could be a marker for arterial thrombosis in SLE patients, whereas IgG anti-oxLDL is not associated with arterial thrombosis [231]. Hasunuma *et al.* [232] reported a specific interaction among Cu^{2+}-oxidized plasma lipoproteins, β2-GPI and anti-β2-GPI antibodies and an involvement of both β2-GPI and an anti-β2-GPI antibody in oxLDL uptake by macrophages.

There was another set of reports suggesting that some aPLs in APS patients are directed to neoepitopes of oxidized PLs or those generated by adduct formation between oxidised PLs and associated proteins [233, 234]. They also hypothesized that one candidate of oxidized phospholipids, that is, 1-palmitoyl-2-(5-oxovaleroyl)-phosphatidylcholine (POVPC), which is one of the oxidized form of 1-palmitoyl-2-arachidonoyl-phosphatidylcholine (PAPC), comes from oxidation of LDL [235, 236].

Against this background, a ligand specific for β2-GPI, namely, oxLig-1, was isolated from Cu^{2+}-oxLDL and its structure was characterized as 7-ketocholesteryl-esterified fatty acid esters which are carboxylated at the ω-position of fatty acid residues, such as oxLig-1 (7-ketocholesteryl-9-carboxynonanoate, i.e., 9-oxo-9-(7-ketocholest-5-en-3b-yloxy)nonanoic acid) [237]. In this study, it was clearly shown that epitopes for anti-β2-GPI autoantibodies expressed on a complex of β2-GPI and oxLig-1, formed by electrostatic interactions.

It was also shown that liposomes containing oxLig-1, a model of oxLDL, are avidly taken up by macrophages, by a process dependent on both β2-GPI and anti-β2-GPI antibodies [237]. This binding might be mediated by the Fcγ receptor because it was reported that the uptake by macrophages of immune complexes containing oxLDL through the Fcγ type I receptor transformed macrophages into foam cells [238, 239], and could accelerate the atherogenic process (Fig. 6) [240–242]. In addition, anti-β2-GPI autoantibodies derived from APS patients, with episodes of arterial thrombosis, were detected in ELISA, using a solid phase β2-GPI complexed with oxLig-1.

Several interesting reports have been published concerning a possible association with β2-GPI, anti-β2-GPI antibodies, and atherosclerosis. George *et al.* [243] showed that oxLDL, but not native LDL, aggravates the manifestations of experimental APS. These findings strongly suggest that oxLDL is sequentially targeted not

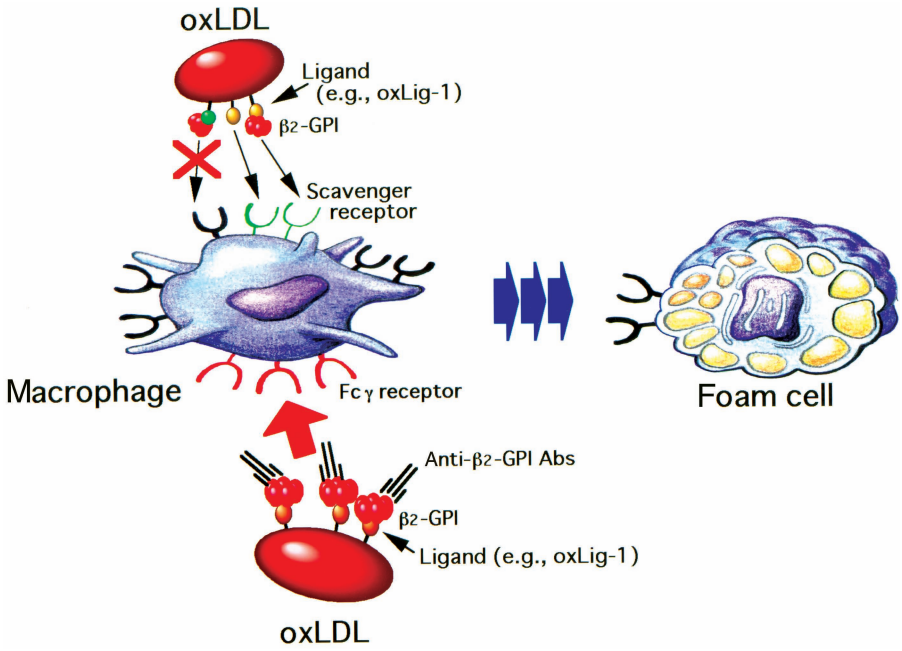

FIGURE 6 Possible mechanisms of anti-β2-GPI antibody-mediated formation of foam cells.

only by antibodies directly reactive for negatively charged phospholipids but also by anti-β2-GPI antibodies via β2-GPI adhesion. It was shown that LDL-receptor-deficient mice fed a chow diet and immunized with β2-GPI have accelerated atherosclerosis [243]. They also found that β2-GPI is abundantly expressed within subendothelial regions and intimal–medial borders of human atherosclerotic plaques, and that it colocalizes with monocytes and with CD4-positive lymphocytes [244]. Thus, there is increasing circumstantial evidence of an autoimmune mechanism involving β2-GPI and oxLDL in the atherogenesis in APS.

Pregnancy Morbidity

The clinical manifestations related with aPLs, such as fetal death, growth impairment, and preeclampsia, are consequences of impaired placental function. It is likely that those placental dysfunctions are due to the uteroplacental circulation disorder related with thrombosis. Many early reports showed thrombosis and necrosis in placentas from patients with APS [245–247]. In fact, 82% of placentas from individuals with aPLs had thrombosis or infaction [248].

A common finding in the placental bed of pregnancies complicated by aPLs is an increase in atherosclerotic lesions, described as "acute atherosis." The uptake of oxLDL by macrophages is recognized to be an important step in atherogenesis. Thus, aPLs and β2-GPI may combine *in vivo* to enhance atherogenesis in spiral arteries, thereby contributing to complications of pregnancy.

However, the histological findings of placenta in APS cases are nonspecific and not all of APS placentas have thrombotic change [249]. Placental thrombosis may be only one of the mechanisms of pregnancy morbidity in APS. The nonthrombotic functional problems in gestational tissues may be also involved. di Somone *et al.* [250] demonstrated that anti-β2-GPI antibodies bound to trophoblast in the presence of β2-GPI, leading to the impairment of gonadotropin secretion.

Acknowledgments

We thank Professor Masahiro Ieko, Department of Medicine, Health Science University of Hokkaido, for helpful discussions, and Dr. Olga Amengual for her fruitful suggestions and comments on the manuscript.

THE CLINICAL ASPECTS OF THE ANTIPHOSPHOLIPID SYNDROME

Munther A. Khamashta
Graham R. V. Hughes

The antiphospholipid syndrome (APS) is a noninflammatory autoimmune disease. The most critical pathologic process is thrombosis, which results in most of the clinical features suffered by these patients. Recurrent thrombosis together with an adverse pregnancy history and the presence of persistently elevated levels of anti-phospholipid antibodies (aPL) defines the syndrome [1].

The last decade saw a rapid increase in worldwide interest related to APS, firstly because the biological peculiarity of the disease in which autoantibodies cause thrombosis, and secondly because APS is recognized as one of the most frequent causes of acquired thrombophilia [2].

DIAGNOSTIC APPROACH TO THE ANTIPHOSPHOLIPID SYNDROME

The diagnosis of APS is first and foremost clinical (the patient must have one or more thrombotic or obstetric features of the condition). Laboratory testing for aPL is used to confirm or refute the diagnosis. The 1999 International Consensus Statement on preliminary classification criteria for definite APS provides simplified criteria for the classification of APS (Table 1) [3]. These criteria have been validated [4]. A patient with APS must manifest at least one of two clinical criteria (vascular thrombosis or pregnancy morbidity) and at least one of two laboratory criteria (positive lupus anticoagulant (LA) or medium-to-high titer β_2-glycoprotein I-dependent IgG or IgM anti-cardiolipin antibody (aCL), confirmed on two separate occasions, at least 6 weeks apart). Many of the patients reported to have the syndrome have SLE and can be regarded as having secondary APS. Some patients do not have any underlying systemic disease. These patients may be regarded as having primary APS [5]. For research and classification purposes, the term primary is useful, although there appear to be few differences in complications related to aPL antibody or in antibody specificity in the presence or absence of SLE [6, 7]. Although some patients with primary APS progress to systemic lupus, most do now show such progression [8].

Whereas LA is reported as being positive or negative, aCL are reported in terms of international units (designated GPL for IgG binding and MPL for IgM binding). In most laboratories there is substantial concordance between LA activity and aCL antibodies, with approximately 70% of patients with definite APS having both LA and aCL antibodies. However, these antibodies may not be identical, either because they detect different epitopes altogether, or because they have different affinities to various epitopes in different test systems. Because there is no definitive association of specific clinical manifestations with particular aPL, both LA and aCL testing should be routinely carried out in seeking the diagnosis of APS.

The aCL is the more sensitive test for APS, while LA is more specific. However, the specificity of aCL antibodies for APS increases with an increasing antibody titer [9]. Low positive aCL results should be viewed with

TABLE 1 International Consensus Statement on Preliminary Criteria for the Classification of the Antiphospholipid Syndrome

Clinical criteria

1. Vascular thrombosis
   One or more clinical episodes of arterial, venous, or small vessel thrombosis, occurring within any tissue or organ. With the exception of superficial venous thrombosis, thrombosis must be confirmed by imaging or Doppler studies or histopathology. For histopathological confirmation, thrombosis should be present without significant evidence of inflammation in the vessel wall.
2. Pregnancy morbidity
   A. One or more unexplained deaths of a morphologically normal fetus at or beyond the 10th week of gestation, or
   B. One or more premature births of a morphologically normal neonate at or before the 34th week of gestation, or
   C. Three or more unexplained consecutive spontaneous abortions before the 10th week of gestation.

Laboratory criteria

1. Anti-cardiolipin antibodies
   Anti-cardiolipin antibodies of IgG and/or IgM isotype in blood, present in medium or high titer, on two or more occasions, at least 6 weeks apart, measured by a standardized enzyme-linked immunosorbent assay for ß$_2$-Glycoprotein I-dependent anti-cardiolipin antibodies.
2. Lupus anticoagulant
   Lupus anticoagulant present in plasma, on two or more occasions at least 6 weeks apart, detected according to the guidelines of the International Society on Thrombosis and Hemostasis in the following steps:
   - Prolonged phospholipid-dependent coagulation demonstrated on a screening test, for example, activated partial thromboplastin time, kaolin clotting time, dilute Russell's viper venom time, dilute prothrombin time, textarin time.
   - Failure to correct the prolonged coagulation time on the screening test by mixing with normal, platelet-poor plasma.
   - Shortening or correction of the prolonged coagulation time on the screening test by addition of excess phospholipid.
   - Exclusion of other coagulopathies, for example, factor VIII inhibitor, or heparin, as appropriate.

[a] Antiphospholipid syndrome is considered definite when at least one of the clinical criteria and one of the laboratory criteria are met. Modified from Reference 3.

suspicion; they may be found in up to 5% of normal individuals and should not be used to make the diagnosis of APS.

The demonstration that autoimmune aCL are directed against a β_2-glycoprotein I or an epitope formed by the interaction of phospholipids and β_2-glycoprotein I led to the development of assays for anti-β_2-glycoprotein I antibodies and other phospholipid binding plasma proteins [10]. A number of studies have highlighted the significance of testing for antibodies directed to β_2-glycoprotein I and prothrombin–phosphatidylserine complex as an alternative enzyme-linked immunosorbent assay with higher specificity than the conventional aCL assay [11, 12]. Because of the lack of standardization of these assays, their immediate application remains questionable. However, some authorities recommend testing for anti-β_2-glycoprotein I in patients strongly suspected to have APS, but in whom tests for LA and aCL are negative [13, 14].

Clinicians should recognize that the International Consensus Criteria were developed primarily for research purposes to ensure more uniform characterization, as well as subcategorization, of patients included in studies. We view this objective as crucial for credible investigative efforts and for appreciation of subtleties of treatment. As with other autoimmune conditions, such as SLE, there are individuals who present with one or more clinical or laboratory features suggestive of APS but in whom the diagnosis cannot be made by the relatively strict International Consensus Criteria. In such cases, experienced clinical judgement is required for best care.

CLINICAL FEATURES

Thrombosis

Arterial and venous thrombosis can be present in APS, distinguishing this from other prothrombotic states such as protein C, S, or anti-thrombin III deficiency, where only venous thrombosis occurs. Any organ and any size of vessel (small, medium, or large) can be affected; thus, the range of clinical features is extremely wide.

In the venous circulation, thrombosis of the deep veins of the lower extremities has been reported most frequently (occasionally after the use of oral contraceptive pills containing estrogen). It is often recurrent and may be accompanied by pulmonary embolism. It has been estimated that up to 19% of patients with deep vein thrombosis and/or pulmonary thromboembolism are suffering from aPL coagulopathy and may demonstrate a positive LA test, aCL, or both. Other reported sites of thrombosis include the axillary, ocular, renal, hepatic and sagittal veins, and the inferior vena cava.

The APS is now considered one of the most frequent causes of the Budd-Chiari syndrome [15]. aPL have been implicated in the development of adrenal vein thrombosis leading to Addison's disease [16]. Venous events usually occur at single sites and these can recur at the same or different sites, months or years apart.

Unlike other known clotting disorders, arterial thromboses are a major feature of the APS. Occlusions of the intracranial arteries has been reported most frequently, with the majority of patients presenting with stroke and transient ischemic attacks (TIAs). Other arterial thromboses have involved the retina, coronary, mesenteric, and peripheral arteries. The clinical presentation depends on the anatomic site occluded. Malignant hypertension with renal insufficiency secondary to thrombosis of the renal glomeruli and renal thrombotic microangiopathy (without classic lupus nephritis) has also been associated with the presence of aPL [17]. As with venous thrombosis, arterial events occur at single sites usually and can recur months or years later.

Central Nervous System Manifestations

Central nervous system (CNS) involvement is common in patients with APS. The original description of the syndrome in 1983, stressed the importance of cerebral features in these patients [18] and highlighted the frequency of intractable headache or migraine, epilepsy, chorea, and cerebrovascular accidents (TIAs or visual field defects or progressive cerebral ischemia) [19]. Although the mechanism of neurological involvement in patients with APS is thought to be thrombotic in origin, a number of other neuropsychiatric manifestations cannot be explained solely by hypercoagulability. Table 2 summarises CNS manifestations reported to be associated with the presence of aPL.

TABLE 2 Central Nervous System Manifestations Associated with the Presence of Antiphospholipid Antibodies

Cerebrovascular disease
Transient ischemic attacks
Ischemic strokes
Acute ischemic encephalopathy
Cerebral venous thrombosis

Sensorineural hearing loss
Guillain-Barre syndrome
Transient global amnesia
Ocular syndromes
Dystonia-Parkinsonism
Cognitive dysfunction
Dementia
Other psychiatric disorders
Depression
Psychosis

Stroke and TIAs are the most common neurological complications of APS. These are also the most frequently reported presentation of arterial thrombosis in APS [20]. The association between cerebrovascular disease and aPL was described in the early studies [21, 22] and these antibodies are now internationally recognized as an important etiological factor and may be present in up to 7% of all patients who have suffered a stroke [23]. They should be sought especially in young patients with strokes, where they may account for up to 18% [24]. A growing body of evidence supports an association between aPL and ischemic stroke not only in SLE and/or APS but in unselected populations as well [25].

An ischemic stroke can be isolated or multiple and recurrent. The risk of recurrent stroke appears to be increased in APS and patients occasionally present with multi-infarct dementia [26, 27]. It is unclear whether the presence of aCL at the time of initial stroke increases the risk of recurrence in an unselected population. Levine *et al*. [28] examined in a prospective study 81 consecutive patients with aPL who developed focal cerebral ischemia. The mean age of this cohort was younger than the average atherothromboembolic stroke victim with women being more commonly affected than men. Significantly, the frequency of conventional stroke risk factors was lowest in the group of stroke patients with the highest levels of IgG aCL reactivity. Moreover, patients with highest IgG aCL had the shortest times to subsequent thrombo-occlusive events, mainly represented by cerebral infarction often occurring within the first year of follow-up, supporting that IgG aCL represented a risk factor for recurrent stroke.

Angiograms typically demonstrate thrombotic occlusion of intracranial branch or trunk vessels, but in one-third of the cases, these studies may be normal. Magnetic resonance imaging (MRI) is consistently more sensitive than computed tomography in detecting infarcts in patients with APS [29]. Brain MRI in aPL patients with ischemic stroke shows cortical abnormalities consistent with large vessel occlusion. aPL patients often present small foci of high signal in brain white matter, which are often defined as consistent with the

presence of small vessel disease. In some cases, emboli from cardiac valvular vegetations may account for stroke or TIAs, and echocardiograms are advisable, particularly where there is no evidence of large vessel occlusion [30–33].

A less common form of cerebral thrombotic disease associated with aPL is sagittal venous sinus thrombosis [34]. As with stroke, venous sinus thrombosis in patients with APS occurs at a younger age than in individuals without aPL and shows a higher rate of postthrombosis migraine and more cerebral infarctions in imaging studies. However, other causes such as factor V Leiden mutation resulting in activated protein C resistance should be excluded.

Acute ischemia of the eye is a major feature of APS, with retinal and choroidal vessel involvement being the most common finding [35–37]. Patients usually complain of transient blurred vision or amaurosis fugax, transient diplopia, decreased vision, transient field loss associated with headache, or photopsy. It is important to distinguish this aPL-induced thrombotic retinopathy from that seen in SLE patients as a result of vasculitis or atherosclerosis. Optic neuropathy also occurs in SLE patients. One study found an association with aPL mainly when optic neuropathy was unilateral [38].

Sudden sensorineural hearing loss, often presenting as sudden deafness, can occur in some patients with APS. Toubi *et al*. [39] reported a 27% prevalence of positivity for aCL in 30 unselected patients with sudden or progressive sensorineural hearing loss. Naarendorp and Spiera [40] reported on 6 SLE patients with sudden sensorineural hearing loss; all 6 patients were positive for aCL or LA. They concluded that acute onset of sensorineural hearing loss in the presence of aPL may be a manifestation of APS, and that anticoagulation treatment was to be recommended for these patients.

Clinical syndromes mimicking multiple sclerosis (MS), mainly in its relapsing–remitting pattern, are reported to occur in association with aPL [41–43]. It can be difficult to distinguish MS from APS clinically and on MRI. Certainly the ischemic changes produced by APS in the white matter may be indistinguishable on MRI from those of MS (Fig. 1). In our experience, a careful medical history, a previous history of thrombosis or fetal loss, an abnormal localization of the lesions in brain MRI, and the response to anticoagulant therapy might be helpful in the differential diagnosis. Although controversial, we believe that testing for aPL should become routine in all patients with MS, especially if there are atypical features [41, 44, 45]. For the patient, the importance of a treatable differential diagnosis of APS cannot be understated [46].

Many other neurological abnormalities have been reported in APS, but these are not clearly linked to thrombosis. These include transverse myelopathy, chorea, seizures, Guillain-Barre syndrome, psychosis, and migraine headaches.

One of the most prominent features in patients with APS is headache. This symptom, a common complaint of APS patients in clinical practice, can vary from classic migraine to almost continuous incapacitating headache. Although important in clinical practice, the association between migraine and aPL in the published literature, is still controversial. Tietjen *et al*. [47] studied a large population, and failed to demonstrate an association between the presence of aCL and migraine in subjects younger than 60 years of age. Similar results have been reported previously [48]. Our most recent experience in applying the 1999 American College of Rheumatology criteria for neuropsychiatric syndromes to a large cohort of SLE patients (323 patients), showed a prevalence of headache similar to that of the general population, but aPL were significantly more prevalent in the group of patients with headache compared to those without headache [49]. We did not find a higher prevalence of aPL in migraine than in other types of headache. Interestingly, in some of our patients with severe headache resistant to conventional treatment,

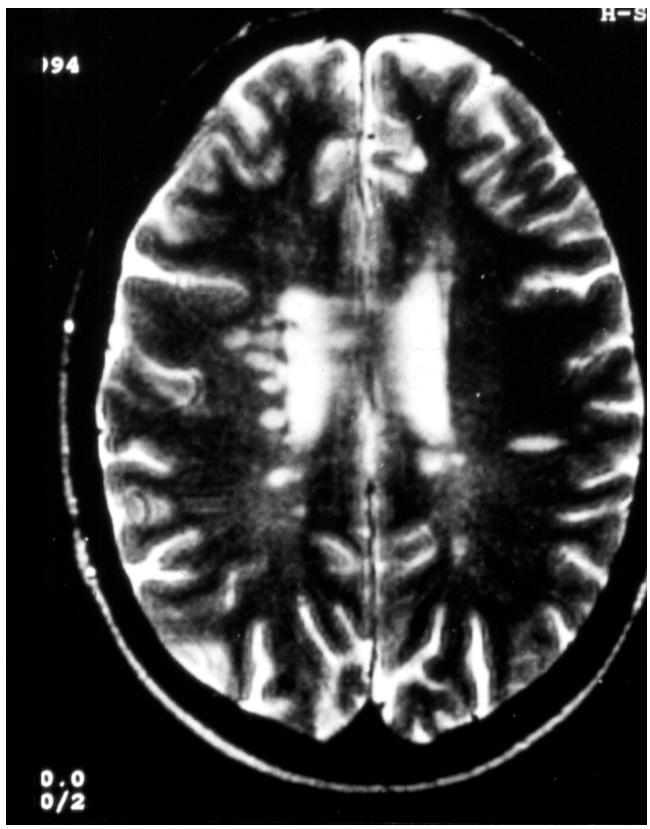

FIGURE 1 Livedo reticularis.

complete or partial remission of the headache was noticed when treatment with aspirin, heparin, or warfarin was started for thrombotic events [50, 51]. Furthermore, the relationship between migraine and stroke has been widely studied [52–55]. The predictive value of variables such as gender, the presence or absence of a family history of migraine, use of oral contraceptives, high blood pressure, diabetes, heart disease, and smoking has been analyzed and related to the development of "migrainous stroke." None of these studies analyzed the presence of aPL as an independent risk factor for stroke in their patients. In our series, 8 patients, all young women, developed stroke after some years of migraine [50]. This highlights the importance of considering the presence of aPL in patients with migrainous stroke or even with severe persistent headache, especially in young women.

Neuropsychiatric manifestations in APS ranges from mild cognitive dysfunction to severe dementia [56–59]. Patients affected by mild cognitive dysfunction often complain of poor concentration or forgetfulness. Verbal memory deficits, decreased psychomotor speed, and decreased overall productivity have been significantly correlated with elevated aPL levels. Some of these patients had never had a history of stroke and gross neurological examinations were normal. Computed tomography scans in these patients are usually normal and MRI studies frequently show scattered areas of nonspecific increased signal intensity. These areas may increase or decrease in both size and number over time and may not represent permanent injury.

The recognition of subtle forms of cognitive dysfunction has been greatly facilitated by the application of formal neuropsychological assessment mainly in patients with SLE. Menon *et al*. [59] and Hanly *et al*. [58] showed that SLE patients persistently positive for aCL (medium high titer) had significantly lower scores on a variety of neuropsychological tests than SLE patients negative for aPL. Denburg *et al*. [57] also found that LA-positive patients performed worse than LA-negative patients in measures of verbal memory, cognitive flexibility, and psychomotor speed. Some of these patients had no previous history of any neuropsychiatric involvement, suggesting a direct relationship between the presence of aPL and cognitive impairment. Whether these cognitive deficits result from recurrent cerebral ischemia or whether there are other underlying mechanisms remains unknown. Anecdotal reports of improvement of cognitive disorders after initiation of anticoagulation therapy for other reasons in APS patients, may provide some support for the theory that arterial thrombosis and/or ischemia represent the primary cause of this type of CNS dysfunction. Although MRI is a highly sensitive method for detecting cerebral lesions, new imaging techniques such as positron emission tomography or single photon emission computed tomography may provide objective information about cerebral damage and the possible underlying mechanisms in APS patients with cognitive dysfunction.

Mosek *et al*. [60] examined the relationship of aPL and dementia in the elderly. They found that 5 of the 87 (6%) demented patients, but none of the 69 controls, had significantly elevated IgG aCL levels. None of the patients had features of an immune-mediated disease. The role of aPL antibodies in these patients, with apparently diffuse brain disease, is currently unknown.

Although depression and psychosis have been associated with aPL, it had been postulated that autoantibodies, and specifically aPL, may represent an adverse response to neuroleptic treatment. Schwartz *et al*. [61] studied 34 unmedicated patients without known autoimmune disorders admitted with acute psychosis. aCL and LA were determined before and after neuroleptic treatment. They found that 32% of the unmedicated psychotic patients had positive aPL (24% IgG aCL and 9% LA). Of the 22 patients followed up after medication, 32% showed moderate titers of IgG aCL and 18% LA positivity. This study showed an increased incidence of aPL in psychotic patients and that the presence of these antibodies cannot be simply assumed to be a result of the treatment.

Seizures have been consistently associated with the presence of aPL in SLE patients and are well described in patients with primary APS [49, 62–65]. The etiology of seizures in APS patients may be associated with cerebral infarction but some authors have suggested that aPL interact directly with neuronal tissue [29]. Intriguingly, aPL can also reduce a γ-aminobutyric acid receptor-mediated chloride current in snail neurones [66]. This effect might lower seizure threshold.

Other syndromes that are rarer but no less important have been associated with the presence of aPL; for example, chorea was reported in early descriptions of the syndrome [18, 67]. In an extensive review of 50 APS patients with chorea, the role of estrogens in this disorder is highlighted (6 patients were receiving the oral contraceptive pill and 4 developed chorea during pregnancy or the puerperium) [68]. Although striatal ischemia can cause this symptom, some studies using positron emission tomography have shown increases in lentiform and caudate nucleus metabolism, which returns to normal when the patient recovers [69].

Skin Manifestations

A wide variety of cutaneous manifestations have been reported in patients with APS (Table 3), and these

very often constitute early signs of the disease. The majority of these lesions can be explained by vascular occlusion, frequently demonstrable by histopathological examination [70].

Livedo reticularis (racemosa) is the most frequently associated cutaneous manifestation in patients with the APS (Fig. 2). Livedo reticularis is a dusky, violaceous, vascular discoloration of the skin with a network pattern, which usually appears over the upper and lower limbs. The association between livedo reticularis and aPL was first reported by Hughes in 1983 [19] and was confirmed in subsequent studies [71–73]. Many cases of Sneddon's syndrome, defined as the clinical triad of stroke, livedo reticularis, and hypertension, may represent undiagnosed APS [74]. The relationship between livedo reticularis and other clinical manifestations and its value as a predictor for the risk of thrombosis need further investigation [75].

Skin ulcers are also common in APS. Histopathological analysis of the skin specimens often demonstrates thrombosis of the small vessels with vascular proliferation and minimal inflammatory changes [76]. Skin ulcers normally appear in the extremities, although they may be more widespread and sometimes leave white atrophic scars. Treatment with steroids or immunosuppression is usually ineffective, and some successfully treated cases can be explained by the coexistence of an underlying connective tissue disease with a vasculitic process [77]. Treatment with antiplatelet agents, oral anticoagulation, or even antifibrinolytic therapy can be effective [78, 79].

The prevalence of subungual splinter hemorrhages is less than 5% in patients with APS [80]. Although the causes are many, including infectious processes and vasculitis, multiple lesions in different fingers in a patient with primary or secondary APS should alert the physician to the occurrence of other thrombotic events [81].

Digital gangrene has been described in primary and secondary APS and widespread superficial skin necrosis appears in around 3% of APS patients. Its onset is

often acute; lesions are purpuric and painful and are localized to the limbs, head, and buttocks. There are several case reports of extensive skin necrosis as the first manifestation of APS [82]. Some of them occurred without any obvious trigger factor [83], but in others, skin necrosis followed the onset of infection or surgery [84].

A variety of other cutaneous lesions resembling vasculitis, including purpura, tender nodules, papules, and palmar-plantar erythema, have been described in APS [70]. Histologically, the absence of vasculitis and the finding of noninflammatory thrombosis of small arteries or veins of the dermis and hypodermis are characteristic of skin lesions in APS.

Heart Manifestations

The antiphospholipid syndrome has a variety of cardiac manifestations. The most important are valve disease, coronary artery disease, and, less commonly, cardiomyopathy and intracardiac thrombus. These lesions appear in primary and secondary APS.

A number of studies have documented the prevalence of valve disease in SLE and primary APS patients [30, 85, 86]. Valve disease is present in around 48% of patients with SLE and aPL, and in only 21% of SLE patients negative for aPL. Studies involving only patients with APS show that from 35 to 75% had valvulopathy [31, 32, 87]. In addition, aPL were significantly higher (21%) in a group of unselected patients with heart valve disease when compared with control subjects (9%) [88]. A positive correlation between levels of aPL and the presence of valve damage has been described [89]. In this study, 50% of SLE patients with high levels of aCL had valve disease compared with 37% of patients with lower levels and with only 14% of SLE patients negative for aPL [90]. There is also some data supporting the relationship between valve lesions and the presence of aPL with some evidence suggesting that markers of endothelial cell activation are upregulated in valves from APS patients [91]. Deposition of immunoglobulins in the valves suggested a possible association between this deposition and the activation of the endothelial cells in APS.

Two morphologic echocardiographic patterns can be discerned: valve masses (vegetations) and valvular thickening. The predominant functional abnormality is regurgitation, whereas stenosis is rarely seen. The mitral valve is the most commonly affected site, followed by the aortic valve. Involvement of the tricuspid or pulmonary valve has also been described [92]. Mitral or aortic regurgitation is rarely severe enough to cause symptoms and requirement for valve replacement is distinctly uncommon. Valvular abnormalities of APS is different from that seen in rheumatic heart disease. In APS valvular thickening is diffuse, whereas in rheumatic heart disease thickening is more localized, present at leaflet tips, and often associated with thickening, fusion, and calcification of the chordae tendinae.

A study described the echocardiographic lesions of 29 patients with primary APS [87]. Transesophageal echocardiography was performed in all these patients at the onset of the study and in 13 of 19 patients 1 year later. This second echocardiogram showed no changes in the lesion in 6 patients and new lesions in the remaining 7. All received anticoagulant or antiaggregant treatment during the year of the study. The authors concluded that anticoagulant or antiaggregant treatment does not diminish the size of the valve lesions, although there are anecdotal reports of vegetations resolving with high-intensity anticoagulation [93].

Coronary artery disease has been documented in APS patients. Early descriptions by Hamsten *et al*. in 1986 [94] have been confirmed by prospective studies showing that elevated levels of aCL in a non-SLE population imply an increased risk for the development of myocardial infarction [25, 95, 96]. The prevalence of aCL in patients with myocardial infarction is between 5 and 15% [97, 98]. Although this prevalence may not justify routine screening in patients with myocardial infarction, its measurement may be important in patients under the age of 45 years if they have previous venous or arterial thrombosis or an adverse pregnancy history (e.g., recurrent miscarriages, fetal death). In patients with SLE, particularly women between 35 and 44 years of age, the risk of cardiovascular events is over 10 times higher than in healthy women of similar age [99]. Around 35% of SLE patients are positive for aPL, and the contribution of aPL to the development of myocardial infarction in this population may indeed be substantial.

Different antibodies have been implicated in the development of coronary artery disease in APS patients. aCL is directed against different antigenic structures. Some of them recognize phospholipids, some recognize phospholipid binding proteins such as β_2-glycoprotein I, and some may be directed against cross-reactive epitopes common with oxidized low-density lipoprotein (LDL) [100]. The presence of antioxidized LDL is considered to be a marker of atherosclerosis. Two prospective studies have shown that these antibodies are predictive for myocardial infarction in the general population [98, 101]. aCL levels were associated with antioxidized LDL antibodies, and the joint effect of these two different populations of antibodies was additive for the risk of myocardial infarction. In another study, including a large population of patients with different manifestations of coronary artery disease (109 patients

with coronary artery bypass surgery, 106 patients with balloon angioplasty, 101 patients with acute myocardial infarction, and 99 patients with acute myocardial ischemia), it was shown that anti-oxidized LDL antibody titers were significantly higher in the group with acute myocardial infarction than in other groups in men but not in women. The titers of aCL did not differ among the patient groups. Neither of the autoantibodies was associated with recurrent coronary events. aCL were inversely correlated with dietary intake of vitamin E and polyunsaturated fat in men with coronary heart disease [102].

Kidney Manifestations

Renal involvement is a prominent feature in APS. Initially underestimated, it is currently the subject of numerous studies [103].

Hypertension is the most common clinical manifestation present in more than 40% of patients. It can be present as mild, severe, or even malignant hypertension. Pathogenic mechanisms leading to hypertension include thrombosis in a trunk of the renal artery (renovascular hypertension) and intrarenal vascular lesions [17, 104–106]. These lesions can cause hypertension via stimulation of the renin–angiotensin–aldosterone system. All patients with APS and hypertension should be investigated for renal involvement (especially renal artery stenosis), because hypertension is often the only early clinical manifestation. Although renal involvement, when it occurs, is usually chronic with renal insufficiency slowly progressing, acute renal failure can also occur. In the study by Nochy *et al*. [107], which included 16 patients with primary APS, 90% had hypertension, which was severe in 31% and malignant in 12%. Renal insufficiency was present in 87% and 2 patients had acute renal failure.

Thrombosis of renal arteries and veins has been described in APS patients [105, 108, 109]. This occlusion can be caused by different mechanisms such as *in situ* thrombosis, or in the case of arterial thrombosis, it can also be the consequence of an embolic event resulting from a damaged cardiac valve. Treatment with anticoagulant drugs or transluminal angioplasty has been successful if the problem was detected at an early stage [110].

Anti-phospholipid antibodies have been anecdotally detected in some patients with end-stage renal disease (ESRD), though the data is conflicting [111, 112]. Although Brunet *et al*. [111] found a prevalence of aPL of 31% (aCL = 15.5%, LA = 16.5%) and a clear association between the presence of LA and vascular access thrombosis, Fabrizi *et al*. [112] reported a lower prevalence of aPL (8.8%). The presence of aPL was not associated with factors such as age, cause of ESRD, time on hemodialysis, type of hemodialysis membrane, or thrombotic events. Only one patient positive for LA had recurrent thrombosis of the access graft and native veins.

Although the outcome of renal transplant in patients with SLE is not different from that of other populations, it is possible that the presence of aPL may modify the prognosis. A number of studies have reported a poor outcome, with high rates of graft loss as a result of thrombotic events in patients with SLE positive for aPL [113–115]. Most of the patients included in these studies were not fully anticoagulated. In patients with primary APS, the observed outcome has been even worse, with recurrence of the disease as a thrombotic microangiopathy in the graft despite intensive anticoagulant therapy [116]. Vaidya *et al*. [115] undertook a multicenter study, including 502 ESRD patients waiting for renal transplant. They found that 93 (19%) of these patients were positive for aCL. Only 23 of 93 cases fulfilled the criteria for APS (previous thrombotic episodes, including documented thrombotic microangiopathy or adverse pregnancy history). Eleven of these 23 patients received kidney transplants. Four were treated with oral anticoagulation, and 7 did not receive any anticoagulant drug. All 7 patients without anticoagulant treatment lost their allografts within 1 week as a result of thrombosis. Only 1 of the 4 patients treated lost the graft because of thrombosis. Interestingly, of the remaining 70 aCL-positive patients without any other feature of APS, 37 received a renal transplant, and none of them lost the allografts as a result of thrombosis. These observations suggest that all patients with APS should be fully anticoagulated as part of the posttransplant therapeutic regimen [117].

The histologic findings of the renal lesions in APS have been extensively reviewed [107, 118, 119]. Daugas *et al*. [119] delineated the clinical and histologic manifestations found in patients with APS and renal involvement. APS nephropathy is clinically manifest by a syndrome of vascular nephropathy, associating hypertension, acute and/or chronic renal insufficiency, and low grade proteinuria. Histologically, APS nephropathy is a vaso-occlusive process associating, side-by-side, acute thromboses (thormbotic microangiopathy) and chronic vascular lesions (arterial fibrous intimal hyperplasia, arteriosclerosis, and organized thromboses, with or without recanalization). The authors emphasized the importance of recognizing this characteristic histologic picture for diagnostic and therapeutic purposes. The presence of APS nephropathy in conjunction with lupus nephropathy probably augments the risk of evolution toward ESRD, because it is associated with higher creatinine levels at time of diagnosis, increased interstitial fibrosis, and systemic hypertension.

Lung Manifestations

Patients with APS may develop a broad spectrum of lung disease. Pulmonary thromboembolism and pulmonary hypertension are the most common complications, but microvascular pulmonary thrombosis, pulmonary capillaritis, and alveolar hemorrhage have also been reported [120].

Pulmonary embolism is a frequent complication of deep venous thrombosis and occurs in around 30% of APS patients [121]. It may be the first manifestation of the disease. Recurrent pulmonary embolism may lead to thromboembolic pulmonary hypertension.

The prevalence of pulmonary hypertension in APS associated with SLE and the primary APS has been estimated to 1.8 and 3.5%, respectively [6]. In most cases, the mechanism has been pulmonary emboli, although *in situ* thrombosis remains a possibility [122].

Although quite a rare manifestation, some APS patients may present with diffuse alveolar pulmonary hemorrhage. The common symptoms are fever, cough, dyspnea with or without hemoptysis, hypoxemia, and diffuse pulmonary infiltrates. The diagnosis is usually made by open lung biopsy, which shows microvascular thrombosis and secondary alveolar hemorrhage with or without pulmonary capillaritis. Treatment with corticosteroids usually leads to dramatic improvement [123].

Hematologic Manifestations

The most frequent hematologic manifestation of APS is thrombocytopenia. It is present in 25% of patients though rarely severe enough to cause hemorrhage [124]. The platelet count often remains stable for many years; then, for reasons that are often obscure, the count drops, sometimes catastrophically. Occasionally, patients with APS may present only with severe thrombocytopenia but later develop pregnancy loss or thrombosis. The exact role of aPL in thrombocytopenia is still unclear. More recent data have shown that thrombocytopenia probably results from specific anti-platelet glycoprotein antibodies [125–127]. Galli *et al*. [125] found antibodies to the specific platelet membrane glycoproteins IIb/IIIa and Ib/IX in 40% of patients positive for aPL; there was a significant correlation between these antibodies and thrombocytopenia.

Hemolytic anemia may be present in some patients with APS and is sometimes associated with the presence of thrombocytopenia, the so-called "Evans syndrome." Although a positive direct Coombs' test is not rare in APS patients (10–20%) hemolytic anemia is uncommon. A significant correlation has been found between aPL and hemolytic anemia, although the association with different isotypes of aCL is still controversial. Some authors found an association with IgM isotype [72, 128]; however, this has not been confirmed in other studies [5, 6, 129]. The pathogenic mechanisms for aPL-related hemolytic anemia are not clear. aPL may bind directly to the red blood cell membrane, but factors such as anti-erythrocyte antibodies or immune complexes fixed to red blood cells may also play a role.

Obstetric Manifestations

Recurrent pregnancy loss, typically in the second trimester, is one of the most consistent features of APS [130]. Many cases of APS are diagnosed after investigation for recurrent miscarriage. The prospective fetal loss rate in primary APS is reported to be 50 to 75% [131]. Some studies suggest this rate may be as high as 90% in patients with SLE and secondary APS [132]. The risk of fetal loss is directly related to the antibody titer, particularly the IgG aCL [9, 133], although many women with recurrent miscarriage have IgM aCL antibodies only. It is impossible to predict which women are likely to develop complications in pregnancy, and some women with persistently elevated aPL titers and a history of thromboses with or without thrombocytopenia have no fetal complications at all. Previous poor obstetric outcome remains the most important predictor of future risk [134, 135].

In pregnancies that do not end in miscarriage or fetal loss, there is a high incidence of preeclampsia, intrauterine growth restriction (IUGR), placental abruption, and premature delivery [134, 136]. It is important to note that the most recent classification criteria for APS have been amended to highlight the fact that not only fetal loss but premature birth before 34 weeks as a result of preeclampsia, placental abruption, or IUGR and positive aCL, or LA may allow the patient to be labeled as having APS [3].

Varying high rates of preeclampsia has been reported in women with APS, which contributes to the high rate of preterm delivery in this condition. Raised aCL levels have been reported in association with severe early onset preeclampsia [136]. The weight of evidence supports aPL testing in women with early onset (<34 weeks of gestation) severe preeclampsia.

Units that manage patients with severe manifestations of APS such as thrombosis and previous stillbirth [134, 137] have a higher incidence of complications in pregnancy than those that recruit women predominantly from recurrent miscarriage clinics [138, 139]. In our unit, we run a multidisciplinary team service, where most APS cases have either been identified by rheumatology (association with SLE) or hematology (previous thrombosis) colleagues. Many patients are referred for

specialist management after previous poor obstetric outcome. Our live birth rate is 70 to 80%, and in a previous study from our unit, the incidence of preeclampsia was 18%, the percentage of babies born with birth weights less than the 10th centile for gestational age was 31% and the percentage of infants delivered prematurely (<37 weeks) with a mean gestation of approximately 34 weeks was about 43% [134]. Approximately 70% of these women were delivered by cesarean section, and 7% of babies died in the neonatal period as a result of problems related to prematurity. Regular ultrasound scanning for fetal growth is recommended in these patients and, in specialist units (including our own), assessment of uterine artery Doppler waveforms is performed in the mid-trimester [140]. The presence of mid-trimester uterine artery notches in high-risk pregnancies is associated with preeclampsia, IUGR, and intrapartum asphyxia with a sensitivity of 90% and a positive predictive value of 60% [141]. In high-risk pregnancies, abnormal uterine artery Doppler velocimetry is also of some value in predicting placental abruption, a common feature of APS pregnancies, but gives no indication as to the timing of this event [142].

Catastrophic Antiphospholipid Syndrome

A minority of patients with APS present with an acute and devastating syndrome characterized by multiple simultaneous vascular occlusions throughout the body, often resulting in death. This syndrome, termed catastrophic APS, is defined by the clinical involvement of at least three different organ systems over a period of days or few weeks with histopathological evidence of multiple occlusions of large or small vessels [143]. Although the same clinical manifestations seen with primary and secondary APS occur as part of catastrophic APS, there are important differences in prevalence and in the caliber of the vessels predominantly affected. Ischemia of the kidneys, bowels, lungs, heart, and/or brain are most frequent, but rarely adrenal, testicular, splenic, pancreatic, or skin involvement have been described. Occlusion of small vessels (thrombotic microangiopathy) is characteristic resulting in symptoms related to dysfunction of the affected organs. Depending on the organs involved, patients may present with hypertension and renal impairment, acute respiratory distress syndrome, alveolar hemorrhage and capillaritis, confusion and disorientation, or abdominal pain and distension secondary to bowel infarction. Precipitating factors of catastrophic APS include infections, surgical procedures, withdrawal of anticoagulant therapy, and the use of drugs such as oral contraceptives.

Other Manifestations

Avascular necrosis of bone is an uncommon complication in lupus patients and clearly associated with high steroid dosage. We have noted an increased risk of avascular necrosis in individuals positive for aPL, possibly as a result of small arterial occlusions, notably of the head of the femur [144].

Rare cases of bone-marrow necrosis have been reported secondary to APS [145, 146].

Many patients with APS seem to develop widespread arteriopathy. The systemic narrowing of major arteries is similar in many respects to the widespread endarterial disease seen in some patients after heart–lung transplantation. Thus, aPL might be associated with accelerated vascular disease, including atherosclerosis [147]. More recent work has suggested that aPL are directed against oxidized phospholipids, following the observation that oxidation of cardiolipin is required, even in the present of β_2-glycoprotein I, for it to be recognized by purified IgG fractions and monoclonal antibodies from APS patients [148]. These findings raise the possibility that oxidized LDL, as oxidized cardiolipin, may act as an immunizing antigen leading to the generation of aPL, providing an additional link between atherogenesis and APS.

Some clinicians are convinced that aPL are associated with infertility. Additionally, some clinicians recommend that infertile women who have aPL and are undergoing *in vitro* fertilization should be treated with heparin to improve the rate of pregnancy. However, experts disagree regarding the relationship between aPL and infertility. There is also substantial evidence that treatment with heparin does not alter the rate of pregnancy following *in vitro* fertilization [149, 150].

EPIDEMIOLOGY

The epidemiology of aPL is still being investigated worldwide. Efforts are being made in clinics throughout the world to assess the importance of this factor in recurrent abortion, stroke, myocardial infarction, epilepsy, and so on. Prospective studies have shown an association between aPL and the first episode of venous thrombosis [151] the first myocardial infarction [95], and the first ischemic stroke [25]. A critical issue, therefore, is the identification of patients with aPL who are at increased risk for a thrombotic event.

Anti-phospholipid antibodies, using standardized techniques, are detected in less than 1% of apparently normal individuals and in up to 3% of the elderly population without clinical manifestations of the APS. Among patients with SLE, the prevalence of aPL is

much higher, ranging from 30 to 40% [152]. For otherwise healthy control subjects there are insufficient data to determine what percentage of those with aPL antibodies will eventually have a thrombotic event or a complication of pregnancy consistent with the APS. In contrast, APS may develop in 50–70% of patients with both SLE and aPL after 10–20 years of follow-up [153, 154].

The specificities of aPL antibodies probably differ in various disorders. Large retrospective studies of patients with thrombotic complications suggest that those with high concentrations of IgG aCL appear to be at greatest risk for thrombosis, whereas the risk of clotting appears to be much lower in patients with infection-related aPL [155].

The effect of race only has been adequately studied in African-American and White populations [154, 156, 157]. The frequency of LA and high-titer aCL is significantly less common in African-Americans than in Whites and the APS is more frequent in Arabs compared to the Indian population.

THE CATASTROPHIC ANTIPHOSPHOLIPID SYNDROME

Ronald A. Asherson
Ricard Cervera

INTRODUCTION

A widespread coagulopathy, affecting predominantly small vessels supplying organs, rather than the usual large vessel occlusions of larger veins and arteries seen in the classic antiphospholipid syndrome (APS), in association with elevations of anti-phospholipid antibodies (aPL) (often high levels), was defined in 1992 as the catastrophic APS [1] and in 2002 was called Asherson's syndrome. Isolated cases of this syndrome had previously been reported by others and referred to as "devastating noninflammatory vasculopathy" [2], or "occlusive vasculopathy" [3]. Neither of these terms are used today and the adjective "catastrophic" is universally accepted to describe this syndrome, bearing in mind that many of the complications of systemic lupus erythematosus (SLE) may indeed be "catastrophic" too. Since the original attempt to define the condition [1], which was based on 10 reported cases, many more cases have been reported. A series of 50 patients was analyzed and documented in 1998 [4] and a further 80 patients reviewed in 2001 [5]. Additionally, several reviews on the topic have been published [6, 7]. Therefore, although they represent less than 1% of all patients with APS [8], they are usually in a life-threatening medical situation that requires high clinical awareness in order to institute adequate and effective therapy to achieve amelioration of this condition.

DEFINITION

The main characteristics of this syndrome are: (a) a widespread coagulopathy (noninflammatory), affecting predominantly small vessels involving organs; (b) a minority of patients demonstrate features of the classic APS with involvement of large veins (of the lower limbs usually) or cerebral vasculature; (c) the vascular occlusions occur within days to weeks of a "triggering" event or may occur seemingly spontaneously; (d) the patient may be suffering from SLE often accompanied by an APS, there may have been a history of a previous thrombotic event (venous/arterial), or the event may arise *de novo* in a patient with no previous history of thrombotic events (primary APS); (e) serological testing reveals very high levels of aPL in more than 50% of patients; (f) there is often a moderate to severe thrombocytopenia; and (g) laboratory evidence of disseminated intravascular coagulation (DIC) or microangiopatic anemia may be present (Fig. 1).

The majority of patients suffering from catastrophic APS have been found to be suffering from defined SLE or the primary APS [4, 5], while a minority have had primary Sjögren's syndrome [2], rheumatoid arthritis [9], systemic sclerosis [10], ulcerative colitis [5], or relapsing polychondritis [11]. Additionally, several patients have been documented who have developed catastrophic APS in association with carcinoma or lymphoma [4, 5]. Essentially, the same precipitating factors,

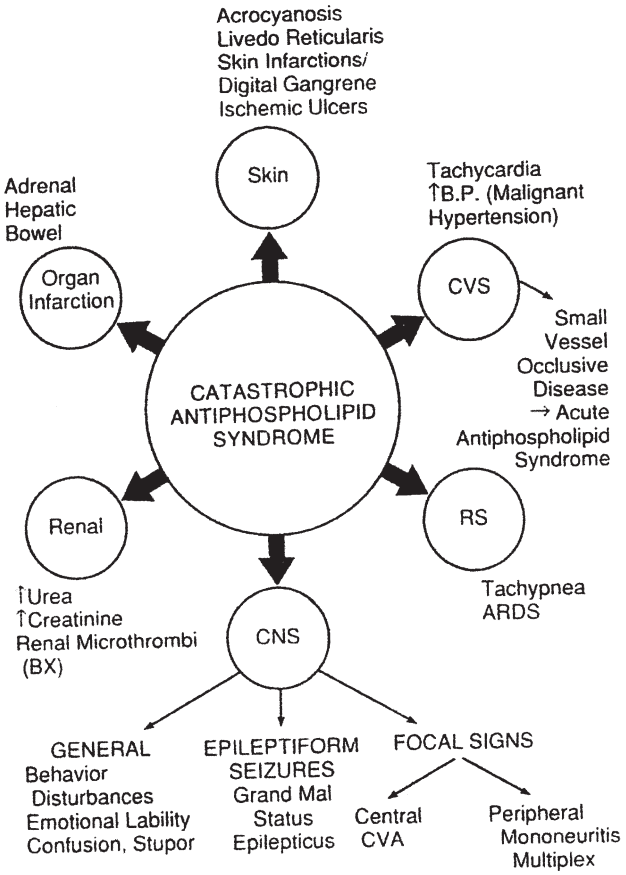

FIGURE 1. Main features of the catastrophic APS.

clinical and laboratory features, and outcome have been documented in the reported cases, irrespective of the etiology of the condition. The patients with SLE have often had a history of a classic APS preceding the development of catastrophic APS and may have been on prophylactic therapy in order to prevent recurrences of thrombotic vascular occlusions (e.g., coumadin, salicylates), as well as on drugs to treat the underlying lupus (immunosupressants, antimalarials, etc.). Control of both the SLE and the APS may have been satisfactory.

PATHOGENESIS

General Characteristics

It appears that, following a sudden "trigger" or insult, the patient is catapulted into multiorgan failure (Table 1) and very often has to be admitted to an intensive care unit for diagnosis and treatment. The trigger may be quite minor or several triggers may be operating simultaneously (the so-called "double" or "treble" hit hypothesis, which applies to any patient presenting with multiorgan failure arising from surgical trauma, sepsis, burns, pancreatitis, etc.) (Fig. 2). The usual factors, which may predispose to thrombosis in patients with a classic APS do not seem to play a role in the pathogenesis of catastrophic APS. These include conditions which are chronic, such as prolonged bed rest, sedentary situations (e.g., long-haul flying), obesity, dyslipidemias, diabetes mellitus, smoking, nephrotic syndrome, and the other hereditary thrombophilias, some recently described (e.g., factor V Leiden mutation, prothrombin mutation). The trigger factors which precipitate catastrophic APS are usually acute and superimposed on patients with the underlying coagulopathy induced by aPL, and what seems to be unique about the patients with catastrophic APS is that, to date, the condition has not been reported and is not seen with other underlying coagulopathies due to the hereditary thrombophilias, implying a basic autoimmune mechanism which is magnified by the "trigger" to cause this often fatal condition. It must be emphasized, however, that in some patients, particular triggers (e.g., warfarin withdrawal) may not result in the catastrophic syndrome, but simply in recurrent thrombosis affecting large vessels. The factors determining which APS patients will develop catastrophic APS rather than recurrent large vessel occlusions are unknown at this time.

TABLE 1 Trigger Factors for the Catastrophic APS

Infections
Trauma (including even minor trauma, such as biopsies, dental extractions, fractures)
Invasive procedures (needle stick injury)
Warfarin withdrawal/low International normalized ratio (INR)
Drug administration (e.g., oral contraceptives)
SLE "flares"
Large clots themselves ("thrombotic storm")

The catastrophic APS may occur in two situations where an underlying hypercoagulable state already exists or develops, that is, carcinoma and the puerperium. Patients with carcinoma may have an underlying hypercoagulable state and this was pointed out by Trousseau in the nineteenth century ("Trousseau's syndrome"). The aPL have been demonstrated in many types of carcinoma patients as well as in those suffering from hematological/lymphoproliferative malignancies [12] and it has been hypothesized that some patients who develop clotting in these conditions may in fact be examples of the APS. Further insults in cancer patients, such as biopsies, have in fact resulted in catastrophic APS when aPL have been present. The sites of the carcinoma are varied and lung, uterus, stomach, and biliary tree have all been reported in association with this con-

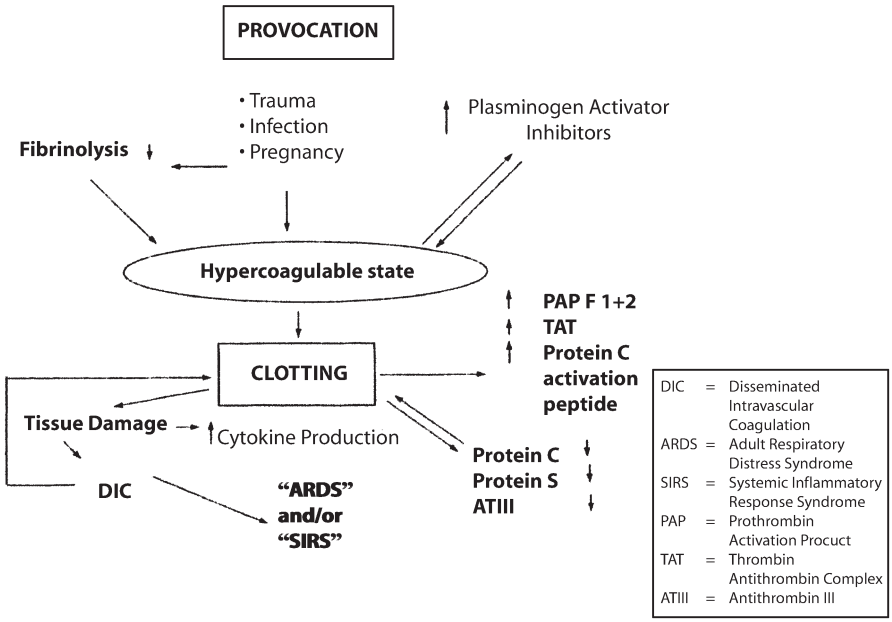

FIGURE 2. Pathogenesis of catastrophic APS.

dition. On the other hand, in the puerperium, there is an alteration in the hormonal milieu as well as in hemostatic equilibrium, both designed and intended to promote healing of the vascular bed consequent on placental implantation. It is well known that classic APS patients may thrombose at this time and, indeed, in patients who have a previous history of thrombosis, it is now recommended that low molecular weight heparin (LMWH) be administered for 6 weeks postpartum in order to prevent vascular occlusions at this time. Several patients with catastrophic APS have been reported who have developed the condition during the puerperium. Catastrophic APS in association with the HELLP (hemolysis, elevated liver enzymes, and low platelet) syndrome, seen during pregnancy, has also been reported [4, 5].

Specific Triggering Factors

Infections

Bacterial infections occurring prior to the onset of catastrophic APS were encountered in 29% of the first series of patients reported [4] and in 36% of the second series [5]. Infections were present in two of the six patients reported by Kitchens [13], and Hayem *et al*. [14] documented a single patient who developed catastrophic APS following a well-diagnosed *Salmonella typhi* infection. In a series of patients reported from Mexico [15], infections were documented in 60% of the eight patients. Other cases also confirmed infections preceding the onset of the condition. Undas *et al*. [16] described a patient whose two episodes of catastrophic APS were clearly precipitated by upper respiratory infections.

This topic has been extensively reviewed [17–19]. By the mechanism of "molecular mimicry" some infectious agents may induce not only aPL but also pathogenetic anti-β_2-glycoprotein I (GPI) autoantibodies. Gharavi *et al*. [17, 18] have identified seven proteins with sequence homology to GDKU and GDKU2 proteins which are the same sequence as found in the β_2GPI binding site for aPL as well as being part of many viruses to which humans are exposed. Immunization of mice with these peptides conjugated to bovine serum albumin in Freund's adjuvant have been shown to produce high levels of aPL and anti-β_2GPI. Other mechanisms may also be responsible for initiating the sudden onset of catastrophic APS following infections. Enterotoxins produced by enterococci/staphylococci as well as other microorganisms ("superantigens") may activate T cells which then may stimulate those B cells already primed for the production of aPL in APS/SLE patients.

Cytokine activation (tumor necrosis factor-α, interleukin-1, mainly) as well as γ-interferon mediated activation of the monocytic/phagocytic system occurs simultaneously. This activation of the inflammatory response leads to phospholipid asymmetry of cell membranes, exposure of anionic phospholipids, normally "hidden" under the surface of endothelial cells and platelets. This endothelial cell activation then initiates the coagulation process resulting in the binding of aPL to β_2GPI. There is also another role for monocytes via tissue factor. Activated endothelial cells secrete

increased amounts of interleukin-l which in turn activates monocytes to produce tissue factor procoagulant. Adherence of monocytes to E-selectin, expressed on activated endothelial cells, induces these monocytes to undergo phenotypic transformation and this induces more expression of tissue factor. The aPL may also bind to adherent monocytes and activate them via an Fc-receptor mediated mechanism and monoclonal aPL have also been shown to induce procoagulant activity [19]. The entire process is clearly extremely complicated with several reactions occurring simultaneously, the end result being thrombosis. The role of cytokine activation and endothelial cells in the pathogenesis of the systemic inflammatory response syndrome (SIRS) and thrombosis has been extensively reviewed by Belmont *et al*. [20].

Generation of Ongoing Clotting by Clot Itself ("Thrombotic Storm")

The paper by Kitchens [13] may be of great importance in the pathogenesis of the condition. Of the six patients he reported as suffering from "thrombotic storm," three were clear examples of catastrophic APS and although aPL were not estimated in the remainder, it is more than probable that they were also examples of the condition. Kitchens hypothsized that newly formed clots in some patients with a preexisting autoimmune hypercoagulable state continue to provide thrombin. Fibrinolysis is depressed by increases in plasminogen activator inhibitors and a state of fibrinolytic "shutdown" occurs. Coagulation activation products including prothrombin activation peptides F 1 and 2, thrombin–antithrombin complexes (TAT), and protein C activation peptide are increased in plasma. At the same time there is a depletion of the body's natural anticoagulant proteins (proteins C and S, antithrombin III). A combination of all these mechanisms leads to continued clotting such as is seen in catastrophic APS. A paper by Amital *et al*. [21] documenting two patients who had developed catastrophic APS which remitted following amputation of the limbs where large vessel clotting had occurred lends credence to this hypothesis, although removal of infected ulcers could also have been partially responsible.

Warfarin Withdrawal/Low International Normalized Ratio

Warfarin withdrawal (e.g., prior to surgical procedure, biopsies, or for hemorrhagic complications attributable to anticoagulation therapy) may be followed by recurrent thrombosis with days to weeks in classic APS patients, but may also lead to catastrophic APS when other trigger factors are also present at the time, for example, infection [4, 5]. In addition, low levels of the international normalized ratio (INR), which are inadequate to protect against thrombosis may also serve to alter the hemostatic milieu when other prothrombotic factors are superimposed. It is well documented that INR levels may fluctuate widely in classic APS patients and this is all the more reason why their frequent estimation is necessary in APS patients and dosages of anticoagulants adjusted accordingly in order to prevent recurrent thrombosis. LMWH is best administered immediately prior to, and following invasive and investigative procedures as well as surgical interventions/biopsies in these patients.

CLINICAL MANIFESTATIONS

General Characteristics

Although patients may present with single organ involvement, for example, dyspnea, deterioration of consciousness, or abdominal pain, the picture very soon changes to that of multiorgan failure and the patient is then usually admitted to an intensive care unit for further investigations and treatment. Unless the clinicians consider a catastrophic APS situation and perform the necessary tests, the diagnosis may very often be missed. A previous history of SLE, thrombosis, etc. should provide clues as to the disease. It should be emphasized that although large vessel occlusions, such as deep vein thrombosis, often complicated by pulmonary embolism and arterial lesions (cerebral, peripheral) do occur (15–20% of patients), the frequency of these lesions is far less than the dominant small vessel occlusive disease affecting organs mainly (intraabdominal, cerebral, cardiac, renal, etc.) which is responsible for most of the clinical picture. Additionally, unusual vessels tend to be involved, for example, scrotal, testicular, ovarian, esophageal, colonic, gastric) which is unlike the distribution seen in patients with the simple or classic APS.

The symptomatology related to the extensive thrombotic disease is of course predicated by the specific organs involved. However, as a consequence of the extensive microvasculopathy and tissue damage, it is accompanied by symptoms related to the SIRS which is essentially not dissimilar to its occurrence with other types of multiorgan failure such as that accompanying septic/endotoxin shock/septicemia, burns, multiple trauma, pancreatitis, etc. Excessive production of cytokines such as tumor necrosis factor-α, interleukin-l, and other cytokines results in a "cytokine storm" which is responsible for such manifestations as cerebral edema

(causing initial confusion and drowsiness), myocardial dysfunction, and the adult respiratory distress syndrome (ARDS) which seems to be the hallmark of the pulmonary involvement in this condition. In some cases, the ARDS may be superimposed on an underlying infective process which itself may have triggered the catastrophic APS by any of the mechanisms described earlier. In addition, there are some of the features of DIC seen in approximately 20% of cases. If is true DIC then this may contribute to the microangiopathic vascular occlusions which take place and may be perpetuating the process itself, as well as leading to diagnostic difficulties in some cases. It is possible that these laboratory features of DIC may simply be a reflection of extensive small vessel endothelial cell damage and ongoing clotting only. The catastrophic APS may be relapsing in a minority of cases but the frequency of this is extremely low as opposed to relapsing thrombotic thrombocytopenic purpura (TTP) .

Specific Organ Involvement

Kidneys

The kidneys are involved in up to 70% of all APS patients. Hypertension (occasionally of the malignant/accelerated variety) may accompany the renal lesions which consist overwhelmingly of renal thrombotic microangiopathy (Fig. 3) which may be demonstrated either by renal biopsy or at postmortem. Death from anuric renal failure is rare, most patients only demonstrating elevated urea and creatinine levels. Hematuria/proteinuria or casts may be seen on urine microscopy.

Lungs

The ARDS dominates pulmonary involvement in most patients. They are dyspneic on initial presentation or rapidly become so. Assisted ventilation usually becomes necessary. Other types of pulmonary pathologies, however, may also be evident and these include embolic disease accompanied by pulmonary infarctions, pulmonary hemorrhage, interstitial infiltration, capillaritis, pulmonary edema, etc. [22]. Major pulmonary arterial occlusion is extremely rare. As mentioned earlier, every effort should be made to identify an infection and the appropriate parenteral antibiotic therapy instituted when indicated.

Nervous System

Gradual progression from initial confusion and disorientation, to drowsiness, semicoma, and coma is seen. In a minority, focal signs, with frank hemiplegias or hemipareses may be evident and seizures (even *status epilepticus*) may occur, although rarely. The focal signs may be consequent on large vessel occlusions similar to those seen with a classic APS. Diffuse microvascular damage dominates the picture though pathologically. Mononeuritis multiplex has been recorded in a few cases and is due to focal vascular involvement of peripheral nerves by small vessel vasculopathy. Severe hypertension may cause hypertensive encephalopathy in

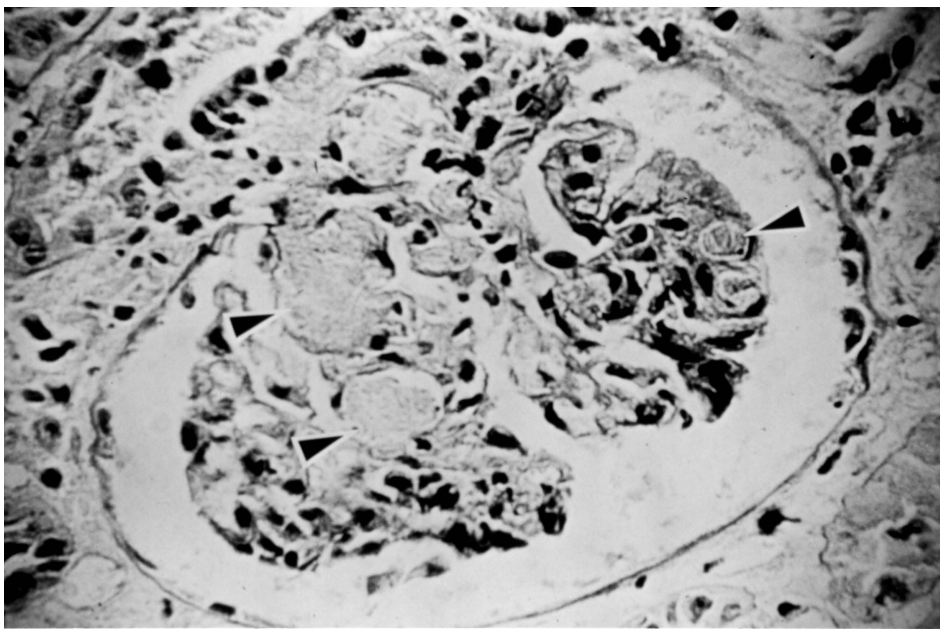

FIGURE 3. Renal microangiopathy.

some. Retinal vascular involvement affecting venules and arterioles may also be seen.

Skin

The dermatological complications seen in the catastrophic APS are essentially similar to those encountered in the simple or classic APS and include *livedo reticularis*, digital ischemia or frank gangrene, superficial skin necrosis, or ischemic (often infected) ulceration of the lower limbs. Frequently, several differing skin lesions may be encountered in the same patient. They are all caused by microvascular occlusive disease of skin vessels except for major ischemic problems which are related to larger vascular occlusions.

Heart

Cardiac microangiopathy leading to a reduced ejection fraction because of myocardial ischemia may be associated with hypotension. Generalized cardiac dysfunction and reduced contractility because of the cytokine storm may also contribute to this state. Cardiac failure may ensue. Myocardial infarctions may be seen when larger vessels are involved and may accompany the microangiopathy. Valve lesions (mitral and aortic) or intracardiac thrombus are often detected in patients with long-standing and preexisting APS for many years.

Gastrointestinal System

Abdominal pain is frequent in patients with catastrophic APS as a presenting feature and may be complained of in approximately one-third of patients. It is due to bowel ischemia. Infarction and peritonitis may occur. Other thrombotic lesions may account for hepatic infarctions (uncommon), thrombotic pancreatitis (usually detected by enzyme elevations only), or ischemic ulceration of the esophagus, stomach, duodenum, small bowel, or colon. A Budd-Chiari syndrome may rarely be encountered. Death may supervene from septic peritonitis or mediastinitis (in the case of esophageal perforation).

Adrenal Glands

The frequency of adrenal involvement in patients with catastrophic APS is extraordinarily high compared to that seen in simple/classic APS patients. It is much more frequent than occlusion of the renal venous trunks which are close by and may be explained by flow or shear dynamics. It is usually bilateral, silent, and forms part of the multiorgan failure. When it occurs acutely, from bilateral adrenal hemorrhage and ensuing hemorrhagic infarction, it may be accompanied by abdominal pain and the differential diagnosis then is from other intraabdominal causes of pain. It has been reported postpartum. A few patients with catastrophic APS have given a history of Addison's disease in the past, often many years previously. Bilateral adrenal hemorrhage has been described as a complication of anticoagulation therapy and with other underlying coagulation abnormalities which predispose to clotting, for example, protein C deficiency, when it may be associated with skin necrosis.

Bone Marrow

Bone marrow necrosis has more recently been described in patients with catastrophic APS and the frequency of this complication is surprisingly high [5] (Fig. 4). It is a relatively uncommon complication of neoplastic diseases, lymphomas, acute leukemia, following radiotherapy, with sickle-cell disease, and severe infections (particularly septic shock states). This complication has been seen in very few patients with simple/classic APS. It seems to be more common in pregnancy or the puerperium.

Other Organs

As in the classic APS, any other organ may be affected by the catastrophic APS, and thrombosis in retina, testes, ovaries, and tendons (Fig. 5), among others, have all been reported.

LABORATORY

More than 50% of patients demonstrate very high levels of anti-cardiolipin antibodies (aCL) and/or positive lupus anticoagulant (LA) tests. The isotype is IgG in 99% of patients. Rarely, an IgM isotype alone may be encountered. Similarly, elevations of antibodies to β_2GPI have been high when measured and are also of the IgG isotype predominantly.

The ANA may be low positive in patients with primary APS and much higher in those suffering from defined SLE. SLE patients usually demonstrate elevated levels of antibodies to double-stranded (ds)DNA. Antibodies to RNP, SS-A/Ro and SS-B/La, may be positive in a minority.

Laboratory features of DIC may be present in up to 20% of cases. These include elevated D-dimers and fibrin degradation products (FDP). Fibrinogen levels may be elevated or reduced. It is unclear whether these features actually indicated the presence of DIC or are

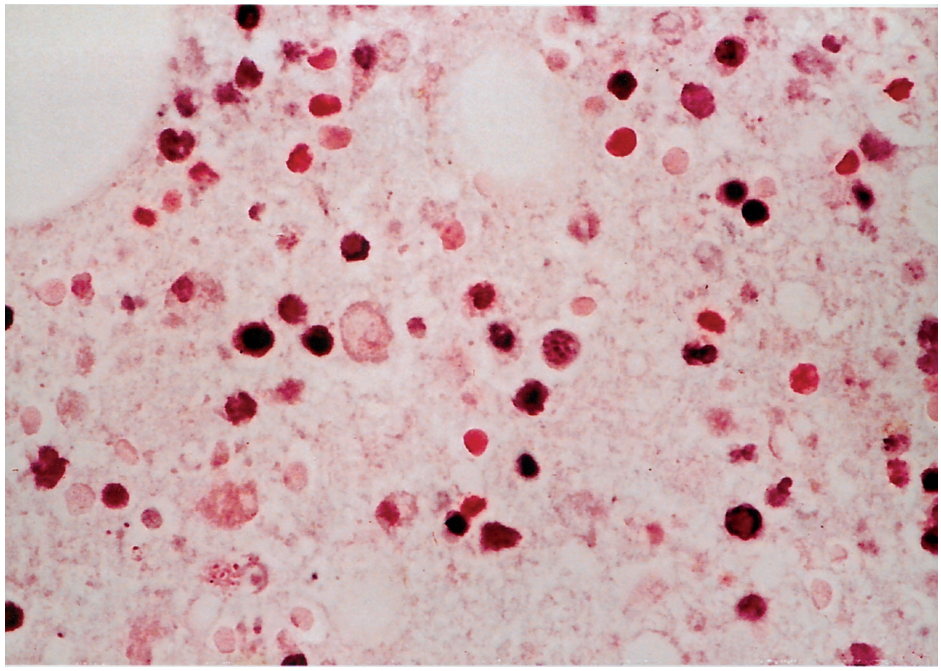

FIGURE 4. Bone marrow necrosis.

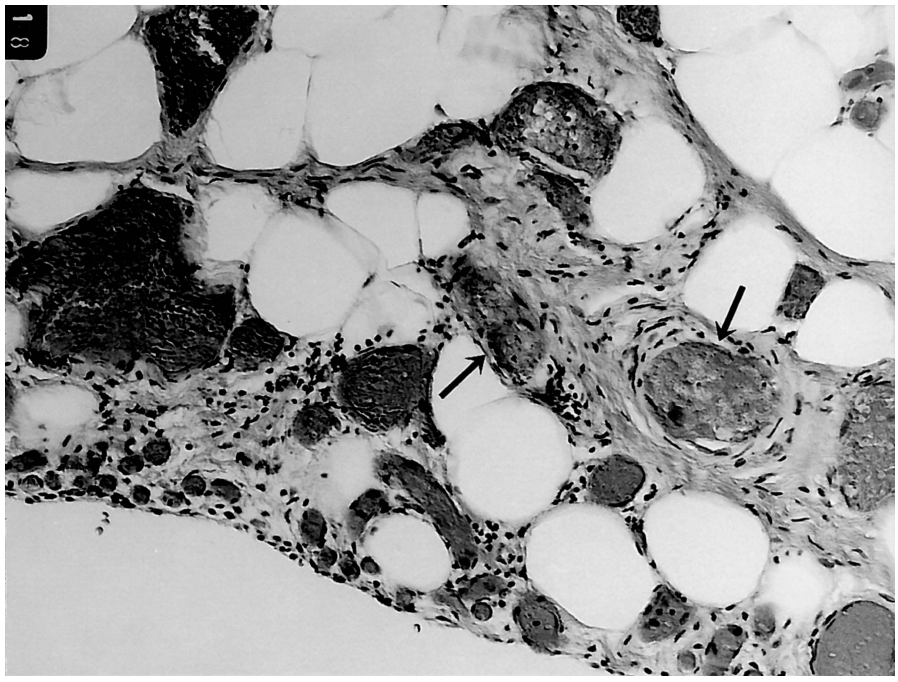

FIGURE 5. Necrosis in tendons.

merely consequent on extensive endothelial damage and ongoing clotting.

The platelet count is decreased in more than 50% of patients and severe thrombocytopenia (below 50×10^9/liter) is seen in a minority. A microangiopathic hemolytic anemia may be present (scanty schistocytes) and may accompany the thrombocytopenia.

DIAGNOSIS

A high index of clinical suspicion is necessary for the diagnosis of catastrophic APS in patients with evidence of both large and small vessel occlusion, affecting multiple organs and systems. The diagnosis may be unduly delayed because, although some of the manifestations

may be clearly evident clinically, for example, deep venous thrombosis (DVT) or stroke, others may present less clearly, for example, renal involvement or nonspecific abdominal pain in cases of mesenteric ischemia or pancreatic thrombosis. In addition, absence of aPL may confuse the clinician. These antibodies may return during the recovery phase or later [23]. Although catastrophic APS may often be the first manifestation of the illness, a previous history of SLE, the primary APS or major vascular occlusive disease might assist the physician in diagnosis. A preliminary set of criteria for the diagnosis of catastrophic APS is presented in Table 2, based on the cumulated published experience of 130 cases with this syndrome [4, 5].

Clinical Diagnosis

Multiorgan presentation and failure is the rule. Involvement of the kidneys is present in 78% of the patients with catastrophic APS, followed by pulmonary (66%), central nervous system (56%), skin (50%), cardiac (50%), gastrointestinal (38%), hepatic (34%), adrenal (13%), and urogenital involvement (6%) [4, 5].

TABLE 2 Preliminary Criteria for the Classification of Catastrophic APS [7]

1. Evidence of involvement of three or more organs, systems, and/or tissues[a]
2. Development of manifestations simultaneously or in less than a week
3. Confirmation by histopathology of small vessel occlusion in at least one organ or tissue[b]
4. Laboratory confirmation of the presence of anti-phospholipid antibodies (lupus anticoagulant and/or anti-cardiolipin antibodies)[c]

Definite catastrophic APS
All four criteria

Probable catastrophic APS
All four criteria, except for only two organs, systems, and/or tissues involvement
All four criteria, except for the absence of laboratory confirmation at least 6 weeks apart due to the early death of a patient never tested for aPL before the catastrophic APS
1, 2, and 4
1, 3, and 4 and the development of a third event in more than a week but less than a month, despite anticoagulation.

[a] Usually, clinical evidence of vessel occlusions, confirmed by imaging techniques when appropriate. Renal involvement is defined by a 50% rise in serum creatinine, severe systemic hypertension (>180/100 mm Hg), and/or proteinuria (>500 mg/24 h).

[b] For histopathological confirmation, significant evidence of thrombosis must be present, although vasculitis may coexist occasionally.

[c] If the patient had not been previously diagnosed as having an APS, the laboratory confirmation requires that presence of anti-phospholipid antibodies must be detected on two or more occasions at least 6 weeks apart (not necessarily at the time of the event), according to the proposed preliminary criteria for the classification of definite APS [24].

Renal Involvement

In these patients, a renal biopsy is indicated in order to diagnose intrarenal arteriolar or glomerular thromboses (renal thrombotic microangiopathy). If renal infarction or renal artery trunk thrombosis is to be excluded, renal angiography (arterial or venous) should be performed.

Pulmonary Involvement

If the radiograph of the chest shows pulmonary infiltrates, a lung biopsy may be indicated in order to identify the presence of hyaline membrane formation, consistent with ARDS or the presence of erythrocytes and iron-staining macrophages, characteristic of the intraalveolar pulmonary hemorrhage. Unusually pulmonary "capillaritis" may be diagnosed on biopsy. If there is a suspicion of pulmonary embolism, a scintigraph study of lungs or an angiogram of the pulmonary circulation must be performed. Additionally, routine sputum cultures and serologies are obligatory in order to rule out any underlying precipitating or complicating pulmonary infection.

Nervous System Involvement

Neuroimaging studies, such as computed tomography or magnetic resonance imaging (MRI) scans of the brain, may reveal major cerebral infarctions or small foci of high signal intensity in subcortical white matter representing areas of subcortical ischemia. In cases of suspected cerebral venous sinus thrombosis, a cerebral angio-MRI is indicated. In order to confirm the presence of status epilepticus, electroencephalography is essential. Electromyography is necessary if mononeuritis multiplex is suspected, and a biopsy of the affected nerves is indicated if the diagnosis is unclear.

Skin Involvement

Diagnosis of these lesions is mainly clinical in patients with multisystemic thrombotic phenomena. Routine ulcer cultures are obligatory in order to rule out infection. Noninflammatory thrombosis in small arteries and/or veins throughout the dermis and the subcutaneous fatty tissue are the main histological findings.

Cardiovascular Involvement

Echocardiographic studies, preferably transesophageal echocardiography, is the technique which allows diagnosis of valvular disease or the presence of intracardiac thrombus in these patients. Routine blood cultures are obligatory in order to rule out true infective endocarditis.

Gastrointestinal, Hepatic, and Pancreatic Involvement

Diagnosis of intestinal ischemia may be confirmed by angiography. Abdominal echography may be useful in case of acute pancreatitis as this will reveal an edematous pancreas or acalculous ischemic gallbladder necrosis. Routine blood cultures are obligatory in order to rule out hepatic abscess. A computed tomography scan of the abdomen may be useful in differentiating this condition from true hepatic infarction and in demonstrating splenic infarctions.

Adrenal Involvement

Diagnosis of the condition is mainly clinical, with a high index of suspicion. Confirmation may be obtained by laboratory findings of hypoglycemia, hyponatremia, hyperkalemia, and mild azotemia combined with a positive test of acute cortisol response to injection of 250 μg of aqueous synthetic corticotrophin. A computed tomography scan will show typical changes of adrenal infarction or hemorrhage.

Urogenital Involvement

Just as with skin involvement, diagnosis of urogenital involvement is mainly clinical in a patient with multiple thrombotic phenomena and scrotal pain. Echography of the testes may be useful in differentiating a testicular torsion.

Ocular Involvement

Fundoscopic examination is compulsory for diagnosis. In some patients, the retinal vessels may appear normal and then, a diagnosis of retrobulbar optic neuritis should be suspected. In these patients, an evoked visual potential may show alteration in conduction velocity of the optic nerve and an MRI scan may reveal small foci of high signal intensity in the optic nerve.

Laboratory Diagnosis

Although the diagnosis of catastrophic APS is based on the clinical picture (multiorgan involvement and failure), the laboratory findings are very important to confirm the clinical suspicion. The following laboratory evaluations are recommended.

Blood Cell Count

Blood cell count may show hemolytic anemia and thrombocytopenia occasionally severe (below 50×10^9/liter). In cases of thrombocytopenia, we suggest that a second platelet count be performed on a sample obtained in citrate as anticoagulant in order to rule out a "pseudo-thrombocytopenia" secondary to EDTA aggregation.

Biochemical Tests

The alterations of these biochemical tests will depend on the organs involved. Routine blood and urine tests, renal function (urea, creatinine), arterial-blood gas level, and cardiac, hepatic, and pancreatic enzymes should be determined.

Coagulation Tests

The activated partial thromboplastin time (aPTT) may be increased if the patient has a lupus anticoagulant. The dilute Russell viper venom time (dRVVT) should also be performed, particularly if the aPTT is negative. In some cases, there are laboratory features of DIC (increased prothrombin time, decreased fibrinogen, and increased fibrinogen/fibrin degradation products). At the time of the acute event, fibrinogen levels may be normal or even increased. Finally, the thrombin time is usually slightly increased but the effect of heparin needs to be taken into account if thrombin time elevations are encountered.

Peripheral Blood Smear

This may reveal scanty fragmented red cells (schistocytes), which are characteristic of microangiopathic hemolysis. In patients with TTP, a related condition, schistocytes are usually plentiful.

Coombs Test

The positivity of Coombs test suggests the existence of autoimmune hemolysis. The Coombs test may, however, be negative.

Anti-phospholipid Antibody Profile

This should include both LA and aCL (IgG and IgM isotypes). Negative testing of aPL may be seen during

the course of thrombotic events, probably due to their consumption, making the diagnosis difficult at the time of the acute event [23]. In these cases, a new sample obtained during the recovery phase should be analyzed. Many laboratories also are able to perform tests to detect antibodies to the cofactor of aCL (β_2-GPI).

Immunology Tests

The ANA may be positive in these patients, although usually at low titers (below 1/320). Higher titers of antinuclear antibodies (ANA) and anti-dsDNA antibodies may be found in patients with defined SLE or "lupus-like disease." The presence of anti-extractable nuclear antigens (ENA) antibodies (anti-Ro, anti-La, anti-RNP, and anti-Sm) is uncommon.

Other Tests

Increased thrombin and plasmin generation markers, such as thrombin–antithrombin and plasmin–antiplasmin complexes, respectively, are usually found. Moreover, other markers of endothelial cell activation elevated in catastrophic APS are cytokines (particularly, interleukin-1 and tumor necrosis factor-α) and the adhesion molecules (intercellular adhesion molecule-1 and E-selectin). However, at the present time, these determinations have only a research value and awaiting these results should not delay other diagnostic and therapeutic procedures. Von Willebrand factor antigen, as an index of endothelial cell damage, however, can now be performed by most laboratories and its estimation is most useful.

DIFFERENTIAL DIAGNOSIS

A careful differential diagnosis is necessary in the presence of multiorgan thrombotic events in a particular patient and this should include catastrophic APS and other microangiopathic syndromes which have in common thrombotic microangiopathy, hemolytic anemia, thrombocytopenia, and involvement of central nervous and renal systems. These include TTP, hemolytic–uremic syndrome (HUS), heparin-induced thrombocytopenia, and the HELLP (hemolysis, elevated liver enzymes and low platelet) syndrome. Additionally, almost one-third of patients with catastrophic APS develop serological or hematological evidence of DIC during the course of their multiorgan illness [4, 5]. All these laboratory features of DIC found in these patients may be explicable on the basis of extensive small vessel endothelial damage. Therefore, DIC should also be included in the differential diagnosis.

Finally, the differential diagnosis should include marantic endocarditis complicated by multiple embolic events, cryoglobulinemia, vasculitis, multiple cholesterol emboli, and heparin-induced thrombocytopenia–thrombosis syndrome. In the latter condition, patients develop thrombosis at any site, especially the skin, within 10–14 days after starting heparin and the first sign is a falling platelet count. This is due to the presence of an antibody which binds to platelet factor 4 and heparin [25, 26]. Platelet aggregation studies and enzyme-linked immunoabsorbent (ELISA)-based assays to identify this platelet factor 4–heparin complex are necessary to establish the diagnosis of this condition. TTP, heparin-induced thrombocytopenia, and DIC will be discussed in some detail.

Thrombotic Thrombocytopenic Purpura

In this condition, studies have identified antibodies in plasma which recognize a proteolytic enzyme (metalloprotease) which is present in normal plasma [27]. This enzyme cleaves large multimers of von Willebrand factor. When it is reduced or rendered inefficient by antibodies directed toward it, these large multimers accumulate and become entangled in subendothelial fibrous components, maximizing von Willebrand factor mediated adhesion of platelets to the subendothelium following vascular damage. Patients with acute TTP have been reported with IgG autoantibodies to this enzyme. In chronic relapsing TTP, the enzyme is reduced or absent. The existence of these large multimers of von Willebrand factor and antibodies to metalloproteases have not been investigated in patients with catastrophic APS and indeed levels of the enzyme have also not been measured. The characteristic pentad of TTP consisting of the early onset of neurological symptoms, renal disease, hemolytic anemia, thrombocytopenia, and fever is seen in 50% of patients with this condition. Several of these features may be present in patients with catastrophic APS. Fever, however, is uncommon in patients with catastrophic APS unless caused by infection. The aPL are not usually present in TTP patients and when they are demonstrated are usually at a low level. There have been several case reports of patients with TTP and aPL. The distinguishing features between the two conditions is the fact that renal disease is usually more serious in patients with catastrophic APS with hypertension, renal infarcts, and renal failure, whereas in TTP it is more subtle and milder. Often there are only abnormalities on urinalysis. Schistocytes are usually abundant in TTP on peripheral smear whereas in catastrophic APS they are scanty if present at all. Microangiopathic hemolytic anemia may be present in both conditions. The clinical presen-

tations may, however, be similar and differentiation difficult in a minority of patients. Catastrophic APS, unlike TTP, has been associated with relapses only infrequently [27–31].

Heparin-Induced Thrombocytopenia

In cases where patients have been placed on heparin prior to the onset of multiorgan failure, this condition has to be seriously considered. Veins, arteries, and the microcirculation may all be involved. Appropriate platelet studies and ELISA-based assays in order to identify platelet factor 4–heparin complex must be undertaken in order to definitively establish a diagnosis of the condition [25, 26].

Disseminated Intravascular Coagulation

Disseminated intravascular coagulation (DIC) is the expression of several pathological processes and occurs as a consequence of the inappropriate activation of the coagulation system induced by tissue factor and other factors released from hypoxic or infarcted tissues [32]. Tissue damage results in thrombin generation at the surface of damaged microvessels. This produces widespread microvascular thrombosis and, in an attempt to maintain the patency of blood vessels, excessive plasmin is generated, resulting in local and systemic fibrinolysis [33].

DIC commonly results from obstetric problems (such as amniotic fluid embolism or placental abruption), intravascular hemolysis by transfusion reactions, sepsis or viremia, burns, disseminated malignancy, or acute leukemia [33]. In the largest series of patients with catastrophic APS, DIC features were present in 28% [5].

Thrombosis and hemorrhage are the major clinical manifestations of this condition, but clinically, microvascular thrombosis in the context of DIC is more often a laboratory phenomenon than a clinical event. Therefore, the commonest presenting clinical manifestation is cutaneous bleeding (petechiae and hemorrhage). Renal involvement may lead to acute renal failure with oliguria and acute tubular necrosis. Generalized central nervous system dysfunction leads to coma and hypoxia and a picture identical to ARDS may be seen in case of lung involvement. Hypotension, shock, and cardiac arrest may occur if the cardiovascular system is involved.

The laboratory diagnosis is based on the presence of thrombocytopenia (usually severe) and prolonged prothrombin, partial activated thromboplastin, and thrombin times, accompanied by the presence of products of fibrinogen/fibrin degradation and low fibrinogen concentrations as well as low levels of antithrombin and protein C concentrations. Schistocytes may be present, but in low number, in contrast to TTP [32].

TREATMENT

The optimal management of catastrophic APS is not known [34] but must have three clear aims: to treat any precipitating factors (prompt use of antibiotics if infection is suspected, amputation for any necrotic organ, high awareness in patients with APS who undergo an operation or an invasive procedure . . .), to prevent and to treat the ongoing thrombotic events and to suppress the excessive cytokine "storm" [13].

Regarding the prevention of catastrophic APS in a patient with classic APS who must undergo an operation or an invasive procedure, high-dose thromboprophylaxis with LMWH appear to be most effective in reducing the risk of postoperative deep venous thrombosis as well as possible catastrophic APS [35–38].

The literature describing treatment of catastrophic APS is confusing since there have been no prospective studies because of the rarity of the condition. Therefore, the treatment of catastrophic APS is not currently standardized. Analysis of the largest series of patients with this condition shows that the combination of anticoagulation plus steroids plus plasma exchange and/or intravenous gammaglobulins has the highest survival rate (70%) [4, 5]. Therefore, when there is a high clinical suspicion of catastrophic APS, the following treatment is suggested (Fig. 6).

First Line Therapies

Anticoagulation

Intravenous heparin administration is necessary to inhibit ongoing clotting and to lyse existing clots which may contribute to the ongoing thrombosis. It is usually necessary to administer more than the usual doses of heparin, monitoring treatment by serial aPTT in order to achieve the correct range. It is recommended that an initial intravenous bolus of 5000 units be followed by continuous infusion of 1500 units/h of heparin, with accurate control of the aPTT ratio. If the clinical course is satisfactory, intravenous heparin must be maintained for 7 to 10 days and then should be replaced by oral anticoagulant therapy (warfarin or coumadin). Although it has been recommended that the INR should be kept over 3.0 [39], a lower range (between 2.5 and 3) could, however, be as effective, with less hemorrhagic problems. Heparin should not be withdrawn before achieving a correct INR with oral anticoagulants.

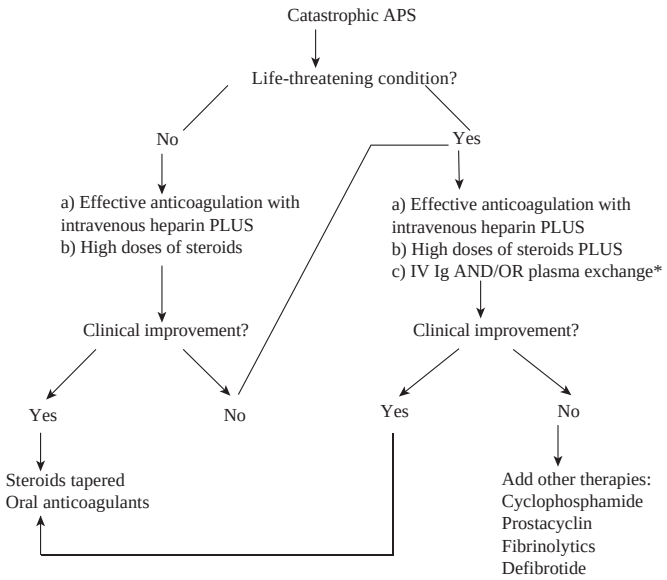

FIGURE 6. Treatment algorithm of catastrophic APS. IVIg, intravenous gammaglobulins. * specially indicated if schistocytes are present.

Steroids

Intravenous steroids are necessary to overcome the excessive cytokine response in these patients [13]. In case of a life-threatening condition, we suggest commencing with intravenous pulses of methylprednisolone (1000 mg daily for 3 to 5 days), followed by high doses of intravenous methylprednisolone (1–2 mg/kg daily). This dose should be tapered according to the therapeutic response.

Second Line Therapies

These are indicated in case of clinical worsening, or in presence of a life-threatening situation.

Gammaglobulins

Intravenous gammaglobulins have been effective in achieving a prompt reduction of the aPL titers in some patients. They are also useful in patients with severe thrombocytopenia (unresponsive to high dose of steroids). The recommended dose is 400 mg/kg daily (approximately 25 g/day) for 5 days.

Plasma exchange

The rationale of this treatment is based on the fact that this is the treatment of choice in patients with TTP all of whom develop microangiopathy. Plasma exchange also removes aPL and will thus benefit the patient. In addition, fresh frozen plasma contains the natural anticoagulants and should be beneficial as these compounds are used up in the clotting process. Therefore, it would be specially indicated in those patients with catastrophic APS who show laboratory features of microangiopathy (schistocytes). plasma exchange should be continued for a minimum of 3 to 5 days but there are no guidelines with regard to the management and duration of this treatment. Neuwelt *et al.* [40], however, used plasma exchange for up to 3 years in a patient with catastrophic APS. It should be taken into account that plasma exchange may interfere with anticoagulant treatment.

Other Therapies

The following therapies should be considered in patients presenting with resistant multiorgan thromboses apparently not responding to the treatment of choice just described.

Fibrinolytics

They may be justified in cases of patients who do not respond to heparin [13]. The main fibrinolytics employed are streptokinase, urokinase, and tissue plasminogen activator and these may be followed by heparin as has been described. Hemorrhage induced by these fibrinolytics can be treated with blood transfusions.

Cyclophosphamide

The largest series [4, 5] did not demonstrate any benefit from the additional use of cyclophosphamide. On the contrary, the addition of cyclophosphamide was associated with a lower survival rate, although these patients may have had more severe disease. However, this drug might be used in cases of severe catastrophic APS, SLE flares, or in those patients with very high levels of aCL to prevent any aPL rebound following plasma exchange or intravenous gammaglobulins infusion [6]. The usual dose that it has been employed is an intravenous pulse of 0.5–1 g/m^2.

Unusual Therapies

The following therapies have not been administered to any significant number of patients with catastrophic APS.

Prostacyclin

Prostacyclin is a naturally occurring substance produced by vascular endothelium. It causes vasodilation

of all vascular beds and it is an extremely potent endogenous inhibitor of platelet aggregation. Prostacyclin has only been evaluated in one patient with systemic sclerosis and catastrophic APS [10]. Continuous intravenous prostacyclin infusion (5 ng/kg/min) was administerd for 7 days but the patient died when therapy with this compound was discontinued.

Ancrod

This substance is a purified fraction of Malayan pit viper venom that has been shown to correct prostacyclin stimulating factor and vascular plasminogen activator deficiencies. However, its use has been described in only one patient who responded to this compound [41].

Defibrotide

This compound is a single-stranded alkali metal salt of DNA fraction that has been shown to act as a potent inhibitor of endothelin I, thrombin-induced platelet aggregation, thromboxane synthesis, as well as a potent inhibitor of a clot formation. Just like ancrod, defibrotide has also been occasionally employed succesfully in patients with catastrophic APS. It is not generally available at the present time and has to be obtained from the manufacturer (CRINAS, Italy).

Intensive Care Therapies

In case of a life-threatening condition or clinical worsening, it must be necessary to admit the patients to an intensive care unit. Rapid and progressive renal failure may require dialysis, the clinical picture of ARDS usually needs mechanical ventilation and close monitoring of inotropic drugs may be required in cases of cardiogenic shock. All these measures play an essential role in the survival rate of patients with catastrophic APS.

In conclusion, the catastrophic APS is a potentially life-threatening condition with a high mortality which requires high clinical awareness. Therefore, it is essential that it be diagnosed early and treated aggresively. The combination of high doses of heparin plus steroids plus intravenous gammaglobulins and/or plasma exchange is the treatment of choice in patients with this severe condition. Additionally, preventive measures in patients with APS may be effective if the development of the catastrophic APS is to be avoided.

HEMATOLOGY: COAGULATION PROBLEMS

Sandor S. Shapiro
Stephen E. F. Spurgeon

LUPUS ANTICOAGULANTS

Lupus anticoagulants (LACs) are immunoglobulins that interfere with *in vitro* phospholipid-dependent coagulation tests [1]. The term was introduced by Feinstein and Rapaport [2] in 1972, although the earliest observations of the phenomenon were reported some 20 years before [3, 4]. Initially recognized in the context of systemic lupus erythematosus (SLE), LACs are now known to occur frequently in patients with other disorders, as well as in individuals with no apparent underlying disease. It is now recognized that LACs and anti-cardiolipin antibodies (ACAs) are separate entities, but both are members of a diverse group of immunoglobulins that bind to phospholipid-bound proteins including, but not limited to, β2-glycoprotein-I (β2GPI) and prothrombin. LACs and ACAs are both associated with a high risk of arterial and venous thromboembolic events [5–8], although the mechanism of this thrombotic risk is still unknown.

In 1980, Thiagarajan *et al*. [9] proposed for the first time a mechanism for LAC action in coagulation tests. They isolated an IgMλ Waldenstrom paraprotein with LAC activity and demonstrated that it had antibody activity against negatively charged phospholipids—phosphatidylserine, phosphatidylinositol, and phosphatidic acid—but not against phosphatidylcholine or phosphatidylethanolamine. They subsequently showed activity of a number of LAC plasmas and sera against cardiolipin, as well [10]. In 1983, Harris *et al*. developed a radioimmunoassay, and subsequently an ELISA, for ACAs and demonstrated a close relationship between the ACA and LAC tests [11].

In this chapter we use the term anti-phospholipid antibody (APL) to denote the presence of a LAC and/or ACA, despite the fact that, as indicated, this is, strictly speaking, a misnomer. We discuss the diagnosis of LACs, the possible thrombotic mechanisms associated with APLs, and the treatment of thrombosis in patients with APLs. We begin with a discussion of tests for LACs, and the relative value of LAC and ACA tests in assessing the risk of thrombosis. For specifics of the ACA ELISA and a more extensive analysis of patient populations using that test, see Chapter 41.

LABORATORY DIAGNOSIS OF LUPUS ANTICOAGULANTS

The minimum laboratory criteria for diagnosis of a LAC have been defined by international agreement [12], and in essence require (1) prolongation of one or more phospholipid-dependent coagulation tests; (2) demonstration that this prolongation is due to the presence of an inhibitor (i.e., that it is not corrected by the addition of an equal volume of normal plasma); and (3) demonstration that the inhibition is not due to interference with the thrombin-fibrinogen reaction and is not directed against the functional activity of a specific coagulation factor.

Several tests are in common use for the detection of LACs, including the activated partial thromboplastin

time (APTT), the tissue thromboplastin inhibition test (TTI) [13, 14], the kaolin clotting time (KCT) [15, 16], the dilute Russell viper venom time (DRVVT) [17], and the dilute APTT [18, 19]. Except for the standard APTT, the other tests depend on the use of reduced concentrations of phospholipid reagents for enhanced sensitivity. The prothrombin time is an insensitive test for LACs, but may be prolonged because of concomitant hypoprothrombinemia [20]. In general, prolongation of any of these tests can be caused by deficiencies of specific clotting factors, by specific inhibitors to clotting factors, or by general inhibitors such as heparin, as well as by LACs. Deficiencies can be ruled out by correction of the prolonged test on addition of an equal volume of normal plasma. In the absence of correction, a specific coagulation inhibitor or the presence of heparin must be ruled out before a LAC can be diagnosed. Heparin can be excluded by the history, as well as by performance of a thrombin time—a test that is prolonged by heparin but is normal in the presence of a LAC. The most common specific coagulation factor inhibitor is an antibody against factor VIII, and the presence of such an inhibitor can prolong the KCT, APTT, dilute APTT, and TTI. The TTI is simply a prothrombin time done in the presence of a high dilution of the usual tissue thromboplastin reagent and, at such dilutions, is sensitive to abnormalities in the intrinsic pathway [21]. The DRVVT should be insensitive to the presence of factor VIII inhibitors, since it is initiated by directly activating factor X to factor Xa. In one study, however, two factor VIII inhibitors were reported to cause minimal prolongation of the DRVVT [22]. In our hands even high-titer antibodies to factor VIII did not prolong the DRVVT [17]. Thus it appears that the DRVVT may be the most specific of the tests for LACs.

The relative sensitivity of LAC tests is more difficult to ascertain. Part of the difficulty stems from the fact that the sensitivity of many of the tests depends on the method of plasma preparation (since the presence of residual platelets, particularly if the plasma is frozen before testing, decreases sensitivity [23]), on the source of phospholipid [22, 24, 25], and on the type of activating agent [26, 27], and has been reported to be decreased in the presence of high levels of factor VIII [28] and fibrinogen [29]. In addition, valid comparisons of tests are difficult to make because of variations in test reagents between laboratories, because tests have frequently been modified from their original descriptions, and because of variability in apparent test sensitivities from patient to patient.

With these caveats, a review of the literature suggests that, overall, the KCT is the most sensitive test, followed by the dilute APTT, the DRVVT, and the TTI [12, 15–19, 30–33]. It is important to recognize that, even using the most sensitive phospholipid reagent, the APTT is the least sensitive of all the tests, and that the DRVVT, the dilute APTT, and the KCT may be positive in some patients with a normal standard APTT [14, 16]. For example, Lo *et al*. [30] reported that of 18 patients positive by the KCT, 17 were positive by the DRVVT, TTI, and dilute APTT, but only 16 were positive by the APTT. Several other of the studies mentioned have also compared the KCT with other LAC tests and have found it to be somewhat more sensitive. On the other hand, the KCT, the dilute APTT, and the TTI are more or less sensitive to abnormalities of the entire intrinsic pathway, and are, therefore, prolonged in the presence of the most common coagulation factor inhibitors.

With the exception of the KCT, all other tests require addition of phospholipid, and results of those tests vary with the source of phospholipid. While the phospholipid content of most coagulation reagents is poorly characterized, there is a suggestion that the lower the PS content, the more sensitive the reagent is to the presence of LACs [25, 34].

Several confirmatory tests have been proposed in the event a prolonged LAC test is discovered. In the platelet neutralization procedure [21] the APTT is repeated after addition of a platelet concentrate; prolongations due to the presence of a LAC are generally normalized by the platelet concentrate. Triplett *et al*., in their original publication [21], found that 13 of 13 APTTs that were prolonged because of the presence of a LAC were normalized by the addition of platelets; in contrast, 10 of 11 patients with specific inhibitors had no shortening of the APTT under these conditions. However, occasional LACs are not corrected by the platelet neutralization procedure. A somewhat similar test was introduced by Rosove *et al*. [35], in which high concentrations of phospholipid are used to normalize the prolonged APTT (high PL-APTT). However, the high PL-APTT may not always be normal in patients with LACs. In fact, one study [29] found that the high PL-APTT was positive in only 10 of 18 patients with LACs, tending to be negative in LAC patients who did not have SLE. Furthermore, this test does not distinguish well between LACs and factor VIII inhibitors [31]. In summary, a positive confirmatory platelet neutralization procedure or high PL-APTT is very useful, but a negative test does not absolutely rule out a LAC. A third test was developed by Rauch *et al*. [36, 37], who demonstrated that LACs react with hexagonal-phase phosphatidylethanolamine and that addition of this phospholipid to the PTT would neutralize the prolongation induced by presence of a LAC [38].

Since no single test has been shown to identify all patients with LACs, while several tests identify 90% of this population, our recommendations are as follows.

1. Sensitive screening tests for LACs should be used. In addition to an APTT, done using one of the 'LAC-sensitive' reagents, to obtain maximum yields, at least one more sensitive test should be employed, such as the DRVVT, the KCT, the TTI, or the dilute APTT.

2. If the LAC screening test is prolonged, a mixing study must be done (equal volumes of normal and patient plasma). If the mixing study is prolonged, a thrombin time must be done to rule out the presence of heparin or other interference with the thrombin-fibrinogen reaction. A prolonged thrombin time casts doubt on the meaning of the LAC screening test and should be investigated further. In many laboratories a reptilase time would then be done, since it is normal in the presence of heparin. Abnormalities of both the APTT and the thrombin time can occur in diffuse intravascular coagulation because of the presence of fibrin split products or, much less commonly, because of the presence of an abnormal fibrinogen or a circulating antithrombin.

3. If the thrombin time is normal, the diagnosis rests between a specific coagulation inhibitor and a LAC. Because of the specificity of the DRVVT, most common specific coagulation factor inhibitors, such as factor VIII and factor IX antibodies, can generally be excluded. A factor V inhibitor would prolong the DRVVT, although these rare inhibitors generally reveal their presence by significant bleeding. Thus, in the presence of clinically significant bleeding, specific tests for a factor V inhibitor should be initiated.

4. A confirmatory test, such as the platelet neutralization procedure, the high phospholipid test, or the hexagonal phase PE test, should be used.

PREVALENCE OF LUPUS ANTICOAGULANTS AND ANTI-CARDIOLIPIN ANTIBODIES IN SYSTEMIC LUPUS ERYTHEMATOSUS

In a comprehensive review of the literature Love and Santoro [5] estimated, using only large, unselected series, that the prevalence of LACs and ACAs in patients with SLE was 28 and 42%, respectively. Similar figures have been reported in more recent studies [7, 39]. Since several different LAC tests were used in the various series, and the upper limit of normal for the ACA tests also varied, the actual figures may be even higher. For example, in three series using an upper limit of only 2 SD above the mean the prevalence of ACAs in SLE was above 50% [40–42]. The differences in incidence of LACs and ACAs in SLE is not merely a matter of test sensitivities. Love and Santoro [5] analyzed series in which patients with SLE had both tests performed: only 45% of ACA-positive patients were also LAC positive, while only 59% of LAC-positive patients were also ACA positive. These findings are consistent with the concept that the two tests identify different populations of antibodies and that these two populations of antibodies can be physically separated.

The prevalence of LACs or ACAs in autoimmune diseases other than SLE has been commented on in several reports. Fort *et al*. [43] measured ACAs in 243 patients with a variety of rheumatic disorders. An elevated frequency of ACAs was found in patients with SLE (38%), rheumatoid arthritis (33%), and psoriatic arthritis (28%). Another study of 90 patients with rheumatoid arthritis (using a cutoff of 4 SD above the normal mean) found 44 (49%) to be ACA positive [44]. Harris *et al*. [45] also studied ACA levels in a variety of collagen–vascular diseases: 39% of SLE patients and 32% of patients with other rheumatic diseases were noted to be positive. LACs and/or ACAs have also been found in lymphoproliferative disorders [46, 47], in acute infections [48], during drug therapy [49, 50], and in individuals with no underlying disease [47].

PREVALENCE OF THROMBOSIS IN PATIENTS WITH LUPUS ANTICOAGULANTS OR ELEVATED ANTI-CARDIOLIPIN ANTIBODIES

The risk of thrombosis in LAC/ACA patients has been examined by many authors, largely through retrospective analysis. By combining the published data, it appears that about one-third of all patients with LACs have had at least one thrombotic event [52]. Among SLE patients, 42% of the LAC-positive and 40% of the ACA-positive individuals had a history of thrombosis; in contrast, the prevalence of thrombosis in LAC-negative or ACA-negative SLE patients was only 10–18% [5]. Generally, the follow-up periods giving rise to these figures have not been specified, but in three studies of LAC-positive patients with SLE or other connective tissue disorders followed for at least 5 years the prevalence of thrombosis was 50–70% [53–55]. When only unselected series were evaluated, the prevalence of thrombosis in LAC/ACA-positive patients with SLE was as high as 62% [7, 39, 56]; the length of follow-up in these studies was not given.

Thrombotic events involve both the arterial and venous circulation; in LAC-positive patients with SLE or related disorders, approximately 60% of thrombotic events were venous and 40% were arterial [46, 47, 53, 54, 57, 58]. The most common site of venous thrombosis was a lower extremity, while the most common

site of arterial thrombosis was the cerebral arterial system.

Thrombosis also occurs in LAC-positive or ACA-positive patients with non-SLE autoimmune disorders [41, 57] and in individuals with no apparent underlying disorders; however, the prevalence of thrombosis in these groups has not been firmly established. In two series of patients with rheumatoid arthritis, the combined prevalence of thrombosis was 10% in ACA-positive patients and 6% in ACA-negative patients [43, 44]. The frequency of thrombosis in patients with LACs secondary to drug therapy is not certain, but is probably low. Gastineau *et al*. [46] reported that none of 14 patients with drug-related LACs had experienced thrombotic events. On the other hand, Triplett and co-workers [12] reported a 24% incidence of thrombosis in 34 patients with drug-induced LACs. Since most of these patients were receiving procainamide or quinidine, and may have been at increased risk because of underlying cardiac disease, it would have been informative to know the prevalence of thrombosis in a matched group of LAC-negative patients on the same drugs. Thrombosis in patients with LACs secondary to 1ong-term chlorpromazine therapy seems to be an infrequent occurrence [49], although it has been reported occasionally [51]. Thrombosis has also been reported in two LAC-positive patients receiving haloperidol and fluphenazine [50].

Patients with AIDS have a high incidence of LACs and elevated ACAs [59–64]. However, the risk of thrombosis in this group appears to be minimal.

MECHANISMS

The causes of the increased thrombotic risk are unknown, although several mechanisms have been posited. For example, Carreras and co-workers [65, 66]. observed inhibition of prostacyclin (PGI_2) synthesis and/or release by aortic rings or cultured endothelial cells exposed to LAC plasma or IgG. However, subsequently there have been several conflicting reports using similar systems [57, 67–71], leaving the role of this mechanism unresolved. Several investigators have reported that plasma or IgG from patients with LACs interferes with thrombin/thrombomodulin-dependent protein C activation or with thrombomodulin function [72]. Protein C in its activated form inactivates coagulation factors Va and VIIIa; protein S is a cofactor in this reaction, and Marciniak and Romond have reported defective phospholipid- and platelet-dependent degradation of factor Va in clotting plasma from patients with LACs [73]. This important observation suggests that LACs may interfere with the Ca^{2+}-dependent interaction of activated protein C with phospholipid in a manner analogous to that previously shown for factor X and prothrombin [1, 2]. It is of interest that several reports have described depressed levels of protein S, although not of protein C, in many individuals with LACs, with or without SLE [1, 74, 75].

Other mechanisms also may be involved. For example, there are conflicting reports that patients with LACs have decreased cell-related fibrinolytic activity [74, 76–79], although no direct evidence for such a mechanism has been adduced. It is possible that LACs might alter platelet function, leading to an increased thrombotic risk, a suggestion consistent with the observation that thrombocytopenia is frequently seen in patients with LACs [1, 13, 80, 81]. It is clear from this discussion that no single mechanism has so far been put forth that can explain the risks of thrombosis in patients with LACs and ACAs.

The most important new mechanistic insight into this problem has come from the realization that patients with LACs/ACAs do not, as a rule, make antibodies to cardiolipin or other phospholipids, but rather to a variety of proteins having in common an ability to form a complex with phospholipids [1, 8, 70, 82]. These proteins probably form neoepitopes on combining with phospholipid and, perhaps by this mechanism, become antigenic. Of these, β_2-glycoprotein I (apolipoprotein H) and prothrombin have had the most attention. β_2-glycoprotein I is required for detection of the vast majority of ACAs in the standard ACA ELISA, and an ELISA for β_2-glycoprotein I has been advocated by several investigators as a more specific predictor of thrombosis than the standard ACA ELISA [83–90]. $Beta_2$-glycoprotein I is also required for the activity of many LACs [91–93], and a number of human and murine monoclonal antibodies to this protein act as LACs when added to normal plasma [94]. However, it has been shown that many other LACs require the presence of prothrombin for their activity [92, 93, 95], and coagulation tests may show differential sensitivity to these two types of LACs [93]. In addition, antibodies to protein C [96], protein S [96], prekallikrein [97], tissue factor pathway inhibitor (TFPI) [98], and annexin V [99, 100] have been described. In each case it is possible to picture a disturbance in function that might give rise to a thrombotic risk. Furthermore, mounting evidence suggests that the endothelium itself may be the target of at least some anti-phospholipid antibodies [101–104] and that plasma thrombomodulin levels may reflect vascular injury induced by such antibodies [105, 106]. Thus no one mechanism may explain the multiple clinical manifestations of what is called the antiphospholipid syn-

drome, and separate causes may predominate that account for the venous thrombosis, arterial thrombosis, fetal loss, and thrombocytopenia seen in this syndrome. Were this to be the case, it is possible that the predictive value of current laboratory tests may depend on the clinical event being evaluated and that new tests may be required to define specific clinical risks.

Several *in vitro* studies have implicated annexin V in the thrombotic diathesis seen in the APS. Annexin V is a protein with a high, calcium-dependent, affinity for anionic phospholipids. It has been suggested that annexin V may have anticoagulant properties because it can displace bound prothrombin or factor Xa from phospholipid surfaces. It has been reported that ACAs can inhibit annexin V binding to a phospholipid surface in a β2-glycoprotein-I-dependent manner [107]. Much of the data on annexin V has been generated by Rand [108]. Rand *et al*. have shown that annexin V expression is decreased on the apical surface of placental villi in APL-positive patients with a history of recurrent spontaneous abortions [109] and on membranes isolated from villi cultured with APL IgG fractions [110]. Furthermore, they have reported that, by displacing annexin V, APLS do, in fact, create a procoagulant environment [111]. However, Willems and co-workers [112, 113] found that the high-affinity binding of annexin V to phospholipid membranes and membranes of activated platelets was unaffected by the presence of ACA–β2-glycoprotein-I complexes, which could not displace annexin V from procoagulant surfaces.

LUPUS ANTICOAGULANTS, ANTICARDIOLIPIN ANTIBODIES AND RELATED ANTIBODIES AS RISK FACTORS FOR THROMBOSIS

The relative value of LACs and ACAs as predictors of thrombosis has been examined by several authors. Harris *et al*. [11] and Boey *et al*. [53] evaluated groups of patients with SLE and other autoimmune diseases, the former by ACA status and the latter by LAC testing: 38% of ACA-positive and 58% of LAC-positive patients had a history of thrombosis. Love and Santoro [5], in their review, noted that 56% of unselected LAC-positive SLE patients had a history of thrombosis as opposed to only 39% of unselected ACA-positive patients. Galli *et al*. [114], based on a review of several studies, suggested that LAC-positivity is a better predictor of thrombosis than is ACA-positivity. More recently, these authors presented intriguing evidence that DRVVT-positivity was a stronger predictor of thrombotic risk than KCT-positivity [93, 115, 116].

Several studies have suggested that thrombotic risk increases with the ACA titer [42]. One series [45] found that 80% of patients with an ACA titer >7 SD above the normal mean had a history of thrombosis. In another report, 11 of 15 patients with ACA >9 SD above the normal mean had a history of thrombosis; two others had pulmonary hypertension [11]. Hamsten *et al*. [117], in a study of 62 non-SLE patients under the age of 45 years who survived acute myocardial infarction, found 13 patients who were ACA-positive. Seven of eight with an ACA titer >5 SD above the normal mean had additional cardiovascular morbidity; in contrast, only one of five patients with lesser elevations had a new cardiovascular event. Deleze *et al*. [118] noted that the odds ratio of recurrent fetal loss in patients with SLE whose ACA titer was >2 SD above normal was 6.6 compared with ACA-negative SLE patients; SLE patients with ACA titers >5 SD above normal had an odds ratio of 10.5. On the other hand, Triplett *et al*. [119] were not able to document a difference in the incidence of thrombosis between high- and low-titer ACA-positive individuals.

Some of the variability in the results quoted may relate to variation in ACA titers in individuals. For example, Ishii *et al*. [120] found that ACA-positive patients could be separated into two groups on the basis of variation in their ACA titers: group A remained positive during stable disease, whereas group B became negative during stable disease. They found that the incidence of thrombosis was 33% in group A and only 3% in group B. Cerebral infarction was found in 23% of group A and in only 3% of group B; spontaneous abortions were found in 41% of married women in group A as opposed to 7% in group B. Another study of 500 SLE patients found that 47% of patients with persistently positive ACA titers had venous thrombotic events, whereas only 6.1% of intermittently positive patients had venous thrombotic events [42], only 3% of the persistently negative group had a history of venous thrombosis.

Currently a great deal of effort is being directed to an analysis of the relative merits of the measurement of antibodies to a number of proteins, particularly β_2-glycoprotein-I and prothrombin, as indices of thrombotic risk [121–126]. Nojima *et al*. [127] studied a group of 168 SLE patients, of whom 49 had thrombotic complications, 14 had experienced fetal loss, and 38 were thrombocytopenic. They found that elevated IgG anti-β2-glycoprotein-I and IgG anti-prothrombin were significant risk factors for arterial, but not venous, thrombosis. They also found that the presence of antibodies to protein S was a significant risk factor for venous thrombosis and that annexin V antibody elevations directly correlated with a history of fetal loss.

However, these interesting correlations have not been observed by all investigators [128, 129], and large prospective studies are still needed to settle this important issue.

Antibodies to prothrombin are present in 60–75% of individuals with LACs, and mild hypoprothrombinemia—in many cases insufficient to prolong the PT significantly—is present in perhaps 25% of these. A small percentage of patients have moderate or severe depression of prothrombin levels. It is of some interest that such individuals may have a lower than expected risk of thrombosis. Lechner and Pabinger-Fasching [47] reported that none of the three patients in their study with significant prothrombin deficiency had a history of thrombosis. When they reviewed the literature they found that none of the 17 reported LAC patients with prothrombin deficiency had thrombotic complications recorded. Another study of lupus patients reported three additional patients with prothrombin deficiency who had no history of thrombosis [130].

On balance, it appears that coagulation-based tests, particularly the DRVVT, may be better predictors of thrombotic risk than the ACA. However, the issue remains to be decided and studies are currently ongoing to that end.

THE ROLE OF GENETIC RISK FACTORS IN THE THROMBOTIC RISK IN PATIENTS WITH LUPUS ANTICOAGULANTS AND ANTICARDIOLIPIN ANTIBODIES

As mentioned previously, not all patients with persistent LACs or ACAs develop thrombosis. This has led to efforts to identify contributing risk factors in APL patients. In this section, we review the data relating to four of the most studied risk factors [131–133]: (1) factor V Leiden (FVL), (2) the prothrombin G20210A mutation, (3) plasminogen activator inhibitor-1 (PAI-1) polymorphisms, and (4) plasma homocysteine levels and methylenetetrahydrofolate reductase (MTHFR) mutations.

1. Factor V Leiden (FVL) is a point mutation in the factor V gene that results in the substitution of glycine for arginine at codon 506. This mutated factor V is activated normally by thrombin—and, therefore, functions normally as a coagulation cofactor. However, the activated factor V is resistant to cleavage by activated protein C (APC), thus removing an important feedback inhibition of the clotting system, and conferring a risk of thrombosis, primarily venous thrombosis [134–136]. FVL is present in ~5% of the Caucasian population and up to 20% of unselected patients with venous thrombosis, and is the most common of the known genetic risk factors for venous thrombosis.

2. The G20210A prothrombin gene mutation—substitution of adenine for guanine at position 20,210 in the nucleotide sequence—is present in 2–3% of the population and in ~6% of unselected patients experiencing their first venous thrombosis [137]. The mutation does not affect the structure of prothrombin, but results in higher circulating levels of the protein.

3. PAI-1 is a major regulator of fibrinolysis. Elevated PAI-1 concentrations have been observed in a number of thrombotic disorders, including coronary artery disease and myocardial infarction [138]. A genetic polymorphism in the promoter region of the PAI-1 gene, in which either four or five guanines are present, has been described [139]. The 5 guanine (5G), but not the 4G, allele binds a repressor and, as a result, individuals homozygous for the 4G allele have 25% higher PAI-1 plasma levels than 5G/5G individuals [139]. Furthermore, the 4G allele is more easily stimulated by cytokines [140] and by triglycerides in the presence of insulin [132, 138]. Several studies have raised the possibility that the 4G/4G genotype may be a thrombotic risk factor [132, 138].

4. The plasma homocysteine level is an independent risk factor for atherosclerosis, arterial thrombosis [141] and, possibly, venous thrombosis, as well [142]. Elevated plasma homocysteine levels can occur as the result of deficiencies of vitamins B_{12} or B_6 or folic acid, chronic renal failure, hypothyroidism, certain malignancies, drugs, and inherited enzyme abnormalities [133, 141]. One enzyme involved in homocysteine metabolism is MTHFR, which catalyzes the conversion of homocysteine to methionine. Two common genetic variants in the MTHFR gene have been studied, 677C→T (C677T) and 1298A→C (A1298C). Each of these mutant alleles is present in 30–40% of individuals [143, 144]. C677T homozygotes (C677T +/+), but not heterozygotes (C677T +/–), have elevated plasma homocysteine levels. No relationship has been identified between plasma homocysteine and the A1298C mutation [143, 144]. Fragmentary data raise the possibility that compound heterozygosity for the two mutations may be associated with elevated homocysteine levels [143–145]. However, in view of the complexity of plasma homocysteine regulation, the thrombotic risk associated with these mutations is not clear [146]. It is important to emphasize that, even within the normal range, atherosclerotic risk is directly related to the homocysteine level. In view of the ease of reducing homocysteine levels by ~40% with simple dietary supplementation [147], the advisability of intervening in this manner in LAC/ACA-positive patients should be borne in mind (see later).

We will now review the data concerning the possible contribution of these genetic factors to the thrombotic risk in patients with LACs and/or ACAs. Fijnheer *et al*. [56] studied 173 SLE patients, 43 of whom had a history of thrombosis, and found that the presence of either a LAC or a moderate-to-high-titer ACA was a risk factor for both venous and arterial thrombosis. Nine of the 173 patients (5%) had FVL; 4 had a history of venous thrombosis. Only 2 of the 173 SLE patients—both with a history of thrombosis—were positive both for a LAC and FVL. Although suggestive, these numbers are too small to draw statistical conclusions.

Hansen *et al*. reviewed the histories of 99 LAC/ACA-positive patients, 78 of whom had thrombosis—41 venous, 25 arterial, 12 both venous and arterial [148]. They found that hypertension, hyperlipidemia, tobacco use, and diabetes were significant risk factors for arterial thrombosis. FVL and prothrombin G20210A appeared to be predictors of venous thrombosis. Specifically, 8 of the 99 patients were FVL-positive and all experienced thrombosis—4 venous, 1 arterial, and 3 both venous and arterial. Three of the 99 patients had the G20210A mutation, and all had thrombotic events —2 venous and 1 both arterial and venous. These numbers, though highly suggestive, did not attain statistical significance when each mutation was analyzed separately—only when the FVL and the G20210A data were grouped together did the differences become significant.

Galli *et al*. [149] evaluated 152 consecutive unselected LAC-positive patients—48 with SLE, other autoimmune diseases, or cancer—and found an increased thrombotic risk in patients with FVL: 5 individuals had FVL and all had a history of venous thrombosis. Of the remaining 147 patients, 68 (46%) had a history of thrombosis. This difference just achieved statistical significance ($p = 0.047$). The presence of prothrombin G20210A or MTHFR C677T did not confer additional thrombotic risk. The authors concluded that (1) the prevalence of FVL in the LAC-positive patients is similar to that in the general population, and (2) the likelihood of venous thrombosis is significantly greater when both abnormalities are present. However, conclusions from this excellent study, like the others, must be tempered because of the small numbers of patients with inherited thrombophilic risk factors.

Ames *et al*. [150] examined the influence of FVL and MTHFR C677T in 49 individuals with idiopathic (non-SLE) anti-phospholipid antibodies, in 70 patients with a history of spontaneous venous thrombosis (APL status not stated, but 17 of whom were heterozygous for protein C, protein S, or antithrombin), and in 193 healthy subjects. FVL prevalence was 14, 18, and 4%, respectively, in the three groups. When these data were reanalyzed, the prevalence of thrombosis in APL-positive patients was 55 and 67% for the FVL-positive and FVL-negative patients, respectively. Thus these data do not indicate an increased risk in APL patients due to FVL. However, among the 27 APL-positive patients with thrombosis, 7 patients were C677T +/+. Two of the latter also had FVL. These 7 patients experienced their first thrombotic event, on average, at a significantly earlier age than patients who were C677T heterozygous or negative. It should be noted that this study did not measure plasma homocysteine levels, so the direct contribution of elevated homocysteine could not be evaluated. Cappucci *et al*. [151] did measure homocysteine levels in C677T +/+ APL-positive patients and found that these patients had significantly higher homocysteine levels and also experienced their first thrombotic event at a significantly earlier age than patients with APL or C677T +/+ alone.

The role of the PAI-1 polymorphism in APL patients has been investigated in several studies. Forastiero *et al*. [152] studied a group of 105 consecutive unselected APL-positive patients, 69 with and 36 without APS, as well as 200 healthy subjects. The prevalence of FVL, MTHFR C677T, and PAI-1 4G/4G mutations was similar in all three groups, while the prevalence of the prothrombin G20210A mutation was three times higher in the APS-positive than in the APS-negative or control groups (8.7, 2.8, and 2.0%, respectively). However, combinations of G20210A or FVL with PAI-1 4G/4G were significantly more frequent in the APS patients than in the other two groups (5.8, 0, and 0.5%, respectively).

On the other hand, Tassies *et al*. [153]. found that APL-positive patients with a history of arterial thrombosis had a significantly higher frequency of at least one 4G allele (4G/4G or 4G/5G) than patients without arterial thrombosis. Although not statistically significant, PAI-1 activity was somewhat higher in these patients. These differences were not seen for venous thrombosis. Interestingly, although all patients and controls had normal plasma levels of TNF-α and IL-1, four patients had increased levels of IL-6 and all four experienced arterial thrombosis. As previously mentioned, PAI-1 activity is upregulated by cytokines [140], and it is possible that plasma PAI-1 levels may increase in response to inflammation to a greater extent in individuals with the 4G allele.

However, several studies have found no additive effect of these genetic risk factors in APS. Thus, Yasuda *et al*. [154] found no correlation between the PAI-1 4G/5G polymorphism and risk of venous or arterial thrombosis in patients with APLs, and Bentolila *et al*. [155] and Bertolaccini *et al*. [156] found no difference in prevalence of the prothrombin G20210A mutation

between APL patients with and without thrombosis and control groups. Thus, it is not yet clear what role genetic mutations play in the thrombotic risk of the antiphospholipid syndrome. It is unlikely that this state of affairs will change until large prospective studies are designed to examine the issue. However, despite the limitations of our present knowledge, it may be prudent to assume that genetic thrombotic risk factors play some additive role in the clinical events in APS and, thus, it seems logical to screen APL patients for these genetic mutations. Because patients who are homozygous for the MTHFR mutation and APLs may have an earlier age of onset of thrombotic events, presumably due to increased homocysteine levels, we recommend measurement of plasma homocysteine levels in all LAC/ACA-positive individuals. Patients with elevated levels, and even patients in the upper two quartiles of the normal range, should be treated with folate/B_{12}/B_6.

TREATMENT OF THROMBOSIS IN SYSTEMIC LUPUS ERYTHEMATOSUS PATIENTS WITH LUPUS ANTICOAGULANTS OR ANTI-CARDIOLIPIN ANTIBODIES

In this section we review the clinical literature relating to thrombosis in LAC/ACA-positive individuals and attempt to provide guidelines for treatment. However, it must be appreciated that adequate prospective studies of this problem are lacking, and therefore our approach, like that of others, is based on small series and anecdotal reports, intuition, and generalizations from other thromboembolic conditions.

Anticoagulation

In any individual with a risk factor for thrombosis, the question of long-term anticoagulation inevitably arises. Should long-term anticoagulation be instituted on discovery that an individual is persistently positive for a LAC or ACA, on eliciting a history of past thrombosis in such a person, or only after diagnosing an acute thrombotic episode, where it is clear that the risk of recurrence is very high [5, 157]? If only in the last setting, should the type of thrombosis play any role in the decision? In each case, it is important to reiterate that only persistent LAC/ACA positivity is strongly associated with thrombotic risk. Thus it is necessary to perform tests at least twice, at least 1 month apart.

While several retrospective studies make it highly likely that anticoagulation decreases the rate of recurrent thrombosis after a first event [157–159], current clinical opinion would argue against long-term anticoagulation solely due to the discovery of a persistently positive LAC or ACA test. An exception may be the use of anticoagulants temporarily during periods of high risk, such as major surgery or prolonged confinement to bed. One retrospective study of 23 patients undergoing 18 vascular and 33 nonvascular surgical procedures concluded (albeit with no control group) that antithrombotic treatment of LAC-positive patients (steroids, antiplatelet agents, and anticoagulants were used in various combinations) appeared to protect against postoperative thrombotic complications [160]. Another study of 9 patients came to a similar conclusion [161]. In our opinion, it would be reasonable to treat LAC/ACA-positive patients with low-dose heparin (5000 units twice daily subcutaneously) in the event of surgery or during prolonged bed rest.

In the event of acute venous or peripheral arterial thrombosis, treatment should be instituted in the standard way with heparin and oral anticoagulants. Oral anticoagulants should be begun on the first day, as soon as effective heparinization has been established. If the pretreatment APTT is only mildly prolonged by the presence of the LAC, the adequacy of heparinization can be followed with the APTT. When the preheparinization APTT is prolonged more than 10 s above normal, other approaches can be used. The substitution of a phospholipid reagent relatively insensitive to the presence of LACs may allow the APTT to be used for monitoring. Otherwise, the thrombin time may be followed. This test is sensitive to heparin, but is not prolonged by LACs. A reasonable approach would be to heparinize to a thrombin time of about 100–120 s (with a normal of about 15 s). Error on the side of a greater prolongation may not be a serious problem, since at least one study used as an end point a prolongation of the thrombin time to more than 100 s without encountering bleeding problems [162]. Heparinization should be continued for at least 5 days, to include at least 4 days of therapeutic range oral anticoagulation.

Oral anticoagulation should be continued for at least 3 months, as is recommended for any patient with an acute thrombotic episode. Should anticoagulation be continued for life? Collected data suggest that in the absence of continued anticoagulation recurrences are frequent [5, 157, 163]. In two series [47, 57], following cessation of anticoagulation a second deep venous thrombosis occurred in 22 of 35 patients, although the intervening time interval was not always stated. Another study noted 32 separate thromboembolic

episodes in 15 LAC patients, implying a high recurrence rate [164]. Recurrent thrombosis was reported in 6 patients (5 of whom carried a diagnosis of SLE) with high-titer ACAs (>7 SD above normal) 6–12 weeks after coumadin withdrawal: 5 had deep vein thrombosis, while the sixth suffered a myocardial infarction [165]. All had been asymptomatic during prior coumadin therapy of 3 months to 3 years duration. As previously mentioned, in a study of younger men (under age 45) with myocardial infarction, not on long-term anticoagulant therapy, 8 of 13 ACA-positive individuals had reinfarcted within 36 months [117]. In another study, 4 of 6 LAC-positive patients under age 40 with cerebral infarction suffered recurrent arterial thrombosis during a follow-up of 1–7 years [166].

The intensity of anticoagulation with coumadin has been the subject of a number of studies. Although "low" or "intermediate" intensity anticoagulation (INR 2–3) has been reported to be effective in biochemical [167] and clinical studies [168, 169], it appears likely that achieving an INR of 2.5–3.0 may only be sufficient to prevent venous recurrences, and that more intense anticoagulation, to an INR > 3.0, may be required to prevent arterial recurrences [157, 158] In view of the likelihood that recurrences will involve the same side of the vascular tree—arterial vs venous—as the initial episode [158], levels of anticoagulation need to be monitored closely.

In summary, available information suggests that LAC-positive and strongly ACA-positive patients who have suffered a thrombotic episode are at high risk of recurrence. Long-term, probably lifelong, oral anticoagulation seems indicated. Anticoagulation after a venous thrombosis should aim for an INR of 2.5–3.0 and after an arterial episode for an INR of 3.0–3.5, recognizing that, particularly in patients with LACs and a prolonged prothrombin time, the INR may not reflect the degree of anticoagulation and more specialized tests may be required.

The utility of aspirin for the prevention of thrombosis in LAC/ACA-positive individuals has been the subject of conflicting studies. In one large study with a 5-year follow-up, aspirin did not offer protection to LAC/ACA-positive male physicians [170]. On the other hand, aspirin seemed protective in women with LACs/ACAs and a history of pregnancy loss [171], at least when administered together with heparin [172]. Therefore, it would seem reasonable to use aspirin in patients who develop recurrent thrombosis while on adequate oral anticoagulation, especially in cases of arterial thrombosis, including CNS events (see later). However, the combination of aspirin with oral anticoagulants should be employed cautiously, since many LAC/ACA-positive patients with SLE are thrombocytopenic.

Ancrod, an enzyme extracted from Malayan pit viper venom, has been used to treat thrombosis in several LAC-positive patients with SLE [162]. This substance has both anticoagulant and thrombolytic effects. Further studies of its effectiveness may be indicated.

Steroid and Other Immunosuppressive Therapy

Steroids and other immunosuppressive agents have been used frequently in an effort to decrease or eradicate ACAs or LACs. In no case should treatment be undertaken before ascertaining that patients are persistently positive. Even then it is important to be aware of the variability of ACA titers in evaluating results of therapy. For example, in one study, IgG and IgM ACA titers were determined in 53 SLE patients who were followed for over 2 years [173]. Only 21 patients with IgG ACAs (40%) and 25 with IgM ACAs (47%) remained in their original category (negative, low-positive, high-positive). Marked changes, such as from negative to high-positive titers, were sometimes seen. Furthermore, an occasional high-titer IgG ACA has been noted to disappear over time in the absence of therapy or a change in disease activity [174].

The relation between disease activity and LAC/ACA titers is not clear. In one study of 47 patients, elevated IgG and IgM ACA titers were associated with disease activity in only 23% and 9% of patients, respectively [173]. In another study [42], 15 of 19 patients had normal IgG ACA titers during inactive disease; 6 of the 15 became positive when the disease was reactivated. Of the 4 patients with elevated IgG ACA titers during inactive disease, on disease reactivation 2 had no change in antibody titers while in the other 2 titers became normal. Several other studies also give evidence that ACA titers frequently vary quite independently of disease activity [87, 175, 176].

With these caveats in mind, we review the data on steroid treatment of LACs and ACAs. Alarcon-Segovia *et al*. [42] reported that in 8 of 10 patients with active SLE and elevated IgG ACAs, titers became normal within 6 months of instituting steroid treatment; an additional 2 patients became normal after 6–10 months. Titers of IgM ACA fell with treatment in all but 1 of 10 patients. The mean starting prednisone dose in this group was 53 mg/day. Others have reported less successful responses to steroids [120, 173, 175, 177].

The literature examining steroid effects on LACs is somewhat sparser. Without therapy LACs usually

persist, although spontaneous disappearance has been observed both with and without remission of the disease [13]. Treatment with steroids has produced variable results. In some cases LACs disappeared if the primary disorder responded to steroids [13, 178]. Lubbe *et al*. [179] found that the prolonged APTT decreased to normal in five of six LAC-positive women (four had SLE) after 4–8 weeks treatment with prednisone (40–50 mg/day) for recurrent abortion. In contrast, Elias and Eldor [57] found no change in the APTT in eight LAC-positive patients receiving 40–50 mg per day of prednisone. Furthermore, occasional patients have responded to steroid therapy with disappearance of LAC activity, but with no change in ACA titer [177].

The therapeutic efficacy of reducing LAC/ACA levels with steroids is, in any case, unclear. Thrombosis [174] and spontaneous abortion [180] have been reported in patients whose elevated ACA titers responded to steroid therapy. Thus, although steroid therapy has produced a decrease in ACA titer or LAC activity in some patients, the efficacy of steroids in forestalling thrombotic events has generally not been proven. For patients with recurrent thrombosis, long-term anticoagulation must still be regarded as the treatment of choice.

Immunosuppressive therapy with other agents, particularly cyclophosphamide and azathioprine, has been used in some cases [44, 57, 120, 181], but insufficient data are available to draw firm conclusions.

Plasmapheresis has been used in an effort to reduce LAC activity or ACA titer [182, 183], although removal of IgG, half of which is in the extravascular space, is relatively inefficient even with multiple exchanges. In addition, because of continuing IgG synthesis, the effects of plasmapheresis are transient [182], so that this approach is unlikely to have long-term beneficial effects. The combination of regular plasmapheresis with steroid and/or azathioprine treatment may occasionally be effective [184]. Repeated plasmapheresis accompanied by methylprednisolone administration has been used with apparent success in three women with a serious skin necrosis syndrome associated with LACs [185]. Two of the women had previously been treated unsuccessfully with corticosteroids.

Hydroxychloroquine has been used for the treatment of lupus, and several observations have suggested that this agent may have a role in prevention of thrombosis in the setting of APLs [186, 187]. Hydroxychloroquine has been reported to inhibit thrombos formation in an experimental model of APL-induced thrombosis in mice [188]. However, no controlled clinical evaluation of the efficacy of this drug has yet been carried out.

Treatment of Cerebrovascular Events

Monoclonal antibodies to anionic phospholipids react with brain tissue [189], and neurologic impairment has been induced in mice in whom the "antiphospholipid" syndrome has been induced by immunization with monoclonal human anti-cardiolipin antibody [190]. Studies in humans of the relationship between cerebrovascular symptomatology and presence of LACs/ACAs suffer from the paucity of reports in which LACs were measured. In Love and Santoro's analysis [5] 38% of LAC-positive SLE patients had "neurologic disorders" compared with only 21% of LAC-negative patients; 49% of patients with elevated ACAs, compared with only 12% of ACA-negative patients, had neurologic symptoms. Elevated ACAs appeared to be more strongly associated with neurologic disorders of vascular origin (transient ischemic attack, stroke, retinal artery occlusion, amaurosis fugax) than with psychiatric disorders. Several series have investigated the relationship between cerebrovascular occlusive events and elevated ACAs (independent of SLE) and have demonstrated a significant association [57, 58, 191–195].

When examined from another standpoint, roughly one-fourth of ACA-positive patients with cerebrovascular disorders have SLE [196, 197]. However, more than one-half of the patients in these series had at least one other risk factor for cerebrovascular accidents, such as smoking or hypertension. Over one-half of the patients had abnormal cerebral arteriograms [130, 192, 146]. One-third to one-half of the patients had associated systemic thrombotic disease [196, 197]; some had a cardiac source for emboli [198]. Many patients, perhaps the majority, had recurrent events [166, 197, 199]. However, the relationship between LAC or ACA titer and frequency of recurrence has not been established.

Effectiveness of therapy is difficult to judge, since only small series have been published. An analysis of the treatment of 45 LAC/ACA-positive patients with cerebrovascular or neurologic disease noted that 10 of the 25 patients treated with antiplatelet agents (aspirin, dipyridamole, or both) had new events during a mean follow-up period of 12 months [197]. Another author reported a good therapeutic effect of 80-mg aspirin daily, over a follow-up period of 10 months, in a patient who previously had recurrent cerebral ischemic events [200].

Coumadin therapy has been used in LAC/ACA-positive patients with cerebral ischemia. Fisher and McGehee [201] reported that four patients treated with coumadin for a mean of 7 years remained free of recurrence. Another review notes that of four patients treated with oral anticoagulants alone or in combina-

tion with other medication, two on coumadin therapy became asymptomatic, one became asymptomatic when aspirin was added to coumadin, and one continued to have transient ischemic attacks [196]. Two other patients had recurrences while receiving aspirin but became asymptomatic during follow-up periods of 2–2.5 years when coumadin was added [196, 202].

Corticosteroids have been used in patients with cerebrovascular ischemic events, although their utility has not been proven. Levine *et al.* [197] noted that of 13 patients treated with steroids alone or in combination with other modalities, 5 subsequently had transient or permanent events during a 1-year follow-up. Immunosuppressive agents other than prednisone have been tried occasionally, with fairly poor results [166, 196, 203].

In summary, no therapy consistently prevents recurrent events in LAC/ACA-positive patients with cerebrovascular disorders [192, 196]. Oral anticoagulation will obviously be used in patients with associated peripheral thrombotic events. If the cerebral event is embolic from a cardiac source, oral anticoagulation would also be the treatment of choice [197]. In other situations initial therapy lies between aspirin and anticoagulation, a choice that cannot be made on the basis of available evidence. Coumadin appears to have been effective in some patients; on the other hand, aspirin is the only treatment proven effective in decreasing the frequency of recurrent cerebral ischemic events in patients with transient ischemic attacks, irrespective of LAC/ACA status [204]. Clearly, a therapeutic trial is needed in LAC/ACA-positive patients. Ticlopidine, an antiplatelet agent, has been shown to be effective in decreasing the frequency of recurrent cerebral ischemic events in patients with stroke [205]. This agent may have a place in the treatment of LAC/ACA-positive patients as well. When coumadin or aspirin alone has proven ineffective, the combination may be tried [147], but, as previously mentioned, the frequency of thrombocytopenia in this patient population should be kept in mind. A role for corticosteroids or other immunosuppressive agents has not been established, and these drugs probably should be used only in the event of failure of other agents or perhaps as adjuncts to oral anticoagulants and aspirin.

For a more complete treatment of this area, the reader should refer to the review by Brey and Levine [206].

Treatment of Recurrent Fetal Loss

Fetal loss in the first trimester occurs in up to 80% of untreated pregnancies in women with LACs/ACAs and a history of recurrent miscarriage [207]. Several approaches have been taken to the treatment of this vexing problem. Lubbe *et al.* [179] were the first to advocate the use of prednisone (40–60 mg per day) and aspirin (75 mg per day). The utility of this approach was substantiated in several trials, and resulted in an increase in successful pregnancies from about 6% in untreated patients to 50–80% in treated patients [54, 208–210]. However, this therapy is not without complications: cushingoid features occur in almost 100% of women, bothersome acne in most, and, less commonly, the more serious complications of gestational diabetes and hypertension.

Because of concern regarding steroid side effects, other regimens have been explored. Low-dose aspirin (75–80 mg daily) has been effective in some patients. But examination of placentas has occasionally shown persistence of vascular thrombosis [209], and some pregnant women have experienced thrombotic episodes while on this regimen [211].

Heparin therapy has been used as an alternative to steroids. Rosove *et al.* [212], in a study of 14 women with at least one prior fetal loss, used twice daily subcutaneous heparin beginning at the time of patient referral, which averaged 10-weeks gestational age. The mean daily heparin dose was 24,700 units, with a range of 10,000–36,000 units. Heparin or coumadin was continued for variable periods thereafter. Using this regimen, heparin side effects were minor and 14 of the 15 pregnancies resulted in live births at a mean gestational age of 36 weeks. The placentas showed fewer gross infarcts than were reported in previous pregnancies. Since then several controlled studies have shown that the combination of low-dose subcutaneous heparin, administered twice daily in amounts that prolong the APTT to the upper limit of normal or just beyond, together with 80-mg aspirin daily, probably is as beneficial as full-dose heparin and results in a live birth rate of 70–80% [213–218].

Intravenous immunoglobulin (IVIG) has been used in a number of pregnancies [219], despite the fact that IVIG preparations contain detectable amounts of ACAs [220]. However, more recent data, including one controlled trial, suggest that IVIG has little additional to offer beyond low-dose heparin and aspirin [221, 222].

OTHER POSSIBLE RISK FACTORS FOR THROMBOSIS

Approximately 10–15% of SLE patients have thrombotic events in the absence of LACs or ACAs [5]. In these patients other mechanisms may be involved. For example, deficiency of antithrombin (previously called

antithrombin), protein C, or protein S may be present [1]. Antithrombin is an inhibitor of many activated coagulation proteins, most importantly thrombin and factor Xa. Activated protein C is a specific inactivator of factors Va and VIIIa, and protein S is a necessary cofactor in this reaction. Approximately 60% of protein S in the bloodstream circulates as a complex with C4b-binding protein (a protein involved in the regulation of the complement cascade), and about 40% is found free. Only free protein S can serve as a cofactor for activated protein C. In addition, some evidence suggests that protein S itself may have an inhibitory effect on the coagulation system [223].

Several investigators have measured the concentrations of protein C, protein S, and antithrombin in patients with SLE in relation to APL status [130, 224–227]. In general, levels of antithrombin and protein C were not related to the presence of LACs/ACAs or of thrombosis. However, 35–45% of SLE patients had depressed levels of free protein S, and this finding tended to correlate with the presence of LACs/ACAs, although there were many exceptions. However, little or no correlation was found between the presence of a LAC/ACA, subnormal free protein S, and thrombosis.

The role of factor V Leiden, the prothrombin G20210A and the MTHFR mutations, and the PAI-1 4G/5G polymorphism, has already been discussed.

The nephrotic syndrome is a common complication of SLE. Several studies have found measurable levels of antithrombin in the urine of a majority of patients [228–230]. In one study the plasma antithrombin levels were unchanged [229]; however, another study found that both plasma concentration and the functional activity of antithrombin were reduced [228]. A third study 230 of 48 patients included several with SLE. Nine patients had thrombotic episodes, including 4 with renal vein thrombosis; antithrombin concentrations were below normal in 8, and levels correlated with urinary total protein excretion [230]. Free protein S deficiency can occur in the nephrotic syndrome [231], although the relationship of this phenomenon to thrombosis requires further investigation.

Other coagulation factors also may be lost in the urine in the nephrotic syndrome. Depressed plasma levels of these factors may prolong coagulation tests and/or contribute to a bleeding tendency. For example, the nephrotic syndrome is commonly associated with factor XII (Hageman factor) deficiency and may cause a prolonged APTT [232]. This APTT prolongation is not associated with any bleeding tendency but may contribute to the well-known hypercoagulability of the nephrotic syndrome, since it is now recognized that Hageman factor deficiency is accompanied by a mild thrombotic risk. Acquired factor IX deficiency has also been reported, although generally it has not been found to be severe enough to cause spontaneous bleeding [232]. Deficiency of factor VII may occur rarely [232]. Prothrombin deficiency may occur [233], and in patients who also have LACs hypoprothrombinemia might be severe.

Other coagulation factor abnormalities have been reported in SLE. Markedly increased levels of von Willebrand factor and of fibronectin were found in a study of 73 SLE patients [224], but this finding may reflect the presence of patients with LACs, who have been reported to have high vWF levels and abnormal vWF multimeric patterns [234]. In another series of 28 patients with SLE [235], the mean level of factor VIII coagulant activity was increased, especially in patients on steroids. The causes and significance of these changes are unknown.

It has been reported that SLE patients may have increased levels of fibrinopeptide A [236], a cleavage product of the action of thrombin on fibrinogen. In this study of 19 women with SLE, fibrinopeptide A levels appeared to parallel the extent of inflammation and to provide a sensitive index of disease activity. However, studies of prothrombin fragment F1 + 2 levels, another marker of coagulation activation, have not produced consistent results. Levels of fibrin degradation products are generally normal or only minimally elevated [237], implying only minor degrees of activation of the fibrinolytic system. Changes in components of the fibrinolytic system have been studied in SLE only to a limited extent and with conflicting results. Plasminogen levels have been found to be increased or normal in the majority of patients, but may be decreased in a few [130].

COAGULATION FACTOR INHIBITORS AND BLEEDING IN SYSTEMIC LUPUS ERYTHEMATOSUS

As already mentioned, hypoprothrombinemia has been noted in up to 25% of SLE patients with LACs [20]. The mechanism of the hypoprothrombinemia, usually mild but occasionally severe, is probably the rapid clearing of antigen–antibody complexes [238]. Nonneutralizing antibodies to prothrombin may be present in two-thirds of all LAC-positive SLE patients [239]. However, when accelerated clearance of complexes cannot be compensated and substantial decreases in prothrombin are present, bleeding may occur [239–244]. A markedly prolonged prothrombin time (ratio >1.5) in a patient with a LAC should alert one to the possibility of serious hypoprothrombinemia, since only rarely does a LAC directly produce this

degree of prothrombin prolongation [239]. In one study, 67 of 201 LAC patients had a prolonged prothrombin time [46], but only 44 had a prothrombin ratio greater than 1.25 and only 16 had a ratio greater than 1.5. In another study, 15 of 43 LAC patients had a prothrombin time more than 2 s greater than the control [239]; antibodies against prothrombin were demonstrated in 14. In 10 of the 15 patients the prothrombin time was less than 16.5 s (normal range, 11–13 s); all 10 had immunologic levels of prothrombin above 40%, and none bled abnormally. In 5 patients the prothrombin time exceeded 16.5 s; in 2 the prolonged prothrombin time was due to the presence of a potent lupus anticoagulant. In the other 3 the prolonged prothrombin time was associated with severe hypoprothrombinemia; all 3 patients bled. Despite lack of *in vitro* evidence of prothrombin neutralization, infusion of plasma or concentrates does not increase prothrombin levels. There are several reports of a rapid rise of prothrombin levels after treatment with corticosteroids [238, 245–247]; however, the response to steroids is not always so effective [244]. To establish the presence or absence of hypoprothrombinemia in a patient with a prolonged prothrombin time, both prothrombin activity and antigen should be measured.

Among the many types of antibodies found in patients with SLE are functional inhibitors to coagulation factors, most frequently inhibitors to factor VIII. In a survey of 215 nonhemophiliacs who developed factor VIII inhibitors, nearly all IgG, patients with SLE, rheumatoid arthritis, and other autoimmune disorders accounted for 6, 8, and 5% of the patients, respectively [248]. In these disorders, factor VIII antibodies are unlikely to resolve spontaneously or following steroid therapy. In one large series, the combination of azathioprine or cyclophosphamide and corticosteroids, frequently with an initial large intravenous bolus of factor VIII, resulted in the decline or disappearance of the inhibitor in half the patient [248]. In another study, successful eradication of factor VIII inhibitors was seen in 11 of 12 patients treated with the combination of cyclophosphamide, vincristine, and prednisone [249].

Treatment of bleeding in patients with factor VIII inhibitors is determined by the clinical situation. Soft tissue hemorrhage may be managed conservatively. Life-threatening bleeding demands aggressive therapy, including the use of human factor VIII if inhibitor titers are below 5 Bethesda U/ml, porcine factor VIII if the level is higher and the patient's antibody shows little species cross-reactivity, prothrombin complex concentrates, and activated factor VII preparations. Anamnestic rises in antibody titer have occurred as a result of infusion of human factor VIII. Plasmapheresis has been used successfully to lower inhibitor titers [250–254], but repeated plasmapheresis, over a period of several days, is usually necessary.

Intravenous immunoglobulin has been used in patients with spontaneous factor VIII inhibitors with inconsistent results. Other approaches used with occasional success include l-desamino-8-D-arginine vasopressin (DDAVP) [255–258] and cyclosporine [259].

Other coagulation inhibitors are rare. Acquired factor IX inhibitors have been reported in 2 patients with SLE and in 1 patient with a collagen vascular disorder [260]. Inhibitors against factor XI have been observed in about 30 patients without underlying factor XI deficiency [261, 262]; of these, 10 had SLE and another 4 had rheumatoid arthritis. Bleeding manifestations were variable in this group of patients. Of two acquired factor XII inhibitors reported in the literature, one was in a female with SLE; neither bled [261]. The only factor VII inhibitor reported [261] was in a 66-year-old man with a pulmonary neoplasm, elevated ANA titers, and a positive lupus erythematosus preparation, but without clinical evidence of SLE; little bleeding was noted in this patient. There are no reports of factor V or factor X inhibitors in SLE patients. Two of the nine reported cases of inhibitors against fibrinogen occurred in SLE patients [263].

Among the many manifestations of SLE, thrombosis and bleeding are both common occurrences. Our understanding of the causes of bleeding episodes far exceeds our knowledge of the mechanisms of thrombosis. A better insight into the latter, especially in the setting of LACs and ACAs, will not only aid materially in the care of patients with SLE but should also substantially increase our general ability to treat patients with thrombosis.

THE ANTIPHOSPHOLIPID SYNDROME: PATHOGENESIS AND IMPLICATIONS FOR SYSTEMIC LUPUS ERYTHEMATOSUS

Joan T. Merrill

ABSTRACT

Anti-phospholipid antibodies are prevalent in lupus patients and have been implicated in life-threatening thrombotic events. Unfortunately, detecting the presence of these antibodies does not predict the likelihood of thrombosis for an individual nor does it predict when such an event may occur. Numerous reports indicate that isolated patient antibodies interfere directly with various elements of the coagulation cascade. Nevertheless clinicians are left in doubt as to when and for whom anticoagulant therapy is useful. There is an obvious need to determine the coagulation events which trigger the sudden thrombotic episodes that characterize this syndrome, and whether there are measurable clinical parameters which can be used as warning signals for impending thrombosis. This chapter reviews current literature in support of a pathogenic model for thrombosis involving a complex equilibrium between autoantibodies, endothelium, platelets, and coagulation proteins, particularly those which modulate the anticoagulant, protein S. An overall model for thrombotic risk, which takes into account the possibility that there might be multiple potential targets for anti-phospholipid antibodies in the coagulation cascade is now possible. Benign and/or transient autoantibodies which may develop in most people as a result of infection could, in susceptible individuals, spread and persist to the point that a potentially pathologic dysequilibrium exists in the clotting cascade. Even then, serious consequences are rare, awaiting the justaposition of at least two conditions: triggering of a significant thrombotic event and turnover of vascular phospholipids (through apoptosis or inflammation). This creates a primed environment for problems: stress on the system such that the input of anticoagulant proteins becomes most critical, and optimal binding conditions for antibodies that interfere with the function(s) of these proteins. Markers for thrombotic risk, then, might be found among blood tests which provide subtle evidence for vascular oxidation or inflammation, tests which reveal some of the unique functional changes predictive of autoantibody-mediated vascular imbalance, or tests which subcategorize the autoantibodies to each important coagulation protein to detect their pathologic epitope(s).

INTRODUCTION

The heterogenous immunoglobulins known as anti-phospholipid antibodies (APLA) or lupus "anticoagulants" (LA) are prevalent in lupus patients and have been implicated in life-threatening thrombotic events [1–3]. Unfortunately, detecting the presence of these

antibodies in an individual does not predict the likelihood of thrombosis nor does it predict when such an event may occur [4–6]. A pathogenic role for these antibodies is supported by the observation that high titer and IgG isotype confer an increased risk of thrombosis [7]. Additionally, numerous reports indicate that isolated patient antibodies interfere directly with various elements of the coagulation cascade [8–28]. Nevertheless, attempts to correlate specific antibody characteristics with a hypercoagulable state in an individual patient [29] have been unsuccessful to date. Because of this, a clinician is left in doubt as to when and for whom anticoagulant therapy is useful.

Given such widespread uncertainty combined with the potential complications of anticoagulant medications, patients are generally not treated until after some significant morbidity has occurred. Finally, because of the apparent high rate of reoccurrence [30] most patients remain on aggressive anticoagulant therapy indefinitely, regardless of individual need, which simply cannot be predicted. There is an obvious need to determine the coagulation events which trigger sudden thrombotic episodes, and whether there are measurable clinical parameters which can be used as warning signals for impending thrombosis. A remarkable effort has been underway in many laboratories around the world to do just that.

An improved understanding of the pathogenesis of the antiphospholipid syndrome might lead not only to better predictive tests and more rational timing of anticoagulant therapy, but perhaps eventually to novel, more specific and safer therapies, aimed at the specific underlying coagulation disorder(s). The current chapter will describe experimental work which may provide signposts to improved future therapy for patients with this disorder, and will also examine currently available methods of diagnosis, and those anticoagulant and immunosuppressive therapies which either have been tested in preliminary studies or are in more widespread use at the time of this writing. The aim will be to review both the limited state of the art and options which may become available in the near future to manage this difficult complication of systemic lupus.

Primary Secondary Antiphospholipid Syndrome: Is There a Fundamental Difference or Is the Antiphospholipid Syndrome a *Forme Fruste* of SLE?

Clinically, it is not possible to distinguish the manifestations of primary and secondary antiphospholipid syndrome. An intuitive common practice has been to use the accumulated data from patients with or without SLE in discussing or determining therapy for an individual with this syndrome. The rationality of this practice has been borne out by data from two large European cohorts, suggesting that the broad range of coagulative complications are nearly identical [31, 32]. Furthermore, the overall prevalence of thrombosis and thrombocytopenia appears to be the same in patients with or without full-blown SLE [31, 32], and in an additional large clinical study of 110 antiphospholipid patients, there was no significant difference found in the neuroradiologic findings for those with or without SLE [33]. On the other hand, certain of the less well-established antiphospholipid-associated features, including heart valve disease, hemolytic anemia, low C4, and neutropenia, have been found to be more common in those antiphospholipid patients who meet criteria for SLE [32].

As will be discussed later, the antiphospholipid syndrome, like SLE, is characterized by the emergence of a broad range of autoantibodies, which are associated with its clinical features, and which are common to those patients with the primary or secondary syndromes. It seems logical, then, to speculate that the primary antiphospholipid syndrome is nothing more than a partial manifestation of SLE. Anti-nuclear antibodies have been detected in up to 33% of patients with primary antiphospholipid syndrome, and about 8% of these patients have relatives with SLE [34]. Furthermore, patients with primary antiphospholipid syndrome may develop systemic lupus at a later date, although one study, following 165 patients for a median of 78 months, found the emergence of systemic lupus to be relatively rare (<2%) in that time span [35]. On the other hand, when evolution from primary antiphospholipid syndrome to lupus has been documented, it has appeared to be a relatively late phenomenon, occurring at least 10 years after the initial diagnosis [35, 36].

In animal models, the induction of anti-phospholipid antibodies is associated with other lupus-like autoimmune phenomena. Aron *et al*. [37] inoculated both rabbits and mice with β_2-glycoprotein I, a major target antigen for anti-phospholipid antibodies, and found production of anti-phospholipid antibodies, anti-nuclear antibodies, and antibodies to DNA, which could be absorbed by phospholipid micelles, suggesting cross-reactivity between the antibodies to phospholipid and DNA. In a different mouse model, antibodies to heparan sulfate were detected which cross-reacted with DNA, cardiolipin, and RNA polymerase [38]. In addition, antibodies directed against anti-DNA antibodies may be found in some patients with primary antiphospholipid syndrome [39], suggesting an evolutionary relationship between anti-phospholipid and other lupus-related autoantibodies.

Although the immunogenetics of the antiphospholipid syndrome may be complex, a familial tendency to the development of anti-cardiolipin antibodies, lupus anticoagulant, and clinical manifestations of the antiphospholipid syndrome appears to be linked to HLA DR4, DR7, and Drw53 [40–42], whether the disorder is primary or a manifestation of SLE [40]. Not surprisingly, the DR4 association is more likely to involve Anglo Saxons and the DR7 is associated with people of Latin origin [41, 42]. It should be noted, on the other hand, that inheritance of these alleles confers only a modest increased relative risk of developing the antiphospholipid syndrome [41].

Finally, lupus activity per se may contribute to the clinical outcome of patients with the antiphospholipid syndrome. In one study of 19 lupus patients with a history of antiphospholipid syndrome and a diagnosis dating back 5 or more years, lupus activity was found to have been relatively active in the 9 with recurrent thrombotic events as compared to the 10 patients who had no further thrombosis [43]. Lupus flare was also noted to correlate with thrombotic events in some of these patients. Several additional studies have correlated complement activation to thrombosis in the antiphospholipid syndrome [44–49].

Given clinical, pathologic, and genetic similarities between the primary and secondary antiphospholipid syndrome, the current chapter will review physiologic models and treatment strategies for this coagulation disorder without differentiating further between the primary and secondary forms. Furthermore, whether or not it ever becomes possible to distinguish some fundamental difference between idiopathic and lupus-related coagulopathy, the strong association between SLE, SLE flare, and the antiphospholipid syndrome may provide a clue to an underlying pathogenic mechanism common to both the primary and secondary syndromes. Evidence in support of this possibility will be one focus of the following discussion.

PATHOGENESIS OF THE ANTIPHOSPHOLIPID SYNDROME: OVERVIEW OF A COMPLEX DISORDER

It has become increasingly apparent that various anti-phospholipid antibodies have the capability of binding to and potentially interfering with many of the critical elements and structures that regulate hemostasis, including endothelial cells, platelets, monocytes, humoral components, and circulating coagulation factors [50]. It is now thought that the majority of the pathogenic antibodies do not bind phospholipid alone, but rather to various proteins attached to platelet, endothelial, or other phospholipid surfaces [8–28]. Central to the antiphospholipid syndrome, by virtue of their high prevalence, are autoantibodies which specifically bind to either the plasma anticoagulant β_2-glycoprotein I [51], or to prothrombin, the latter of which seems to account for most of the lupus anticoagulant activity [52]. Other phospholipid-binding proteins which have been found to be targets for anti-phospholipid antibodies are listed in Table 1, and by reviewing this extensive list of hemostatic regulating proteins, it becomes obvious that anti-phospholipid antibodies have the potential to disrupt coagulation from multiple directions. Therefore, unlike many of the autoantibodies associated with SLE, a direct role for circulating antiphospholipid antibodies in the disruption of homeostasis now appears not only possible, but likely.

TABLE 1 Phospholipid-Binding Proteins: Targets for Anti-phospholipid Antibodies

An Explanation for the Association between "Lupus Anticoagulants" and a Thrombotic Clinical Syndrome: Autoantibodies May Either Enhance or Inhibit Coagulation, Depending on the Assay Used to Detect This

Lupus anticoagulants were originally identified as circulating plasma factors capable of prolonging the activated partial thromboplastin time, and quixotically associated with a hypercoagulable state. The lupus anticoagulant later became a clinically useful marker for the antiphospholipid syndrome, and has been thought to be more specific for the syndrome than conventional ELISA detection of antibodies to cardiolipin [53]. This seems counterintuitive, since the functional outcome being measured would predict a clinical tendency to bleed rather than thrombosis. There are several possible explanations for this: (1) Lupus anticoagulant func-

tion may be an artifact of *in vitro* testing and the same antibodies may have different functional effects *in vivo*. (2) Lupus anticoagulants may be detectable plasma markers for the presence of structurally similar antibodies which have very different procoagulant effects. Lupus anticoagulants may be closely related but not identical to these pathologic antibodies, and have a tendency to appear in tandem with them during the evolution of a polyclonal immune response.

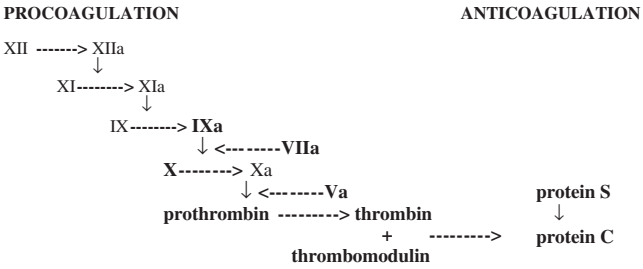

FIGURE 1 Phospholipid-based interactions in the coagulation cascade. Pertinant reactions which occur on a phospholipid background are shown in bold.

An early hypothesis was that most if not all lupus anticoagulants were antibodies with immunologic specificity for the anionic phospholipids which provide active sites in the calcium-mediated binding of vitamin K-dependent coagulation factors. Phospholipids are components in several steps of the coagulation process (see Fig. 1) including the activation of factor X by VIIa and IXa, the prothrombin activation complex, and the proteolytic inactivation of factor VIIa and factor Va by activated protein C. As illustrated in Fig. 2, potential phospholipid-based targets of autoantibody-mediated procoagulant activity might include sites of protein C activation and/or its activity in the proteolysis of factors VIIIa and Va, since inhibition of these elements would be predicted to result in a coagulant effect [54–56].

Assays for activated partial thromboplastin time (APTT) reflect APLA interference with interactions occurring on the left (or procoagulant) side of the picture, so that the net effect of the antibodies in these *in vitro* clotting tests is that of anticoagulation. These anticoagulant effects do not usually have clinical significance *in vivo*. On the other hand, since activated protein C inhibits factors VIIIa and Va, it would follow

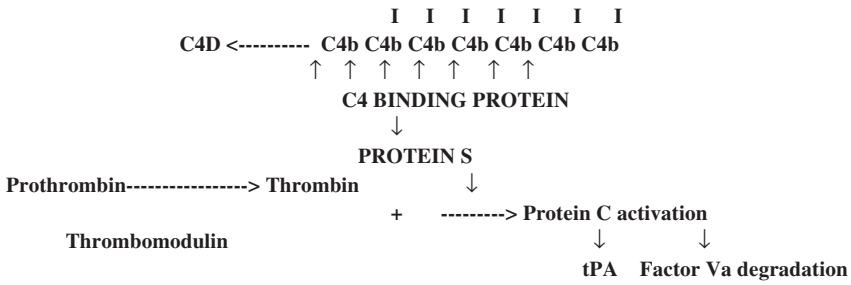

FIGURE 2 Protein S regulation: An interface between the complement system and coagulation. The rate of factor Va degradation by protein C is proportional to the concentration of activated phospholipid-bound protein C. The cofactor activity of protein S requires a one-to-one stoichiometric complex of activated protein C and protein S. In plasma, protein S associated noncovalently in a calcium-dependent manner with C4BP, also approaching a one-to-one stoichiometry (K_d < 3 nM/liter). The C4BP is composed of a small central body with 7 thin projections of molecular weight 70,000. Each of these tentacles can bind and remove C4b from the site of the C3 convertase, making C4b accessible to degradation by factor I, with C4D as a measurable product.

Each C4BP molecule also contains one shorter arm or β chain which binds and inactivates protein S. With physiologic calcium concentrations all available β chain sites are bound such that levels of free or active protein S depend on a molar excess of protein S over available C4BP molecules. Given the high affinity of protein S for phospholipid, protein S may help to localize C4BP to membranes, at which point C4BP remains capable of binding and inactivating C4b. The large C4BP may then sterically hinder more protein S and protein C from binding to the membrane, and inactivates the protein S that is bound to it as well. β2-glycoprotein I may fill the protein S binding site on C4BP as a further control in this system. To the extent that the concentration of C4BP with available protein S binding site is greater than the total protein S concentration minus the concentration of activated protein C, a functional protein S deficiency can occur. We hypothesize that this is what happens in states of disordered complement activation, and in the presence of antibodies which hinder β2-glycoprotein I/phospholipid from performing as regulatory elements.

that interference with protein C interactions by antiphospholipid antibodies might have a thrombogenic effect. Effects of anti-phospholipid antibodies on protein C activity, however, would not be picked up by a standard APTT or the dilute Russell viper venom time (DRVVT) assay, commonly used to detect lupus anticoagulants.

In fact, plasma containing lupus anticoagulant activity, as well as purified antibodies with lupus anticoagulant function have been shown to inhibit anticoagulant proteins [56–62]. It may be that lupus anticoagulants have a dual effect on coagulation *in vivo*. The net outcome of antibody interference and coagulation cascade regulatory adjustments might usually result in hemostatic balance, sporadically in thrombosis, and only rarely in a hemorrhagic consequence, such as is seen clinically in the antiphospholipid syndrome. This net outcome would be determined at any point in time by the dynamic equilibrium between the dysregulating forces of the antibodies and the robustness of complex compensatory adjustments in the coagulation cascade.

On the other hand, there is some evidence to suggest that the lupus anticoagulant function is indeed a laboratory artifact, without physiologic meaning. For example, when 22 IgG fractions which prolonged APTT in a standard assay were subsequently tested using an endothelial cell-mediated prothrombinase reaction only 4 (18%) inhibited prothrombinase in this more physiologic environment [9]. Furthermore, it is now appreciated that most lupus anticoagulants are not specific for phospholipids. About one-third have been found to depend on the anticoagulant, β_2-glycoprotein I for binding and the other two-thirds appear to target prothrombin [63]. Takeya *et al*. have demonstrated that monoclonal antibodies specific for the third and fourth domains of β_2-glycoprotein I , which also have lupus anticoagulant activity, appear to increase the binding between β_2-glycoprotein I and phospholipids [53]. Presumably, increased β_2-glycoprotein I on an activated hemostatic surface would enhance its anticoagulant functions. The association between β_2-glycoprotein I and thrombosis would not be explained by lupus anticoagulants under these circumstances, but the association between lupus anticoagulants and thrombosis might be as bystanders: Antibodies to nearby epitopes on β_2-glycoprotein I, which appear by immunogenic spreading in association with lupus anticoagulants, might interfere with the anticoagulant functions of β_2-glycoprotein I and be the thrombosis-inducing culprits.

A lupus anticoagulant, then, might be defined as any antibody against either prothrombin or β_2-glycoprotein I that either enhances their anticoagulant function(s) or inhibits a procoagulant interaction of these molecules in an *in vitro* assay. The increased specificity of such antibodies for the antiphospholipid syndrome may be the consequence of alternative net effects *in vivo* or result from immunologic spreading giving rise to associated antibodies that bind to tandem structures. Lupus anticoagulants may bind epitopes near to or even overlapping those with procoagulant effects, and thereby be more likely to develop together with procoagulant antibodies than are the broad range of polyclonal antiphospholipid antibodies.

Anti-phospholipid Antibodies Primarily Target Either β_2-Glycoprotein I or Prothrombin: Is There a Role for Phospholipid?

It has become generally accepted that the lipid-binding anticoagulant protein, β_2-glycoprotein I (apolipoprotein H) is necessary for the binding of many anti-phospholipid antibodies in an *in vitro* ELISA assay [64, 65]. It now appears that at least a significant proportion of patients have APLA which bind directly to epitopes on β_2-glycoprotein I, although whether this is a universal phenomenon remains controversial [51, 66–68]. Autoantibodies to β_2-glycoprotein I tend to be low affinity, monoreactive antibodies, specific for this molecule even in the absence of phospholipid as long as there is a negatively charged environment. Anti-β_2-glycoprotein I antibodies are further directed to epitopes which have been preserved across species, and therefore may have some functional significance [64]. One study has demonstrated good correlation between anti-cardiolipin antibody and anti-β_2-glycoprotein I antibody level, light chain association, and IgG subclass, suggesting the possibility that to a large extent the same antibodies are being measured by both assays [52].

Another common protein antigen for anti-phospholipid antibodies is prothrombin [65, 69]. Antibodies to prothrombin may account for more lupus anticoagulant activity than antibodies to β_2-glycoprotein I [63]. The actual prevalence of antibodies to the other lipid binding proteins listed in Table 1 remains to be determined. One study of 22 patients with thrombotic history and IgG anti-phospholipid antibodies found high levels of anti-β_2-glycoprotein I in all 22, anti-prothrombin antibodies in 11 (50%), anti-protein S antibodies in 12, and anti-protein C antibodies in 4 patients [65].

Antibodies which bind to β_2-glycoprotein I, like lupus anticoagulants, appear to correlate better with morbidity in the antiphospholipid syndrome than the general range of anti-phospholipid antibodies do [52, 65, 68, 70, 71]. In at least one study, anti-β_2-glycoprotein I correlated with morbidity better than anti-prothrombin anti-

bodies [65], although in a different study involving 139 patients, both anti-β_2-Glycoprotein I and anti-prothrombin antibodies were significantly associated with the development of deep venous thrombosis ($p = 0.009$ for both) [71].

β_2-Glycoprotein I may have multiple anticoagulant functions, so it appears to be a particularly likely candidate for providing functional epitope(s) to pathologic anti-phospholipid antibodies. For example, β_2-glycoprotein I has been shown to inhibit contact activation of the intrinsic blood coagulation pathway [72], the prothrombinase reaction [73], and lipoprotein lipase-induced factor XII activation [74]. β_2-Glycoprotein I may also be involved in monocyte–endothelial interactions [75]. One report has suggested that β_2-glycoprotein I neutralizes the anticoagulant activity of activated protein C [76], although evidence from our laboratory and others suggests the opposite: that it interferes with inhibition of the protein C cofactor, protein S, serving as an additional anticoagulant cofactor in this system [77, 78].

Given mounting evidence, then, that pathologic anti-phospholipid antibodies are directed against epitopes on β_2-glycoprotein I and possibly other lipid-binding proteins, are phospholipids irrelevant in the antiphospholipid syndrome? The answer is clearly no, since unique phospholipid environments may provide critical modulation of protein structures upon which anticoagulant functions and/or antibody binding depend [66, 67]. Roubey *et al*. have demonstrated that β_2-glycoprotein I-dependent anti-phospholipid antibodies are low affinity antibodies which require bivalent binding to densely packed β_2-glycoprotein I, in order to achieve optimal detection in an ELISA [79]. There is relatively poor binding of these antibodies to β_2-glycoprotein I in fluid phase and markedly improved binding when β_2-glycoprotein I is complexed to phospholipid micelles. In fact, assays which detect autoantibody interactions with β_2-glycoprotein I in the absence of phospholipid depend on the use of γ-irradiated polystyrene plates which, like phospholipid, provide a background surface for the antigen that contains a negative charge. Since there is no γ-irradiated plastic in the vasculature, it can be argued that the standard anticardiolipin assay, in which β_2-glycoprotein I is complexed to phospholipid, may provide a very similar, and more physiologic test for these autoantibodies than the β_2-glycoprotein I-specific test. Similar dependence on either phospholipid or negatively charged polystyrene has been described in the detection of antibodies with specificity for prothrombin [80].

Further evidence of the phospholipid-dependence of β_2-glycoprotein I antibodies has been provided by Hunt and Krilis, who identified a truncated form of β_2-glycoprotein I which was clipped at Lys317/Thr318, a potential thrombin cleavage site. Autoantibodies from patients with autoimmune disease were found to be unreactive with this shortened protein, and did not adhere to cardiolipin [81, 82]. Subsequently, the same group identified a region in the fifth domain of β_2-glycoprotein I which contains both the phospholipid binding site and a region recognized by anti-cardiolipin antibodies [82].

Phospholipids can play critical roles in the detection of autoantibodies which are specific for lipid-binding proteins in two ways: either by modifying the environment to allow increased density of antigen or by modifying the antigen to promote a favorable conformation for antibody binding. In the first case, the improved detection of antibody in the context of a phospholipid environment may or may not be related to the pathogenicity of the antibody. In the second case, it seems more likely that the conformation selecting for pathologic antibodies is related to an important functional conformation of the molecule.

Roubey *et al.* have demonstrated that improved detection of antibodies to β_2-glycoprotein I using oxidized polystyrene plates may be associated with increased density of β_2-glycoprotein I that seems to pack more efficiently on a negatively charged surface, providing a better template for bivalent antibody interactions [79]. In similar studies using prothrombin, Galli *et al*. found increased detection of antibodies to prothrombin when the background was phosphatidylserine instead of oxidized plastic, and in this case the difference did not appear to be due to increased antigen density [80]. Pierangeli *et al*. have furthermore observed that phospholipids may be critical to the lupus anticoagulant function of anti-prothrombin antibodies [66].

It has been suggested by the molecular studies of Ichikawa and co-workers that β_2-glycoprotein I exposes an otherwise cryptic epitope in the presence of phospholipid [83, 84]. Additional evidence for phospholipid-induced modulation of β_2-glycoprotein I conformation was provided by spectroscopic studies. Cardiolipin, which forms a hexagonal crystal lattice in both anhydrous and aqueous environments and β_2-glycoprotein I, which contains 46% β-pleated sheet structure in its purified form, are both significantly altered when bound together. In the case of β_2-glycoprotein I, the β-pleated sheet organization decreases from 46 to 23% [85].

It seems apparent, then, that phospholipids may be intrinsic to the interactions of anticoagulant proteins and autoantibodies both by anchoring and increasing the surface density of at least some of these proteins and

by altering their conformation in ways that may be important both to their hemostatic or anticoagulant functions and to the ability of pathologic antibodies to bind them. It would follow that different phospholipid membrane environments, created by various disease states or degrees of immune activation, might have profound effects on the pathogenicity of anti-phospholipid antibodies. For example, the structure and length of fatty acid chains in phospholipids may play a critical role in the binding of human sera in an antiphospholipid ELISA, with preferential binding of autoantibodies to C18:1 phosphatidlyglycerol [38], and anti-phospholipid antibodies may have increased affinity for lysophosphatidylethanolamine as opposed to phosphatidylethanolamine [86]. A large literature suggesting complexity in the phospholipid preferences of clinical sera containing anti-phospholipid antibodies remains to be tied into the evolving recognition that many if not most of these antibodies are recognizing specific lipid-binding proteins in the context of these phospholipid specificities. As reviewed by Rauch and Janoff, preliminary data suggest that kininogens mediate the binding of antibodies to phosphatidylethanolamine, prothrombin, and/or annexin V may be the targets of anti-phosphatidylserine antibodies, and erythrocyte-binding antibodies may recognize a complex antigen involving phosphatidylcholine [87].

Anionic phospholipids, the most common favorable background to promote the binding of antiphospholipid sera, are normally absent from the extracellular surface of cell membranes, but do redistribute from the inner to the outer leaflets during either cell activation or in the early stages of programmed cell death (apoptosis) [88]. Anti-phospholipid antibodies have been found to bind specifically to apoptotic but not viable thymocytes in a β_2-glycoprotein I-dependent manner [89]. Furthermore, the exposed negatively charged phospholipids, such as phosphatidylserine are thought to be potent surface procoagulants, a phenomenon that is ameliorated by the phosphatidylserine-binding protein, annexin V, which has been found bound directly to the outer surface of apoptotic blebs [88].

The findings suggest that the controversy surrounding whether anti-phospholipid antibodies recognize only phospholipid-binding proteins, or sometimes bind to phospholipid alone or a complex antigen may be spurious. *In vivo*, coagulation-regulating proteins are in close association with phospholipids and they may be tightly complexed during hemostatic events. By targeting either phospholipid or the proximate cofactor proteins, heterogeneous antibodies may interfere with the roles of both in coagulation.

Pathogenic Mechanism for the Antiphospholipid Syndrome: Autoantibodies Interfere with Protein Regulators of Hemostasis, Presented to the Immune System on a Phospholipid Template, Which Itself May Be Activated to Contribute to a Procoagulant State

Endothelial Cell Membranes as a Phospholipid Template and a Procoagulant Surface

Sera containing anti-phospholipid antibodies appear to have a high incidence of reactivity with endothelial cells [90–95]. In one study, 47 of 76 anti-phospholipid antibody positive samples bound endothelial cells and this was significantly more frequent in sera from patients with a history of thrombosis than in those without thrombotic history [90]. In a different experiment 23 of 43 SLE patients had anti-phospholipid antibodies and a higher prevalence of endothelium-reactive antibodies [95]. Similarly when 15 patients with antiphospholipid syndrome were compared to 15 with SLE and no thrombotic history, 13 (87%) of the sera from patients with antiphospholipid syndrome had endothelial cell antibodies and only 7 (47%) with SLE alone reacted with endothelial cells [92]. Anti-endothelial cell antibodies were also detected in 20 of 30 patients (67%) with anti-phospholipid antibodies and associated thrombotic history, but in none of 30 patients with thrombosis but no associated anti-phospholipid antibodies [91]. In the latter study there was also no association found between endothelial-binding antibodies and other autoantibodies including ANA, anti-dsDNA and anti-neutrophilic cytoplasmic antibodies.

Some data have suggested the hypothesis, as formulated by Meroni *et al*. [25], that a significant proportion of antibodies binding endothelial cells are actually anti-β_2 glycoprotein I antibodies [92–94]. Monoclonal anti-β_2 glycoprotein I antibodies have been found to bind endothelial cells [93, 94] in a β_2 glycoprotein I-dependent manner [94], and this was associated with increased IL6, adhesion molecule upregulation, and secretion of 6 keto-PGF1α, suggesting activation of endothelium by antibodies in a direction likely to contribute to a procoagulant state.

Other evidence of endothelial activation by endothelium-binding autoantibodies includes increased release of von Willebrands factor [90, 95], higher levels of prothrombin fragments and tissue type plasminogen activator [95], and the observation that membrane lipid turnover may be triggered by these antibodies such that anionic phospholipids are detectable on the surface of the bilayer [93].

β_2-Glycoprotein I is probably not the only endothelium-associated antigen targeted by anti-phospholipid antibodies. A 70-kDa protein has been immune-precipitated from endothelial cells by endothelium-reactive IgG fractions of 5 of 6 patients with anti-phospholipid antibodies [90]. There have been many reports of interference by anti-phospholipid antibodies with anticoagulant proteins that act by binding phospholipids on the surface of endothelial cells *in vivo* [9]. For example, anti-phospholipid antibodies (or plasma containing lupus anticoagulants) have demonstrated effects on the anticoagulant activity of protein C. This has been confirmed using lupus anticoagulant fractions from patients with APLA by a number of laboratories, studying the formation of the thrombin–thrombomodulin complex as well as protein C function using a chromogenic substrate and an assay of factor Va degradation [15, 56–61]. Amer *et al*. demonstrated that one anticoagulant could interfere with an activated protein C-mediated clotting time assay without inhibiting protein C amidolytic function [58]. Lo *et al*. [62] demonstrated inhibition of the anticoagulant activity of activated protein C using plasma from 20/21 patients with APLA. Marciniak and Romond [56] found decreased rates of protein C-mediated factor Va degradation in 15 plasma samples from patients with lupus anticoagulants as compared to controls, and furthermore plasma with LA activity decreased or abolished the factor Va degradation when mixed with normal plasma. All patients in this study were receiving no immunosuppressive or anticoagulant therapy and there were no acute thrombotic episodes. This suggests that the inhibition of protein C activity is a chronic function of these antibodies, occurring in clinically compensated patients, and not necessarily related to the events which lead to acute thrombosis. On the other hand, a chronic deficit in protein C function might still be a predisposing factor for thrombosis which then increases in importance when compensatory mechanisms fail.

Endothelial-Associated Cells as Phospholipid Templates and Procoagulant Factors

Other endothelium-associated structures may play a role as phospholipid-containing templates. Simantov *et al*. found that IgG from patients with anti-phospholipid antibodies increased monocyte adhesion to endothelial cells, dependent on β_2-glycoprotein I but not LPS, Fc interactions with monocyte receptors, or immune complexes [75]. Production of tissue factor by monocytes, a measurement of procoagulant activity, may be induced by anti-phospholipid antibodies or lupus anticoagulants [20, 21]. Pathology of placentas in patients with antiphospholipid-associated fetal loss suggests thrombosis of uteroplacental arteries as well as ischemic damage to placental villi [96]. Annexin V, a phospholipid-binding protein with potent anticoagulant effects has been found to be markedly reduced on placental villi in these patients, and appeared to be decreased in cultured trophoblast cells or endothelial cells in the presence of anti-phospholipid antibodies [97].

Platelets as Phospholipid Templates and Regulators of Hemostatsis

Anti-phospholipid antibodies are known to bind to platelet membrane structures [24, 98–102] and this may result in either thrombocytopenia or hemostatic activation [24]. An association between anti-phospholipid antibodies and immune-mediated thrombocytopenia (ITP) has also been established [98]. In ITP, antibodies to phospholipid membrane-bound glycoproteins have been pathogenically linked to the development of thrombocytopenia, and in one study, 27 of 68 sera with anti-phospholipid antibodies were also found to react to the same glycoproteins [98]. In a different report, anti-platelet glycoprotein antibodies were detected in 15 of 22 plasmas containing lupus anticoagulant activitiy [99]. Antibodies to platelet glycoproteins do not appear to select patients with a history of thrombosis, although there does seem to be a significant correlation with thrombocytopenia [98, 99].

Activation of platelets by a thrombotic stimulus causes a turnover in membrane phospholipids to expose anionic phospholipids on the surface. β_2-glycoprotein I binds preferentially to activated platelets, and β_2-glycoprotein I-dependent anti-phospholipid antibodies have been found to increase their adhesion to platelet surfaces sixfold when the platelets are activated with thrombin and a calcium ionophore [100]. β_2-glycoprotein I also enhances thromboxane A2 biosynthesis by platelets in response to anti-phospholipid antibodies [101], suggesting an additional procoagulant role for the antigen–antibody complex.

Thrombocytopenia occurs in 20–40% of patients with the antiphospholipid syndrome [103] but severe thrombocytopenia and hemmorhage are relatively rare. The actual incidence of platelet function abnormalities in association with anti-phospholipid antibodies is unknown, but decreased platelet aggregation has been observed at our institution on several occasions (J. T. Merrill, unpublished data). Conversely, one investigation of 21 lupus anticoagulant positive samples noted accelerated platelet aggregation by a calcium independant microscopic assay (not using a standardized platelet aggregometer) [104]. It may be that polyclonal antibodies with proaggregation and antiaggregation effects on platelets cancel each other out. Interestingly,

according to data compiled by the Italian Registry of Antiphospholipid Antibodies [31], the rate of clinical thrombosis is significantly decreased in patients with severe thrombocytopenia, although not in those with mild reductions in platelet counts.

Other Phospholipid-Rich Structures as Phospholipid Templates: Cholesterol Transport Vesicles Support an Atherogenic Mechanism for Anti-phospholipid Antibodies

Monoclonal anti-cardiolipin antibodies from the NZW/BXSB mouse model of antiphospholipid syndrome, have been found to cross-react with oxidized low-density lipoprotein (LDL), and a significant correlation was found between binding to cardiolipin and to oxidized LDL [26]. Oxidized LDL may be important in atherogenesis as a mediator of foam cell formation and cell cytotoxicity. Shoenfeld's group has studied the ability of LDL to increase experimentally induced antiphospholipid syndrome in mice. In this model, mice develop an antiphospholipid-like syndrome after receiving an intradermal injection of anti-cardiolipin antibodies [105]. Mice which were subsequently infused with oxidized LDL developed a more severe clinical picture, consistant with worsening antiphospholipid syndrome, including decreased platelet couts, prolonged PTT, and higer fetal resorption rates.

Low levels of apolipoprotein A1, the major protein constituent of high-density lipoprotein [106–108] is also associated with increased risk for atherosclerosis. Accelerated cerebrovascular and heart disease is a complication of systemic lupus, and Lahita *et al*. reported low levels of apolipoprotein A1 in lupus patients, correlated with the presence of anti-phospholipid antibodies [109]. We subsequently isolated a gene for apolipoprotein A1 from a mouse cDNA library screened with serum from a lupus patient who had a CVA [28]. Antibodies against plasma lipoproteins have previously been reported in patients with immune diseases [110–112]. Since natural antibodies binding specifically to apolipoprotein A1 had been described in a murine model [113], attempts were made to identify similar autoantibodies in patients with SLE using standard ELISA and Western blot techniques, but these were at first unsuccessful. Others had observed that apolipoprotein A1 has markedly altered epitope expression in different aqueous and charged phospholipid environments [114–120]. Accordingly, γ-irradiated, oxidized ELISA plates, such as those that were successful in identifying antibodies to β_2-glycoprotein I, were used as an alternative antigen-binding surface, and high-titer antibodies were then identified in the sera of 5/30 patients with lupus [28]. We next collected 520 samples during a 3-year period from 175 patients, including 114 with American College of Rheumatology (ACR) criteria for SLE and 35 with primary antiphospholipid syndrome. These were tested for antibodies to apolipoprotein A1 and positive sera were retested for binding to apolipoprotein incorporated into reconstructed nascent or mature high-density lipoprotein (HDL).

Autoantibodies specific for apolipoprotein A1 were found in 32.5% of patients with SLE and 22.9% of patients with primary antiphospholipid syndrome, associated with concomitant presence of anti-phospholipid (anti-β_2 glycoprotein-I) antibodies [121]. When reconstructed nascent and mature HDL molecules were compared as antigen-containing environments, positive sera reacted best to apolipoprotein A1 embedded in mature HDL molecules. These data confirmed a high prevalence of specific antibodies to apolipoprotein A1 in patients with systemic lupus, and suggest a relatively high affinity of these antibodies for apolipoprotein A1 in mature HDL-like proteoliposomes. Furthermore, there appears to be some at least circumstantial association between the presence of anti-apolipoprotein A1 antibodies and anti-phospholipid antibodies, as suggested both by the relatively high prevalence of anti-apolipoprotein A1 in patients with primary antiphospholipid syndrome and the fact that the majority of patients with anti-apolipoprotein A1 also have anti-phospholipid antibodies.

It can be speculated that an unchecked autoimmune process might give rise to polyclonal antibodies with evolving specificities that move from one protein target to another along a continuous, negatively charged phospholipid surface in a manner similar to the antibody spreading which has been described in several animal models [122, 123]. It is interesting, therefore, that autoantibodies specific both for delipidated β_2 glycoprotein-I and delipidated apolipoprotein A1 are best detected by the use of oxidized, γ-irradiated plates which mimic a negatively charged phospholipid environment.

As has been found with β_2-glycoprotein I, some evidence supports a model in which the most immunogenic epitopes of apolipoprotein A1 are exposed only in the phospholipid milieu of HDL. It is known that different regions of apolipoprotein A1 differ in antigenicity [124] and that apolipoprotein A1 has altered epitope expression in aqueous and charged phospholipid environments [114–120]. Curtiss and Smith [125] described a region at residues 90–105 of apolipoprotein A1 exposed when the protein was incorporated into HDL, but not in aqueous phase. Banka *et al*. [126] found two monoclonal antibodies, derived from immunization of mice with HDL, that were directed against an overlapping peptide of this same region of apolipo-

protein A1 and interfered with its function as the LCAT cofactor.

Phospholipids, then, may play a key role in exposure of cryptic immunogenic and functional epitopes of apolipoprotein A1, which may have relevance both to *in vivo* movement of cholesterol and during the detection of autoantibodies *in vitro* [115–120, 126].

Endothelial activation, increased monocyte adhesion (see previous section) as well as antibodies to oxidized LDL and to apolipoprotein A1 have now been associated with the antiphospholipid syndrome. Taken together these data support the hypothesis that autoantibodies arising in association with anti-phospholipid antibodies may contribute to a wider spectrum of intravascular dysfunction than those inducing the sudden, dramatic thrombosis that characterizes the antiphospholipid syndrome. This may help to explain the reported associations of anti-phospholipid antibodies and myocardial infarction [45, 127] or the premature atherosclerosis that has been described in patients with SLE.

Given the known importance of phospholipids to the function of coagulation proteins, and given these insights into the role of phospholipids in promoting structural modifications to β_2-glycoprotein I and apolipoprotein A1, it can be appreciated that phospholipid may have a widespread, profound role in hemostatic regulation, both functionally and immunologically.

There Are Many Autoantibodies, but Few Are Thrombotic

Antibody spreading has been defined as a natural consequence of the humoral immune response to autoantigens [122, 123]. Given the demonstration that autoantibody specificities can and do spread over associated structures on contiguous surfaces, it seems logical that in a dysregulated autoimmune state such as SLE, anti-phospholipid antibodies might similarly develop unchecked and spread their targets over a wide range of closely associated lipid-binding proteins on interacting phospholipid surfaces of endothelial cells, platelets, and circulating lipoproteins. It would then follow that the culmination of such an evolution might be complete dysregulation of the coagulation mechanism, such as is seen in the minority of patients who develop the malignant antiphospholipid syndrome.

A workable disease model for this syndrome, however, must take into account the apparent contradiction between the wide scope of the antibodies, their comprehensive capabilities for doing harm, and the seemingly unpredictable, sporadic nature of the coagulopathy in most patients. The disease model should furthermore aim to explain the intermittent nature of the thrombosis in a manner that might lead to better predictive testing, and/or provide a strategy to spare therapy for those who do not need it.

Phospholipids Tie Together a Complex Disease Model

Figure 2 demonstrates that it may be possible to develop a simplified, combined model which integrates the concept of phospholipid–protein modulation with the spreading of autoantibodies to develop fine specificities for disparate hemostasis-regulating proteins embedded in endothelial, platelet, and cholesterol transport membranes along continuous phospholipid structures. The net pathogenicity of the antibodies, whether in the short term (hypercoagulable state) or long term (atherosclerosis) would depend on multiple factors. These include the functionality of the specific proteins involved, the epitope(s) bound by specific antibodies, antibody avidity and affinity, which in turn may be influenced by the local density of antigen and antibody or the structure and net charge of the phospholipid environment in which a given antigen is embedded. Finally, both the immune and coagulation systems are finely tuned mechanisms containing many checks and balances. It seems intuitively obvious that pathologic thrombosis results only when multiple dominoes have fallen. In order to differentiate between the low grade prethrombotic state that may chronically exist in this illness and factors which predict risk for acute life-threatening events, it seems logical to focus on clinical clues suggesting risk for sudden collapse in some critical aspect of coagulation feedback regulation.

Pathogenesis of the Antiphospholipid Syndrome: Clues from the Association with SLE. The Coagulopathy Is Sporadic and SLE Is a Disease Characterized By Sporadic Complement Activity

Optimally a disease model would also shed light on various unexplained clinical features of the antiphospholipid syndrome, such as its link to SLE and the fact that in some patients there is a link between thrombotic events and SLE flare [43], in other patients, a link only to pregnancy. In fact, these unanswered questions can be considered as clues to the pathogenesis of the antiphospholipid syndrome, and will be used to develop a new model for thrombosis which specifically addresses them. Although it is likely that the antiphospholipid syndrome is, even in its simplest construct, multifactorial, the current focus will be on a potential coagulation mechanism which is of particular interest because it

involves the most prevalent antiphospholipid antigen, β_2-glycoprotein I, because it can address each of the questions listed earlier, and because there has been increasing clinical evidence in support of this model in human patients.

The coagulation system is recognized as a finely tuned network of checks and balances. APLA may persist for a long time prior to a clotting event. Because the clinical syndrome occurs intermittently, it seems likely that critical components of the coagulation disorder itself are sporadic. In patients in whom antibodies are persistent, but thrombosis is sporadic, acute thrombotic events may be the result of factors which arise intermittently to impair regulatory elements. Under normal circumstances, such regulatory elements might successfully compensate for additional, more chronic deficits induced by anti-phospholipid antibodies. At the time of a thrombotic event, these compensatory mechanisms might fail to operate because the checks and balances of the coagulation cascade become transiently impaired. This model is consistent with the understanding that the coagulation system exists in a complex dynamic equilibrium with internal controls against dysregulation.

Coagulopathy associated with anti-phospholipid antibodies may occur in the presence or absence of systemic lupus erythematosus, but the striking association between SLE and APLA syndrome (APLAS) should be taken into account in considering the pathogenesis of either the primary or secondary syndrome. Since SLE is characterized by intermittent activation and dysregulation of the complement system, it is tempting to speculate that a complement disorder underlies the acute coagulopathy and that this is even a factor which connects lupus and nonlupus patients with antiphospholipid syndrome. In this model, a major clotting event would only occur in the context of events which led to concomitant activation of both complement and coagulation. In the case of a lupus patient this may be a systemic dysregulation of complement activity. In the case of a woman with no disorder other than recurrent fetal loss, it might be a more local problem occurring in the specialized context of the pregnant state in the altered intravascular milieu of the uteroplacental arteries.

Complement activation has been reported in association with the antiphospholipid syndrome and may independently induce hypercoagulability as well [43–49]. Complement activation has been associated with acute manifestations of the antiphospholipid syndrome both in at least one convincing animal study and in human subjects, clinically [43, 44, 46] and with *in vitro* procoagulant activities of anti-phospholipid antibodies [102]. In one study, a direct association of acute antiphospholipid syndrome and complement activation was detected, when the complement membrane attack complex (Sc5b-9) was measured in 26 patients with either TIA or complete cerebrovascular accident. Nine of 13 anti-phospholipid antibody positive patients had abnormal complement levels as opposed to only 1 of 13 anti-phospholipid negative patients with brain ischemia ($p = 0.0018$) [44]. We found elevated complement split products, including C4D, in 6/6 patients with SLE, APLA, and recent thromboembolism (J. T. Merrill, unpublished data). In light of this, it is of particular interest that a logical link between the complement and coagulation systems has more recently been associated with acute manifestations of the antiphospholipid syndrome (see later).

C4b-Binding Protein: A link between Protein C, Its Cofactor Protein S, and the Complement System

Activity of the key anticoagulant feedback modulator protein C, can be inhibited *in vitro* by anti-phospholipid antibodies [59–61]. On the other hand, protein C activity can be enhanced 10-fold by normal plasma levels of its cofactor, protein S. A dynamic equilibrium in the amount of circulating, active protein S may be a critical regulator of the activity and anticoagulant functions of protein C, serving as a final modulation loop in a complex chain of coagulation checks and balances.

Reports of a transient and reversible acquired protein S deficiency at the time of thrombosis in patients with anti-phospholipid antibodies are therefore particularly interesting [128–134]. In several studies, acquired free protein S deficiency was associated with both anti-phospholipid antibodies and procoagulant laboratory measures in patients with SLE and/or the antiphospholipid syndrome [21, 131, 135–137]. On the other hand, some attempts to correlate more chronic deficits of protein S function with the presence of anti-phospholipid antibodies and/or a distant history of clotting events have resulted in either no association or changes with questionable clinical significance [138, 139]. It should be stressed that the phenomenon being sought could either be transient, occurring only at the time of a clotting event, or local, occurring only at the vascular site where the occlusion occurs, and therefore not measurable in a peripheral venous blood sample.

Functional deficiency of free protein S results from enhanced binding of protein S by its circulating plasma inhibitor, C4BP [128]. Given the association of the antiphospholipid syndrome with systemic lupus it is intriguing that C4BP is also a suppressor of the complement system [140, 141]. Each C4BP molecules may

contain up to seven complement-binding subunits and only one shorter arm or β chain which binds and inactivates protein S. It is apparent that C4BP circulates in two forms, a high molecular weight form, containing the protein S-binding β chain (β+) and a lower molecular weight form without this protein-S binding subunit (β–). Levels of total C4BP have been documented to rise in acute phase responses, and more specifically in SLE flare [141]. One study suggests that most of the increase in C4BP is made up of (β–) isoforms, and that in a controlled acute phase response, protein S rises with molar equivalence to the (β+) form [142], essentially providing compensation for the complement activation and allowing normal levels of free protein S to persist. It is unclear how applicable these data are to severe inflammatory states since the average increase in total C4BP in that study was only to 162% and in some acute phase responses levels may rise to 400% [142]. More importantly it has been well documented that in some inflammatory conditions, including acute phase responses, sepsis, disseminated intravascular coagulation (DIC) and systemic lupus, and in specialized states such as pregnancy or during the use of hormonal therapies, free protein S levels do decrease, relative to an increase in C4BP [128–130, 141, 143–147]. One study of 24 patients with severe infection found that the free protein S was significantly decreased relative to an increase of C4BP with evidence of hypercoagulability as well [144]. This kind of functional protein S deficiency is usually transient, but is associated with risk for thrombosis [128].

We hypothesize that a unique disturbance of the normal checks and balances of the complement system occurs in patients with the antiphospholipid syndrome and alters the binding equilibrium between C4BP and protein S. This may become a particular problem at a critical juncture of a lupus flare or in the special environment of the uteroplacental interface in certain pregnant women. In fact, in normal pregnancy, complement deposition reflective of classic pathway activation is found locally in the uteroplacental arteries [148–151]. Furthermore, protein S declines and C4BP levels increase reaching a peak in the second trimester when abortion is most frequent in the antiphospholipid syndrome [152, 153].

Some evidence suggests the possibility of a circulating plasma factor which regulates and opposes the inhibitory binding of protein S by C4BP [154]. Clinical support for this hypothesis was provided by one description of a patient who was found to have abnormally increased binding of protein S by C4BP in the presence of calcium [155]. This was corrected by the addition of normal human plasma, strongly suggesting that the patient had a deficiency of a plasma constituent which inhibits calcium dependent association of protein S with its inhibitor. Intriguingly, one study of 73 patients with anti-phospholipid antibodies found deficiencies of free protein S but not increased C4BP in patients with lupus anticoagulants, indicating abnormal uptake of protein S by C4BP which was unrelated to its plasma levels [135]. This might be explained by interference of these antibodies with a normal plasma regulator of protein S–C4BP binding.

As discussed earlier, the phospholipid-binding anticoagulant protein β_2-glycoprotein I is a likely candidate as a primary antigen for pathologic anti-phospholipid antibodies [70]. The structure of β_2-glycoprotein I is that of repetitive sushi domains, homologous to members of the complement control superfamily, including consensus sequences strongly homologous with C4BP [156]. Antibodies to β_2-glycoprotein I have been found to inhibit factor Va degradation by activated protein C and its cofactor protein S, suggesting a role for β_2-glycoprotein I in promoting the protein C–protein S anticoagulant function [157]. In a preliminary report, Walker found that β_2 glycoprotein-I interferes with the binding of protein S to C4BP [158], although the functional significance of this binding in fluid phase plasma was not known. Based on these data, we undertook experiments to determine whether β_2-glycoprotein I interferes with binding and functional inhibition of protein S by C4BP [78, 159]. We found that fluid phase β_2-glycoprotein I interferes with capture of protein S by immobilized C4BP and that β_2-glycoprotein I reverses inhibition of protein S anticoagulant function by C4BP in a dose-responsive manner. This effect was reversed, in an epitope specific manner by one of four monoclonal antibodies specific for human β_2-glycoprotein I [159]. Subsequently, after we and others found a high prevalence of antibodies specific for protein S in patients with lupus and/or the antiphospholipid syndrome [162–164], we found that dual reactivity of antibodies to both protein S and β_2-glycoprotein I described an interesting subset of patients with a strong correlation to a history of thrombotic events [164]. We and others have also noted an anecdotal relationship between free protein S deficiency and the presence of these autoantibodies [162, 164]

Taken together, these data suggest a model to explain at least a key subset of sporadic thrombosis associated with anti-phospholipid antibodies. Anti-β_2-glycoprotein I antibodies interfere with its ability to counter the inhibition of protein S by C4BP. Antibodies to protein S may impair this relationship in a synergistic manner. This chronic imbalance is normally compensated by a controlled release of different C4BP subunits. Alteration of systemic or local complement equilibrium in lupus, pregnancy, or other as yet undefined physiologic

states leads to excess C4BP containing protein S-binding subunits and/or because of antibody interference with β_2-glycoprotein I, a functional protein S deficiency is either initiated or worsens to a critical point, resulting in thrombosis.

In this model, even though complement activation might be a local vascular phenomenon, increased circulating total C4BP and/or β_2-glycoprotein I might be identifiable and measurable in patients. Problems which may arise in their detection include the possibility that antibodies to β_2-glycoprotein I may quickly remove it from the circulation and thereby decrease its apparent concentration and the finding that the degree of protein S binding to C4BP may be in delicate balance depending on the medium in which it is measured, in particular the calcium concentration [160, 161]. This may apply to the binding and measurement of β_2-glycoprotein as well. Further studies of these relationships are ongoing in a number of laboratories and it can be hoped that with further work in this area, greater insight into the acute pathogenesis of the antiphospholipid syndrome may emerge.

IMPLICATIONS FOR LUPUS

Pathophysiologic Implications for Lupus

What do insights about anti-phospholipid antibody pathophysiology contribute to our understanding of lupus? This intriguing question can be approached from the point of view of what is special about these antibodies. Unlike most autoantibodies, the antigenic targets of anti-phospholipid antibodies are not intracellular proteins. The targets themselves are ubiquitous bloodstream proteins that would be considered normally accessible to immune surveillance. Given this indisputable fact, the mechanistic evidence reviewed earlier provides a unique kind of circumstantial confirmation of two important hypotheses that have emerged in the study of lupus pathophysiology: (1) autoantibody spreading (2) the existence of cryptic epitopes. Circumstantial support for the former is provided by the fact that once patients develop autoantibodies to one, relatively accessible bloodstream protein, the immune response would be more likely to spread to a ligand for that protein (complementary structure) than to an unrelated structure. We have confirmed a circumstantial association between antibodies to protein S and its ligand, β_2-glycoprotein I but not to prothrombin, another antiphospholipid target, which is consistent with this model [164]. Direct evidence that there are cryptic epitopes for phospholipid-binding proteins have also been reviewed previously [84, 85, 120, 121]. Circumstantial evidence in support of this model is provided by the fact that patients only develop pathologic thromboses sporadically and intermittantly. If antigenic determinants were freely accessible in their most avid form at all times, it would seem less likely that this would be the case.

Clinical Implications for Lupus: Integrating an Evolving Pathophysiologic Model into Current (Albeit Limited) Approaches to Predicting Thrombotic Risk for Patients

A better understanding of pathologic anti-phospholipid antibodies and the epitopes they bind may someday lead to safer and more specific therapies for this disorder. However, the current standard of care is simply to recognize the association between these antibodies and recurrent thrombosis and to initiate anticoagulation therapy after a serious thrombotic risk has been confirmed. Given the limited therapeutic options at this time, and the limited scope of predictive testing despite new insights into likely pathogenic models, therapeutic issues primarily revolve around when and for whom to initiate global anticoagulant treatment and how aggressive the treatment should be. Critical to these decisions is the ability to utilize the available tests wisely in determining an accurate diagnosis and establishing thrombotic risk to the patient. Since pathologic epitopes, functional studies for potential thrombotic risk, are neither widely available nor clinically validated, we must rely on a less well-integrated mix of clinical clues which may be, at best, indirect markers for patients at risk. However, by keeping the concepts discussed previously in mind, and reviewing the clinical risk factors that have been more or less validated to date, there seems to be compelling reason at this time not to rely today on a single test at a single time point or a single, relatively minor event to rule the diagnosis of this syndrome in or out, or in predicting future risk for a given patient.

Clinical Predictors of Outcome

Assays to Detect Anti-phospholipid Antibodies: What to Order and How to Interpret It

Despite laudable international efforts to introduce conformity into both ELISA and lupus anticoagulant assays, current widely available tests to detect antiphospholipid antibodies are not well standardized. Nevertheless the published literature has relied almost completely on these assays as the only means of distinguishing antiphospholipid patients, and it is this literature upon which current understanding of the epidemiologic features of the disorder rests.

The association of thrombotic risk with high titer IgG anti-cardiolipin or anti-phoshpholipid antibodies, especially if combined with a positive assay for lupus anticoagulant, has been confirmed in several different studies [7, 164–167]. In one 4-year follow-up of 321 women with anti-phospholipid antibodies, patients with IgM or lower level IgG anti-cardiolipin antibodies were not at risk for antiphospholipid-related disorders [166]. However, 12 of 129 patients who had either IgM or low IgG at the start of this study, developed higher levels of IgG or lupus anticoagulants during the 4-year period. Of these, half experienced at least one thrombotic complication [166]. This indicates that lupus patients or other patients at risk should be retested for anti-phospholipid antibodies over time if negative, particularly if they develop new or recurrent clinical symptoms suggestive of the antiphospholpid syndrome.

This brings up the question of whether it makes sense to test each patient by multiple techniques to increase the sensitivity of these assays, as has been suggested repeatedly in the literature [34, 80, 168–171]. In one study of 1513 sera from 399 patients [169], 60% of the samples containing anti-phospholipid antibodies reacted to phospholipids other than cardiolipin, the most commonly used phospholipid in commercial assays. Considering only the more pathologic IgG subtypes, reactivity to phosphatidylserine was more prevalent than reactivity to cardiolipin. Reactivity to phosphatidylethoanolamine was also relatively common [169]. In another report of 141 sera tested using both anionic and zwitterionic phospholipids 79 phospholipid-reactive sera were found. Of these 11 reacted with noncardiolipin phospholipid, of which 7 patients had a history of ether recurrent fetal loss or thrombotic events [168]. This confirms the need to use more than just the anticardiolipin assay in obtaining a diagnosis for high risk patients. In one intriguing study, IgG from women with clinical features suggestive of the antiphospholipid syndrome but negative at one point in time in both anti-phospholipid antibodies and lupus anticoagulant assays, were tested in a murine passive immunization model, causing significantly more fetal loss in the mice than control IgG [170]. Either low titer anti-cardiolipin or anti-phosphatidylserine antibodies were subsequently found in some, but not all of these women.

It seems likely that the laboratory analysis of antiphospholipid antibodies will continue to evolve over the coming years. Bilayer phospholipids of varying composition may be used increasingly to provide a more physiologic substrate in the detection of these antibodies in combination with various lipid-binding proteins [172]. Given the multiple protein antigens now associated with the antiphospholipid syndrome, and the emergence of clinical tests to detect anti-β_2-glycoprotein I and antiprothrombin antibodies, assays to detect antibodies for a wider range of lipid-binding proteins such as protein S, thrombomodulin, tissue factor, or annexin V may also become available in the near future, although their ultimate usefulness as add on testing in whole protein assays remains to be determined. It is now understood that some lupus anticoagulants are directed against β_2-glycoprotein, some against prothrombin, and some antibodies against β_2-glycoprotein and prothrombin are not lupus anticoagulants [80]. Whether or not antibodies predictive of pathology can be definitively ruled in or out based on some combination of these assays remains to be determined, but it seems unlikely. Major advances in the development of specific and sensitive assays for the diagnosis of the antiphospholipid syndrome await more comprehensive understanding of the coagulation disorder(s) and the specific epitopes involved on the coagulation proteins that may be involved.

Some commercial antiphospholipid assays incorporate mixed phospholipids and β_2-glycoprotein into one ELISA. Since it is now thought that different phospholipid environments may differentially affect detection of anti-β_2-glycoprotein antibodies, it is not clear that the net effect of this mixture would increase the range or sensitivity of this assay. It seems logical, however, to use up to three different assays from the more easily available common testing methods first, such as an anticardiolipin and/or antiphosphatidylserine test plus lupus anticoagulant assays (here, too, sensitivity may be increased employing three different LA tests, including one employing hexagonal phase phospholipids). Where available, an anti-β_2-glycoprotein immunoassay should be employed using γ-irradiated ELISA plates, which, by eliminating phospholipid-specific antibodies associated with infections, may be more specific for the autoimmune syndrome. To further analyze the sera of patients for whom there is a high suspicion of this syndrome but the previously mentioned tests are negative, it might be worth obtaining a more comprehensive testing battery, particularly if a laboratory can be found capable of testing for antibodies to β_2-glycoprotein against different phospholipid backgrounds.

Positivity in a specific anti-β_2-glycoprotein I immunoassay has been more closely associated with the clinical manifestations of the antiphospholipid syndrome than positivity in conventional anticardiolipin ELISA [101, 173]. Unlike the anticardiolipin assay, there appears to be less chance of false-positive results for syphilis patients using the assay specific for β_2-glycoprotein I [16, 174]. This assay, which at any given point in time appears to be specific but not sensitive in detection of the antiphospholipid syndrome [101], has become commercially available.

Anti-phospholipid antibodies produced by syphilis patients can be distinguished from autoimmune anti-phospholipid antibodies by several methods. In one report, 20 SLE patients and 16 syphilis-infected patients with high titer IgG anti-phospholipid antibodies were further tested. Antibodies from syphilis patients had lower avidity, predominance of κ light chains, and IgG1 or IgG3 subclasses, whereas antibodies from lupus patients had higher avidity, λ light chains, and IgG2 or IgG4 subclasses [175]. In a different study, a similar finding distinguished sera reacting only to cardiolipin (predominance of IgG3 and IgG1) from those which reacted to anticardiolipin plus β_2-glycoprotein I (IgG2, λ light chain predominance) [52]. It therefore appears that syphilis patients are more likely to have true anti-phospholipid antibodies, further characterized by κ light chains and IgG1 or IgG3 subclasses. Autoimmune patients, especially those at risk for the antiphospholipid syndrome are more likely to have β_2-glycoprotein I-dependent anti-phospholipid antibodies, characterized by λ light chains, IgG2, or possibly IgG4. However, unlike syphilis-infected individuals and patients infected with other viruses, anti-phospholipid antibodies arising in the context of Parvovirus B19 exposure do not appear to be similarly distinguishable from autoimmune anti-phospholipid antibodies [176]. The clinical significance of this finding remains unclear.

It has not yet been possible to identify distinguishing characteristics of antibodies which can predict which patients with SLE and anti-phospholipid antibodies are at increased risk for thrombosis. For example, one attempt to differentiate anti-phospholipid antibodies from SLE patients with fetal death on the basis of isotype, subclass, lupus anticoagulant activity, phospholipid specificity, and avidity, found no associations [29].

In summary, the lack of standardization in the tests currently available to clinicians, coupled with evidence that patient results may change over time using these assays, indicates that patients at risk should be tested using more than one technique and retested over time if negative, particularly if they develop new or recurrent clinical symptoms suggestive of the antiphospholipid syndrome. It seems obvious, however, that to avoid excessive false-positive diagnoses, the use of more than one assay in the detection of the antiphospholipid syndrome should only be used for patients at apparent high clinical risk, and in the absence of other explanations for thrombosis. Multiple assays may not only increase the sensitivity of detection, but positive results on multiple assays can be considered confirmatory, and to some extent prognostic. For example, three assays positive for anti-phospholpid antibodies at conception has been associated with a major risk for obstetric complications [171].

The antiphospholipid syndrome was identified as a poor prognostic factor for survival in one cohort of 667 patients, and a stepwise cox multivariate analysis suggested that this was primarily attributable to either thrombocytopenia or arterial occlusions [177]. A different group of 360 patients with lupus anticoagulants with or without anti-phospholipid antibodies were followed in a 4-year prospective study. Thirty-four developed thrombotic complications, suggesting an overall incidence of 2.5%/patient year. Two independent risk factors identified were history of previous thrombosis or presence of an IgG anti-cardiolipin antibody with a binding strength of greater than 40 international units [178]. Of some concern, 4 patients in the original group of 360 developed non-Hodgkins lymphoma.

Other Considerations to Help Establish Thrombotic Risk

Immunologic tests such as the assays discussed earlier do not establish thrombotic risk for patients until some morbidity, usually a life-threatening thrombotic event, has occurred. There are a few additional tests which might indicate the likelihood of thrombotic risk prior to clinically obvious disease, but it has not as yet been determined whether these should be used either routinely in lupus patients with high titer anti-phospholipid antibodies or to initiate anticoagulation earlier than might occur under the current standard of care. In certain clinical situations these tests might also be helpful in establishing a diagnosis when the history suggests the possibility of thrombosis but remains equivocal.

Pregnancy Loss

Spontaneous abortion in the antiphospholipid syndrome is strongly associated with fetal loss, as opposed to earlier first trimester loss, but first trimester loss is also well described in this syndrome. In one study of patients with recurrent pregnancy loss [179], the specificity of fetal death for patients with anti-phospholipid antibodies was 76%. Conversely, the specificity of two or more early first trimester abortions for the ability to select patients with anti-phospholipid antibodies was 6%. Nevertheless, in the same study, although more than 80% of women with anti-phospholipid antibodies had at least one fetal death by history, only 50% of overall anti-phospholipid antibody-related abortion involved fetal death. This leaves a clinician in doubt about what to do in a second pregnancy when a lupus patient with high titer IgG anti-cardiolipin antibodies suffers a first trimester pregnancy loss. It is apparently not warranted to initiate heparin in a subsequent pregnancy on the basis of this insufficient evidence [180].

However, this is often a highly charged issue for patients, who request to know if anything more can be done diagnostically.

One strategy, if the loss is late enough and tissue available, is to have the placenta examined. Given the fact that villous infarction is rare in first trimester abortion, finding this clear-cut clue in the placenta from a patient with anti-phospholipid antibodies might alter the strategy for the next pregnancy [181]. One study also indicates that IgG anti-cardiolipin antibodies can be eluted from placentae of patients with the antiphospholipid syndrome but not from controls [182]. Not surprisingly, β_2-glycoprotein I is also found bound to both normal and control placentae, located in the syncytiotrophoblast [182].

There is evidence that placental pathology in the antiphospholipid syndrome is repeated in subsequent pregnancies [183]. Therefore, when antiphospholipid positive lupus patients with past early first trimester loss reach term or near term in a subsequent pregnancy, placental pathology should not be overlooked due to the happy outcome, especially with low birth weight infants. Similarly, when a subsequent pregnancy reaches the second trimester in a patient for whom there is some but not definitive suspicion of the antiphospholipid syndrome, fetal size should be closely monitored. One study also suggests that abnormal resistance of uterine arteries at 18–24 weeks gestation (measured by velocimetry) may predict pregnancies at increased risk for obstetric complications [171].

Cerebrovascular Monitoring

Optimally, patients with high titer IgG antiphospholipid antibodies and established transient ischemic attacks (TIAs) should be anticoagulated before serious cerebrovascular accidents occurred. However, in practice, TIAs may or may not be clear-cut from a patients description, if they are described at all. A thorough history is obviously of primary importance, but even so, there is a large gray zone between the description of fearful, but equivocal symptoms, and making a commitment to lifelong, or at least indefinitely long anticoagulation. CT or MRI neuroimaging findings in patients with possible TIAs may also be difficult to interpret. Results range from cerebral atrophy to focal infarcts, which appear to be fairly common and are of uncertain significance [184]. On the other hand angiography of these patients may demonstrate more dramatic abnormalities, including clear-cut stenosis and subclinical occlusions [184]. There is one report suggesting that single photon emission computerized tomography (SPECT) may be useful in demonstrating decreased cerebral blood flow in patients with the antiphospholipid syndrome [185], although its usefulness as a predictive test remains unclear. A relative decrease in total cerebral circulation and increased asymmetry of arterial blood flow has also been reported, using ultrasonic duplex scanning to distinguish between patients with SLE who did or did not have concomitant antiphospholipid syndrome [186]. Again, the usefulness of this interesting approach in predictive testing remains to be evaluated. Lockshin's group has found strong evidence for a cardioembolic etiology in antiphospholipid-related stroke [187], so the importance of obtaining an echocardiogram for patients with known or suspected TIA cannot be overstressed. In an additional study either anti-cardiolipin antibody or lupus anticoagulant were found in all 35 of 41 patients with Sneddon's syndrome (defined as cerebrovascular disease and livedo reticularis). Thirty-four percent of these patients had evidence of ischemic heart disease and 13/32 of these patients were found to have mitral valve thickening, again suggesting a link between the heart and the brain. Although arterial occlusion accounts for most reports of cerebrovascular accidents in the antiphospholipid syndrome, hemorrhagic venous infarction (in the context of dural sinus thrombosis) has also been described [188], stressing the importance of confirming a pure thrombotic event prior to initiating anticoagulation, even in patients with this syndrome.

Monitoring the Kidney

There is evidence to suggest that the kidney may be a more frequent target organ in the antiphospholipid syndrome than may have been previously appreciated [189]. Clinical manifestations may easily be confused with lupus nephritis, including proteinuria, hypertension, and/or acute renal failure. The pathology is clearly thrombotic, however, stressing the importance of renal biopsy in patients with SLE and apparent renal disease, since the first line of therapy for thrombotic kidney disease is probably anticoagulation rather than immune suppression.

Drug-Induced Anti-phospholipid Antibodies

Anti-phospholipid antibodies have now been found in association with medications known to induce lupus-like syndromes [190, 191]. Our laboratory found a high incidence of anti-phospholipid antibodies in patients taking procainamide, whether or not there was clinically evident drug-related lupus [190]. These antibodies have characteristics similar to autoimmune anti-phospholipid antibodies, as opposed to the infectious type [190, 191], including direct binding to β_2-glycoprotein I in the oxidized plate system [191]. It remains to be determined whether these antibodies increase risk for thrombosis in a population that may already be at high risk for heart and vascular disease.

The Epidemiology of Recurrence: Is Risk Predictable?

It is widely accepted that recurrent thrombosis in the antiphospholipid syndrome has a tendency to mimic the original thrombotic event, with arterial thrombosis following arterial occlusion and venous following venous [192]. Although clinical observation appears to follow these observations to a significant extent, the study cited involved only 20 patients, and none were followed during subsequent pregnancies. Clinical experience confirms the impression that thrombotic patterns tend to be repetitive to the point that some patients, followed for many years, specifically suffer recurrent deep venous thrombosis (DVT) or, alternatively, recurrent pregnancy loss, but no other sequelae of the syndrome. Several studies performed in an attempt to predict risk factors for pregnancy, however, confirm the intuitive impression that there are multifactorial outcomes in this multifactorial disease, citing, along with the known risks of high IgG anti-phospholipid antibodies and history of previous miscarriage, the additional factors of thrombocytopenia and/or other previous thrombotic events as predictors of adverse pregnancy outcome [31, 178, 193].

PATHOPHYSIOLOGY OF DRUG-INDUCED LUPUS

Raymond L. Yung
Bruce C. Richardson

PATHOPHYSIOLOGY OF DRUG-INDUCED LUPUS

Since the initial reports of iatrogenic autoimmunity in the 1940s [1], over one hundred drugs have been implicated in the induction of lupus and lupus-like illnesses [2, 3]. Drug-induced lupus (DIL) is perhaps one of the clearest examples of an environmental agent directly causing a systemic autoimmune disease. Since the inciting factors of most autoimmune diseases remain unknown, the observation that specific drugs can induce autoimmunity in susceptible individuals provides a unique opportunity to study early steps in the pathogenesis of autoimmunity. The significant overlap in signs, symptoms, and serologic findings between idiopathic systemic lupus erythematosus (SLE) and DIL suggests that DIL is also a valid model for the study of idiopathic lupus. Thus understanding the mechanisms underlying DIL will likely have important implications for understanding the mechanisms causing idiopathic SLE.

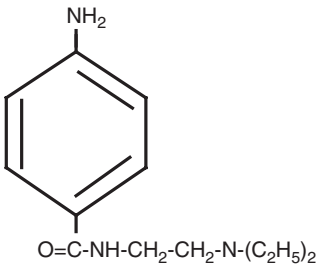
Most investigations into the mechanisms of DIL have focused on procainamide and hydralazine, since these drugs are most frequently implicated in DIL. However, different drugs can cause diverse clinical manifestations with different autoantibody specificities, suggesting that more than one mechanism may be involved. Furthermore, a drug may trigger autoimmunity by more than one mechanism. Advances, including the development of murine models of DIL, have helped clarify the pathophysiology of this disease and its relationship to idiopathic lupus and autoimmunity in general. This chapter will review proposed mechanisms of DIL and summarize the current theories for the pathogenesis of DIL, with an emphasis on *in vivo* models.

STRUCTURES OF DRUGS CAUSING DRUG-INDUCED LUPUS

The drugs implicated in DIL include antihypertensives, antiarrhythmics, antibiotics, anticonvulsants, psychotropic agents, and anti-inflammatory medications. Although drugs implicated in DIL have diverse pharmacologic properties, it is tempting to postulate that they, or their metabolites, may share a common pathogenic epitope, or pharmacophore, responsible for eliciting autoimmunity in affected patients. The drugs most commonly associated with DIL contain aromatic amines, hydrazines, sulfhydryl groups, or a phenol ring [4] (Fig. 1). However, the considerable overlap between clinical features of DIL caused by drugs with these diverse chemical structures suggests that no single configuration is responsible for DIL.

ANTI-DRUG ANTIBODIES

Lupus-inducing drugs are generally poor immunogens, and antibodies raised against them have not been shown to be pathogenic in humans or experimental systems. In support of this, only 6% of patients with



Procainamide

procainamide-induced lupus have antibodies against procainamide, compared to 50% of all patients receiving the drug [5]. Interestingly, "natural" antibodies to procainamide have been found in sera of 19–35% patients with idiopathic lupus and rheumatoid arthritis, and in up to 30% of healthy adults never exposed to the drug. These data suggest that development of clinical DIL from procainamide does not depend on the presence of anti-drug antibodies, and that these antibodies are unlikely to cross-react with autoantigens *in vivo* to cause DIL. However, antibodies to a drug–macromolecule complex may cross-react with unrelated autoantigens to cause clinical disease. For example, in one report, all patients with active hydralazine-induced lupus demonstrated anti-hydralazine antibodies [6]. In a second prospective study, anti-hydralazine antibodies were detected in 16 of 21 patients who had received the drug for 1 year [7]. The high incidence of anti-hydralazine antibodies, together with the structural similarities between hydralazine and the nucleotide adenosine, led to the suggestion of possible molecular mimicry and antibody cross-reactivity as a pathogenic mechanism for hydralazine-induced lupus. In support of this, Yamauchi *et al*. [8] demonstrated that rabbits hyperimmunized with hydralazine conjugated to human serum albumin can produce anti-hydralazine antibodies that cross-react with DNA.

Treatment with anti-TNF (tumor-necrosis factor) therapies has been associated with the appearance of anti-nuclear antibodies (ANA), anti-double-stranded (ds)DNA and occasionally clinical lupus [9]. Approximately 13% of patients exposed to infliximab develop infliximab-specific antibodies. Antibody development is lower in recipients on concurrent immunosuppressants such as methotrexate or azathioprine. The presence of antibodies to infliximab increases the likelihood of an infusion reaction but does not predict the development of autoantibodies or DIL. Nonneutralizing antibodies

to the TNF receptor portion or other protein components of etanercept are present in up to 16% of rheumatoid arthritis patient receiving etanercept. There does not appear to be any correlation between antibody development and clinical response or autoimmunity.

DRUG–DNA INTERACTIONS

A number of mechanisms have been proposed to explain how procainamide and hydralazine cause DIL, based on the observation that both procainamide and hydralazine bind polynucleotides *in vitro*. The resulting drug–DNA structures may potentially be more immunogenic than the native DNA molecule. In addition, the amino and hydrazine groups of procainamide and hydralazine are reactive with nucleoproteins [10–15] which may augment their immunogenicity. This raises the possibility that DNA may be modified by these agents in a fashion analogous to haptens, making the DNA more antigenic. These two drugs, and to a lesser extent, isoniazid and D-penicillamine, have also been shown to induce a stable transition from the B (right-handed) to Z (left-handed) configuration of synthetic DNA [16]. DNA in the Z configuration is more immunogenic [17, 18] and the drug–DNA complex may cause the formation of some of the autoantibodies found in DIL. Several studies have demonstrated anti-Z-DNA antibodies in hydralazine-treated patients [19–21] with one reporting that 82% of sera from hypertensive patients receiving hydralazine had evidence of anti-Z-DNA antibodies [20]. In four patients where sera were drawn sequentially, the investigators were able to show that the antibodies developed after the initiation of hydralazine. In this context it is significant that increased levels of natural polyamines have been demonstrated in sera from patients with active idiopathic lupus [22] and some of these polyamines are capable of inducing Z-DNA conformation, possibly contributing to the anti-Z-DNA antibodies demonstrated in idiopathic lupus [23–25]. Hydralazine may also stabilize another unusual and potentially immunogenic form of DNA, known as triplex DNA [26]. Up to 72% of sera from hydralazine-treated patients may have antibodies against triplex DNA. At present, the clinical relevance of these observations is unclear.

DRUG–HISTONE INTERACTIONS AND ANTI-HISTONE ANTIBODIES

Histones are highly conserved DNA-binding proteins that are rich in basic amino acids. There are five major histone subclasses: Hl, H2A, H2B, H3, and H4. (see Chapter 12.) Antibodies against histone subunits are commonly detected in patients with DIL. However, the precise role of these and other autoantibodies in the pathogenesis of DIL is unclear. There are considerable discrepancies among published studies on the fine specificity of anti-histone antibodies in patients with DIL. Part of this may be due to the purity of the substrates used and the different assay conditions employed [27]. In addition, the specificity of anti-histone antibodies appears to differ from those found in idiopathic SLE [28, 29]. Hydralazine has been shown to interact with soluble DNA–histone complexes [30]. The resulting change in structure makes the histone more resistant to proteolytic digestion. The altered structure may also be more immunogenic, suggesting an explanation for the high incidence of anti-histone antibodies in these patients. Different drugs also induce anti-histone antibodies with different fine specificity. It is worth noting that anti-histone antibodies can have higher affinity to native than purified histones. Burlingame *et al*. [31] examined the reactivity of anti-histone antibodies in lupus patients, and demonstrated preferential binding to chromatin and selected histone–DNA subnucleosome complexes compared to purified DNA. Consistent with this, Mohan *et al*. [32] studied autoreactive T-cell clones from lupus-prone mice, and showed that 50% of the clones had specificity against nucleosome antigens and not free DNA or histones. These observations raise the possibility that the immunogenic form of DNA may be the nucleosome, possibly modified by drugs. A pathogenic role of histone or anti-histone antibodies has not been demonstrated. However, one study suggested a statistical correlation between the presence of anti-(H2A-H2B), anti-(H2A-H2B)-DNA, anti-chromatin antibodies, and proteinuria in idiopathic lupus [31].

ABNORMAL IMMUNE REGULATION

Inconsistent results have been reported concerning the *in vitro* effects of lupus-inducing drugs on cells of the immune system. Depending on the concentrations tested, procainamide either promotes or inhibits the mitogenic response of peripheral blood lymphocytes [33–36]. Low concentrations of procainamide hydroxylamine (PAHA), a reactive oxidized metabolite of procainamide, have been shown to enhance lymphocyte mitogenic responses and promote B-cell immunoglobulin (Ig) secretion. Opposite effects, however, have been reported when higher concentrations of the drug were tested [35, 36]. Another report found that sera from patients receiving procainamide will inhibit the Concanavalin-A mitogenic response of peripheral

blood mononuclear cells from normal and procainamide-treated patients [37]. Similarly, T cells from patients with procainamide-induced lupus demonstrate decreased proliferative responses [38]. Most, but not all, researchers report B-lymphocyte activation and increased Ig production in procainamide-treated patients [39–41]. Patients with active procainamide-induced lupus have circulating B cells that spontaneously secrete Ig, and B-cell Ig production in response to pokeweed mitogen is enhanced [42, 43] similar to patients with idiopathic lupus. In one *in vitro* study, researchers showed that procainamide may inhibit T-cell suppressor activity, resulting in excessive B-cell activation. Yet another report found increased Ig production in procainamide-treated patients without concomitant change in T-cell suppressor function [43]. The reason for the inconsistent reporting is not clear, but may in part be related to conditions under which the assays were performed.

The effects of other lupus-inducing drugs on cellular immune responses are less well studied. Peripheral blood lymphocytes of patients with hydralazine-induced lupus have been shown to have a higher transformation index compared with lymphocytes from untreated patients [44]. Litwin *et al*. [45, 46] examined hydralazine-treated patients, and found normal delayed hypersensitivity responses as measured by skin testing. The peripheral blood lymphocytes from the same group of patients had normal mitogenic responses, but had increased proliferation after incubation with hydralazine–albumin conjugates. Decreased suppressor T-cell function, with enhanced B-cell Ig production, has been reported in patients taking methyldopa, and in normal T-cells treated with methyldopa *in vitro*. Others, however, found depressed peripheral blood mononuclear cell mitogenic responses after methyldopa treatment [47]. Diphenylhydantoin was found to inhibit lymphocyte proliferation [48], but had no effect on T-cell suppressor function [49].

A number of cytokine/anticytokine therapies have more recently been reported to cause autoimmunity in humans. Between 0.15 and 0.7% of interferon-α (IFN-α) treated patients develop a lupus-like illness [50, 51]. Interestingly, IFN-α levels are increased in idiopathic lupus and may correlate with anti-DNA antibody titers [52]. It has been postulated that IFN-α may modulate autoimmunity through its effects on apoptosis. However, this is uncertain because IFN-α has been shown to upregulate the expression of both the pro-apoptotic Fas ligand [53] and the antiapoptotic Bcl-2 [54] genes on lymphoid cells. Because IFN-α induces IFN-γ expression, it is also possible that IFN-α-induced lupus occurs in part through IFN-γ-dependant mechanisms. There are additional data showing that the cytokine may activate autoreactive T cells by stimulating viral superantigen production [55]. Finally, another report suggests that IFN-α may drive the autoimmune response in lupus by inducing monocyte differentiation into antigen-presenting dendritic cells [56].

The mechanism behind anti-TNF therapy-associated lupus is unclear. Serum levels of TNF and soluble TNF receptors are increased in patients with idiopathic lupus, and may correlate with lupus disease activity [57–59]. TNF and interleukin-1 (IL-1) β expression are also increased in the kidneys of MRL/lpr mice with autoimmune lupus nephritis [60]. In contrast, NZB/NZW F1 mice have low serum TNF levels. TNF supplementation prior to the onset of nephritis in these mice delays proteinuria and improves survival, but does not affect anti-DNA antibody production [61]. One postulated mechanism is that anti-TNF antibodies may bind to TNF-α-bearing cells, inducing apoptosis and the release of potentially immunogenic nuclear antigens into the circulation [9]. Interestingly, newly described members of the TNF/TNF receptor family of proteins, including B-cell-activating factor (BAFF, also known as BlyS, zTNF4) and APRIL, and their receptors TACI, BCMA, and BAFF-R, have been implicated in the pathogenesis of lupus [62]. However, the relationship of these molecules and TNF antagonist-induced autoimmunity is unclear.

GENETIC FACTORS

Human Leukocyte Antigen and Complement

Extensive studies have documented the association between specific major histocompatibility complex (MHC) alleles and the development of idiopathic lupus [63, 64]. These include human leukocyte antigen (HLA)-DR2 and HLA-DR3, and class III C4A and C4B null alleles of complement (reviewed in Chapters 4 and 5 of this book). In contrast, there are only limited and sometimes conflicting reports of HLA associations in DIL. Initial studies from England by Batchelor *et al*. [65] showed that 79% of patients with hydralazine-induced lupus expressed the HLA-DR4 allele, compared with 25% of asymptomatic patients receiving hydralazine. Twenty-five of the 26 patients with hydralazine-induced disease were also slow acetylators. No association between the presence of DR4 and acetylator phenotype was found. In 1987, a second English study [66] also reported an association between the HLA-DR4 allele and hydralazine-induced lupus. The researchers found that 70% of their 20 patients studied were HLA-DR4 positive, compared with 33% of the

general population. Of note, 6 of the 20 patients were also included in the initial study by Batchelor *et al*. [65]. In contrast, a third study from Australia failed to find an increased incidence of HLA-DR4 in 18 patients with hydralazine-induced disease when compared to untreated controls [67]. It now appears that the putative HLA association in the initial English study may be the result of linkage disequilibrium with the complement C4 null allele. C4 is encoded at two loci, C4A and C4B, located between the class I MHC and HLA-DR genes. Multiple alleles, including null or nonfunctioning alleles, are present within each of these loci [68]. When the researchers from the English study reexamined their patients, they found a much higher incidence of the C4 null allele in the study group (16 of 21 patients, or 76%) compared with controls (35 of 82 patients, or 43%) [69]. The observed HLA-DR4 association is possibly the result of linkage disequilibrium between the C4-null-DR4 haplotype and the C4 null trait. Of note, partial deficiencies of C4, especially the C4A isotype, are risk factors for idiopathic lupus. The occasional patients with total C4 deficiency have a high incidence of the disease [70].

Another potential pathogenic mechanism in DIL also involves the complement system. The classic complement pathway plays an important role in removing circulating immune complexes [68]. Some of the drugs implicated in DIL, including hydralazine, penicillamine, isoniazid, and metabolic products of procainamide, have been shown to inhibit the covalent binding of C4 to C2 [68, 71, 72]. This may inhibit the activation of C3 by the classic pathway, resulting in defective immune-complex clearance. Increased amounts of circulating immune complexes have been reported, but not consistently, in patients with DIL [68, 73].

Very few studies have examined possible HLA associations in other forms of DIL. One report suggested an association between HLA-DR6Y and procainamide-induced lupus [74]. Fifty-three percent of the clinically affected patients were HLA-DR6Y positive, compared with 25% of procainamide-treated patients who were asymptomatic but ANA positive, and 17% of controls. However, this has not been confirmed by other investigators [75]. Another report suggested an association between HLA-Bw44 and chlorpromazine-related autoimmunity [76]. Forty-six percent of patients with chlorpromazine-induced autoantibodies were HLA-Bw44 positive, compared with 19% of the normal population. HLA-DR4 was linked with penicillamine-induced lupus in one study [77]. Another study, however, failed to confirm the association, but found increased frequencies of HLA-All and B15 in a group of penicillamine-treated rheumatoid arthritis patients [78]. In summary, there has not been any consistent report of an HLA association in DIL. Genetic factors predisposing patients to DIL are likely to lie outside the MHC region.

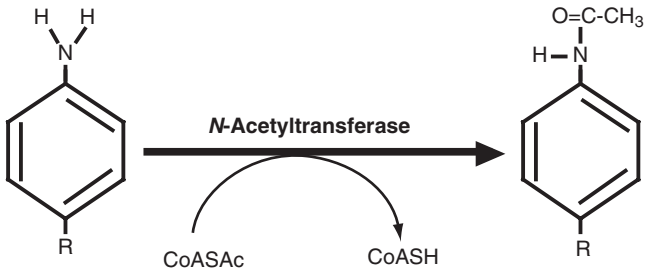

FIGURE 2 *N*-acetyltransferase catalyzes the acetylation of aromatic amines by acetyl-coenzyme A (CoASAc).

Acetylator Phenotype and DIL

Acetylation is the dominant pathway for the metabolism of aromatic amines and hydrazines. The enzyme responsible for this chemical conversion is *N*-acetyltransferase (Fig. 2). The enzyme(s) is found primarily in the liver and gut, although acetylation activity has also been detected in human erythrocytes and peripheral blood mononuclear cells [79]. The rate of acetylation of a drug is influenced by genetic factors. Individuals who are phenotypically slow acetylators are homozygous for the recessive allele, and fast acetylators are either heterozygous or homozygous for the dominant allele encoding the hepatic acetyltransferase gene. Humans with the slow acetylator phenotype have decreased or absent *N*-acetyltransferase activities in the liver [80]. Drugs known to be metabolized by this pathway include procainamide, hydralazine, isoniazid, sulfapyridine, sulfadimidine, dapsone, an amine metabolite of nitrazepam, and some carcinogenic aromatic amines [81]. Nongenetic factors may also affect the rate of acetylation. For example, acetylation rate is decreased in patients with renal insufficiency [82] and increased with ethanol ingestion [83].

There are approximately equal numbers of people with the slow and fast acetylator phenotypes in North America [84]. Although DIL can occur in patients with either phenotype, the majority of patients who develop procainamide or hydralazine-induced lupus have the slow acetylator phenotype [65, 85–87]. Individuals who are slow acetylators develop autoantibodies after a shorter exposure to hydralazine than do fast acetylators (Fig. 3), and are also more prone to developing the clinical manifestations of hydralazine-induced lupus [65, 85, 86, 88, 89]. Perry *et al*. [85] were the first to document the relationship between hepatic acetyltransferase activity, hydralazine, and the development of ANA and

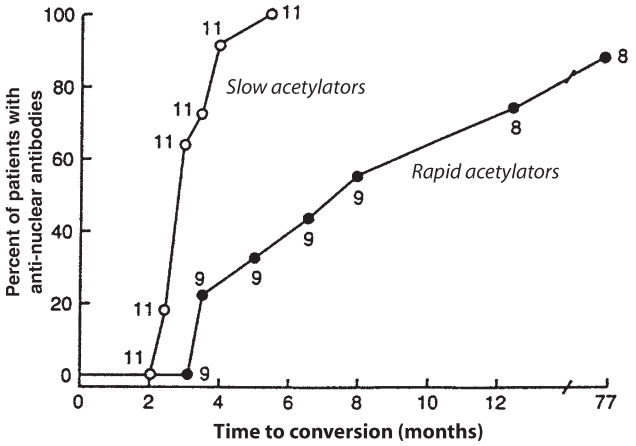

FIGURE 3 Rate of development of procainamide-induced ANA in slow acetylators (open circles) and rapid acetylators (closed circles) with time. (From Woolsey *et al*. (1987). *N. Engl. J. Med.* **298**, 1157, with permission.)

DIL. Of the 57 patients receiving hydralazine in their study, 33 were slow acetylators and 24 were fast acetylators. Twelve patients developed hydralazine-induced lupus, and all were slow acetylators. The cumulative dose and the steady-state concentration of the drugs are important factors in determining the onset of DIL. The incidence of DIL is about the same in patients with the slow and fast acetylator phenotypes, if the serum concentration of procainamide is maintained at the same level [90]. *N*-Acetylprocainamide (NAPA), a metabolite of procainamide, does not have the same lupus-inducing potential as the parent drug [91], suggesting that the aromatic amino group in procainamide may be important in inducing this disease. This suggests that the primary amino or hydrazine group on the parent drugs, rather then their metabolites, may be important elements in the pathogenesis of procainamide and hydralazine-induced lupus.

Only a small number of drugs implicated in DIL utilize the acetylation metabolic pathway. The contribution of a patient's acetylation phenotype in determining the development of DIL appears to vary with different drugs. Although acetylation is the primary determinant of the serum half-life of isoniazid, patients who are slow acetylators and receive the drug have been reported to be both equally likely [92] or more likely [93, 94] to develop ANAs and clinical disease, compared with fast acetylators.

Acetylator Phenotype and Idiopathic SLE

The association between slow acetylator phenotype and some forms of DIL suggests that acetylation inactivates the inciting drug, and it thus provides protection. Unless other environmental aromatic amines play a role in the etiology of idiopathic lupus, there should be no relationship between acetylation phenotype and idiopathic lupus. Initial studies by Reidenberg and Martin [95] showed that 71% of patients with idiopathic SLE may be slow acetylators, compared with the 52% expected incidence in the general population. Subsequent studies, however, showed positive associations, statistically insignificant associations, or no association between acetylator status and idiopathic lupus [96–106]. The association, if present, appears to be small. It is highly doubtful that genetic slow acetylation plays a significant role in the pathogenesis of idiopathic lupus. The varying results in different studies may be in part due to the use of historical controls, or variation of other unidentified geographic factors important in idiopathic lupus [96].

NEUTROPHIL-MEDIATED OXIDATIVE METABOLISM

Because lupus-inducing drugs have diverse chemical structures and pharmacological actions it has been postulated that these agents may cause clinical autoimmunity via common reactive oxidative metabolites. This model postulates that reactive oxygen species released by neutrophils modify xenobiotics, resulting in toxic metabolites. Immune cells including monocytes and Langerhans cells possess more limited amounts of enzymes such as myeloperoxidase and prostaglandin H synthase but may have some activity. Hepatic metabolism involving the microsomal mono-oxygenase system and esterases also produces some potentially toxic compounds. These highly reactive agents are very labile and generally do not circulate in the body in the active forms. A role for these reactive metabolites in immune responses therefore must involve contact with immunocytes in the liver, or locally within areas of inflammation (Fig. 4). Peripheral blood neutrophils can oxidize procainamide to the toxic metabolite PAHA [107]. Mixing experiments and cell-free studies suggest that myeloperoxidase and reactive oxygen radicals are released by activated neutrophils during this chemical transformation [107–109]. Therapeutic levels of six different lupus-inducing drugs, including hydralazine, were found to be cytotoxic to EL4 cells when cultured in the presence of activated neutrophils [109]. It is possible that PAHA, oxygen radicals, and other metabolic byproducts contribute to the cytotoxicity [109, 110]. Kinetics of inhibition assays suggest that the observed cytotoxicity may be related to the ability of these drugs to serve as substrates for the myeloperoxidase enzyme. However, these highly reactive drug metabolites are

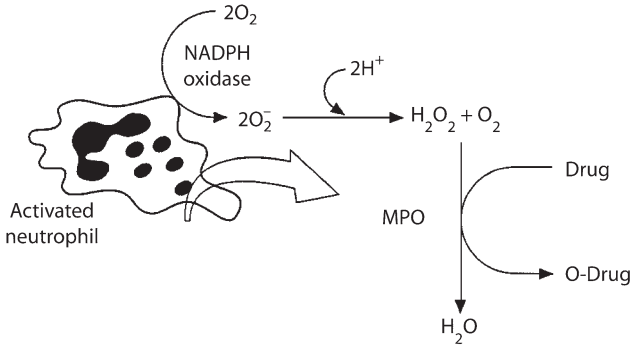

FIGURE 4 Mechanism for biotransformation of drugs by activated neutrophils. (From Rubin, R. L. (1994). *Lupus* **3**, 479, with permission.)

unstable and it has been difficult to detect their presence *in vivo*. Of interest but uncertain significance are the observations that PAHA and its nitroso derivatives have also been shown to bind covalently to histones [111], and autoantibodies to myeloperoxidase have been found in the serum of patients with DIL [112, 113]. These observations are consistent with the notion that myeloperoxidase-mediated metabolism may be involved in the pathogenesis of drug-induced autoimmunity.

Kretz-Rommel and Rubin examined the possibility that local production of PAHA may affect processes involved in T-cell tolerance to self-antigens [114]. Partial activation of T cells through T-cell receptor (TCR) engagement in the absence of costimulating signals can induce anergy to peptide antigens. Interference with this process may potentially affect autoimmune tolerance, resulting in the production of autoreactive T cells. Kretz-Rommel and Rubin [114] showed that treatment with PAHA, but not procainamide, will block the induction of anergy in cloned T cells by anti-CD3 antibody. Although PAHA is unstable in solution, its effects on T-cell anergy may be up to 8 h long. This model suggests that colocalization of potentially autoreactive T cells, activated neutrophils, and persistent inflammation is required to maintain the tolerant state. However, it is uncertain whether the concentrations of PAHA achieved *in vivo* approach the 1–5 μ*M* concentrations necessary to modify tolerance *in vitro*.

EPIGENETIC MECHANISMS

Evidence suggests that epigenetic mechanisms may also play a role in the pathogenesis of DIL and idiopathic lupus. In particular, biochemical modification of chromatin can affect gene expression and may be important in the induction of autoimmune diseases. These posttranslational modifications include methylation of DNA [115–118] and the phosphorylation, acetylation, and adenosine diphosphate (ADP)-ribosylation of histones [119].

ADP-Ribosylation and DIL

Limited studies have been performed examining the effects of lupus-inducing agents on ADP-ribosylation of histones. Poly-(ADP-ribose)-polymerase (PADPRP) is a chromatin-bound enzyme that catalyzes the transfer of ADP-ribose from nicotinamide to histones, including HI and H2B [120]. Autoantibodies reactive to HI and H2B, and to poly-(ADP-ribose) (PADPR) and PADPRP, have been demonstrated in patients with DIL and idiopathic lupus [121–123]. Interestingly ultraviolet light (UV), which has been implicated in the activation of lupus, also activates PADPR [124]. These observations have prompted further studies. Ayer *et al*. [125] examined the effect of procainamide and hydralazine on PADPRP activity in human T- and B-cell lines. These investigators found that therapeutic concentrations of procainamide increased PADPRP activity by up to 2.5-fold. Hydralazine and NAPA also increased the enzyme's activity, though to a smaller degree. It is possible that ADP-ribosylation of intracellular molecules, including histone proteins, may alter the structure and increase the immunogenicity of the self-antigens.

T-Cell DNA Hypomethylation and DIL

Evidence indicates an association between abnormal methylation of T-lymphocyte DNA and some forms of DIL. DNA methylation refers to the postsynthetic methylation of cytosine at the 5 position [115, 116, 126–129] and is one of the mechanisms regulating gene expression. For genes regulated by DNA methylation, hypomethylation of regulatory sequences correlates with gene expression, whereas methylation results in transcriptional suppression. DNA methylation can affect gene expression by several mechanisms. The methylation of cytosine residues can prevent the binding of some transcription factors if located in their recognition sequences. In addition, a family of specific nuclear proteins recognize and bind the methylated sequences, preventing the binding of transcription factors. Finally, it is now clear that the process of DNA methylation acts in concert with a related epigenetic process, that of histone deacetylation, in chromatin remodeling and suppression of gene transcription. Some methylcytosine binding proteins like MeCP2 attract a chromatin inactivation complex containing histone deacetylases, which condenses chromatin into an inactive configuration, inhibiting interactions

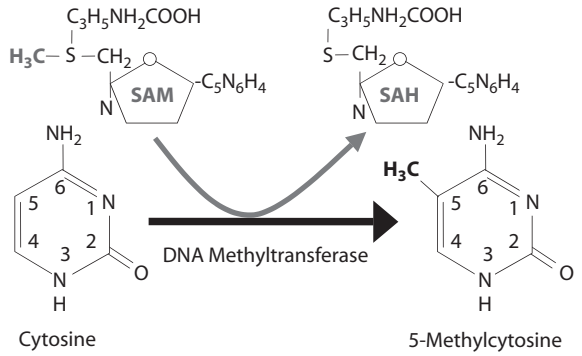

FIGURE 5 Formation of 5-methylcytosine. DNA methyltransferase enzyme catalyzes the transfer of the methyl group (CH_3) from *S*-adenosylmethionine (SAM) to (deoxy) cytosin producing 5-(deoxy)methylcytosine and *S*-adenosylhomocystine (SAH). (From Attwood *et al*. (2002). *Cell Mol. Life Sci.* **59**, 241, with permission.)

with transcription factors required for gene expression [130].

DNA methylation patterns are replicated during mitosis by the enzyme DNA (cytosine-5-)-methyltransferase 1 (Dnmt1) [115]. During mitosis, Dnmt1 recognizes hemimethylated CpG dinucleotides in the parent and daughter DNA strands, and catalyzes the transfer of the methyl group from *S*-adenosylmethionine to the cytosine residues in the unmethylated daughter DNA strand, producing symmetrically methylated sites and maintaining methylation patterns [131–134] (Fig. 5). The importance of DNA methylation is evidenced by its role in X-chromosome inactivation [135], and by its role in genomic imprinting [136]. Disruption of the *Dnmt1* gene in embryonal stem cells results in abnormal development and embryonic death [137], suggesting that DNA methylation is important in ontogeny. Additional DNA methyltransferases have been identified in the past few years, including Dnmt3a and Dnmt3b. In contrast to Dnmt1, these enzymes will methylate both unmethylated and hemimethylated DNA equally well, and may function as *de novo* methyltransferases. Homozygous deletion of these enzymes also causes death during embryonic development or in the early neonatal period [130].

Certain drugs inhibit the DNA methyltransferases, modifying methylation patterns with sometimes striking effects. For example, 5-azacytidine (5-azaC), an irreversible DNA methyltransferase inhibitor, causes 10T1/2 cells to differentiate into myocytes, adipocytes, and chondrocytes by altering expression of genes determining cellular differentiation [116, 138]. This approach has been used to clone the *MyoD* gene, which regulates myocytic differentiation [139, 140]. The observation that classic DNA hypomethylating agents like 5-azaC can affect the activity of histone deacetylases [141] suggests another potential mechanism whereby lupus-inducing drugs may alter gene expression and promote autoimmunity. However, the role of histone deacetylation has not been examined in DIL.

The role of DNA methylation in regulating T-cell function and gene expression has more recently been examined. 5-azaC treatment of cloned, antigen-specific $CD4^+$ cells caused them to lose their requirement for nominal antigen and respond to autologous antigen-presenting cells (APC) alone [142–145], thus becoming autoreactive. This was confirmed using a panel of $CD4^+$ antigen-specific human cloned cells, PHA activated polyclonal $CD4^+$ human T cells, cloned murine antigen-specific $CD4^+$ T cells, alloreactive murine $CD4^+$ T cells, and Concanavalin-A-activated $CD4^+$ murine T cells. This autoreactive response is specific for autologous or syngeneic APC, and requires specific MHC class II and T-cell antigen–MHC receptor interactions, indicating that the autoreactive response uses the TCR to transmit one of the activation signals.

The autoreactivity correlates with an approximately 10-fold overexpression of leukocyte function antigen-1 (LFA-1) (CDlla-CD18) on the surface of the treated cells [142–145], and transfecting human or murine T-cell clones with LFA-I causes an identical autoreactivity [146, 147]. In either 5-azaC-treated or LFA-1-transfected cells, small amounts of antibody to CD11a or intercellular adhesion molecule I (ICAM-1) (CD54), an LFA-1 ligand [144, 146, 147], completely inhibits the autoreactive response to APC without antigen, while only minimally inhibiting the response to the same APC presenting specific antigen. This suggests that LFA-I overexpression might contribute to the autoreactivity, and inhibiting the effects of the additional LFA-1 molecules reverses the effect. LFA-1 is a member of the β2 integrin family of adhesion molecules, and serves to stabilize the interaction of the TCR with class II MHC molecules on APC [148, 149]. Others have also shown that LFA-1–ICAM interactions are particularly important when the affinity of the TCR–class II interaction is low [150]. LFA-1 overexpression may cause autoreactivity by overstabilizing the normally low-affinity interaction between the TCR and class II MHC molecules, allowing T-cell activation by the class II determinants alone or with other peptides than those normally recognized by the T cell.

The observation that normal, antigen-specific T cells can be made autoreactive through chemical exposure prompted studies examining the relevance of this phenomenon to autoimmunity. A similar situation, in which $CD4^+$ T cells respond to host MHC determinants, occurs in the murine chronic graft-vs-host (GVH) disease model. In this system, adoptive transfer of $CD4^+$ T cells from a parent strain into the F1 hybrid of certain his-

toincompatible parental strains results in the development of an autoimmune disease with features of human lupus [151, 152]. The recipients develop an immune–complex glomerulonephritis, splenomegaly, and arthritis, as well as an autoimmune liver disease. Serologic features include hypergammaglobulinemia, ANA, and anti-double-stranded DNA (dsDNA) antibodies. Subsequent studies demonstrated that therapeutic concentrations of procainamide or hydralazine inhibit DNA methylation in human and murine T cells [153–155]. Procainamide was subsequently shown to reversibly inhibit human T-cell DNA MTase activity in a dose-dependent fashion [153, 154]. Activated normal human and murine $CD4^+$ T-cell clones treated with therapeutic concentrations of procainamide or hydralazine also became autoreactive, similar to 5-azaC-treated cells [142–145]. This autoreactivity also correlates with increased LFA-1 expression. Conversely, NAPA, a metabolite of procainamide that does not cause lupus, is about 100-fold less potent in its ability to induce T-cell autoreactivity *in vitro*. More recently, it was shown that UV light, implicated in activating lupus, also inhibits T-cell DNA methylation, increases LFA-I expression, and induces autoreactivity at relatively modest doses [146]. It is likely that DNA demethylating drugs also affect other methylation sensitive genes that may contribute to autoimmunity. Our group examined the effects of 5-azaC on the expression of approximately 7000 T-cell genes using a microarray genome scanning approach [156]. One hundred eighteen genes were identified that have greater than two-fold increases in expression following the drug treatment, including IFN-γ and CD70 as B-cell costimulating molecules, and perforin as a molecule participating in cytotoxic responses.

Defects in signal transduction have been identified in lupus T cells that may account for the aberrant cellular and humoral immune responses in lupus patients [157]. Evidence has shown that Dnmt1 is upregulated following T-cell stimulation in part by signals transmitted through the MAPKK-catalyzed ERK phosphorylation pathway, and that decreased signaling in the pathway may result in T-cell DNA hypomethylation in lupus patients [158]. Interestingly, although hydralazine has no direct effect on Dnmt1 activity, it may indirectly decrease Dnmt1 expression and function via inhibition of the ERK signaling pathway [159, 160]. Together, these studies suggest that certain environmental agents may also induce T-cell autoreactivity by inhibiting T-cell DNA methylation, thereby altering T-cell gene expression.

T cells made autoreactive by treatment with DNA methylation inhibitors interact with other cells of the immune system in a way that could contribute to the development of autoimmunity. For example, coculture of B lymphocytes with $CD4^+$ T cells treated with DNA methylation inhibitors, including 5-azaC, procainamide, and hydralazine, induces differentiation of the B cells into IgG-secreting cells, without the addition of antigen or mitogen [161]. An identical amount of antibody secretion was induced with supernatant from activated treated or untreated cells, suggesting that the autoreactive T cells were activated by MHC determinants on autologous B cells, and the T cells then secreted B-cell differentiation factors, such as IFN-γ, interleukin-4 (IL-4) and/or IL-6, activating the B cells. However, a role for cell–cell communication through surface molecules such as CD40 and the CD40 ligand [162] has not been excluded. This mechanism could contribute to the polyclonal B-cell activation observed in patients with procainamide-induced lupus [39–41]. In addition, the autoreactive cells spontaneously induce apoptosis in autologous or syngeneic macrophages [144, 145] through pathways including Fas, TWEAK, and TRAIL [163]. These studies have led to the proposal that a similar T-cell modification occurring *in vivo* could result in the release of intracellular and nuclear antigens. If the autoreactive T cells traffic to lymphatic tissue such as the lymph nodes or spleen, macrophage lysis in the immediate proximity of B cells and other T cells, together with the release of cytokines like IL-4 and IL-6, might contribute to the generation of autoantibodies. Macrophage lysis in the liver or spleen may also contribute to impaired immune-complex clearance.

T-Cell DNA Methylation in Idiopathic Lupus

The DNA hypomethylation model suggests that certain chemical agents can inhibit T-cell DNA methylation, modify T-cell LFA-1 expression, and induce autoreactivity. Furthermore, the autoreactive T cells can interact with MHC-identical B cells and macrophages, inducing macrophage apoptosis and B-cell activation, and *in vivo* the same cells can cause a disease with many manifestations of human lupus (see the following section Animal Models). This model thus predicts that patients with active lupus might have hypomethylated T-cell DNA, T cells that overexpress LFA-1 and lyse autologous macrophages, and evidence for B-cell activation due to IL-4 or IL-6 production. Evidence for these predictions has been sought in patients with active lupus. Using reverse-phase high-pressure liquid chromatography (HPLC) to quantitate total genomic deoxycytosine (dC) content, patients with active, but not inactive, lupus were shown to have significantly less d^mC content than age-matched controls [164]. A small decrease was also found in T cells from some patients

with rheumatoid arthritis, but not in T cells from patients with chronic infections, osteoarthritis, gout, or multiple sclerosis. These results have been confirmed by an independent group [165]. The lupus patients also had approximately one-half the amount of T-cell DNA MTase enzymatic activity as healthy controls and rheumatoid arthritis patients. This decrease is similar to that achieved *in vitro* with procainamide [164] and suggests that impaired DNA MTase activity may be common to T cells from lupus patients and the *in vitro* model. More recent evidence suggests that this may be due to a failure to upregulate Dnmt1 following T-cell stimulation, possibly due to a defect in the ras signaling pathway [166]. Evidence for T-cell LFA-1 overexpression has also been sought. A subset of peripheral blood T cells were found to express high levels of LFA-1 relative to other cell surface markers in 25 of 49 lupus patients compared with no increase in LFA-1 in more than 50 controls, including normal individuals, patients with active infections, and patients with multiple sclerosis. There was also a strong positive correlation between the number of cells expressing high levels of LFA-1 and clinical disease activity [161]. These observations have been confirmed by an independent group [167]. When isolated from other T cells, the population with high LFA-1 expression was found to be autoreactive, in that the cells spontaneously lysed autologous, but not allogeneic, macrophages, again similar to T cells treated with DNA hypomethylating agents. Patients with active lupus were found to have circulating apoptotic monocytes, suggesting that macrophage killing was occurring *in vivo* [168]. Finally, IL-6 overexpression by T and B cells also occurs in lupus patients [169–171], and anti-IL-6 will inhibit the spontaneous B-cell Ig secretion characteristic of lupus. Together, these observations are consistent with the predictions generated by the DNA hypomethylation model, and suggest that a similar mechanism may contribute to idiopathic lupus. However, whether similar changes in T-cell DNA methylation, LFA-1 expression, and T-cell autoreactivity occur in DIL remains to be established.

ANIMAL MODELS

Early Animal Models

Since the initial description of DIL, investigators have tried to reproduce the disease in animals. Most of these reports involved administering large (and often nonpharmacological) amounts of test drugs to laboratory animals. Unfortunately, the majority of studies have yielded conflicting results, or results with uncertain clinical significance. As early as 1956, Comens reported induction of a lupus-like disease in dogs given large doses of oral hydralazine over a few weeks to months [172]. Disease manifestations included anemia, hypergammaglobulinemia, lupus erythematosus (LE) cells, renal disease (fibrinoid degeneration and "wire-loop" lesions), weight loss, weakness, convulsions, and sometimes death. Other researchers were able to reproduce the acute, severe, and prolonged illness induced in dogs given toxic doses of hydralazine, but were unable to confirm the more specific lupus-like features such as the presence of LE cells or renal disease [173, 174].

A few researchers investigated the effects of lupus-inducing drugs in guinea pigs, in part because of a report that this species produces LE cells when given serum from human lupus patients [175]. Oral hydralazine was found to induce LE cells in 7 out of 15 guinea pigs [176]. A few of these animals also developed anemia, leukopenia, elevated α2 globulins, anorexia, weight loss, and eventually death within 4 months. However, histologic abnormalities were not documented. Braverman and Lerner [177] fed hydralazine to guinea pigs (10–100 mg/kg) for up to 3 months, and demonstrated that 17% of the animals developed LE cells and/or ANAs in their blood or sera. Minimal thickening of the renal glomerular basement membrane was seen in 17% of the animals, but otherwise no histologic abnormality was found. In a similar experiment, Leovey *et al*. [178] found circulating anti-hydralazine antibodies in up to 71% of guinea pigs receiving oral or intramuscular hydralazine. Twenty-three percent and 27% of these animals also developed LE cells and ANA activity, respectively. Increased α2 globulins, anemia, leukopenia, interstitial myocarditis, thickening of the glomerular basal membrane, iridocyclitis, chronic hepatitis, and amyloid-like substance in the liver and spleen were also occasionally observed. Ellman *et al*. [179] immunized guinea pigs with hydralazine in Freund's complete adjuvant, and showed strain-specific differences in anti-hydralazine antibody production and delayed hypersensitivity to hydralazine. ANA and anti-DNA antibodies were not detected, and strain differences in hepatic acetylation rates were not confirmed.

Cannat and Seligmann [180] administered hydralazine and isoniazid orally to two inbred strains of mice, BALB/c and C57BL/6, for 3–12 months. They demonstrated that mice treated with either drug developed a positive ANA test after 6 months of treatment, in titers significantly greater than age-matched controls. Ten Veen and Feltkamp [181] examined the development of ANA and anti-native DNA antibodies in three inbred strains of mice (BALB/c, C57BL/6, and A/Jackson) receiving hydralazine, isoniazid, procainamide, α-methyldopa, and chlorthalidone in their drinking water. They were able to detect increased ANA

production in all treated mice compared with age-matched controls. Anti-native DNA antibodies were detected in A/JAX mice without drug treatments, confirming a previous report [182]; otherwise no increased titers of anti-native DNA antibody were found. IgG and IgM deposition was found in the kidneys of treated and untreated mice. These investigators also described increased glomerulosclerosis and immune-complex glomerulonephritis in drug-treated mice, beyond expected age-related changes [183]. The ability of different drugs to induce autoantibody production or clinical disease in other animals has also been tested. Yamauchi *et al*. [184] immunized rabbits with hydralazine–human serum albumin conjugates over 12–17 weeks, and found rising titers of anti-hydralazine, anti-single-stranded DNA (ssDNA), and anti-native DNA antibodies. Histologic changes were not observed in the immunized rabbits. Administration of hydralazine subcutaneously or orally failed to induce DIL in rats [185] or swine [186].

In summary, earlier attempts to establish animal models of DIL have yielded at best mixed results. In general, these studies have not gained wide acceptance, often because of failure of other investigators to reproduce the findings. In many instances, the doses of drugs administered to the animals were much higher than therapeutic doses that caused DIL in humans. Finally, most studies only reported induction of LE cells or the presence of a positive ANA test with no histologic evidence for disease.

Recent Animal Models

In Vivo Effects of PAHA

PA14A, a reactive metabolite of procainamide discussed previously, has more recently been shown to induce autoantibodies in mice, possibly by interfering with central T-cell tolerance [187]. Anti-chromatin antibodies were detected in C57BL/6 × DBA/2 Fl mice following two intrathymic injections with PAHA. Interestingly, the PAHA-induced antibodies showed specificity to the (H2A–H2B)–DNA complex, similar to that found in the sera of many patients with procainamide-induced lupus. The immune response appears to be clonally restricted, as there was no evidence of polyclonal B-cell activation. Similar to earlier reports of DIL in animal models, however, no evidence for histologic changes was presented. Thus, this model suggests a mechanism by which procainamide can induce autoantibodies, although their pathologic significance is uncertain. Limiting this model, though, is that high concentrations of PAHA (20 µl of a 4 m*M* solution injected into each thymic lobe) are required. How such high concentrations of this highly reactive metabolite would be generated in the thymus, and whether a similar result would be found following thymic involution and analogous to the elderly patients usually receiving procainamide, is uncertain.

In Vivo Effects of T-Cell DNA Hypomethylation

The effects of T cells modified by treatment with DNA methylation inhibitors have been examined *in vivo*. In the first published report, DBA/2 mice were used, in part because this strain does not develop autoimmunity, and in part because others have used this strain successfully in the chronic GVH model [151, 152, 188]. Alloreactive and mitogen-stimulated $CD4^+$ T-cell lines, established from DBA/2 mice, were treated with 5-azaC or procainamide, and shown to overexpress LFA-1 and respond to syngeneic APC without antigen, similar to human cells [144]. The treated T cells secreted IL-4, IL-6, and IFN-γ, suggesting that both Th1 and Th2, or ThO, cells were present. The autoreactive cells also killed syngeneic macrophages without antigen, similar to the human system [143]. The autoreactive cells were then injected intravenously into normal unirradiated female DBA/2 mice. The recipients developed hematuria, proteinuria, and red-cell casts beginning 7–21 days after each injection and lasting 7–14 days. Histologic analysis demonstrated a proliferative glomerulonephritis with IgG, IgM, and IgA immune-complex deposition, as well as IgG deposition at the dermal–epidermal junction resembling the lupus band test. Antibodies to histones and ssDNA in titers comparable to those found in New Zealand Black/New Zealand White (NZB/NZW) mice were also found in the mice receiving drug-treated cells. Controls included mice receiving untreated cells, heat-killed 5-azaC-treated cells, or unstimulated procainamide-treated $CD4^+$ T cells. The controls did not develop pathologic or serologic findings.

These results were confirmed using a cloned conalbumin-reactive murine Th2-cell line (D10.G4. 1, $H\text{-}2^k$, derived from AKR mice) [145]. Procainamide and 5-azaC treatment again induced LFA-1 overexpression and autoreactivity. Drug-treated cells, as well as untreated cells, produced IL-6 and relatively smaller amounts of IL-4, but no detectable IL-2 or IFN-γ. Syngeneic macrophages were again found to die by apoptosis following coculture with either drug-treated cells alone or with untreated cells plus conalbumin. Chromium and fluorescein labeling studies demonstrated that autoreactive as well as untreated cells homed to the spleen, as predicted by the model and by earlier trafficking studies [189, 190]. Adoptive transfer of the autoreactive D10 cells into AKR mice produced

a more severe immune-complex glomerulonephritis, pulmonary alveolitis, and central nervous system lesions resembling human lupus with vascular fibrinoid necrosis, cerebral infarcts, and sterile meningitis. Other pathologic findings included liver lesions with periportal inflammatory infiltration and bile duct proliferation resembling primary biliary cirrhosis. The mice also developed significant titers of anti-ssDNA, anti-dsDNA, and anti-histone antibodies. The reason for the difference in disease severity between the DBA/2 and AKR models is not known. Possible explanations include the use of a cloned Th2 line in the AKR model, with less inhibition by Thl cells, or differences in the genetic makeup of the hosts. However, a more recent study showed that cloned Th1 cells overexpress LFA-1 and become autoreactive following 5-azaC treatment, similar to Th2 cells [191]. Adoptive transfer of the autoreactive Th1 cells also induces similar anti-DNA antibodies. Comparison of effector mechanisms suggests that the T-cell cytokine repertoire is probably not crucial in this system. In contrast, macrophage/monocyte killing is common to all three models and may be an important early step providing antigenic nucleosomes and decreasing clearance of apoptotic materials.

The D10 model has also been used to compare relative potency of procainamide, NAPA, hydralazine, and phthalazine. NAPA does not cause DIL, whereas phthalazine is the parent compound of hydralazine but lacks the hydrazine side chain, which has been implicated in autoimmunity. Procainamide and hydralazine are also more potent DNA methylation inhibitors than NAPA [155]. Mice receiving hydralazine and procainamide developed a similar disease. Phthalazine was less potent than hydralazine, and NAPA had no effect in this system. These results lend further credibility to the DNA hypomethylation model, and suggest a reason for the differing potencies of these drugs for inducing DIL.

Gender predisposition to lupus has also been examined in the DNA hypomethylation model. Lupus is predominantly a female disease, and sex hormones have been shown to play an important role in modulating immune responses in humans and murine models of lupus [192–194]. Consistent with data from humans and autoimmune prone mice, normal female mice receiving procainamide-treated T cells develop a more severe disease, and have higher titers of autoantibodies than age-matched male recipients [195]. Oophorectomized female mice develop a much milder disease, with anti-DNA titers similar to orchiectomized and normal male mice receiving drug-treated cells.

Further studies demonstrated gender-specific effects of T-cell trafficking *in vivo*, with up to seven times as many T cells homing to the female spleens compared to male spleens, and this female-specific increase in splenic homing also decreased following oophorectomy. Splenectomized females did not develop autoantibodies or autoimmune pathology, supporting an important pathogenic role for the spleen in this model. These studies also indicated that relatively few cells accumulating in the spleen (a total of approximately 360,000) are sufficient to induce autoimmunity in mice [195]. These observations suggest that female-specific increases in T-cell trafficking to the spleen may cause increased disease severity in this model, presumably due to effects of female sex hormones on T-cell trafficking patterns. Estrogens have been reported to upregulate endothelial cell adhesion molecule expression [196], providing a plausible explanation for the gender-specific differences in T-cell trafficking observed. However, the effect of gender appears to be less prominent in DIL [2]. Since DIL affects primarily older individuals, this may be due to the decline in sex-hormone production with aging. Alternately, gender-specific factors may play a less important role in DIL.

In summary, two well-documented *in vivo* models have been described that suggest mechanisms that could contribute to the pathogenesis of DIL. The PAHA model generates autoantibodies resembling those seen in procainamide-induced DIL. Limitations of the model are described earlier. The DNA methylation model provides a common mechanism for procainamide and hydralazine, but the pathologic lesions produced more closely resemble idiopathic lupus than DIL, which characteristically spares the kidney and central nervous system [2]. Furthermore, both systems are somewhat artificial, and evidence that either is operant in human DIL remains indirect. Further studies will be required to determine whether the PAHA model, the DNA methylation model, neither, or both contribute to human DIL. However, it is reasonable to propose that both mechanisms contribute to human DIL. The diseases induced by procainamide and hydralazine have distinct differences, including clinical manifestations and autoantibody specificity [2]. It is possible that the influence of PAHA could modify disease manifestations induced by DNA hypomethylation resulting from procainamide treatment, accounting for these differences. It is anticipated that both models will be useful for understanding DIL and possibly idiopathic lupus as well.

XENOBIOTICS

Environmental exposure to certain toxins, known as xenobiotics, has been linked to the development of lupus-like illnesses and autoimmunity in humans and in

several animal models. Selected environmental factors include heavy metals, occupational and industrial contaminants, foods, and dietary supplements. This is a broad field, and it is difficult to discuss every environmental agent linked to autoimmunity. Therefore, only selected agents, including those with more recent associations, will be discussed. Interested readers are referred to some excellent reviews on this subject [197–202].

Foods and Dietary Supplements

L-Canavanine

A lupus-like syndrome associated with the ingestion of the nonessential amino acid L-canavanine has been described in humans and animals. Dietary supplements containing alfalfa were initially implicated in triggering disease exacerbations in lupus patients [203]. In 1981, Malinow *et al*. [204] reported that ingestion of alfalfa seeds was the cause of a reversible autoimmune hemolytic anemia and pancytopenia in one patient. L-Canavanine was subsequently shown to be the principal ingredient in alfalfa seeds responsible for this disease. Primates fed alfalfa seeds, alfalfa sprouts, or L-canavanine developed a similar disease, with hemolytic anemia, high-titer ANA, and anti-dsDNA antibodies. Withdrawal of alfalfa seeds from the diet results in resolution of the clinical condition, although autoantibodies remain detectable for up to 2 years [205, 206].

L-Canavanine is an amino acid structurally similar to L-arginine, and can compete with L-arginine for the charging of transfer RNA (tRNA) Arg. The isoelectric point of canavanine is lower than arginine. The substitution may change the structure and function of the resulting proteins, including arginine-rich histone proteins, altering their immunogenicity [207, 208]. L-Arginine also affects the immune system, including the arginine–nitrous oxide pathway. L-Canavanine may therefore influence the immune system by several mechanisms. At high doses, this nonessential amino acid inhibits the proliferative response of human mononuclear cells to mitogens through its effect on DNA synthesis. L-Canavanine may also affect B-cell function. Under *in vitro* conditions, L-canavanine can alter the surface charge of B cells, but not T cells, from NZB/NZW Fl mice [209]. It is possible that the activated B cells cause increased incorporation of canavanine into surface proteins, modifying the surface charge [210]. Interestingly, L-canavanine can also stabilize DNA in the more antigenic Z configuration [198]. The enhanced antigenicity may contribute to the development of anti-DNA antibodies.

Anilines and L-Tryptophan

Two more recent epidemics of environmentally induced autoimmunity highlight the pathologic potential of chemicals the human body may be exposed to and their clinical sequellae. Ingestion of rapeseed oil denatured with aniline was responsible for reports of toxic oil syndrome (TOS) in Spain in 1981 [211]. Affected patients developed acute pneumonitis, followed by a chronic illness characterized by a scleroderma-like skin disease, neuromyopathy, and sicca syndrome. Eosinophilia, elevated IgE, and occasionally the presence of ANAs and other autoantibodies were also reported. A second outbreak of a similar disease, the eosinophilic myalgia syndrome (EMS), was reported in the late 1980s [211, 212]. Epidemiologic studies identified the dietary supplement L-tryptophan, an essential amino acid, as the causative agent in the outbreak. Although not conclusive, it appears that contaminants or by-products introduced during the manufacturing process by a single manufacturer may be the culprit [212]. The precise mechanism underlying this disease has not been worked out, and only a small percentage of people who ingested the offending agents were affected. Human and animal studies suggest that immunogenetic and metabolic phenotypes are important factors in the expression of both diseases.

Increased frequencies of HLA-DR3 and HLA-DR4 [198], enhanced T-suppressor cell activity, and antibodies to T and B cells have all been reported in patients with TOS. Interestingly, patients with TOS may also have abnormal tryptophan metabolism, including abnormal IFN-γ activation of indoleamine-2,3-dioxygenase, an enzyme involved in tryptophan breakdown metabolism. A number of studies have been performed using a variety of animal systems. Unfortunately, no animal model of TOS that truly resembles the human disease has been described. Mice fed aniline develop high serum IgE titers and increased IL-1β, IL-6, and IFN-γ [213]. It was suggested that a breakdown in tolerance and polyclonal B-cell activation may be important in this disease. Only one study reported lung toxicity in rats [214], with other researchers reporting uniformly negative lung pathology in a number of animal systems [215–217]. In one long-term study, rats were fed for 200 days with "case oil" obtained from the National Center for Food and Nutrition in Majadahonda [218]. These rat developed a large increase in dermal collagen deposition. Electron microscopic analysis showed increased collagen fibers of uniform diameter arranged in thick bundles. A pathogenic mechanism for TOS akin to GVH has also been proposed [219–221]. Both diseases display a biphasic clinic course. 1-phenyl-5-vinyl-2-imidazolidinethione (IZT), a possible constituent of

unrefined rapeseed oils and a possible reaction product of aniline, shares structural similarities with anticonvulsants (such as phenytoin) and antithyroid drugs known to be capable of inducing GVH or lupus-like illnesses in humans. However, only traces of IZT could be found in the case oils. The role of IZT in TOS is currently unclear [222, 223].

Eosinophilic myalgia syndrome has been linked to HLA-Aw33, HLA-B44, and HLA-DR6 [224]. Abnormal tryptophan metabolism, enhanced kynurenine production, and roles for IFN-γ and transforming growth factor β (TGF-β) have all been proposed for this disease. Kynurenine is a metabolic product of L-tryptophan. Of interest, increased urinary excretion of kynurenine and plasma kynurenine levels has been reported in patients with scleroderma, CREST syndrome, and eosinophilic fasciitis [225, 226]. Female Lewis rats fed with L-tryptophan have enhanced tryptophan metabolism with increased plasma L-kynurenine levels [227, 228]. Other features of this model include suppression of the hypothalamic–pituitary–adrenal (HPA) axis and pathologic findings including fasciitis and perimyositis. However, several features of the human disease are absent in this model, including pulmonary and skin involvement and peripheral or tissue eosinophilia. The role of eosinophils in this and other eosinophilic rheumatic diseases is unclear. Cytokine-mediated activation of eosinophils, with resulting degranulation and release of toxic products (e.g., major basic protein, eosinophil-derived neurotoxin), may contribute to tissue injury [212]. Other alterations of cellular immunity have also been described, including phenotypic changes in peripheral blood mononuclear cells and activation of peripheral T lymphocytes. A contaminant, termed peak E, was isolated from contaminated oil [229, 230]. The compound was determined to be 1,1′-ethylidenebis(tryptophan), composed of two L-tryptophan molecules joined by an ethylidene bridge. A definitive pathogenic role of this novel amino acid in EMS has not been established. Despite clinical similarities with TOS, a convincing link between EMS and TOS has not been shown [231].

Heavy Metals

Gold, mercury, cadmium, and to a lesser extend lithium, chromium, and zinc have all been associated with autoimmune diseases. Lupus-like illnesses have been reported with exposure to gold, chromium, and lithium. How various heavy metals can induce autoimmunity is unclear. One proposed mechanism is that they may modify nuclear antigens by binding to carboxyl, nitryl, sulfhydryl, and phosphoryl groups, rendering them immunogenic.

Gold

Gold salts have been used in the treatment of human diseases for centuries, and are still an important therapy for rheumatoid arthritis. Between 1 and 3% of rheumatoid arthritis patients receiving gold salts develop a reversible autoimmune thrombocytopenia [232]. This is associated with the development of antibodies that bind to platelets in the presence of gold or its metabolites. The thrombocytopenia occurs following weeks to months of treatment, and is usually reversible within a week after cessation of therapy. Six to 17% of gold-treated patients also develop nephropathy with proteinuria [233, 234]. Biopsy studies suggest that most cases of renal disease are due to membranous glomerulonephritis. Other changes, including minimal change glomerulonephritis and interstitial nephritis, have also been reported.

The pathogenic mechanisms underlying gold-induced renal disease are unclear. HLA-DR3 and HLA-B8 have been shown to be a risk factor for gold-related renal disease in rheumatoid arthritis patients, and may be present in up to half of these patients [235]. Immune-complex deposition is commonly found in the glomeruli of affected patients, and is important in membranous glomerulonephritis. Mononuclear phagocytes can metabolize Au (I) to Au (III), a reactive metabolite, *in vitro* [236, 237]. It is possible that subsequent oxidation of nuclear proteins may allow sensitization of T cells to the modified antigen. To help understand this disease, an animal model of gold-induced autoimmunity was developed. Brown Norway (BN) rats injected with gold salts develop an autoimmune disease, with polyclonal B-cell activation, lymphoproliferation, IgE hypergammaglobulinemia, and the production of autoantibodies [238]. These animals also develop an immune-complex glomerulonephritis. Anti-glomerular basement membrane antibodies, anti-tubular basement membrane antibodies, and anti-brush border antibodies have all been demonstrated. There may be strain specificity in this model, since Lewis rats receiving gold do not develop glomerulopathy, although evidence of interstitial nephritis and polyclonal B-cell activation can still be found. However, the substantial differences between this model and gold-induced human disease make the relevance of the model to the human disease uncertain, and the mechanisms involved remain unknown.

Mercury

Mercury was once widely used as a component of laxatives, diuretics, and teething powders. The heavy metal can still be found in fish, dental amalgams, electrical

products, pharmaceuticals, and paper and pulp mills. Renal complications, including proteinuria, nephrotic syndrome, and immune-mediated glomerulonephritis have all been documented following mercury exposure [239, 240]. A role for mercury in the generation of anti-mitochondrial antibodies and in human primary biliary cirrhosis has been proposed. Mercuric chloride may interact with disulfide- or thiol-groups in bile duct cells, altering the structure of mitochondrial enzymes and increase their immunogenicity [241, 242]. Similarities between clinical features of Kawasaki's disease and mercury intoxication, including fever, erythematosus mucosa, lymphadenopathy, and increased IgE levels, have been noticed by different authors. However, no definite association has yet been found [243–245].

A number of well-characterized animal models of mercury-induced autoimmunity have been described [246–250]. In most cases, the animals develop autoantibodies and kidney disease following mercury treatment. Features of mercury-induced autoimmune disease in BN rats include IgE hypergammaglobulinemia, autoantibodies to ssDNA and glomerular basement membrane, lymphoproliferation, mucositis, a Sjögren's-like syndrome, and an immune-complex glomerulonephritis. The renal disease in mercury-treated rats is characterized by a two-stage process, with initial linear then granular deposition of IgG anti-laminin antibody in the glomerular and tubular basement membrane.

Studies of animal models suggest that susceptibility to mercury-induced autoimmunity may be genetically controlled, with considerable variation in the autoimmune features among the strains and species studied [251, 252]. Granular deposits of IgG, IgM, and C3 have been detected in the kidneys of mercury-treated mice, and eluates from immune deposits of SJL mice contain anti-nucleolar antibodies. B10.S mice developed anti-nuclear (e.g., anti-chromatin and/or anti-histone) and anti-nucleolar (e.g., anti-fibrillin, or U3 ribonucleoprotein (RNP)) antibodies, with IgG deposition in vessel walls and glomerular basement membranes. Development of anti-fibrillarin ANAs in mercury-treated mice has been linked to the I and S regions of the H2 complex. In SJL mice, susceptibility to anti-nucleolar antibody production resides in the $H2^a$ locus, is inherited in a codominant fashion in crosses with strains carrying the $H2^b$ and $H2^d$ haplotypes, and is strongly modulated by non-H2 genes. Rats that carry the RT1 haplotype (Lewis, Fischer 344) do not develop autoimmunity, in contrast to the Rtn haplotype, which are susceptible to anti-glomerular basement membrane and laminin antibodies. Rats with other haplotypes show intermediate susceptibility.

Mercury-induced autoimmunity is a T-cell dependent disease, and shares some similarity with the murine chronic GVH autoimmunity model. Normal BN rats develop the disease following adoptive transfer of $CD4^+$ T cells from mercury-treated rats [253, 254]. Host $CD8^+$ cells are important, as treatment with anti-CD8 antibodies exacerbates the disease [255]. T-cell depleted rats (BN rnu/rnu and BN "B" rats) do not develop mercury-related autoimmunity, unless their T cells are reconstituted [256]. Finally, low-dose cyclosporin-A can ameliorate this disease in rats, supporting a role for T cells [257]. Autoreactive T-cell clones have been isolated from mercury-treated animals, and a T-cell response to modified Ia antigens may produce autoimmunity by mechanisms similar to chronic GVH disease [258]. It has also been proposed that T cells recognizing mercury–nuclear protein (e.g., fibrillarin) complexes may result in cross-reactivity with the native self-antigen, possibly by epitope spreading.

A role for anti-idiotype antibodies in mercury-induced autoimmunity has also been proposed. B cells producing antibodies recognizing a V κ-associated idiotype on anti-glomerular-basement-membrane antibodies have been isolated from BN rats [259]. Corresponding auto-anti-idiotypic antibodies can be identified in BN mice with the disease. However, a pathogenic role for these anti-idiotypic antibodies has not been confirmed. Other mechanisms implicated in mercury-related autoimmunity include a possible role for cytokines. Depressed IL-12 production, as well as preferential expansion of Th2 T cells and upregulation of IL-4, have both been reported [260, 261].

Cadmium

Exposure to cadmium in the workplace has been linked to the development of renal disease, including proteinuria and interstitial and glomerular disease [197]. Rodents may be more prone to develop cadmium-induced autoimmune disease than humans. Susceptibility to cadmium toxicity varies with different animal strains, underscoring the importance of genetic factors. Sprague Dawley rats treated with this heavy metal have been reported to develop proliferative glomerulonephritis with immune-complex deposition and anti-laminin antibodies [262]. On the other hand, BN rats are resistant to the disease. Low levels of exposure are sufficient to cause ICR mice to develop ANAs. Finally, BALB/c mice will develop autoantibodies after treatment with high-dose cadmium, but C57BL/6 mice are resistant. Again, the mechanism is unknown.

Vinyl Chloride and Industrial Solvents

Exposure to vinyl chloride has been linked to a number of different autoimmune diseases in humans.

These include a scleroderma-like illness, Raynaud's phenomenon, mixed connective tissue disease, arthritis, neuropathy, and vasculitis [263]. Ingestion of trichloroethylene and other chemicals in well water may also be responsible for an outbreak of a lupus-like syndrome in Arizona [264]. Similar to most environmental exposures, the underlying pathogenic mechanisms are poorly understood. Vinyl chloride appears to be toxic to endothelial cells [265]. The resin can bind to nucleotides, and may induce production of antibodies against nuclear antigens [266]. The oxidized metabolites of vinyl chloride are highly reactive [267]. They can bind to both sulfhydryl and amino groups, causing oxidative cell damage with increased immunogenicity of altered self-antigens. Rats exposed to vinyl chloride for prolonged periods of time have increased collagen deposition in the skin.

Silica, Silicon, and Silicones

Silicon is the second most abundant element on the earth. In nature, it is found in combination with oxygen to yield various forms of silicas, silicates, glasses, and sand. Silicone is a synthetic polymer containing a repeating Si—O backbone, and the organic groups attached to the silicon atom via silicon—carbon bonds determine the class of silicone. Exposure to silica dust has been linked to the development of autoimmune diseases, including scleroderma, and to a lesser extent rheumatoid arthritis. A more recent Spanish report examined the incidence of systemic autoimmune diseases in a group of workers at a scouring-powder factory [268]. The scouring powder is composed of 90% silica. Seventy-two percent of the patients were found to be ANA positive, and 64% of the 50 studied workers were found to have a systemic autoimmune illness. These included 6 patients with Sjögren's syndrome, 5 with scleroderma, 3 with SLE, 5 with a lupus-scleroderma overlap, and 19 with an undefined collagen disease. The incidence of lupus and other autoimmune diseases in this group is much higher than would be expected in the general population. Although interesting, further studies will be needed to determine if the association truly exists.

Silica particles have been shown to induce IL-1 production by macrophages [269]. Animal studies also suggest a potential role for TNF-α. This proinflammatory cytokine may potentially play a role in inflammatory and fibrotic reactions. Workers exposed to silica may have decreased numbers of circulating T cells, and increased numbers of circulating B cells [270]. Hilar lymph nodes in some patients also showed reversal of normal T-helper cells: suppressor-cell ratios, with increased T-helper and decreased T-suppressor cells.

Considerable controversy exists regarding the role of silicone breast implants in the induction of autoimmune diseases, including scleroderma and SLE [271–274]. The pathologic and immunologic effects of silicone have been studied in detail [275, 276]. However, the clinical significance of these observations is unclear. Local inflammatory changes are common. Pathologic studies often show granulomatous, macrophage-rich chronic inflammatory reactions. Silicone has been found to exhibit adjuvant activity in a rat model, and monocytes and macrophages produce IL-1β when exposed to silicone rubber in culture. Fibroblasts have twice as much rough endoplasmic reticulum when they are grown on silicone surfaces compared with polystyrene, and mice exposed to silicone gel have increased numbers of granulocyte-macrophage colony-forming units in the bone marrow, increased hepatic macrophage uptake of radio-labeled sheep erythrocytes, and reduced responsiveness of natural killer cells against YAC target cells. However, despite anecdotal case reports of an association between silicone breast implants and autoimmunity, large numbers of epidemiologic studies including meta-analysis of up to 24 studies have failed to show a causal relationship with any specific autoimmune disease including lupus [277–281].

Hair Dye and SLE

Hair dye has been proposed as a possible etiologic agent in SLE. Hydrazine, an aromatic amine implicated in DIL (see previous discussion), is a common component of hair dyes, and the compound can be absorbed through the scalp [282, 283]. One case-control study suggested an association between permanent hair dye use and connective tissue disease [284]. However, other researchers were unable to confirm this finding [285, 286]. At present, it seems unlikely that this exposure is a significant risk for the development of SLE.

CONCLUSIONS

Many mechanisms have been proposed for how various drugs may cause DIL. Of these, the evidence is best for procainamide and hydralazine, in part because these have been the most extensively studied. The more recent development of animal models for autoimmunity induced by these two drugs is likely to greatly accelerate our understanding of the underlying mechanisms involved.

DRUG AND ENVIRONMENTAL LUPUS: CLINICAL MANIFESTATIONS AND DIFFERENCES

Anne-Barbara Mongey
Evelyn V. Hess

INTRODUCTION

There are increasing numbers of reports and case series of patients who develop lupus-like syndromes following exposure to certain medications and environmental agents. There have been at least 70 pharmacological and other agents implicated in the development of drug-related lupus with more recent reports implicating minocycline, the statin agents, and tumer necrosis factor (TNF) α inhibitors. The most commonly reported clinical features include constitutional symptoms, arthralgias/arthritis, serositis, and the development of autoantibodies. Typically there is resolution of clinical features on discontinuation of the medication, although autoantibodies may persist for prolonged periods of time. There is evidence to suggest that genetic factors play a role in determining which patients develop lupus-like syndrome. Physicians need to be aware of possible associations between the development of autoimmune-like features and exposure to medications and other therapies.

Systemic lupus erythematosus (SLE) is an autoimmune disease for which the etiology(ies) remain undetermined despite intensive research. There is evidence to suggest that genetic factors play a major role in the pathogenesis of this disease. However, results from monozygotic twin studies [1] would indicate that other, most likely environmental, factors are required for the induction of the disease. There have been many reports in the literature of the development of autoimmune phenomenon, such as autoantibodies and autoimmune-like diseases, following exposure to certain environmental agents including chemicals and drugs. The term drug-related lupus (DRL) refers to the development of a lupus-like syndrome following exposure to a certain drug. Typically there is a rapid resolution of the lupus-like clinical features following removal of the offending agent, although autoantibodies may persist for some time. With the introduction of new pharmacological agents, including biological agents, there has been an increase in the number of reports of drug-related lupus syndromes. Unfortunately, many of these reports are in the form of case reports that provide weak evidence for an association between the ingestion of a particular agent and the development of a lupus-like syndrome. In the absence of good controlled prospective studies on large numbers of patients, it can be difficult to confirm a definitive association between the ingestion of an agent and the development of an autoimmune-like disease. In some cases, exposure to the so-called offending agent may either have been coincidental with or even possibly have resulted in the induction of idiopathic SLE. It is important to try to make the distinction between this and the development of drug-related lupus since, in the case of the latter, removal of the offending agent should result in resolution of the

lupus-like syndrome. Ideally, one would like to confirm the association by rechallenge with the offending agent; however, this is seldom done in clinical practice. With the ever increasing availability of new medications, biological therapies, and herbal and other alternative remedies, physicians need to be aware of possible associations between the development of autoimmune-like diseases and the ingestion of these agents.

HISTORY

The first report of an association between ingestion of a drug and a lupus-like syndrome was made in 1945 by Hoffman [2] in which he described the development of fever, rash, myalgia, and nephritis in a 19-year-old man receiving sulfadiazine. Further reports implicating sulfonamides and penicillin followed in the 1950s [3–6] but since then, there has been no further evidence to support a definite association. It is now thought that an association with either of these drugs is unlikely and that previous reports may represent coincidental development of idiopathic SLE. It is also possible that the infection, for which the antibiotic was prescribed, may have played a role in the development of SLE as suggested by the current increasing speculation on a relationship between viral and bacterial infections and SLE. Hydralazine was first incriminated in 1953 by Morrow *et al.* [7]. Since that time there have been numerous other reports confirming this association [8, 9]. Anticonvulsants were first incriminated in 1957 when Lindqvist reported the development of a lupus-like syndrome in two patients administered mesantoin [10]. Procainamide, which is the most common cause of DRL, was first implicated by Ladd in 1962 [11]. A report from France in 1966 suggested an association with isoniazid which was subsequently supported by others [12, 13]. In 1971, Fabius and Gaulhofer [14] implicated the psychotrophic agents. Since the 1970s at least 70 pharmacological and other agents have been reported to be associated with DRL (Table 1). These include a variety of antiarrhythmic, antihypertensive, antipsychotic, antithyroid, antibiotic, antirheumatic, and various biological agents. With increasing physician awareness and introduction of new medications it is likely that this number will continue to increase. It is more common to find reports of an association with serological changes alone than with the development of DRL.

DEFINITION

There are as yet no established criteria for the diagnosis of DRL. The American College of Rheumatology requires 4 of 11 specified criteria to be present in order

TABLE 1 Drugs Definitively Associated with Drug-Related Lupus

Chlorpromazine
Hydralazine
Isoniazid
Methyldopa
Minocycline
Procainamide
Quinidine

Other drugs associated with drug-related lupus

Acebutolol	Metrizamide
Acecainide	Minoxidil
Allopurinol	Nalidixic acid
Aminoglutethimide	
Amoproxan	Nitrofurantoin
Anthiomaline	Nomifensine[a]
Anti-tumor necrosis factor alpha	Oxyphenisatin
Atenolol	Oxyprenolol
Atorvastatin	*Para*-amino salicyclic acid
Benoxaprofen	Penicillamine
Captopril	Penicillin
Carbamazepine	Perazine
Chlorprothixene	Perphenazine
Chlorthalidone	Phenelzine
Cimetidine	Phenopyrazone[a]
Cinnarazine	Phenylbutazone[a]
Clonidine	Phenylethylacetylurea[a]
Danazol	Phenytoin
Diclofenac	Practalol[a]
1-2-dimethyl-3 hydroxy-pyride-4-1	Prazosin
Diphenylhydantoin	Primidone
Disopyriamide	Prindolol
Enalapril	Promethazine
Estrogens	Propafenone
Ethosuximide	Prophythiouracil
Ethylphenacemide	Propranolol
Gold salts	Psoralen[a]
Griseofulvin	Pyrathiazine
Guanoxan	Pyrithoxine
Ibuprofen	Quinine
Interferon alpha	Reserpine
Interferon gamma	Simvastatin
Interleukin 2	Spironolactone
Labetalol	Streptomycin
Leuprolide acetate	Sulindac
Levadopa	Sulfadimethoxine
Levomeprazone	Sulfamethoxypyridazine
Lithium carbonate	Sulfasalazine
Lovastatin	Tetracyclines
Mephenytoin	Tetrazine
Mesalazine	Thionamide[a]
Methimazole	Thioridazide
Methlysergide[a]	Timolol eyedrops
Methylthiouracil[a]	Tolazamide
Metoprolol	Tolmetin
	Trimethadione

[a] No longer available.

to diagnose idiopathic SLE [15]. However, patients with DRL frequently present with less than 4 of these features. A temporal association between the ingestion of an agent and the development of the lupus-like features is required to make the diagnosis. Unlike drug hypersensitivity, it generally requires weeks to months of exposure to an agent before DRL develops. There should be remission of the clinical features with a decrease in the autoantibody titers following withdrawal of the offending agent. Recurrence of the syndrome following reintroduction of the agent would provide confirmatory evidence for an association but this is seldom done in clinical practice given the large number of alternative medications available. The development of anti-nuclear antibodies (ANAs) alone is not sufficient to diagnose DRL. It is now known that many patients will develop anti-nuclear antibodies while taking certain medications but the majority do not appear to develop the features of a lupus-like syndrome. Hence, the development of a positive ANA in the absence of other clinical features is not sufficient reason to discontinue the medication.

PREVALENCE

The real prevalence of DRL is unknown. It has been estimated that approximately one million people in the United States have idiopathic SLE and that up to 5% of these may be related to the ingestion of a pharmacological agent. The prevalence of DRL among certain populations is influenced by the pattern of drug prescription within these groups. With the increasing availability of alternative drugs and therapies, it is likely that the incidence of procainamide- and hydralazine-related lupus will decrease. However, physicians need to be alert to the possibility of new associations, including possible associations with biological agents, herbs, and other such compounds which are being used more frequently.

DEMOGRAPHIC FEATURES

The demographic features of DRL largely reflect those of the diseases for which the incriminated drugs are being prescribed. Hence, DRL occurs more frequently in the elderly population because of their higher incidence of diseases for which the drugs are prescribed. Exceptions include the anticonvulsant drugs and minocycline. Anticonvulsants are more commonly prescribed for children and, hence, most of the reports of anticonvulsant-related lupus have been described in younger age groups [16, 17]. Minocycline is generally used to treat acne in young females and, therefore, minocycline-related lupus has been most frequently reported in this population. In contrast to idiopathic SLE which has a male to female ratio of 1:9, DRL occurs only slightly more frequently in females [16, 18]. This reflects the demographic features of the underlying diseases for which the drugs are prescribed. Drug-related lupus in the United States occurs more frequently in Caucasians than in African-Americans, unlike idiopathic SLE.

CLINICAL FEATURES

Specific clinical features for the diagnosis of DRL have not as yet been defined (Table 2). Hence, the ARA revised criteria for the classification of SLE are often used as a guideline. However, as noted most patients with DRL have fewer than four criteria. A set of ascertainment criteria has been proposed by the

TABLE 2 Frequency of Clinical and Laboratory Features in Idiopathic SLE and DRL

Features	Idiopathic SLE	DRL
Constitutional	40–85	40–50
Arthralgias/arthritis	75–95	80–95
Myalgias	40–80	35–57
Rash	50–70	0–30
Lymphadenopathy	23–67	<15
Pleurisy	42–60	0–52
Pleural effusion	16–20	0–33
Pulmonary infiltrates	0–10	5–40
Pericarditis	20–30	0–18
Hepatomegaly	10–31	0–25
Splenomegaly	9–46	0–20
Renal involvement	50	0–13 (Hydralazine)
Neurological involvement	25–70	0–2
Anemia	30–90	0–53
Leukopenia	35–66	0–33
Thrombocytopenia	20–50	0–10
Positive Coomb's	18–30	0–23
Elevated ESR	50–75	60–93
Anti-nuclear antibodies	>95	100
Antibodies to histones	50–70	>95
Antibodies to dsDNA	50	<5
Anti-Sm antibodies	25	<5
Hypocomplementemia	40–65	0–25
Rheumatoid factor	25	20–40

Environmental Study Section of the American College of Rheumatology [19]. These include a positive ANA.

In the majority of patients, the symptoms are relatively mild compared with idiopathic SLE and acutely ill patients are rarely seen. DRL patients frequently present with constitutional symptoms such as malaise, low grade fever, and myalgia, which may occur acutely or insidiously. Articular features such as arthralgias and arthritis occur in over 80%. Arthralgias occur more commonly than frank arthritis. As seen with idiopathic SLE, there is typically symmetrical polyarticular involvement of mild to moderate intensity. Articular involvement most commonly affects the small joints of the hands followed by wrists, elbows, shoulders, ankles, and knees. Typically the synovial fluid is noninflammatory although inflammatory fluids have also been reported [20]; effusions are an uncommon finding. Pleuropulmonary disease occurs most frequently in procainamide-related lupus. Manifestations include pleurisy, pleural effusion, and pulmonary infiltrates. Pulmonary parenchymal disease has been reported in up to 40% of these patients unlike idiopathic SLE in which it is relatively uncommon [21]. LE cells may be found in pleural fluid of both DRL and idiopathic SLE patients and may be helpful in ruling out other possible causes for effusions, such as pneumonia and pulmonary infarction which can occur in the elderly population. Pericarditis is another manifestation of DRL occurring most frequently in procainamide-related lupus [22]. It may be complicated by the development of a pericardial effusion and even tamponade [23, 24]. LE cells may be detected in the pericardial fluid. Constricted pericarditis has been reported although it is an extremely uncommon manifestation of DRL [25]. Pericarditis has also been associated with mesalazine-induced lupus [26–29].

Other clinical features of idiopathic SLE, in particular dermatological, renal, and neurological features are rare in DRL. There have been reports of discoid lesions occurring with the use of griseofulvin and etanercept [30–32] and two reports of acute neutrophilic dermatosis "Sweet's syndrome" related to the use of hydralazine [33, 34]. The classic malar rash is rarely noted. Elkayam *et al.* [35] reported cutaneous involvment among 5 of 7 patients with minocycline-related lupus, of whom 3 had livedo reticularis and 2 had subcutaneous nodules. None of the 3 patients with livedo had anti-cardiolipin antibodies. Tournigand *et al.* [36] reported the recurrence of a lupus-like syndrome, characterized by arthralgias, fever, and a maculopapular eruption in a 14-year-old girl who had restarted minocycline after previously developing minocycline-related lupus. A few patients have been reported to have hepatosplenomegaly [37] and minocycline has been implicated in the development of an autoimmune hepatitis [38].

Renal involvement has been noted in patients receiving hydralazine [39, 40], although renal biopsy findings are generally minimal and often difficult to distinguish from hypertensive-related changes. However, there have been some reports of patients developing acute nephritis which has resolved on discontinuation of the hydralazine [41]. Reported histopathological findings included focal, segmental, membranous proliferative, and necrotizing glomerulonephritis which are indistinguishable from those seen in idiopathic SLE [39, 42, 43]. While improvement was noted in the majority of patients following discontinuation of the drug, some required treatment with steroids and other immunosuppressant agents while others failed to respond at all. It is unclear whether failure to respond reflected some underlying renal insufficiency secondary to another disease process such as hypertensive-related renal insufficiency. Clinical neurological disease occurs very rarely in DRL although there are a few reports of peripheral and cranial neuropathy occurring in procainamide and hydralazine DRL [44–46]. Vasculitis has also been reported as a manifestation of DRL [42, 47–52]. Lawson *et al.* reported the occurrence of cutaneous vasculitis in 2 of 23 patients with minocycline-induced lupus [51]. Cases of anti-neutrophil cytoplasmic antibodies (ANCA)-positive vasculitis, particularly when associated with anti-myeloperoxidase antibodies, have been associated with exposure to certain medications, such as hydralazine and propylthiouracil [52].

LABORATORY FINDINGS

Laboratory, including hematological, abnormalities occur less commonly in DRL than idiopathic SLE. One needs to keep in mind that many of the patients will exhibit abnormalities as a result of the underlying disease for which the medication has been prescribed. The erythrocyte sedimentation rate (ESR) is frequently elevated and often reaches moderate to high values; it quickly returns to the normal range with resolution of the clinical features of DRL. C-reactive protein is increased in cases of minocycline induced lupus. A mild, generally normochromic, normocytic, anemia may be seen although severe hematological abnormalities are rare [53]. Mild leukopenia and thromobcytopenia can also occur. A positive Coombs test has been reported in patients receiving methyldopa, procainamide, and chlorpromazine [54–59]. Hemolytic anemia has been reported in some patients receiving methyldopa [60].

Increased immunoglobulin levels may occur but less frequently than with idiopathic SLE. Circulating immune complexes have been described in procainamide- and hydralazine-related lupus [61, 62]. There have been a few

reports of decreased C3 and C4 levels in patients with procainamide- and quinidine-related lupus [63, 64]. However, levels tend to return to normal on discontinuation of the drug. Persistently low complement levels should suggest idiopathic SLE. Deposition of immunoglobulins at the dermal–epidermal junction (lupus band test) has been reported in patients with DRL secondary to procainamide and penicillamine [65, 66]. Immunoglobulin and complement deposition has also been noted in the glomeruli of a few patients with hydralazine-related lupus [40,43,67].

It is generally accepted that anti-nuclear antibodies need to be present in order to diagnose DRL, although their presence alone is not sufficient to make the diagnosis. Typically a diffuse/homogeneous staining pattern is seen although other patterns have occasionally been reported. The antigenic specificity of these antibodies are more restrictive compared with idiopathic SLE [68]. In particular, antibodies to the Sm antigen have rarely been described in DRL and their presence should strongly suggest idiopathic SLE. Antibodies to double-stranded (ds)DNA are uncommon findings in drug-related lupus but they have been reported to develop in patients treated with TNF-α inhibitors, sulphasalazine, and minocycline [69–71]. Studies by Charles *et al.* indicated that the incidence of anti-dsDNA antibodies among patients receiving infliximab varied according to the assay used [71]. Their data suggested that high affinity anti-dsDNA antibodies were more predictive of the development of lupus-like syndromes. Antibodies to single-stranded DNA are a relatively common finding but are considered nonspecific. Positive rheumatoid factors have also been reported [57] and considered to be nonspecific most likely representing cross-reactivity with anti-histone antibodies.

The homogeneous/diffuse fluorescent ANA staining pattern represents binding of antibodies to chromatin which consists of DNA and histones. There are five different histone proteins, namely H1, H2A, H2B, H3, and H4 seen in humans. The specificity of the autoantibody for these different histone proteins varies between the different drugs. Anti-histone antibodies seen in patients receiving procainamide commonly react with the H2A–2B dimer, its complex with DNA, and also with chromatin itself [72, 73]. It has been suggested that IgG antibodies to (H2A–2B)–DNA complex and to chromatin are specific for drug-related lupus while IgM antibodies to this complex and antibodies directed against the H2A–2B are most commonly found in asymptomatic patients receiving procainamide [73]. Antibodies against the (H2A–2B)–DNA complex have also been reported in DRL secondary to isoniazid, quinidine, sulfasalazine, penicillamine, and timolol [64, 74–76]. Antibodies from procainamide patients also exhibit reactivity with individual subfractions, most commonly the H1 [77]. Anti-histone antibodies from patients with hydralazine-related lupus recognize a broader array of autoantigenic epitopes including the individual histones H1, H3, and H4 and the H2A–2B and H3–H4 complexes [78–80]. Antibodies from procainamide-related lupus patients have also demonstrated reactivity with the H3–H4 complex but to a lesser degree than that to the H2A–2B complex [79]. Antibodies to the H1 and H2B subfractions have been reported in quinidine-related lupus [81]. It has been suggested that a switch from the IgM to IgG isotype precedes the development of lupus-like syndrome in patients receiving procainamide and this may also be true for other drugs [82]. While anti-histone antibodies are frequently found in DRL they are also found in idiopathic SLE and hence are not considered diagnostic for drug-related lupus [68, 77, 83]. In addition, anti-histone antibodies are not a common feature of minocycline-related lupus. In contrast, antibodies to double-stranded DNA are highly specific for idiopathic SLE and their presence would tend to rule out a diagnosis of drug-related lupus although they have been described in patients with minocycline-related lupus and patients receiving infliximab [35, 71].

Anti-phospholipid antibodies and lupus anticoagulants have been reported with drug-related lupus. They have been described in patients receiving chlorpromazine, perphenazine, procainamide, quinine, quinidine, hydralazine, sulfasalazine, and minocycline [35, 51, 59, 84–101]. These antibodies are most frequently of the IgM subclass and in prospective studies have not been associated with a significant increase in thrombotic events [84, 101] although there have been individual case reports suggesting an association [87, 89, 93].

Anti-neutrophilic cytoplasmic antibodies giving a perinuclear pattern (p-ANCA) on indirect immunofluorescence have been associated with the use of some medications. These include minocycline, sulphasalazine, hydralazine, and propylthiouracil [35, 51, 52]. Anti-neutrophilic cytoplasmic antibodies have been described with hydralazine-related lupus; these antibodies react with myeloperoxidase and elastase [102–104]. Choi *et al.* determined the prevalence of exposure to medications associated with ANCA-positive vasculitis among 30 patients with the highest titers of anti-myeloperoxidase antibodies among 250 patients in whom p-ANCA and anti-myeloperoxidase antibodies had been assayed [52]. Of the 30 patients, 10 (33%) had been exposed to hydralazine, 3 (10%) to propylthiouracil, 2 to penicillamine, one to sulphasalazine, and 2 to allopurinol. All patients had clinical and histological findings typical of ANCA-positive vasculitis. There was a strong association between the presence of anti-elastase and/or anti-lactoferrin antibodies and exposure to these medications. Although not all the 30 patients

had documented histological findings diagnostic of ANCA-positive vasculitis, all had the typical features of this entity. There are also reports associating anti-myeloperoxidase antibodies with exposure to hydralazine and propylthiouracil in the absence of vasculitis (105–107).

It is difficult to estimate the incidence of drug-induced ANCAs because of the lack of prospective studies. Choi *et al.* evaluated sera prospectively collected as part of three separate double-blind controlled trials for ANCA seroconversion [108]. The three prospective studies consisted of a 40-week trial of minocycline and a 37-week trial of sulfasalasine, both for treatment of rheumatoid arthritis, and a 104-week trial of penicillamine for the treatment of early systemic sclerosis. Sera of 12 patients from the combined total of 228 patients contained anti-myeloperoxidase antibodies, but no patients seroconverted to a positive ANCA during the duration of the respective studies. Hence, the exact role of drugs in the development of ANCAs remains unclear.

Lymphocytotoxic antibodies have been reported in patients with drug-related lupus secondary to procainamide, hydralazine, and phenytoin [109–112].

Antibodies to hydralazine and procainamide have been reported in patients receiving these medications [113, 114]. Antibodies against the incriminated drug appear to occur more frequently in patients with hydralazine-related lupus compared to those with procainamide-related lupus. The actual significance of these antibodies has yet to be defined.

DIFFERENTIAL DIAGNOSIS

Since many of the features of drug-related lupus are relatively nonspecific, it can be difficult to make a definitive diagnosis. A variety of inflammatory, infectious, and other autoimmune diseases can present with similar features and patients may not give accurate histories of previous medication usage as noted by Gordon and Porter [70]. In particular it is often difficult to differentiate DRL from idiopathic SLE. Since renal, cutaneous, neurological, and severe hematological involvement is rarely seen in drug-related lupus, the presence of these features would suggest idiopathic SLE. Demographic features may also be helpful in distinguishing between these two diseases since, with the exception of anticonvulsants and minocycline, DRL generally occurs more frequently in elderly Caucasian males in contrast to idiopathic SLE. The presence of antibodies to double-stranded DNA, Smith, and Ro antigens would favor idiopathic SLE. Other differential diagnoses would include infections, in particular viral syndromes which are a recognized cause of arthropathies. However, in most cases of virus-related arthropathy the symptoms resolve spontaneously within a matter of weeks to months. Osteoarthritis is a frequent finding in the elderly population and the articular symptoms of DRL may be mistaken for this especially if the symptoms are of an insidious onset. The diagnosis of DRL related to the use of minocycline and TNF-α inhibitors may be particularly problematic since both of these drugs are used to treat rheumatoid arthritis and it may be difficult to distinguish the development of DRL from a flare of rheumatoid arthtitis. Supervised rechallenge with the suspected medication may be helpful in confirming the diagnosis as suggested by the study by Lawson *et al.* [51].

THERAPY

The definitive treatment is withdrawal of the offending agent. In some cases, this can be difficult since many patients are on multiple medications. Generally, there is significant improvement in the symptoms within days of discontinuation of the medication. Rarely, it may take some weeks for improvement to occur. However, occasionally some patients with persistent symptoms may require further therapy. Nonsteroidal anti-inflammatory agents are useful to treat constitutional symptoms such as low grade fevers, arthralgias, and myalgias and may also be used to treat pleuritis and pericarditis. In patients with more severe involvement, such as large pleural or pericardial effusions, steroids are required. Generally these can be successfully tapered once the clinical features have resolved. Pericardectomy has been used in the treatment of constrictive pericarditis secondary to procainamide. In the rare instance where a patient requires continuation of the offending medication for medical reasons, symptoms have been treated with either a nonsteroidal anti-inflammatory agent or steroids. However, with the greater availability of alternative medications, in particular the antiarrythmic agents, this is rarely if ever necessary.

COMMENTS ON CERTAIN DRUGS ASSOCIATED WITH DRUG-RELATED LUPUS

Many of the incriminated drugs have (1) an arylamine or hydrazine functional group, (2) a sulfhydryl or thiono sulfur group, or (3) are hydantoins possibly metabolized to phenol. Since not all individuals exposed to a certain drug will develop autoimmunity, this suggests that other factors may be very important. Certain

individuals may metabolize drugs and other agents at a faster rate than others. Polymorphisms of genes coding for enzyme systems exist and these may be important in determining exposure time of the host to certain agents or their metabolites. Study of the metabolites of the various compounds is very important to determine if a metabolite(s) is involved in the autoimmune phenomenon. A number of polymorphisms have been reported for the cytochrome P450 enzyme system which is known to play an important role in the metabolism of both endogenous and exogenous agents.

Hydralazine

Hydralazine was introduced as a new antihypertensive agent in 1952 and it is generally accepted to be the first drug definitively associated with DRL [7]. Reports have indicated that between 24 and 54% of patients receiving hydralazine develop anti-nuclear antibodies; however, only 2 to 21% of patients develop lupus-like symptoms [9]. The most common symptoms are fever, malaise, arthralgias, and arthritis. Serositis may also be seen but occurs less commonly than with procainamide-related lupus. Renal involvement has also been reported with this drug although in some cases it is unclear whether the renal manifestations may not in fact be related to the underlying hypertension. The development of hydralazine-related lupus is dose related. Patients receiving greater than 200 mg per day of hydralazine have a significant increase risk of developing DRL compared with those receiving smaller doses [48]. The risk has also been related to the acetylator phenotype which is under genetic control [115]. DRL occurs more commonly in patients who are slow acetylators. This is believed to be due to the slower rate of inactivation of the parent compound through acetylation of its hydrazine group by the hepatic acetyl transferase enzymes.

The development of hydralazine-related lupus has been linked to the HLA Class II and III genes. In 1980, Batchelor *et al.* reported a frequency of 79% for the HLA-DR4 antigen in patients who developed hydralazine-related lupus compared to 25% in asymptomatic hydralazine-treated controls [18]. However, a subsequent study by Brand *et al.* of 18 Australian patients with hydralazine-related lupus failed to show an increased frequency of the HLA-DR4 antigen compared with a control group from Melbourne [116]. A study by Russell *et al.* [117], reported a frequency of HLA-DR4 antigen of 70% among 20 patients with hydralazine-related lupus compared with a frequency of 33% in the general population. Six of these 20 patients had been included in the 1980 study by Batchelor *et al.* A further study by the Batchelor group examining a possible role of polymorphisms of the HLA Class III gene noted a significant increase in the frequency of one or more null alleles of the genes coding for C2, C4A, and C4B among 21 cases with hydralazine DRL compared with 82 normal controls [118]. Of interest was the finding of a significantly higher frequency of the HLA-DR4 antigen among the patients compared with the controls. The genes which code for C2, C4A, and C4B are located on chromosome 6 adjacent to the HLA DR regions and their alleles exhibit linkage disequilibrium with HLA DR alleles. In particular, the C4B null allele is in linkage disequilibrium with HLA-DR4 antigen. It has therefore been postulated that it may be the C4 null allele in linkage disequilibrium with the DR4 antigen that is important in determining susceptibility to the development of DRL in patients receiving hydralazine. If no linkage disequilibrium exists between the HLA-DR4 and the C4 null alleles among the Australian population, this could explain the discrepancy between the results of the previously mentioned studies.

Anti-phospholipid, lymphocytotoxic, anti-neutrophilic cytoplasmic antibodies and antibodies to poly A and Z-DNA have been described in patients receiving hydralazine in addition to anti-nuclear and anti-histone antibodies [99, 102–104, 111, 119, 120]. The pathogenic significance of these autoantibodies have yet to be elucidated. The frequency of hydralazine-related lupus appears to have decreased during the more recent years as the dosages and use of the drug have decreased.

Procainamide

Procainamide is a class I antiarrhythmic agent and is believed to be the commonest cause of DRL in the United States. A positive ANA has been reported to develop in up to 90% of patients [72]. Approximately 30% of these patients will subsequently develop DRL [121]. The duration of therapy prior to the onset of symptoms varies from 1 month to as late as 12 years with an average of 1 year [57]. Common features include constitutional and musculoskeletal symptoms with approximately half of the patients developing pleuropulmonary involvement and/or pericarditis. Although there is a weaker relationship with acetylator status compared to hydralazine, it has been reported that patients with a slow acetylator phenotype will develop ANAs and DRL after a shorter duration of therapy compared to those with a fast acetylator phenotype [121]. However, this difference in phenotypes is less obvious if the dose is titrated such that the plasma levels of the drug are equivalent between the two groups [122]. A more recent study did not find an association between slow acetylator status and the development of procainamide-related lupus although patient numbers

were small [123]. However, this suggests that other factors are involved. A positive association of DQβ1 DQw7 (split of DQw3) with antibodies to histone subfractions (H2A–2B), Z-DNA, and poly A has been reported in asymptomatic patients receiving PA [124].

As with hydralazine, lymphocytotoxic, antiphospholipid antibodies, lupus anticoagulants, and antibodies to poly A and Z-DNA have been described in patients on procainamide [72, 88–94, 109]. Antibodies to procainamide have also been reported [114].

Isoniazid

Anti-nuclear antibodies develop in approximately 20–25% of patients receiving isoniazid; however, less than 1% of patients develop a lupus-like syndrome [125]. Common features of isoniazid-related lupus include fever, arthralgias, and arthritis and less commonly serositis. IgG anti-nuclear antibodies against the nucleohistone complex (H2A–H2B)–DNA have been reported in a patient with isoniazid related lupus [126]. Since other antituberculous agents and tuberculosis itself have been reported to be associated with ANAs and rheumatoid factors, it may be difficult for the clinician to determine if isoniazid has a pathogenic role in the development of new lupus-like symptoms. Although isoniazid is also inactivated through acetylation, no association between acetylator phenotype and the development of ANA and/or DRL has been reported [127, 128].

Quinidine

Quinidine is another class I antiarrhythmic agent associated with the development of DRL. The first report by Kendal and Hawkins was published in 1970 [129]. At least 29 further reports of quinidine-related lupus have appeared in the English literature since then [130]. Quinidine-related lupus occurs primarily in older White patients (mean age of 63 years) and equally in men and women. There has been one case report in an 11-year-old girl. Typically, symptoms develop after 1–18 months of therapy, and resolve within 1–4 weeks. Of interest is the report of development of quinidine-related lupus in two patients who had a previous history of procainamide-related lupus [131]. In both cases, there had been resolution of the symptoms following discontinuation of procainamide and prior to the institution of quinidine.

The most common clinical features are those of arthralgias and arthritis which are characterized by symmetrical involvement of the hands and wrists and less commonly involvement of the shoulders and knees. Hence, it may be mistaken for rheumatoid arthritis. Less frequently reported features include fever, rash, serositis, and hepatic and neurological involvement, primarily manifested by carpal tunnel syndrome and peripheral neuropathy. Thrombocytopenia and leukopenia have been reported in 47 and 24% of patients, respectively. Hypocomplementemia has been reported in a few patients. While the ANA fluorescence pattern associated with DRL is typically homogeneous, both speckled and homogeneous patterns have been seen in patients with quinidine-related lupus. Both IgG and IgM classes of anti-histone antibodies have been reported which may demonstrate reactivity with H1, H2B, and the complexes H2A–2B and H3–H4 [130]. The lupus anticoagulant has also been described.

There have been three cases of development of polyarthropathy alone in patients receiving quinidine which resolved on discontinuation of the drug and recurred on rechallenge [64]. None of these three patients, however, had a positive ANA and the articular symptoms were milder than those usually seen with quinidine-related lupus. The duration of therapy was shorter and the symptoms resolved within 1 week of discontinuation of the drug. It is unclear whether these may represent a variant of quinidine-related lupus.

Quinine, an antimalarial drug analog of quinidine, has also been reported to be associated with the development of autoantibodies and a lupus-like syndrome [98].

Anticonvulsants

Many anticonvulsants have been implicated in the development of DRL, of which the most common are the hydantoins, ethosuximide, trimethadione, and carbamazepine [16, 17, 132–135]. There have also been reports implicating primidone and valproate [136]. The demographic features of anticonvulsant-related lupus differ from the other forms of DRL in that the majority of patients have been children and young females. Problems arise in deciding whether the development of lupus-like symptoms in patients receiving anticonvulsants represent a form of DRL or are in fact a manifestation of idiopathic lupus of which the seizure disorder is the presenting feature. This may pose particular diagnostic and management problems in adults as there may be a history of continuing convulsions and possibly psychiatric problems.

Some studies have reported a higher frequency of ANAs in children receiving anticonvulsants. Beernik and Miller [16] reported that 11 of 48 children receiving anticonvulsant therapy at a pediatric neurology clinic had anti-nuclear antibodies although none had any symptoms suggestive of lupus. They also reported 5 patients with anti-nuclear antibodies and lupus-like

symptoms. Singsen and colleagues reported that 14 of 70 patients receiving anticonvulsants associated with DRL had high titers of ANA compared with low titers in 5 of 23 receiving phenobarbitol and 1 of 50 controls [17]. In addition, they reported 5 patients who developed a lupus-like syndrome while receiving ethosuximide characterized by fever, malaise, rash, arthritis, and serositis. There was resolution of these symptoms in 4 of 5 children following discontinuation of ethosuximide although 3 did require prednisone. Histone antibodies have been described in a patient who developed DRL secondary to ethosuximide [137]. Interestingly, there does not appear to be a relationship between phenobarbital and DRL and there is only one case report suggesting a relationship with one of the benzodiazepines. The report described a photosensitive skin eruption resembling discoid lupus, mild leukopenia, and positive ANA and rheumatoid factor in a 7-year-old girl during clobazam therapy [138]. There was resolution of the cutaneous lesions and autoantibody disappearance following discontinuation of this drug. A study by Verrot *et al.* of 163 patients attending a medical center specializing in epilepsy found that 41 patients (25%) had anti-nuclear antibodies compared with 10% of the controls [139]. But no statistical association was found between the presence of anti-nuclear antibodies and the type of epilepsy, the kind of antiepileptic drug, or the age or sex of the patient. However, the numbers were relatively small and hence, may not have allowed for an association to be detected. IgG class anti-cardiolipin antibodies were found in 31 patients, although no patient had a history of a thrombotic event.

Chlorpromazine

Anti-nuclear antibodies occur in 20–50% of patients treated with chlorpromazine [140], but a lupus-like syndrome develops in less than 1%. Typical features are fever, arthralgias/arthritis, serositis, and cutaneous features [87, 141]. Photosensitivity and malar rashes have been reported which have resolved on discontinuation of the drug. Over 50% of patients have been reported to have splenomegaly. Significant elevation of IgM, prolongation of PTT, and both lupus anticoagulant and anti-cardiolipin antibodies have been described in patients receiving long-term chlorpromazine therapy [84, 101]. Canoso and de Oliveira [84] noted that 54 of 96 of these patients had IgM lupus anticoagulants and, of these, 31 had IgM and 4 had IgG anti-cardiolipin antibodies; 5 patients had anti-cardiolipin antibodies alone. Only 3 patients developed thrombotic episodes over a median follow-up period of 5 years suggesting a low risk for thrombosis. A study by Zarrabi *et al.* [59] noted that 41 of 47 patients receiving chlorpromazine for greater than 2.5 years had a circulating anticoagulant. It should be noted that many of the patients studied in the reports were hospitalized for psychiatric and psychological disorders raising the question of whether or not these disorders may have represented a manifestation of SLE. This points out the great importance of follow-up studies for all drugs and environmental agents to observe the consequences of discontinuation of the possible offending agent.

Beta Blockers

Anti-nuclear antibodies occur in 10–30% of patients receiving beta blockers. Of these, acebutolol has been the drug most commonly implicated followed by labetalol (14–16%), oxprenolol (13%), metoprolol (12%), propranolol (10%), and pindolol (10%) [142–146]. ANA titers tend to rise with duration of therapy and decrease following discontinuation of the drugs. Lupus-like syndromes rarely occur with these agents although there are reports implicating practolol, acebutolol, labetalol, and pindolol. There is also a case report of a lupus-like syndrome developing in a patient receiving ophthalmic timolol which was associated with markedly elevated IgG antibodies to the (H2A–2B)–DNA complex [76].

ACE Inhibitors

Anti-nuclear antibodies have been reported in patients receiving captopril and enalapril [147–153]. Reidenberg *et al.* [147] noted that 10 of 37 patients developed anti-nuclear antibodies while receiving high doses of captopril. Three of 9 patients receiving enalapril developed a positive ANA test (titer greater than 1:160) during a 6-week follow-up study by Schwartz *et al.* [151]. Of interest was the fact that none of these patients were ANA-positive prior to starting the drug. There have been a few case reports implicating captopril as a cause of DRL. Two patients developed serositis and anti-nuclear antibodies which resolved on discontinuation of the drug [149, 152]. Another patient developed myalgia, arthralgia, photosensitivity, anti-nuclear antibodies, and IgG antibodies to H2A–2B dimer after taking captopril for 2.5 years; there was significant improvement in the clinical symptoms following withdrawal of the medication [153].

Sulfasalazine

Sulfasalazine was first implicated in drug-related lupus in 1965 when Alarcon-Segovia *et al.* described the development of a lupus-like syndrome and LE cells in 5 patients receiving sulfasalazine for treatment of

ulcerative colitis [154]. Since then, there have been a number of reports on the development of autoantibodies and lupus-like syndromes in patients receiving this drug for treatment of inflammatory bowel disease and arthropathies [69, 75, 100, 154–163]. Dekeyser *et al.* reported the development of anti-nuclear antibodies in 13 of 77 patients with spondyloarthropathy while receiving sulfasalazine [155]. The most common clinical manifestations of sulfasalazine-related lupus are arthralgias, arthritis, pleuritis, pericarditis, and pleural effusions. There have been two reports of a patient developing cardiac tamponade [157, 161]. Fevers and a variety of cutaneous lesions have also been described. Anti-histone antibodies including IgG antibodies to the H2A–2B dimer and (H2A–2B)–DNA complex have been noted [75]. Some patients have had anti-cardiolipin and anti-neutrophil cytoplasmic antibodies [100, 163]. Mielke *et al.* [69] reported that 20 of 24 patients with inflammatory arthritis treated with sulfasalazine developed double-stranded DNA antibodies although only one developed symptoms of DRL. The occurrence of these antibodies was transient in the majority of patients.

Gordon *et al.* evaluated 100 patients with rheumatoid arthritis who were enrolled in a prospective randomized trial comparing sulphasalazine and auranofin for the development of ANAs and lupus-like syndromes [164]. Fourteen (19%) of 72 patients treated with sulphasalazine who were either ANA-negative or weakly ANA-positive at the start of the study became strongly ANA-positive during the study. This compared with an incidence of 14% among 80 patients randomized to receive auranofin. Despite the development of ANA positivity no patient developed a lupus-like syndrome. This suggests that the occurrence of ANA positivity either prior to or during treatment with sulphasalazine does not preclude treatment with this medication.

Gunnarrson *et al.* evaluated the prevalence of lupus-like reactions among 41 consecutive patients with early rheumatoid arthritis who were treated with sulphasalazine as single therapy for at least 6 months [165]. Two patients developed anti-dsDNA antibodies after approximately 12 months of treatment and 1 of these patients also developed a photosensitive rash. Another patient developed biopsy proven membranous nephritis, compatible with lupus nephritis, after 26 months of treatment with sulphasalazine. One patient developed a sun rash and increasing titers of ANA after 6 months of therapy and a fourth patient, who developed anti-dsDNA antibodies remained asymptomatic. All 4 patients were ANA-positive. Sixteen (39%) patients had ANAs prior to institution of sulphasalazine and 13 (32%) were ANA-positive following 6 months of therapy. Patients who developed lupus-like features did not have a significantly higher ANA titer. However, there was a correlation between ANA positivity and a speckled pattern prior to initiation of treatment, regardless of titer, and the development of lupus-like features. Three of the 4 patients who developed lupus-like features had the HLA DR 0301 haplotype compared with 4 out of 37 patients without lupus-like symptoms. The occurrence of this SLE-related HLA haplotype among those patients who developed a lupus-like syndrome suggests a genetic role for the development of sulphasazine-induced lupus. Increased interleukin (IL)-10 levels were also seen in these patients.

Since increasing numbers of patients are being treated with sulfasalazine for inflammatory arthropathies, such as rheumatoid arthritis and spondyloarthropathies, one must consider the possibility of development of DRL in any patient who has a significant increase in their articular symptoms.

It has been suggested that it is the sulfonamide component of sulfasalazine that is responsible for the development of the autoimmunity since sulfonamides have previously been associated with DRL. However, there are a number of reports implicating mesalazine as a cause of DRL suggesting that the presence of sulfapyridine is not necessary. Dent *et al*. described the development of pleuropericarditis, fever, and a positive ANA in a patient receiving mesalazine [26]. Kirkpatrick *et al*. reported that four patients with inflammatory bowel disease, treated with 5-aminosalicylic acid (5-ASA), developed ANA-positive-arthralgias and inflammation which resolved rapidly following discontinuation of the 5-ASA compounds [166]. Timsit *et al*. reported the case of a patient with Crohn's disease who developed polyarthritis, alopecia, lymphoneutropenia, positive ANA, and antibodies to histones, Smith, and RNP while being treated with mesalazine [167]. There was rapid resolution of the clinical features and a decrease in the levels of autoantibodies with discontinuation of the medication. Vayre *et al*. described the case of a 53-year-old male with Crohn's disease, for which he had been treated for approximately 8 years with mesalazine, who developed chest pain, ST segment elevation, and a small pericardial effusion [27]. Resolution of these features occurred following discontinuation of mesalazine. Molnar *et al*. reported the case of a 29-year-old woman with inflammatory bowel disease, treated with mesalazine for approximately 2 months, who developed pericarditis and a moderate size pericardial effusion which responded to the institution of steroids, despite the fact that she remained on mesalazine [28]. She also had a positive p-ANCA. Sentongo and Piccoli reported the case of a child who developed pericardits, believed to be secondary to treatement of mesalazine [29]. Gunnarsson *et al*. described the case of a 43-year-

old female with Crohn's disease who developed polyarthritis involving the small joints of her hands, wrists, ankles, and MTP joints [168]. ANA and IgG anti-cardiolipin antibodies were markedly positive, anti-histone antibodies were positive, and antibodies to dsDNA were borderline elevated. Her clinical features resolved within 2–3 weeeks of discontinuation of the medication, although her ANA and IgG anti-cardiolipin antibodies were still positive 1 year later. She was noted to be DQA1*0501 haplotype positive. This haplotype has previously been reported to occur more frequently among patients with sulphasalazine-induced lupus syndrome suggesting a genetic predisposition [169].

Minocycline

Minocycline hydrochloride is a semisynthetic tetracycline used for a variety of infections and for the long-term treatment of acne vulgaris. It was first associated with DRL in 1992 by Matsuura *et al*. [170]. There have been at least 56 further cases reported in the literature since then [35, 36, 38, 51, 70, 171–177]. Minocycline has also been implicated in the development of autoimmune hepatitis [38]. In addition to case reports, there have been a number of case series of lupus-like syndromes developing among patients receiving minocycline [171, 177]. In contrast to other forms of DRL, a similar gender profile to that of idiopathic SLE has been observed since the great majority of these cases have occurred in young women who were being treated for acne, although it may occur in men. Autoimmune hepatitis has been reported to occur in the majority of men who develop minocycline-related lupus [35].

The most commonly reported features include constitutional symptoms, rash, polyarthralgias, an inflammatory arthritis which tends to affect the small joints of the hands, wrists, shoulders, and ankles in a symmetrical fashion, and autoimmune hepatitis [36, 175, 176, 178]. Pleuropulmonary involvement has been described in some patients, and livedo reticularis has also been noted [35, 38, 174]. Elkayam *et al*. reported cutaneous involvment among five of seven patients with minocycline-related lupus, of whom three had livedo reticularis and two had subcutaneous nodules [35]. None of the three patients with livedo had anti-cardiolipin antibodies and only two had positive ANAs. Dunphy *et al*. reported that two patients treated with minocycline developed erythema on their legs, two an urticarial eruption, one patient thrombocytopenia, and another patient anemia [178].

Anti-nuclear antibodies and p-ANCAs with titers varying from 1:80 to 1:1280 are a common finding [35, 51, 178]. Anti-dsDNA and anti-cardiolipin antibodies occur less often and anti-histone antibodies, which are a common finding in other forms of drug-related lupus, are not commonly seen in patients with minocycline-induced lupus. Duration of minocycline therapy prior to the onset of symptoms varies from a few weeks to up to 10 years. As with other forms of drug-related lupus, there is resolution or significant improvement of the clinical features in most cases following the drug withdrawal although some patients have required institution of steroids. Serological features also improve following discontinuation of minocycline, although they can persist for several months following discontinuation. The autoimmune hepatitis tends to resolve more slowly [35]. There are reports of an allergic type fulminant type hepatitis and of hypersensitivity-like reactions consisting of fever, lymphadenopathy, and skin eruption developing in patients receiving minocycline [175].

Gordon and Porter [70] reported the clinical and serological features of a case series of 20 patients diagnosed with minocycline-related lupus over a 5-year period in the west of Scotland. Minocycline had been prescribed for a mean of 25 months, range of 3–60 months, prior to the onset of symptoms. Fifteen patients were female and 5 were male, with the mean age of 24 years. Twenty patients had arthritis with some patients complaing of lethargy, myalgia, and fever. Discontinuation of minocycline led to resolution of symptoms in all patients after a mean of 15.7 weeks (range of 2 to 56 weeks). All patients had a positive ANA, 2 patients had anti-cardiolipin antibodies, and 1 patient had a positive p-ANCA. Eight of 20 (40%) patients had antibodies to dsDNA, of which 2 were positive using the *Crithidia* assay. Antibodies to dsDNA had disappeared and ANA titers decreased during the follow-up period. Six of the patients who had initially denied talking minocycline developed a recurrence of symptoms after a mean of 4.5 days (range: 2–7 days) of restarting minocycline. Two of these patients required treatment with steroids and 5 received hydroxychloroquine. Thus, denial of previous use of minocycline does not rule out the possibility of minocycline-related lupus and rechallenge with the medication may be helpful in establishing the diagnosis.

Some patients have been rechallenged with minocycline and have developed a recurrence of their joint symptoms within a few days. Lawson *et al*. reported on the series of 23 patients with minocycline-induced lupus [51]. All the patients complained of polyarthralgias with 3 patients having synovitis of the MCP and PIP joints and one patient an effusion. Cutaneous vasculitis occurred in 2 patients. Five patients complained of impaired concentration and poor memory and 1 patient had neuropathy. Nineteen patients had positive ANAs with titers varying from 1:40 to greater than 1:16,000. Four patients had antibodies to ds-DNA by ELISA and

Crithidia assays and 10 patients had positive p-ANCAs, with the majority having titers of 1:160 or greater. Of these 10 patients, 7 had antibodies to myeloperoxidase. Anti-histone antibodies were not detected in the 9 patients in whom they were sought. Following discontinuation of minocycline, 10 patients became asymptomatic within 1 month, 9 patients had improved within 1–6 months, and 3 within 6–12 months; it took 2 years for the symptoms to resolve in 1 patient. Four patients with severe disease required treatment with corticosteroids. There was no correlation between duration of treatment with minocycline and the time taken for resolution of the symptoms following discontinuation of the drug. Anti-nuclear antibodies remained strongly positive in 4 patients but became negative in the remainder of patients within 2 years of withdrawal of minocycline. Recurrence of symptoms occurred within hours of restarting minocycline in 5 patients. Ten additional patients underwent a supervised rechallenge with minocycline. There was a recurrence of symptoms in 7 patients within 12 h and in the remaining 3 patients within 72 h of ingesting a single 100-mg dose of minocycline. Two patients who were rechallenged required a short course of steroids; all subjects were asymptomatic again within 2 weeks. Elkayam *et al*. rechallenged 5 patients with a single dose of 50 mg of minocycline: all 5 patients developed arthralgias within 24 h that subsequently resolved spontaneously [35]. Thus, supervised rechallenge may be helpful in confirming the diagnosis in some patients.

In a case control study of 27,688 acne patients, Sturkenboom *et al*. reported an 8.5 risk of developing a lupus-like syndrome among patients who were current users of minocycline compared with previous and nonusers of tetracycline combined [179]. Current exposure to minocycline and a cumulative dose above 100 defined daily doses increased the risk 16-fold. Among females, there were 17.2 cases of lupus-like syndrome per 100,000 prescriptions for oxytetracycline and 52.8 cases per 100,000 prescriptions for minocycline, suggesting that minocycline is more likely to induce lupus-like syndromes compared with other forms of tetracycline. There are early reports implicating tetracycline in DRL. However, it is generally considered that the association with tetracyclines is weak and reported cases may in fact represent an exacerbation of SLE. Work by McHugh *et al*. suggests that minocycline-induced toxicity may be mediated through an oxidized metabolite and be myeloperoxidase dependent [180]. The enzymes involved in the metabolism of minocycline may bind to a reactive intermediate acting as a hapten, leading to the formation of a neoantigen with consequent induction of an autoimmune response. Herzog *et al*. suggested that there may be an antibody reaction to a metabolite of minocycline which cross-reacts with microsomal chromosomes in the liver [181]. They reported that serum obtained from a patient with minocycline induced autoimmune hepatitis reacted with a 50-kDa protein from rat liver microsomes. Minocycline is known to have immunomodulating properties and has been demonstrated to affect production of cytokines, including TNF-α [182]. These effects on cytokine production may play a role in the development of minocycline-related autoimmunity.

Reports have also suggested a role for MHC Class II genes in the development of minocycline-related lupus. Dunphy *et al*. reported a case series of 14 patients who developed minocycline-induced lupus after using minocycline for a median of 3.8 years (range: 1–10 years) [178]. Discontinuation of minocycline led to resolution of symptoms in all patients within days to 6 months. Recurrence of symptoms was seen among patients, who were rechallenged with minocycline. Sera from all 14 patients had ANCAs giving a perinuclear pattern on indirect immunofluorescence. Eleven patients had elevated anti-myeloperoxidase antibodies and 10 had anti-elastase antibodies which decreased following discontinuation of medication. All 13 patients who were tested were either HLA-DR4 (9 patients) or HLA-DR 2 (4 patients) -positive and all had an HLA-DQB1 allele. The authors suggested that the presence of p-ANCA may be a marker for the development of lupus-like symptoms in genetically susceptible individuals prescribed minocycline. Elkayam *et al*. reported that 4 out of 6 patients whom they had HLA typed had HLA DRβ1*0104 that compared to an expected frequency of 12% in the general Israeli population [35].

Lipid Lowering Agents

There have been some case reports associating the use of HMG-CoA reductase agents with the development of lupus-like syndromes. Lupus-like syndromes have been associated with the use of lovastatin, simvastatin, atorvastatin, and fluvastatin. Ahmad [183] described two patients who developed malaise, inflammatory polyarthritis, and ANAs while receiving lovastatin. Anti-histone antibodies were detected in one patient. Both patients had resolution of these symptoms following discontinuation of the drug and a short course of prednisone therapy. Bannwarth *et al*. described the development of a symmetric polyarthritis, fatigue, and positive anti-nuclear antibodies in a patient receiving simvastatin [184]. There was resolution of the polyarthritis following discontinuation of the drug and a short course of prednisone. Kaur *et al*. reported the development of left-sided chest pain, low grade fevers, and a minimal left pleural infusion and mild pericardial

effusion in a 73-year-old Caucasian female, who had been receiving simvastatin 80 mg/day [185]. She also had a markedly elevated ESR at 111 mm/h, positive CRP at 3.5, and a positive ANA at 1 : 160 homogeneous pattern. Anti-histone antibodies were strongly positive at a titer of 5.4 (normal < 0.8). Discontinuation of simvastatin and institution of prednisone resulted in resolution of clinical features and normalization of the serological abnormalities within 8 weeks. Ahmad *et al*. reported the case of a patient who developed pleurisy and arthralgia after commencement of simvastatin [186].

Hanson and Bossingham reported the development of Raynaud's phenomenon and some "occasional arthralgias" in a 39-year-old male who had been receiving simvastatin (20 mg) daily for 4 years [187]. He also had a positive ANA at a titer >1 : 2560, speckled pattern, but other autoantibodies were negative. Simvastatin was discontinued with improvement in his symptoms although his ANA was still positive at the same titer 1 year later. Khosla *et al*. reported the case of a 79-year-old male who developed fatigue, mayalgia, and pleuropericarditis 3 months after initiation of the therapy with simvastatin [188]. Sridhar and Abdulla reported the development of polyarthritis affecting the hands and right knee, myalgias, and a generalized rash in a 67-year-old woman approximately 1 week after she started fluvastatin (20 mg per day) [189]. However, symptoms did not resolve in spite of discontinuation of medication for more than a month. Initial testing was negative for anti-dsDNA antibodies but subsequent tests were positive for anti-dsDNA antibodies although anti-histone antibodies were negative. The patient subsequently went to develop ARDS syndrome and died. Although this patient was reported as a case of a fluvastatin-induced lupus the features are somewhat atypical in that the symptoms developed relatively quickly after starting the medication and did not resolve with discontinuation.

Obermoserg *et al*. reported the case of a patient who developed severe autoimmune hepatitis, rash, polyarthralgias, and a positive ANA with a titer of 1 : 640 while receiving atorvastatin [190]. Biopsy of the rash confirmed the diagnosis of lupus. The patient also had anti-histone and also strongly positive anti-dsDNA antibodies. Liver biopsy revealed highly active chronic hepatitis which initially did not respond to high-dose steroid therapy but improved when treated with mycophenolate mofetil and tacrolimus.

D-Penicillaimine

D-Penicillaimine-related lupus was first described in patients with rheumatoid arthritis by Harkcom *et al*. in 1978 [191] but has also been reported in those with other autoimmune diseases such as scleroderma and in patients with Wilson's disease and cystinuria. The frequency of D-penicillaimine-related lupus has been reported as high as 2% of rheumatoid arthritis [192] patients and up to 7% of patients with Wilson's disease [193]. The most common clinical manifestations include polyarthritis, pleurisy, leukopenia, thrombocytopenia, and cutaneous involvement. In addition to antinuclear antibodies, some patients have been reported to develop antibodies to double-stranded DNA and hypocomplementemia [191, 193–195]. Penicillaimine therapy has also been associated with the development of other autoimmune phenomena such as myasthenia gravis and polymyositis.

HORMONAL FACTORS

Hormonal factors are believed to play a role in the development of SLE. Bae *et al*. suggested that growth hormone may have precipitated a flare in a 19-year-old male with a 11-year-old history of lupus after he had been treated with a growth hormone for 9 months because of growth retardation [196]. The flare was manifested by a decrease in C3 and C4, elevated anti-dsDNA antibodies, and the development of nephrotic range proteinuria at 1.5 g/24 h. He required treatment with monthly IV bolus doses of cyclophosphamide and high doses of prednisolone; in addition his growth hormone was discontinued. It has been postulated that growth hormone may play a role in preventing apoptosis of mononuclear cells with consequent increased survival of autoreactive immune cells. A study by Ogueta *et al*. reported that transgenic mice that expressed bovine growth hormone developed arthritis and autoantibodies [197]. Higher basal prolactin levels have been found and hyperprolactinemia has been reported to play a role in the development and progression of lupus [198, 199]. These findings are of interest since both growth hormone and prolactin belong to the same receptor family.

BIOLOGICAL AGENTS

Biological agents are being used increasingly to treat a variety of diseases including malignancies, infectious and autoimmune diseases such as rheumatoid arthritis, systemic lupus erythematosus, systemic sclerosis, multiple sclerosis, and psoriasis. These agents include a number of cytokines, such as interferon α, β, γ and interleukin-2 (IL-2), which have immunomodulating affects. Despite considerable therapeutic success, many of the patients receiving these agents develop autoanti-

bodies and in some cases autoimmune-like diseases [200–205]. Treatment with interferon α and β and interleukin-2 (IL-2) has been associated with the development of thyroid autoantibodies, anti-DNA, and anti-nuclear antibodies [201, 205]. In most cases, these autoantibodies disappear following discontinuation of treatment. Anti-nuclear and anti-DNA antibodies may develop as early as the first month of treatment [202].

Some patients develop evidence of autoimmune-like diseases including autoimmune thyroid disease, autoimmune hemolytic anemia, autoimmune thrombocytopenia, lupus-like syndromes, pernicious anemia, and vasculitis [201, 206, 207]. Ronnblom *et al*. [201] reported that 25 (19%) of their 135 patients with carcinoid tumors developed evidence of autoimmune diseases after treatment with interferon α. Reports suggest that autoimmune thyroid disease is more likely to develop in patients with malignancies who have thyroid antibodies prior to the institution of therapy with interferon α [201, 205]. Over 60% of patients with thyroid antibodies who received interferon α were reported to develop autoimmune thyroid disease compared with 7% of those who were antibody negative [202].

Obermoser *et al*. implicated interferon α in the development of a lupus-like syndrome [208]. An 80-year-old woman with chronic myelogenous leukaemia (CML), treated with interferon α developed fatigue, fever, leukopenia, and a multiforme-like erythema on the arms and legs, biopsy of which revealed an interface dermatitis suggestive of lupus erythematosus. ANA was positive at 1:320 titer but antibodies to dsDNA and ENA were negative. Interferon was discontinued and the patient was treated with steroids with subsequent resolution of her clinical features.

Interferon α and IL-2 have been associated with the induction or exacerbation of symmetric inflammatory arthropathies [206, 209]. Three patients treated with IL-2 developed a positive rheumatoid factor, anti-nuclear antibodies, and an inflammatory arthritis [209]. It has been postulated that high-dose interleukin-2 may enhance expression of HLA Class II antigen leading in turn to autoimmunity. Reversible hypothyroidism was reported in two patients treated with granulocyte–monocyte colony stimulating factor who had antibodies to thyroid peroxidase prior to therapy [210].

TUMER NECROSIS FACTOR ALPHA INHIBITORS

Anti-nuclear antibodies and antibodies to dsDNA have been detected in a number of patients following treatment with TNF-α inhibitors. However, to date, only a few patients have been reported to develop a lupus-like syndrome [211].

DeBandt *et al*. reported the development of a lupus-like syndrome in two patients with rheumatoid arthritis treated with etanercept [32]. One patient developed cutaneous lesions on the face and scalp, fatigue, and diffuse pain 3 months after starting etanercept. She had a positive ANA, anti-DNA and anti-cardiolipin antibodies, a low C4, and elevated muscle enzymes. Cutaneous lesions resolved within 1 month with discontinuation of the etanercept. Biological abnormalities returned to normal within 4 months but her polyarthritis became more active. The second was a 50-year-old woman who developed a diffuse erythematous and purpuric eruption with fine scaling of the hands and fingers approximately 4 months after starting etanercept. She also had lymphopenia, thrombocytopenia, an elevated ESR, a positive ANA at 1:640 titer, and anti-dsDNA antibodies were negative. The cutaneous manifestations resolved following discontinuation of the etanercept.

Brion *et al*. reported the development of cutaneous lesions in two patents treated with etanercept for rheumatoid arthritis [31]. The first patient was a 78-year-old woman who developed a diffuse erythematous rash 4 days after her fourth etanercept injection. Biopsy of the rash revealed acute discoid lupus. She was negative for ANA and anti-dsDNA antibodies. The second patient was a 58-year-old woman who developed a widespread rash after her seventh etanercept injection with purpuric lesion on the lower extremities and buttocks. Biopsy revealed findings consistent with a necrotizing vasculitis. Anti-dsDNA antibodies were negative. Both patients' rashes resolved within 2 weeks after discontinuation of etanercept.

Schaible from Centocor reported that low titers of autoantibodies developed in less than 10% of a total of 777 patients who received infliximab as part of several placebo-controlled, randomized clinical, and open trails [212]. He also reported that drug-induced lupus had occurred in less than 1% of these patients and that these lupus-like syndromes resolved on discontinuation of infliximab infusions. A review by Markham and Lamb reported that ANAs were detected in 23% of patients receiving infliximab compared with 6% of placebo recipients during the ATTRACT study [213]. Anti-dsDNA antibodies were found in 16% (54 of 342) of patients receiving infliximab but were not detected in patients who received placebo. Antibodies tended to appear 4–10 weeks (mean of 6.5 weeks) following initiation of treatment. They disappeared spontaneously during or after treatment. No correlation was found between the development of autoantibodies and

infliximab dosages. Three (<0.5%) of approximately 388 patients who have been treated with infliximab as part of clinical trails have developed drug-induced lupus. One patient had Crohn's disease. The other 2 patients had rheumatoid arthritis and had received 10 mg/kg every 8 weeks or 3 mg/kg approximately every 4 weeks in addition to methotrexate. One of these patients developed serositis, fever, and high levels of both ANA and anti-dsDNA antibodies and the other patient developed a rash with evidence of mild perivascular infiltrate. These features resolved on discontinuation of infliximab and treatment with steroids.

Anti-nuclear antibodies developed in 34% of patients treated with infliximab for Crohn's disease although no patient was ANA-positive prior to treatment. Anti-dsDNA antibodies developed in 9% of patients after approximately 4–12 weeks of treatment and disappeared when infliximab was discontinued. More recently, combined verifiable data from the Crohn's disease and rheumatoid arthritis trials indicated that 4 of 987 (0.2%) patients developed a lupus-like syndrome, primarily manifested by rash and fevers with 1 patient developing pleuropericarditis. Of the patients, 3 had rheumatoid arthritis and one had Crohn's disease. Postmarketing surveillance by Centocor revealed a 0.04% incidence among 170,000 patients.

According to FDA data, there have been 14 cases of patients with Crohn's disease who have developed ANAs and lupus-like syndromes while being treated with infliximab. Eight patients developed antibodies to dsDNA. Following discontinuation of the infliximab infusions there was resolution of the lupus-like syndrome in six patients but one patient failed to improve. There were no data available as to whether the other seven patients had resolution of their symptoms following discontinuation of infliximab. Patients had received a median of three infusions of infliximab prior to the development of the symptoms.

Charles *et al*. evaluated sera obtained from 156 patients before and after treatment with infliximab for the presence of anti-dsDNA antibodies using three methods, which included the *Crithidia luciliae* indirect immunoflourescence assay, a commercial Farr assay using mammalian DNA, and a Farr assay that utilized ^{125}I-labeled circular plasmid DNA [71]. Anti-nuclear antibodies were present in 29% of the patients pretreatment, compared with 30% of the controls, and in 53% of the patients after treatment with infliximab. Twenty-two (14%) patients treated with infliximab developed antibodies to dsDNA after a mean of 6.3 weeks, range of 4–10 weeks. No patient had anti-dsDNA antibodies prior to treatment. The anti-dsDNA antibodies were of the IgM class in all patients except for 1 patient who also had IgG and IgA antibodies to dsDNA. One of the patients developed a lupus-like syndrome characterized by fever, dry cough, rash, chronic chest pain, and a pericardial effusion approximately 11 weeks after the initiation of treatment with infliximab. This patient had antibodies to dsDNA detected by all three assays: she was the only patient who had anti-dsDNA antibodies detected by the Farr assay that utilized circular plasma DNA as the antigen. It is believed that this assay only detects high affinity anti-dsDNA antibodies. All of the clinical features and the anti-dsDNA antibodies disappeared within 8 weeks of discontinuation of infliximab.

There has been a speculation that the development of ANAs and anti-dsDNA antibodies among rheumatoid arthritis patients receiving infliximab may result from increased amounts of nucleosomal antigens in the synovium as a result of a rapid decrease in C-reactive protein that occurs during the early phase of treatment with infliximab. C-reactive protein has been postulated to be important in the clearance of this apoptotic material and a sudden decrease in its level may lead to impaired clearance of nucleosomal antigens with subsequent induction of an autoantibody response.

ENVIRONMENTAL AGENTS

A number of chemical agents, heavy metals, and dietary factors have been associated with the development of lupus-like syndromes (Table 3).

TABLE 3 Environmental Factors Reported to Be Associated with the Development of Autoantibodies and Lupus-Like Syndromes

Hydrazines
Tartrazine
Hair dyes
Chemicals used in computer manufacturing
? Trichlorethylene
? Industrial emissions and hazardous wastes
Silica (Quartz)
Paraffin/Silicone
Mercury
Cadmium
Gold
L-Canavanine
Rapeseed oil—toxic oil syndrome
L-Tryptophan—eosinophilia myalgia syndrome

Chemical Agents

Chemical agents that have been implicated include hydrazines and their derivatives, which are present in tobacco, mushrooms, and penicillin and in a variety of compounds used in agriculture and industry, and aromatic amines, which are present in the dyes as azo food dyes such as tartrazine and paraphenylenediamine [214–216]. Reidenberg *et al*. reported the development of a lupus-like syndrome characterized by recurrent episodes of arthralgias, fever, photosensitivity, and a positive ANA in a 25-year-old technician exposed to hydrazine sulfate during her work [214]. Resolution of these features occurred following avoidance of further exposure to hydrazine. Pereyo reported the development of a lupus-like syndrome characterized by arthralgias, myalgias, and photosensitivity following ingestion of tartrazine [215]. Of interest, this patient had previously developed a lupus-like syndrome following treatment with procainamide. A similar lupus-like syndrome consisting of arthralgias, myalgias, malaise, photosensitivity, and a positive ANA developed in another patient following oral challenge with tartrazine. Pereyo also noted that some SLE patients developed exacerbations of their cutaneous disease following ingestion of tartrazine [216].

Paraphenylenediamine is an aromatic amine used commercially as a hair dyeing compound which has been associated with the development of autoimmune-like diseases in animal studies. Studies seeking an association between the use of hair dyes and other compounds in the development of systemic lupus erythematosus in humans have provided conflicting results [217–220]. Hochberg and Kaslow reported an increase in the prior use of hair dyes among 74 patients with SLE in their case control study; however, this increase was not statistically significant [217]. In a subsequent case control study, Freni-Titulaer *et al*. reported an association between the use of hair care products and the development of a variety of connective tissue diseases including SLE [218]. Although crude analysis found an association between the development of connective tissue diseases and the use of a variety of hair care products, including hair dyes, hair permanent solutions, and hair spray, only the association with hair dyes remained statistically significant after multivariate analyses were performed. Petri and Allbritton failed to find a statistically significant association between the development of SLE and prior exposure to hair permanents or dyes in their case-controlled study of 218 lupus patients [219]; nor did they find a statistical significant association between subsequent usage of hair products and lupus activity. A further case-controlled study of 159 patients by Reidenberg *et al*. did not find a statistically significant association between environmental exposures to amines, including the use of hair dyes, and the development of SLE [220]. In a cohort study Sanchez-Guerrero *et al*. investigated the possible role of permanent hair dye usage in the development of SLE using data obtained from the Nurses health study, which is a prospective cohort study involving 106,390 women as participants who have been followed for up to 14 years [221]. The age-adjusted relative risk for development of SLE among users of permanent hair dye was 0.96 which was not significantly different from that of the never-users. In addition, the risk of developing SLE was not related to the duration of use of the hair dye, age at first use, or frequency of uses of these dyes. Similarly, a more recent study by Hardy *et al*. did not find a significant association between various hair treatments, including permanent and nonpermanent dyes, bleach, highlights, and lowlights in the development of SLE [222]. These authors evaluated 150 SLE patients by interviewed administered questionnaire and compared the results to 300 controls from the same geographical region. Of interest, a significant negative association was noted between ever having used highlights and SLE with cases having used highlights less frequently than the healthy controls. The reason for this is unclear although it did not appear to be an artifact of analysis since there was not an unusually low number of responses from participants.

Cooper *et al*. conducted a population based case control study that assessed smoking and hair treatments as risk factors for the development of systemic lupus erythematosus [223]. Two hundred and sixty-five patients who had been diagnosed with SLE by rheumatologists in eastern North Carolina and South Carolina and 355 age-, sex-, and state-matched controls were evaluated. Data collection consisted of a structured 60-min in person interview that obtained information on the use of smoking and hair treatments, which included use of permanents to curl or straighten hair, permanent hair dyes, and temporary hair dyes. A positive history was defined as lifetime use of 5 or more times. Analysis was limited to experiences that occurred prior to the age of diagnosis of SLE or reference age for controls. There was no association between history of smoking and risk of developing SLE. There was a small increase in the risk of developing SLE among women who had used permanent hair dyes. The association was somewhat higher with longer duration of use. There was little evidence of an association with use of temporary dyes or of permanents or straighteners and risk of developing SLE. These results would suggest at the most a weak association between the usage of permanent hair dyes and risk of developing SLE.

Thus, while some smaller studies had suggested an association between hair dye usage and the development of SLE, the more recent larger studies have failed to show a significant risk.

Vojdani *et al*. reported evidence of immune dysregulation, including development of autoantibodies such as IgM rheumatoid factor and anti-nuclear nuclear antibodies, in a significant number of workers who had been chronically exposed to a variety of different chemicals in computer manufacturing plants [224]. Their study population included 289 subjects with a history of 10 years or greater exposure to industrial chemicals including phthalic anhydride, formaldehyde, isocyanate, trimellitic anhydride, aliphatic, and aromatic hydrocarbons who were compared to a group of 120 nonexposed individuals. They noted significant elevation of both IgG and IgM chemical-hapten antibodies directed against some of these chemicals in addition to significantly elevated levels of antibodies to myelin basic protein, anti-nuclear antibodies, IgM rheumatoid factors, and immune complexes. As of this time, no further follow-up reports or confirmation of this study has been published.

Kilburn and Warshaw reported an increased prevalence of anti-nuclear antibodies and lupus-like syndromes among people chronically exposed to well water contaminated by trichlorethylene and other chemicals in the Tucson, Arizona area [225]. Their study group of 362 subjects exposed to contaminated well water was compared to a control group of 158 nonexposed individuals living in southwest Phoenix. They used the 1971 ARA preliminary criteria for SLE and found a statistically significant increase in the frequency of arthritis/arthralgias, Raynauds phenomenon, malar rash, "heliotropic skin lesions" and seizure/convulsions among the study group compared with the controls. ANAs in a titer of 1:160 or greater were seen in 10.7% of the study group compared with 4.7% of the controls. However, some of the subjects with the high ANA titers had other predisposing factors for the development of ANA, the clinical data was collected by questionnaires and the 1971 rather than the 1982 ARA criteria for SLE were used. A higher than expected prevalence of SLE was subsequently reported among individuals living in Nogales, Arizona [226] and among an African-American community in north Georgia who had a long-standing exposure to industrial emissions and hazardous wastes [227]. However, all these reports have yet to be confirmed. Studies by Sanchez-Roman *et al*. [228] and Conrad *et al*. [229] have suggested an association between the development of lupus syndromes and heavy exposure to quartz (offending agent probably silica), in Silesian miners who were mostly male. Previous studies have linked exposure to silica with the development of scleroderma [230].

Autoimmune diseases including SLE have been reported to occur after the injection or implantation of paraffin or silicone [231]. There have been at least 100 reported cases of patients developing autoimmune-like diseases up to 25 years after augmentation mammoplasty procedures. In some cases, there has been resolution of the clinical features following removal of the implant [232]. However, most of the evidence has been based on case reports which provide very weak evidence for a causal relationship. More recently, there have been a number of large studies which have failed to confirm an association between the development of autoimmune diseases and silicone breast implants [233–235]. Hennekens *et al*. [236] reported on a retrospective cohort study of 395,543 female health professionals who completed questionnaires as part of the women's health study. Of these, 10,830 women reported having breast implants and 11,805 reported connective tissue diseases. Although they reported a statistically significant association between breast implants and "any connective tissue disease," no association was found with any specific connective tissue disease including lupus. Other studies have also evaluated the risk of implants in the development of connective tissue disease but have not found an association. However, the smaller number of subjects included in these studies would not allow for the detection for relative risks less than 2.0. Hochberg *et al*. in a multicenter case-controlled study examined the possible association of augmentation mammoplasty with scleroderma [237]. Eight hundred and thirty-seven women with a clinical diagnosis of scleroderma recruited from three university-based tertiary care scleroderma clinical research centers were compared to 2507 race-matched local-controlled women. Eleven (1.31%) of the scleroderma patients reported a history of augmentation mammoplasty prior to the diagnosis of their disease compared with 31 (1.24%) of the controls. No statistically significant association between the augmentation mammoplasty and scleroderma was demonstrated.

In a more recent study, Edworthy *et al*. evaluated 1576 women who had undergone breast implantation between 1978 to 1986 for possible connective tissue disease [238]. The women were initially evaluated by an extensive questionnaire and by blood sample and those with features suggestive of connective tissue disease were subsequently assessed blindly by a rheumatologist. Age- and sex-adjusted prevalence rates for rheumatoid arthritis, SLE, scleroderma, and Sjögren's syndrome among the study group were consistent with those published reports for Caucasian women. Breast implant recipients reported significantly greater frequen-

cies of symptoms and in particular "thought problems," "numbness in extremities," "muscle pain," "headache," and "hand pain" than the controls. However, there was no increase in the postsurgical incident rates for any of the connective tissue diseases compared with the control population. Hence, similar to other studies, no significant association was noted between silicone gel filled implants and the development of connective tissue diseases. In addition, serological analysis did not reveal any significant differences between the breast implant recipients and controls when adjusted for age.

Similar results were reported by Karlson *et al*. who evaluated 200 randomly selected women who had had silicone breast implants but did not have a history of connective tissue disease and 500 age-matched nonexposed women, of whom 100 had a connective tissue disease, for the presence of a variety of autoantibodies, including ANAs, antibodies to dsDNA, ssDNA, Smith, RNP, Ro, La, Scl-70, cardiolipin, thyroglobulin, thyroid microsomal, and silicone, rheumatoid factor, and immunoglobulins [239]. Anti-nuclear antibodies were present in 14% of the women with silicone breast implants compared to 20% of healthy controls. There was a higher frequency of anti-ssDNA antibodies at 41% among silicone breast implants compared with 29% for the control group. However, there were no other significant differences in the frequency of antibodies between the two groups. Since anti-ssDNA antibodies are generally considered to have little clinical relevance, the results of these studies would suggest a lack of association between autoimmunity and silicone breast implants. Taken in combination, the results of the aforementioned epidemiological studies would rule out a large increase in the risk for the development of connective tissue diseases as a result of silicone breast implantation. Although associations cannot be definitively ruled out as yet, given the relatively low prevalence of some connective tissue diseases (e.g., scleroderma), any association with the more common diseases (e.g., SLE and rheumatoid arthritis) is unlikely.

A report of the National Science panel established by a U.S. district court order to evaluate whether existing studies, research, and reported observations provided a scientific evidence of an association between silicone breast implants and "classic" connective tissue diseases was recently published [240]. The group evaluated 24 studies which consisted of either human cohort, case-controlled, or cross-sectional studies with at least 10 participants and the appropriate controls. No association between silicone breast implants and any established or atypical connected tissue disease was evident. There was discordance in the reporting of arthralgias, lymphadenopathy, myalgias, sicca symptoms, skin changes, and stiffness between the studies which may reflect differences in symptoms included in the various categories and the small number in some of the studies.

Sclerodermatous-like disease and development of autoantibodies were included among the features of the toxic oil syndrome which first appeared in Spain in 1981 and was related to the ingestion of denatured rapeseed oil, although the specific agent was not identified [241, 242]. Approximately 20,000 people were affected with this syndrome with a marked predominance of females among those with more severe and chronic disease. Patients generally presented with nonspecific symptoms such as fever, malaise, headache, dyspnea, and myalgias associated with peripheral eosinophilia. Subsequently some developed joint contractures, severe myalgias associated with weakness and atrophy, sclerodermatous-like cutaneous lesions, alopecia, Raynaud's, peripheral neuropathy, and sicca syndrome. Many patients were noted to have elevated titers of anti-nuclear and anti-histone antibodies which subsequently decreased and became negative in most cases; anti-dsDNA antibodies were not found. The majority had improvement in their symptoms with less than 10% of patients having evidence of functional limitation or severe organ involvement at long-term follow-up [243]. No further cases have been noted following that one major outbreak.

The eosinophilia myalgia syndrome, which had similar manifestations to the toxic oil syndrome including the development of anti-nuclear antibodies in some patients [244, 245] was first described by the Centers for Disease Control and Prevention in 1989. It was linked to the ingestion of L-tryptophan from certain, most likely contaminated, batches from a particular manufacturer [244, 245]. There was a significant decrease in the incidence of new cases following withdrawal of these L-tryptophan containing products. Fatigue, myalgias, and arthralgias were the most frequent presenting complaints with some patients also having respiratory symptoms. Typically, the patients had peripheral blood esinophilia and muscle biopsies revealed perivascular, primarily mononuclear cell infiltrates. Many patients subsequently developed sclerodermatous-like cutaneous involvement, sensory neuropathies, and pulmonary involvement. As with the toxic oil syndrome, anti-nuclear antibodies were detected but antibodies to double-stranded DNA and other nuclear and cytoplasmic antigens were negative.

Heavy Metals

Chronic exposure to certain metals such as mercury, gold, and cadmium has been implicated in the induction of autoantibodies and immune complex mediated

glomerulonephropathies in both experimental animals and humans [246]. Mercuric chloride has been reported to induce the development of autoantibodies and immune complex mediated glomerulonephropathies in susceptible strains of rats and mice. Anti-nuclear antibodies with specificity for the nucleolar protein, fibrillarin, have been detected in certain strains of mice treated with mercuric chloride for 10 weeks [247]. Observations by Pollard *et al*. suggests that mercury can alter the physicochemical properties of fibrillarin, possibly by chemical modification of the exposed cysteines, which may help explain the antigenic specificity of mercury-induced murine autoimmunity [248]. Other *in vitro* studies by Pollard *et al*. have indicated that modification of fibrillarin by mercuric chloride accompanies cell death; mercury can, then, elicit a specific protease activity that results in cleavage of fibrillarin producing novel protein fragments which may be released and act as sources of antigenic determinants for self-reactive T cells [249]. Other studies by this group indicated that exposure to mercury may significantly accelerate the onset of systemic autoimmune disease in a strain-dependant manner suggesting that genetic susceptibility may predispose to mercury-induced exacerbations of autoimmunity [250]. Genetic predisposition may be important in the development of xenobiotic-induced autoimmunity in humans as well.

Deposits of immunoglobulins and complement have been reported in the glomerular basement in patients exposed to mercury through the use of skin lightening creams containing this metal [251]. Diffuse granular deposits of IgM, IgG, and complement have been noted in the glomerular lesions of patients receiving chronic administration of gold.

Dietary Factors

The ingestion of L-canavanine, a common amino acid found in alfalfa seeds and sprouts, has been associated with a lupus-like syndrome in both humans and monkeys. Adult female cynomolgus macaques fed alfalfa sprouts or seeds were reported to develop anti-nuclear and anti-dsDNA antibodies, hypocomplementemia, and lupus-like features such as antiglobulin positive anemia and glomerulonephropathy [252, 253]. Resolution of the clinical features occurred in some monkeys following discontinuation of alfalfa in their diets with recurrence in three monkeys following the readdition of L-canavanine [254]. Autoimmune-like features including anti-nuclear antibodies have been reported in humans ingesting significant amounts of alfalfa [254]. Two patients had reactivation of their SLE following ingestion of alfalfa tablets [255]. As already mentioned, with the increase in the use of health food products physicians will need to be alert to the possibility of these syndromes occurring in the general population.

CONCLUSION

The cause(s) of systemic lupus erythematosus remains unknown. Genetic factors are believed to play a significant role but results from monozygotic twin studies suggest that other factors are also important. It is therefore likely that exposure to some environmental agent is required to induce the development of the disease. As discussed in this chapter, there is considerable evidence to support a role for environmental agents, including drugs, in the induction of lupus-like and other autoimmune syndromes [256]. Continued study into the possible roles for environmental and infectious agents, most likely viral, in the etiopathogenesis of SLE is required.

CORTICOSTEROID USE IN SYSTEMIC LUPUS ERYTHEMATOSUS

Joseph C. Shanahan
Robert P. Kimberly

GENERAL BIOCHEMISTRY, PHARMACOLOGY, PHYSIOLOGY

Structure of Glucocorticoids

Adrenal steroids have a basic 17-carbon structure consisting of a cyclopentanoperhydrophenanthrane nucleus. This structure is composed of three 6-carbon hexane rings and a single 5-carbon pentane ring (Fig. 1). Glucocorticoids contain 4 carbons in addition to this basic 17-carbon nucleus. The substituent methyl groups are located at positions C-18 and C-19 with a 2-carbon side chain containing C-20 and C-21 which originates at C-17. Twenty-one carbon steroids may have either primarily glucocorticoid or mineralocorticoid properties.

Steroidogenesis starts with cholesterol derived either from the diet or from endogenous synthesis. Adrenal steroid biosynthesis follows three major pathways which lead to glucocorticoids, mineralocorticoids, or adrenal androgens. Glucocorticoids and mineralocorticoids, both 21-carbon molecules, differ at C-17, where the former have a hydroxyl group, and at C-18 where mineralocorticoids have an aldehyde group instead of a methyl group.

Glucocorticoid activity requires a hydroxyl group at carbon-11. Compounds such as cortisone and prednisone, which have 11-keto groups, require *in vivo* conversion to the corresponding 11-hydroxyl compounds, cortisol and prednisone, in order to exhibit glucocorticoid activity. This conversion occurs predominantly in the liver [1, 2]. Whether the presence of liver disease can cause clinically significant impairment of conversion is not clearly established. Topical preparations of glucocorticoids must be 11-hydroxyl compounds since the conversion of 11-keto groups cannot take place locally [3].

Pharmacodynamics

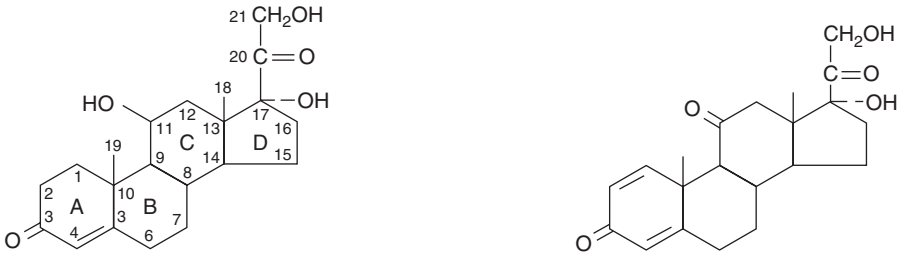
Many factors contribute to the net clinical potency of exogenously administered glucocorticoids. These factors include the adsorption, transport, and metabolism of the steroid compounds.

Bioavailability

In normal subjects receiving equivalent doses of prednisone and prednisolone, comparable plasma levels of prednisolone are achieved [4–6]. Some observations suggest that plasma levels may be more variable after prednisone rather than prednisolone [6]. Bioavailability of both prednisone and prednisolone appears to be equivalent [7–10]. Similarly, studies of prednisolone and dexamethasone in various forms have demonstrated comparable bioavailabilities.

Drug Distribution

Both cortisol and other glucocorticoid derivatives bind primarily to transcortin (corticosteroid-binding



CORTISOL
(HYDROCORTISONE)

PREDNISONE

FIGURE 1 The 21-carbon atom glucocorticoid skeleton consists of a 17-carbon cyclopentanoperhydrophen-anthrane nucleus and four additional carbons. The individual carbon atoms are designated by numbers. The four rings are designated by letters.

globulin; CBG) which occurs normally in plasma. Albumin, functioning as a low-affinity but high-capacity system, binds most of the glucocorticoid not bound to transcortin. Bound steroid is not active, and therefore only a small percentage of administered steroid is able to have physiologic effects. Patients who have had prolonged therapy with a glucocorticoid preparation may demonstrate altered transcortin-binding properties. Both the normal circadian fluctuation in binding capacity and the total capacity are reduced [11]. These alterations represent a second mechanism, in addition to the modulation of endogenous steroid secretion, by which exogenous glucocorticoid administration can influence endogenous glucocorticoid effects.

Changes in the circulating level of transcortin are accompanied by parallel changes in the amount of protein-bound glucocorticoid. Increased CBG and plasma 17-hydroxycorticosteroids are seen in the third trimester of pregnancy and with estrogen-containing oral contraceptive medications. Although plasma levels of glucocorticoids may rise, free levels of endogenously produced steroids remain normal.

Metabolism and Excretion

The principal endogenous glucocorticoids, cortisol and corticosterone, are distributed in a volume which approximates total extracellular fluid space. The plasma concentration is determined by three factors: the rate of secretion, the rate of inactivation, and the rate of excretion of free cortisol. The normal plasma half-life of cortisol is between 60 and 120 min [12].

Glucocorticoids are inactivated by several different biotransformations. 11-Dehydrogenation converts the 11-hydroxyl group, necessary for glucocorticoid activity, to a ketone group. This reversible reaction is a major factor in the regulation of circulating cortisol. Hyperthyroidism markedly accelerates 11-dehydrogenation [13]. Reduction of the double bond in the A-ring leads to dihydro derivatives and reduction of the keto group at C-3 leads to tetrahydro derivatives. These compounds are then conjugated in the liver with glucuronic acid and excreted in the urine. Drugs which activate microsomal enzymes may accelerate steroid inactivation to tetrahydro derivatives [14–21]. Hydroxylation of the ketone group at C-20, cleavage of the C-20 : C-21 side chain, and 6-beta hydroxylation are other transformations leading to inactivation.

Potency and Duration of Action

The net clinical potency of any glucocorticoid preparation reflects both the intrinsic biologic activity and the duration of action. Thus, a long-acting compound has the potential for a greater biologic effect but the correlation between half-life and either potency or duration of action is not precise.

Among the preparations used in clinical settings, the duration of action can be divided into three groups: short-, intermediate-, and long-acting. These classifications are based on the duration of adrenocorticotropin hormone (ACTH) suppression following a single dose as described by Harter [22] (Table 1). Equivalent glucocorticoid dosages are *estimates* based on consolidation of data from several different sources and animal models.

The plasma half-life of various glucocorticoid preparations show a several-fold range [12]. For prednisone, the half-life is approximately 60 min; for prednisolone, 115 to 252 min; for methylprednisolone, from 78 to 180 min; and for dexamethasone, 110 to 282 min [23]. The kinetics of steroid clearance may be dose-dependent in part because of changes in the volume of distribution and because of nonlinear binding of the compound to the transport proteins [24]. The duration of the physiologic effect of glucocorticoids may show even greater

TABLE 1 Therapeutic Glucocorticoid Compounds

Systemic preparations	Potency equivalent
Short-acting	
Hydrocortisone	1
Prednisone	4
Prednisolone	4
Methylprednisolone	5
Intermediate-acting	
Triamcinolone	4–5
Long-acting	
Betamethasone	30
Dexamethasone	25–30

Topical preparations	Brand names
Lowest potency	
Hydrocortisone, 1%, 2.5%	
Low potency	
Fluocinolone acetonide, 0.01%	Synalar
Triamcinolone acetonide, 0.025%	Aristocort
Intermediate potency	
Betamethasone valerate, 0.1%	Beta-Val
Fluocinolone acetonide, 0.025% Cordran	Synalar, Synemol flurandrenolide, 0.05%
Triamcinolone acetonide, 0.1%	Aristocort, Triacet
High potency	
Betamethasone dipropionate, 0.05%	Diprolene, Lotrisone
Fluocinonide, 0.05%	Lidex
Halcinonide, 0.1%	Halog
Triamcinolone acetonide, 0.5%	Aristocort
Very high potency	
Betamethasone dipropionate (with propylene glycol), 0.05%	Diprolene
Clobetasol, 0.05%	Temovate, Cormax
Halobetasol, 0.05%	Ultravate

variability. The duration of action depends on the specific function being monitored, and for any given function, duration may vary with the dose administered [22, 25–27]. Commonly cited durations of action reflect the studies of Harter who used the duration of ACTH secretion suppression following a single dose of glucocorticoid [22]. However, it should be noted that the studies did not examine individual variability between subjects nor did they address any effects of prolonged therapy.

The discrepancy between circulating half-life of given glucocorticoid compounds and the duration of action measured by ACTH suppression demonstrates that the duration of action is not primarily determined by presence of the steroid in the circulation. Steroids pass through the cell membrane and bind to specific receptors in the cytoplasm. The steroid–receptor complexes pass through the cytoplasm into the nucleus where they bind to DNA and alter rates of DNA transcription. Many genes can be affected, both directly and indirectly [reviewed in References 28 and 29]. Thus, the site of action is removed from the circulation per se. Once within the nucleus, the steroid may continue to act or may set into motion a chain of events which can continue for hours or days after the initial stimulus.

Secretion and the Hypothalamic–Pituitary Axis

The secretion of the principal endogenous glucocorticoids, cortisol and corticosterone, is under the control of the hypothalamic–pituitary axis. The hypothalamus secretes corticotropin-releasing factor (CRF) which acts on the anterior pituitary and stimulates adrenocorticotropin hormone (ACTH) secretion. ACTH is a linear polypeptide containing 39 amino acids. The corticotropic actions, however, reside in smaller polypeptide fragments, and the sequence of basic amino acids, Lys-Lys-Arg-Arg, occurring in position 15–18, contain much of the high adrenocorticotropin activity. The biologic half-life of ACTH in the circulation is less than 10 min.

The principal factor controlling the release of CRF and ACTH is the plasma-free cortisol level which acts by a feedback mechanism at the level of both the hypothalamus and the pituitary. This regulation can be modified through the central nervous system (CNS) by a variety of physiologic stresses such as severe emotional trauma, surgery, and pyrogens, each of which elevate ACTH levels and blood glucocorticoid levels. The sleep–wake cycle has an important effect on the pattern of ACTH secretion. Under normal conditions, there is an approximately diurnal pattern in the plasma level of ACTH with a peak just prior to wakening and a nadir just prior to sleep.

Because plasma glucocorticoid levels feed back to the hypothalamic–pituitary–adrenal axis (HPA) to control endogenous steroid secretion, exogenous steroids can alter normal HPA regulation and suppress the ability of the HPA to respond to stress with an increased production of ACTH. The ability of different glucocorticoid preparations to suppress the HPA varies but does not correlate well with the circulation half-life of the compound. The potential for HPA suppression is also dependent on the timing of the exogenous dose in relation to the sleep–wake cycle. Administration synchronized with the normal ACTH peak has less suppressive potential than doses given at the time of the ACTH nadir.

Prednisone given in a dose of more than 15 mg a day suppresses the HPA within about 1 week [12, 30]. Doses between 7.5 and 15 mg a day take approximately 1 month although some patients may not suppress if the

single dose is given only in the morning. Early morning doses of 5 mg of prednisone or less do not suppress the hypothalamic–pituitary axis [31, 32] although the same dose given in the afternoon can alter CRF release and obscure cyclic cortisol secretion [32, 33]. Harter [22] examined the effects of a single dose of different glucocorticoid preparations in a single patient and demonstrated substantially longer suppression after use of long-acting compounds such as dexamethasone. There is, however, substantial variability among the different subjects [34, 35]. Consequently, most physicians emphasize the use of short-acting preparations such as prednisone.

Although the duration of suppression depends in part on the dose and duration of the therapeutic course which lead to suppression [32, 36], there is clear variation among individuals. Streck and Lockwood [37] demonstrated that a 5-day course of 50 mg of prednisone daily affected cortisol production of up to 5 days. Longer courses of high-dose therapy may lead to HPA suppression which does not reverse completely for 6 months. The adrenal component of cortisol production may take as long as 1 year to recover appropriate responsiveness despite adequate ACTH levels [12]. Supplementation with exogenous glucocorticoids during the year after long-term high-dose therapy is usually recommended for physiologically stressful situations such as surgery with general anesthesia, although uncertainty and controversy do exist [38, 39].

Special Situations

There are several clinical situations in which the handling of glucocorticoids may be altered.

Liver Disease

The conversion of prednisone to prednisolone is impaired in patients with active, severe liver disease [5, 6, 40]. However, this appears to be counterbalanced by a decreased rate of clearance of prednisolone from the blood in such patients [6]. The fraction of glucocorticoid bound by plasma proteins may be altered [5, 40] and may lead to variable free plasma levels of prednisolone after oral doses of either prednisone or prednisolone [6]. Low serum albumin levels have been associated with a concomitantly increased frequency of prednisone side effects. Despite these various effects, they appear small and often counterbalancing. Potential adjustments of glucocorticoid dosages in the presence of liver disease are complex and unpredictable. Thus, there is no clear indication to use prednisolone rather than prednisone in patients with liver disease or to reduce the dose of glucocorticoid in patients with marked hypoalbuminemia [41] and normal hepatic function. A modestly lower dose may be appropriate in the setting of marked hypoalbuminemia and active liver disease.

Pregnancy

Glucocorticoids do cross the placenta and may induce subnormal responsiveness to ACTH [42, 43]. Hypothalamic pituitary suppression and Cushing's syndrome are not clinically significant in a neonate born to a mother taking glucocorticoids [44, 45]. Since hydrocortisone, prednisone, and prednisolone are more susceptible to inactivation by placental enzymes than are dexamethasone and betamethasone, prednisone and prednisolone are the preferred drugs for use in pregnancy.

Maternal glucocorticoid therapy is not associated with an increased incidence in congenital anomalies in newborns [45–47]. Reduction in fetal size has been suggested but not differentiated from the effects of the underlying disease per se. However, in comparison to various control interventions, prednisone administration was associated with an increased rate of prematurity in three separate trials of prevention of pregnancy loss in women with anti-phospholipid antibody syndrome [48–50]. Although intrauterine growth retardation was not observed more frequently among those treated with prednisone, preeclampsia and gestational hypertension occurred more commonly in prednisone-treated subjects [48, 50]. Both prednisone and prednisolone occur only in low concentration in breast milk [51] and consequently, glucocorticoid therapy for the nursing mother does not pose a major hazard for the infant.

Selective Steroid Compounds

The ideal therapeutic corticosteroid would possess only the desired beneficial effect with no other accompanying side effects. Such dissociation of actions could result from novel chemical structures with selective agonist properties, selective access to appropriate target tissue sites, or perhaps the development of new properties. Examples include dexamethasone and betamethasone, two synthetic corticosteroids which dissociate glucocorticoid from mineralocorticoid activities through chemical modification of the basic corticosteroid structure. Although glucocorticoid effects are retained, many mineralocorticoid side effects are avoided. A different approach to selectivity has been taken with raloxifene, a nonsteroidal benzothiophene that is classified as a selective estrogen receptor modulator [52, 53]. In human studies, raloxifene appears to have tissue-specific estrogen-agonist or -antagonist

activity which is putatively beneficial for bone mineral density and serum cholesterol.

Other steroid compounds have attempted to achieve a higher glucocorticoid therapeutic ratio by further structural modifications of the basic molecule. Deflazacort, a prednisolone analog with an oxazoline group at carbon 17, has reduced lipid solubility and may have a greater effect on circulating, rather than sessile, cells. Relatively smaller changes in the urinary excretion of calcium and less hyperglycemia with deflazacort compared to equipotent anti-inflammatory doses of prednisone may indicate some sparing of carbohydrate metabolism and calcium balance [54–59]. Modification of drug access to and distribution in tissues may also be achieved by specialized drug delivery systems, such as incorporation into liposomes [60–63]. Neither deflazacort nor liposome delivery, however, has received much attention.

As the actions of corticosteroids at the transcriptional and cell-signaling levels have become more clearly defined, increasingly specific therapeutic targets are available for novel steroids. The concept of "dissociated steroids" now refers to synthetic compounds that retain either the positive or negative effects on gene transcription. Many of the anti-inflammatory effects of corticosteroids stem from inhibition of NF-κB- or activated protein-1 (AP-1)-mediated transcription of inflammatory mediators, including cytokines and cell adhesion molecules. However, some anti-inflammatory and immunosuppressive effects of corticosteroids are mediated by enhancing transcriptional activity. Dissociated steroids retain the ability to repress the transcriptional activities of NK-κB or AP-1, but are no longer capable of interacting with glucocorticoid receptor (GR) response elements to initiate new gene transcription. The steroid antagonist RU486, for example, fails to activate glucocorticoid receptor-mediated gene transcription, yet significantly reduces transcription of AP-1-dependent genes [64]. By retaining certain properties, dissociated steroids exert strong anti-inflammatory effects but avoid the complications associated with transcription of GR-dependent genes. However, some adverse effects of corticosteroid therapy may be due to transrepressive functions. Therefore, further study is required to assess the clinical impact of dissociated corticosteroids in animal models and humans.

MECHANISMS AND ACTIONS

Overview

In inflammatory rheumatic diseases such as systemic lupus erythematosus, glucocorticoids are used both as an anti-inflammatory and as immunosuppressive agents. The exact mechanisms of these general effects are complex and include alteration of both the trafficking of circulating immunocompetent cells and the actions of such cells [65–70] (Table 2). Thus, decreased neutrophil margination and altered peripheral lymphocyte transendothelial cell migration may be important. Similarly, modulation of the synthesis and release of inflammatory mediators and cytokines, reduction of cell surface expression of cytokine receptors and MHC class II molecules, induction of lymphocyte cell death, and modification of intracellular communication among immunocompetent cells may underlie some of the effects of glucocorticoids. These effects may represent both pharmacologic and physiologic actions.

The general schema for the action of glucocorticoids involves the binding of the glucocorticoid to specific intracellular, cytoplasmic receptors in the target cell after passive movement of the steroid through the cell membrane [28, 29]. The glucocorticoid–receptor complex is rapidly translocated to the nucleus where steroid–receptor complexes form homodimers, which subsequently bind to specific regions of DNA (glucocorticoid response elements; GREs). This binding modifies the rate of DNA transcription with resultant effects manifested by alterations in protein synthesis [71]. Thus, many of the effects of glucocorticoids are mediated through transcriptional factors and protein mediators. The role of the intercalation of steroids into cell membranes and lysosomes is less well defined. Glucocorticoids also have negative effects on the promotion of gene transcription by NF-κB and AP-1. These transcriptional complexes are activated by the exposure of cells to inflammatory cytokines such as tumor necrosis factor (TNF)-α and interleukin-1 (IL-1). On activation, NF-κB and AP-1 shed inactivating proteins, permitting translocation to the nucleus where they bind DNA promoters for cytokines, cell adhesion molecules, and other critical mediators of immune and inflammatory processes. Activated GR inhibits NF-κB and AP-1 gene transcription through transcriptional cross talk which likely takes several forms, including direct protein interaction [72–74], upregulation of NF-κB inhibitors, particularly the cytosolic inactivator I-κB [75–77], and competition for limited transcriptional coactivator molecules [78, 79]. Activated GR also inhibits intracellular signaling cascades, including the JAK-STAT system, which contributes to the negative effects of corticosteroids on lymphocyte proliferation and differentiation [80].

The presence of glucocorticoid receptors in many different cell types helps to explain the broad range of biologic effects observed with glucocorticoid administration. Lymphocytes, monocytes and macrophages, osteoblasts, liver cells, muscle cells, fat cells, and

TABLE 2 Anti-inflammatory and Immunosuppressive Mechanisms of Corticosteroid Action

Anti-inflammatory effects	Mechanism of action	Clinical outcome
Antagonism of transcription factors (NF-κB, AP-1, NF-AT)	1. Up-regulates synthesis of transcription factor inhibitors (I-κB, GILZ) 2. Direct interaction between GR and transcription factors, inhibiting protranscriptional activity 3. Competition for essential transcriptional cofactors (CREB-binding protein, SRC-1)	1. Reduction in production of TNF-α, IL-1, GM-CSF, IL-6, IFN-γ, IL-12 2. Reduced expression of IL-8, ICAM-1, ELAM-1, VCAM-1, E-selectin, RANTES, MCP-1
Reduction of cytokine and chemokine expression	1. Synthesis of destabilizing protein reduces mRNA half-life 2. Transcriptional inhibition via direct GR or GRE antagonism and reduction of transcription factor activity (see earlier)	3. Decreased substance P and inducible nitric oxide synthetase expression
Inhibition of arachidonic acid release by enhanced lipocortin activity	1. Rapid translocation of cytosolic lipocortin to cell surface 2. Increased transcription of lipocortin mRNA	Reduced production of prostaglandin mediators of inflammation
Immunosuppression	**Mechanism of action**	**Clinical outcome**
Inhibition of IL-2/IL-2R activity	1. Direct suppression of IL-2R mRNA levels (possibly through transrepression) 2. Up-regulation of GILZ and other mechanisms of NF-κB inhibition) 3. Inhibition of IL-2 signaling by blockade of STAT 5 activation (possibly by inhibition of tyrosine phosphorylation	Modulation of T-cell activation
Inhibition of dendritic cell (DC) function	1. Impaired antigen-presenting function 2. Reduced expression of costimulatory molecules 3. Suppression of IL-12 production 4. Apoptosis of dermal/interstitial DC precursors	
Preferential enhancement of Th2-type cytokine profile	Down-regulation of IL-12 activity 1. Inhibition of STAT 4 phosphorylation (rapid onset but mechanism unknown) 2. Down-regulation of IL-12 receptor	1. Enhanced TGF-β and IL-10 production 2. Reduction of inflammatory cytokines

fibroblasts are among the cell types with such receptors [81, 82]. The presence of intracellular receptors and effects on DNA transcription helps to explain why the biologic effect of glucocorticoids may be so much longer than the plasma half-life. However, quantitative glucocorticoid receptor protein does not necessarily correlate closely with glucocorticoid action since there are many tissue specific effects [67].

A recurrent question in steroid therapy is the equivalence of different types of glucocorticoid compounds. Data regarding this issue depend on the biologic system under evaluation. For example, Rosenberg and Lysz [83] demonstrated that hydrocortisone, methylprednisolone, and dexamethasone, used at equipotent anti-inflammatory doses, did not show equivalent effects on some aspects of *in vitro* cellular immunity. In their systems, methylprednisolone was more effective in suppressing the generation of cytotoxic lymphocytes than dexamethasone. Hofman and colleagues studied the effects of various corticosteroids on cultured CEM-C7 T cells and L929sA fibrosarcoma cells [84]. Triamcinolone, dexamethasone, betamethasone, clobetasol, prednisolone acetate, and hydrocortisone all reduced TNF-α-induced NF-κB activation to a similar extent in L929sA cells. In contrast, hydrocortisone and prednisolone were less effective inducers of apoptosis in CEM T cells in comparison with the other agents. Since "anti-inflammatory" and "immunosuppressive" potency may not be equivalent, identification of the pathophysiologic property underlying the desired clinical effect is

of paramount importance. Recognition of the appropriate steroid-responsive pathophysiologic mechanism allows questions regarding both the specific glucocorticoid compound and optimal dosage range to be investigated directly. It is also important to realize that there are some species differences in glucocorticoid responsiveness [85], that there may be some organ specific differences in drug levels [86], and that some *in vitro* studies may use concentrations of glucocorticoids higher than those achievable in man [67].

Metabolic Effects

By conventional standards, the term *glucocorticoid* describes those corticosteroids which have a dominant effect on intermediary metabolism [87]. The actions of glucocorticoids are anti-insulin-like and include effects on protein, carbohydrate, and nucleic acid metabolism. Glucocorticoids have a catabolic effect on protein metabolism manifested by increased degradation and decreased synthesis of protein in many tissues. During steroid therapy, plasma amino acid levels may rise significantly. Glucocorticoids stimulate glyconeogenesis in part by mobilization of glycogenic amino acid precursors. Increased gluconeogenesis and decreased glucose transport into cells and utilization in peripheral tissues lead to an increase in blood glucose. Hepatic glycogen content is increased by glucocorticoids. Glucocorticoids also promote lipid catabolism by increasing lipolysis in peripheral fat depots and potentiating the activation of cellular lipase by agents such as catecholamines and pituitary peptides. Increased mobilization of free fatty acids and glycerol also promotes glycogenesis.

Glucocorticoids directly stimulate hepatic synthesis of enzymes such as tryptophan pyrrolase and tyrosine aminotransferase. These enzymes may participate in diminished protein metabolism and cytolysis of lymphoid tissue and muscle.

Glucocorticoids may have mineralocorticoid properties. Enhanced renal tubular sodium reabsorption can increase glomerular filtration rate, increase free water clearance, and lead to clinically apparent peripheral edema. Enhanced potassium excretion by renal tubular cells can lead to the low serum potassium. Although these actions on sodium and potassium handling are mediated primarily by the kidneys, they may also be expressed by cells in the intestinal mucosa and sweat glands. The degree of mineralocorticoid activity varies among different glucocorticoid compounds with cortisone and hydrocortisone having the largest and betamethasone and dexamethasone having the least.

Corticosteroids play an important role in the maintenance of adequate vascular tone both by a direct effect on blood vessels and by a synergistic effect with catecholamines. The net effect of corticosteroids may be either vasoconstrictive or vasodilatory depending on the specific vascular bed, the resting tone of that bed, and the nature of any concomitant pathologic process [88, 89]. Interaction with specific receptors on vascular smooth cells [90, 91] and induction of angiotensin converting enzyme activity in vascular endothelial cells [92] are both mechanisms involved in the action of corticosteroids in regulation of local blood flow in vascular beds.

Anti-inflammatory Effects

The effects of glucocorticoids on inflammation reflect the complexity of the inflammatory process itself [70]. No single mechanism underlying the net effects on inflammation has been identified although modification of the synthesis of specific proteins, mediated at the level of transcription, is a common theme [28, 29]. Glucocorticoids exert an anti-inflammatory effect primarily by inhibiting the production of cytokines and cell adhesion molecules. Inhibition of cytokine production is mediated primarily by repressing the transcriptional activity of NF-B and AP-1. Additionally, glucocorticoids exert posttranscriptional effects, directly inhibiting cytokine functions by reducing cytokine mRNA half-life and blocking cytokine-mediated intracellular signaling. Protranscriptional activity of activated glucocorticoid receptor includes the production of inhibitors of NF-κB and AP-1 function, as well as upregulation of anti-inflammatory products, such as the nonfunctioning, decoy IL-1 type II receptor [93]. Gene expression studies of peripheral blood monocytes in normal human subjects treated with dexamethasone have employed DNA microarray technology to evaluate the effects of glucocorticoids [94]. Dexamethasone down-regulated certain proinflammatory cytokines, yet up-regulated expression of important components of innate immunity, including complement factors and toll-like receptors (TLR-2 and TLR-4). In addition, glucocorticoids altered the regulation of certain genes depending on the state of activation of the cell. Therefore, the impact of glucocorticoids may vary depending on cell type, but also on the state of activation. Ultimately, the ability of glucocorticoids to retard the recruitment of neutrophils and monocyte-macrophages to inflammatory sites, by reducing cytokine and chemotaxin activity, represents a major component of the anti-inflammatory potential of steroids [67].

A single dose of glucocorticoid accelerates the release of mature granulocytes from the bone marrow, decreases the migration of neutrophils from the circulating pool, increases the circulating half-life of the neutrophils [66, 95, 96], and leads to a neutrophilic

leukocytosis with a peak level at 4–6 h after administration [66, 97]. The decreased accumulation of neutrophils at an inflammatory site reflects a summation of several different effects. Glucocorticoids decrease the local vasodilatation and capillary permeability which may decrease local exudation, edema formation, and leukocyte migration [67]. Glucocorticoids may modify chemotaxis and decrease the adherence of inflammatory cells to the vascular endothelium [98–103], due in part to changes in the expression and function of various cell adhesion molecules including members of the immunoglobulin supergene family (e.g., ICAMs), various integrins (e.g., LFA1 and CR3) and various LEC-CAMs (e.g., ELAMs) [104–106].

Glucocorticoids cause a monocytopenia peaking 4–6 h after administration [107, 108]. Recovery of the baseline circulating populations occurs within 24 h. Inhibition of the accumulation of monocyte-macrophages at inflammatory sites probably involves similar mechanisms to those which impede the accumulation of neutrophils. Impaired recruitment of stimulated monocytes contributes to the suppression of delayed hypersensitivity responses induced by steroids [109].

In addition to decreasing the recruitment, glucocorticoids exert an anti-inflammatory effect by modifying a number of cell functions. Steroid therapy can depress the bactericidal activity of monocytes [110, 111] and may reduce the phagocytic activity of both neutrophils and monocytes [112, 113]. As applied to IgG-mediated phagocytosis, this latter effect may be related to modulation of Fc receptor expression on the cell surface. However, glucocorticoids do not have a consistent effect on the constitutive expression of Fcγ receptor number or function in several *in vitro* systems [114–120]. Steroids do appear to block the production of gamma-interferon (γ-IFN)-rich lymphokines which can decrease Fcγ receptor density [121]; but given the presence of γ-IFN, steroids may augment the interferon-induced enhancement in Fc receptor expression [122]. The distinction between the action of glucocorticoids on constitutive and on induced functions may explain why *in vivo* studies have not always yielded consistent findings [123, 124].

Glucocorticoids can be effective inhibitors of prostaglandin synthesis [125–128]. Unlike nonsteroidal anti-inflammatory drugs (NSAID) which inhibit the cyclo-oxygenases, steroids decrease the release of the substrate, arachadonic acid, from phospholipid stores. This effect is mediated by the induction of a polypeptide, macrocortin or lipomodulin, which inhibits phospholipase A_2 action [129–132]. Thus, glucocorticoids can inhibit the production of arachidonate metabolites from both the cyclo-oxygenase and lipoxygenase pathways.

Immunosuppressive Effects

The actions of glucocorticoids on immune responses are complex, but the net effect is generally a suppression of immune function. This suppression reflects the summation of altered leukocyte movement, of decreased leukocyte function, and of alterations in a variety of humoral factors.

Administration of glucocorticoids causes a lymphopenia which reaches a nadir at 4–6 h and which resolves within 24–48 h [66, 107, 108, 133–139]. The duration and the nature of the lymphocyte subpopulations affected depend on the dose of steroid given. The $CD4^+$ T inducer/helper subset shows a greater absolute and percentage decrease than the $CD8^+$ T cytotoxic/suppressor subset [107, 108, 137, 139]. As a consequence, the T4/T8 ratio decreases with steroid therapy and shows larger changes as the dose of steroid increases. B lymphocytes show an absolute decrease in number but usually no change in percentage; non-T/non-B lymphocytes show an increase in percentage, especially with doses of prednisone greater than 30 mg [107, 108, 137].

Lymphopenia results from a redistribution of circulating lymphocytes with apparently effective egress from the intravascular space but inefficient return from lymphoid organs [66, 67, 138, 140]. Since splenectomized subjects show the same lymphopenia as those with intact spleens, some redistribution to the bone marrow may occur. Whether the more profound impact of glucocorticoid administration on $CD4^+$ cells relative to $CD8^+$ cells reflects a greater representation of $CD4^+$ cells in the recirculating pool remains for further investigation. This redistribution, however, emphasizes the possibility that changes in peripheral lymphocyte function after *in vivo* administration of steroid may reflect changes in both cell populations and cell function.

Although a short course of glucocorticoids may decrease serum immunoglobulin levels in humans [141–143], the effect on the humoral immune response is variable. Among the factors contributing to this variability may be the dose of glucocorticoid, the nature of the antigenic stimulus, and the type of response (primary or secondary) being elicited. At lower concentrations of glucocorticoids in some experimental systems, stimulation of antibody formation can be seen [144–145]. This effect may require the combined action of both glucocorticoid and other soluble factors on a target cell(s) with glucocorticoids serving as a permissive or as an amplifying component for those factors. Inhibition of antibody production by steroids might result from a number of mechanisms. The circulating traffic of monocytes can be suppressed, the access of monocytes to sites of antigen localization diminished

[107, 108], and perhaps, antigen processing decreased. Glucocorticoids inhibit production of interleukins and other cytokines and may also alter the expression and function of cytokine receptors [145–153]. These cytokines may have direct effects on B cells, or indirect effects through changes in T helper cell function.

Various aspects of cell-mediated immunity are suppressed by glucocorticoids. Steroids decrease proliferation in the mixed leukocyte reaction and in response to mitogens [67, 154, 155] and alter T-lymphocyte-mediated cytotoxicity [156, 157]. Glucocorticoids inhibit interleukin-2 (IL-2) production by lymphocytes, which is important in the maintenance of T-cell proliferation [146], as well as the production of IL-3, granulocyte–macrophage colony stimulating factor (GM-CSF) and γ-IFN [147]. IL-2 and other cytokines critical for T-cell differentiation and proliferation signal through a common pathway, JAK-STAT, which is inhibited *in vivo* by dexamethasone [80]. Some effects of steroids on cell-mediated immunity may reflect effects of changes in circulating monocyte populations, decreases in the production of monokines such as IL-1, or inhibition of the response of macrophages to various lymphokines [158]. Suppression of cutaneous delayed hypersensitivity is an effect of delayed monocyte recruitment to the local site [159].

T-cell activation requires antigen presentation and delivery of a costimulatory signal. Dendritic cells (DC) efficiently activate T cells and appear critical to primary immune responses. Glucocorticoids impair several DC functions and thus reduce the ability of these cells to activate T cells. Dexamethasone has been shown to impair antigen-presenting function *in vivo*, and reduces expression of costimulatory molecules *in vitro* [160]. *In vitro* studies have shown that superantigen-stimulated DCs, pretreated with glucocorticoids, exhibit reduced potential to induce γ-IFN production from $CD4^+$ T cells. This glucocorticoid effect is attributed to a reduction in IL-12 production of activated DCs [161]. Immature DCs exposed to glucocorticoids *in vitro* have decreased T-cell stimulatory capacity and acquire Th2 bias [162, 163]. In addition, glucocorticoid effects may vary among cell types to exert various alterations of immune responses. For example, Woltman and colleagues have shown *in vitro* corticosteroids exposure of $CD34^+$ hemopoeitic dendritic cell precursors specifically inhibits the development of $CD14^+$-derived interstitial/dermal DCs, while no effect was seen on the development of Langerhans cells [164].

The capacity for glucocorticoids to have both stimulatory and inhibitory effects on immune function makes simple predictions about the clinical effects of these agents in autoimmune disease difficult. Such complexity may be less surprising now that the interrelationship between the immune system and the hypophyseal–adrenal axis is increasingly appreciated [70, 165]. Some thymic peptides have corticotropin-releasing factor activity and some cytokines from lymphocytes and monocytes can affect endogenous corticosteroid concentrations [166, 167]. However, despite lack of knowledge about precise mechanisms, glucocorticoid administration in many lupus patients results in reduction of autoantibody titers and circulating immune complexes, an increase in complement levels, and a general amelioration of disease activity.

Immunosuppression-Pulse Therapy

Very large doses of intravenous corticosteroids may have effects which differ either in quality or in quantity (duration and/or magnitude) from conventional oral dosages. Concentration-dependent effects on lymphocyte blastogenesis were suggested in early *in vitro* studies [154]. Similarly, the maximum effect of corticosteroid-induced suppression of mixed lymphocyte cultures (MLC) appeared between methylprednisolone concentrations of 1–10 μg/ml [168]. This plasma level is achieved *in vivo* approximately 2 h after an intravenous dose of 1 g of methylprednisolone in an average adult [169, 170]. Although some studies have suggested a slightly longer duration of depression of lymphocyte responsiveness to mitogens after an intravenous dose of 1 g of methylprednisolone [171] and more prolonged changes in natural killer cell activity [172], other investigators have found no greater alterations in either circulating cell populations or reactivity in assays of cellular immunity with large intravenous doses of glucocorticoids as compared to conventional oral doses [173, 174]. Adequate data on serum IgG levels in normals and patients with rheumatic diseases are not available. However, Trotter and Garvey [175] found the fall in serum IgG in patients with multiple sclerosis was no greater with high-dose intravenous corticosteroids than with alternate-day oral steroids.

Dose-dependent inhibition of granulocyte aggregation, perhaps mediated by the C5a complement fragment, has been suggested by Hammerschmidt and co-workers [176]. Since substantial inhibition was seen at 1 mg/ml of methylprednisolone, such inhibition, or similar effects on other inflammatory processes, may contribute to the clinical impact of very high dose intravenous corticosteroid.

CLINICAL APPLICATIONS

Corticosteroids are central to the management of SLE, but their optimal role often prompts vigorous discussion on clinical rounds and sharp debates in the

literature. The principal issue is the balance of potential risks and potential benefits, magnified by the long duration of therapy which is usually anticipated in the management of lupus. The decision to use systemic glucocorticoids requires knowledge of the natural history of the disease presentation and evidence regarding the impact of treatment on the long-term outcome. Although much is known about the course of lupus and the impact of glucocorticoids, there is room for reasonable debate and disagreement.

Several general guidelines are appropriate. Whenever possible, topical preparations should be used for dermatological manifestations. With systemic glucocorticoid therapy, the smallest dose should be prescribed for the shortest possible period. Preparations with less mineralocorticoid activity should be used whenever possible. Agents which have a prolonged duration of action should be avoided because of the difficulty in regulating dose and duration of action. When the clinical situation permits, alternate-day therapy and adjunctive agents, such as nonsteroidal anti-inflammatory drugs, should be used to minimize the required steroid dose. Finally, the presence of other medical conditions, such as diabetes mellitus, osteoporosis, hypertension, tuberculosis, or psychiatric illness which might predispose to steroid complications, should be considered in monitoring therapy.

An obvious but important caveat applies to corticosteroid treatment in lupus. Many of the steroid-responsive signs and symptoms of SLE can be caused by other processes which may be worsened by steroid use. The pulmonary infiltrate may be bacterial pneumonia, and the abdominal pain may reflect a perforated viscus rather than sterile serositis. The severe joint pain may be aseptic necrosis, not inflammatory arthritis. The list of possibilities is long but the mandate is clear. Careful differential diagnostic evaluation is an important preliminary to the use of glucocorticoids.

Preparations and Routes of Administration

Topical Therapy

Many cutaneous manifestations of systemic lupus can be managed with topical therapy rather than systemic administration of corticosteroids. All glucocorticoid preparations for local use are 11-hydroxyl compounds which eliminate the need for biotransformation in the liver. These preparations are usually grouped into low, intermediate, and high potency categories; the fluorinated compounds as a rule demonstrate greater biologic activity (Table 1). The efficacy of topical steroid preparations in a given clinical setting is related to the potency of the compound, the concentration of the active drug in the vehicle, the nature of the vehicle, and the percutaneous penetration of the compound. In general, ointments facilitate hydration of the skin, enhance permeability, and increase penetration of active drug. The presence of inflammation, adequate hydration of the skin, and occlusive plastic wraps all facilitate penetration of drug into the skin. The presence of calloused skin, as on the feet, decreases penetration.

As a general approach, topical therapy is usually started with a stronger preparation and, once control of the cutaneous manifestations is achieved, less potent preparations are used. Lower potency steroid preparations are preferred for regions with thin skin such as the face, axilla, groin, and genital area. Since generic topical corticosteroids may formulate their vehicles differently from their brand-name counterparts, their efficacy may vary somewhat. Within each grouping in Table 1 efficacy is generally similar [177]. The costs of different compounds may vary greatly.

Intra-articular Therapy

In carefully selected situations, intra-articular corticosteroids may be useful adjunctive therapy for management of inflammatory arthritis [178, 179]. Clinical efficacy is determined by potency, dosage, and chemical formulation. Longer action of steroids prepared for intra-articular injection is achieved by the use of less soluble depot formulations. Usually, a sustained therapeutic effect is preferable for inflammatory arthritis to avoid abrupt symptomatic rebound.

Methylprednisolone acetate, prednisolone tebutate (Hydeltra-TBA), dexamethasone acetate (Decadron-LA, Dalalone DP), betamethasone acetate (Celestone Soluspan), and triamcinolone hexacetonide (Aristocort) are long-acting, repository preparations which can be used for intra-articular injections. The sodium phosphate or succinate salts of these compounds are soluble and have a much shorter effective duration of action. Intra-articular steroids can cause facial flushing [180], suppression of endogenous hydrocortisone levels [181], change in plasma salicylate levels [182], induction of hyperglycemia [183], precipitation of a sickle-cell crisis in susceptible individuals [184], and other systemic effects [185, 186].

Systemic Therapy

Oral and intravenous administration are the primary modes of systemic corticosteroid therapy. Intramuscular injection is usually reserved for special circumstances such as limited vascular access. Some steroid may be absorbed systemically with topical, inhalational, or intra-articular therapy.

Prednisone is the most commonly used compound for oral administration. Prednisolone and methylprednisolone are other short-acting oral preparations with little mineralocorticoid effect. Dexamethasone has the least mineralocorticoid action, but it has all the difficulties of managing a long-acting compound. Methylprednisolone sodium succinate, prednisolone sodium succinate, and dexamethasone sodium phosphate are the soluble forms of glucocorticoids most commonly used in the management of systemic lupus. Hydrocortisone sodium succinate has substantial sodium-retaining properties and is used less frequently.

Therapeutic Situations

Although a great difference of opinion exists as to what constellation of clinical and laboratory findings constitute an indication for steroid treatment [187–198], several situations provoke little debate. The acutely and dangerously ill patient ("lupus crisis") often with high fever, extreme malaise, and other symptoms of active lupus including pleuritis, arthritis, and vasculitic rash deserves systemic steroids in the range of 1 mg/kg of prednisone (for equivalent) per day in divided doses [199]. The hematologic manifestations of severe hemolytic anemia with a hematocrit less than 20 or marked thrombocytopenia with a platelet count less than 40,000–50,000 per mm^3 are also indications for steroid therapy [187, 188, 190, 191]. In the setting of "lupus crisis," the use of steroids is prompted not only by the severity of illness, but also by the reasonable expectation that steroids will ameliorate the flare of disease and that the course of high-dose steroids will be of relatively short duration. Accordingly, the benefit is potentially large and the risk modest in comparison. For the patients with hemolytic anemia or thrombocytopenia, steroids are usually effective in decreasing splenic sequestration. Since the progress can be easily and directly monitored, steroid usage can quickly be adjusted to the smallest possible dose and the side effects kept to a minimum.

Glucocorticoid therapy for major organ involvement including the kidneys and the central nervous system is more problematic.

Renal

Corticosteroids are used commonly in the management of lupus nephritis. The initial clinical observations of Pollak and associates [200, 201], made more than three decades ago, suggested that high-dose prednisone treatment helped to prevent or postpone the onset of renal failure. A similar experience was reported by Boelaert *et al.* [202] in the mid-1970s. Although these data did not result from stratified randomized trials, in combination with a general enthusiasm for steroid therapy in SLE [202–204], they formed the basis for current glucocorticoid use in lupus nephritis.

Unlike the use of steroids in "lupus crisis" or in the context of profound hematologic abnormalities, the immediate clinical consequence of drug administration on lupus nephritis may be inapparent or of uncertain clinical significance. Furthermore, the therapeutic goal is usually a long-term preservation of renal function rather than an immediate reversal of processing clinical manifestations. Thus, the basis for any therapeutic decision in lupus nephritis requires the integration of several disparate bodies of data. These data deal with disease mechanisms, natural history, prognostic indices, drug complications, and outcomes in relation to specific therapeutic interventions.

Pollak reported the effects of high- and low-dose oral corticosteroids on the clinical outcome of patients with lupus glomerulonephritis [200, 201]. The histologic term "glomerulonephritis" indicated a proliferative and/or membranous lesion of the glomeruli associated with tubular and interstitial tissue changes. This was distinguished from "glomerulitis" which did not include significant tubular damage or interstitial changes. Glomerular lesions were more severe in the glomerulonephritis group. Within the group of patients with active glomerulonephritis and a serum urea nitrogen level of 30 mg/dl or less at the start of therapy, administration of high steroid (average 47.5 mg/day prednisone for 6 months) treatment significantly improved survival compared to low steroid (average 10 mg/day prednisone) treatment. No benefit of high-dose therapy in terms of survival was reported for patients with urea nitrogen levels greater than 30 mg/dl at the start of therapy. Using improvement in renal function rather than survival as an outcome measure, Boelaert *et al.* [202] found that high-dose corticosteroid was more likely to lead to improvement in function than low- or no-dose corticosteroid. Not all of Boelaert's patients had urea nitrogen levels less than 30 mg/dl at the start of therapy.

Other authors have also concluded that glucocorticoid therapy is beneficial in lupus nephritis [205–207]. Yet controversy over this point remains. Some investigators could detect no effect overall [208–210] while others remained impressed with the individual variability of both the natural history and the response to therapy [211]. Part of the difficulty with these studies include small patient numbers, variable histologic definitions of the groups being tested, differing (and sometimes unspecified) measures of outcome, and the absence of a treatment comparison group.

Several different therapeutic strategies have evolved as a result of the controversy surrounding the interpretation of data on corticosteroid therapy for lupus nephritis. Since histologic classification of renal biopsy specimens, a measure of end-organ damage, can provide a broad prognostic outline, one general approach emphasizes the use of histologic appearance of glomerular involvement to determine therapeutic strategy. Histologic assessment might emphasize the pattern and extent of glomerular involvement as described by the World Health Organization classification scheme [212, 213]. Alternately, the degree of disease activity and/or chronicity has been evaluated as a useful therapeutic guide [214, 215]. More severe and active lesions are indications for more aggressive therapy. A second approach emphasizes serologic abnormalities as indicators of the degree of activity of the presumed pathophysiologic process. Thus, persistent abnormalities are considered an undesirable circumstance although support for this assumption is not always consistent [216]. According to this therapeutic strategy, sufficient corticosteroids are administered to normalize these serologic values [217, 218]. Unfortunately, neither of these approaches is free of difficulty. The occurrence of clinically silent, but histologically severe nephritis [219, 220] makes selection of patients by clinical criteria for renal biopsy problematic. Histologic transformations from one biopsy class to another are well recognized [212, 221–224]. Serologic abnormalities do not consistently identify patients at high risk for severe disease [216] and may fluctuate spontaneously [225].

Despite the difficulties with the extensive literature on lupus nephritis, several guidelines for the use of glucocorticoids can be formulated. These guidelines recognize that lupus nephritis is often an episodic disease with acute flares which may be managed with limited courses of therapy. Thus, patients with newly documented moderate renal disease such as mesangial glomerulitis and focal glomerulonephritis would receive oral prednisone in the range of 40 mg/day for 6 to 8 weeks. Either an early clinical response in terms of serologic activity, urinary sediment, quantitative urinary protein secretion, and renal function or the early development of substantial drug toxicity would prompt an appropriate gentle taper of the prednisone dose. In the absence of biopsy material, a patient presenting with modest protein excretion and normal renal function might receive a moderate therapeutic course of corticosteroids. The absence of a clinical response over a 6- to 8-week interval would make a biopsy of even greater interest since diffuse proliferative glomerulonephritis would warrant a trial of high-dose therapy.

For patients with diffuse proliferative glomerulonephritis and its accompanying clinical manifestations of proteinuria and possibly renal insufficiency, a course of high-dose oral prednisone in the range of 60–80 mg/day is warranted. As with the more moderate therapeutic strategy, the dose is tapered with the occurrence of significant toxicity, with indications of a clinical response, or with the completion of a predetermined course of 6 to 8 weeks of treatment. In some centers, the lack of response to an adequate course of high-dose therapy would prompt the use of an additional agent [189, 190, 192, 226–228].

Membranous glomerulonephritis in lupus patients is usually treated more conservatively than diffuse proliferative disease. Although there is no unanimity, some experience suggests that the clinical course of patients with membranous nephropathy is not as aggressive [223, 229]. Accordingly, a trial of moderate- to high-dose prednisone is attempted and if quantitative protein excretion responds to therapy, the lowest dose which maintains reasonable protein balance and which is tolerated in terms of toxicity is continued. Alternate-day steroids may be useful in this situation. High-dose alternate prednisone [230] and alternating courses of high-dose intravenous methylprednisolone and chlorambucil [231] have been useful in the management of adult idiopathic membranous glomerulonephritis.

The tempo of renal disease is an important dimension in planning a therapeutic strategy. Marked renal insufficiency as a result of slowly progressive deterioration implies sclerosis of glomeruli and nephron dropout. Such progression may not be on an immunologic basis and usually does not improve with glucocorticoid therapy. Abrupt development of renal insufficiency, however, is an indication for immediate and aggressive corticosteroid therapy. The probability for improvement is much greater and the outcome is usually evident within several weeks [232–233]. This setting may be suitable for high-dose intravenous methylprednisolone therapy.

Central Nervous System

Accurate classification of central nervous system events in patients with systemic lupus is the obvious, but not necessarily straightforward, first step in the management of central nervous system disease [234–236]. Among the many causes of neurologic signs and symptoms, infection, isolated seizure, hypertensive seizure, and hypertensive encephalopathy do not deserve treatment with corticosteroids. Severe headaches, attributed to SLE after all other causes have been excluded, may occasionally be treated with steroids [237]. Episodes of psychosis can be problematic. When attributed to SLE, they may be treated with both steroids and psychotropic agents, but the differentiation of lupus-induced and

steroid-induced psychosis remains difficult [190, 238, 239]. Among systemically and seriously ill patients, CNS events may be complex in origin and reflect an amalgam of metabolic effects, drug influences, and possibly active lupus directly affecting the brain. Corticosteroid therapy in such a situation is often guided primarily by non-CNS considerations with the hope that the neurologic manifestations will resolve as the rest of the medical picture improves.

In the presence of an abnormal cerebrospinal fluid examination and/or focal neurologic findings in a lupus patient, the diagnosis of lupus CNS involvement is made after excluding other possibilities. If the relevant pathophysiologic process is steroid-responsive, then the patient should receive corticosteroids. Although the possibility of underlying vasculitis is often raised, this process has been difficult to document pathologically. Consequently, corticosteroid therapy is approached empirically and is individualized for each patient.

Several guidelines are available [240, 241]. Aseptic meningitis caused by lupus is usually treated with high-dose prednisone, 60–80 mg/day, until clinical manifestations have resolved. Frequent seizures, unresponsive to antiepileptics and to correction of any underlying metabolic abnormalities, deserve treatment with corticosteroids starting at 60–80 mg prednisone or equivalent per day. In status epilepticus, all three management approaches—antiepileptics, metabolic corrections, and steroids—must proceed almost simultaneously. Patients with cerebrovascular accidents in the absence of another explanation such as anti-phospholipid antibodies may receive a trial of steroid therapy. Such treatment is usually directed toward a presumptive underlying vasculitis and the prevention of additional events rather than toward amelioration of current manifestations. Vasculitis is often difficult to document. Movement disorders such as chorea-athetosis and hemiballismus may respond to moderate high-dose corticosteroids with the dose being titrated to the lowest amount able to control symptoms. Other focal neurologic disorders such as transverse myelopathy are treated with glucocorticoids, but the heterogenous experience with these presentations suggests that the dose and duration of therapy need to be individualized. For the patient with coma attributed to SLE, very large doses of steroids are used. The duration of therapy is often determined either by side effects or by the patient's ultimate outcome.

Other System Involvement

Other major organ systems may be involved in systemic lupus and require corticosteroid therapy. Acute lupus pneumonitis, which presents with dyspnea, diffuse acinar infiltrates, and occasional gross hemoptysis [242], can be life-threatening and requires the use of high-dose steroid therapy until improvement is realized. Acute reversible hypoxemia, often with a normal chest X ray, usually responds quickly to high-dose steroids [243]. Other pulmonary manifestations of lesser severity (such as fleeting infiltrates) and of greater chronicity (such as diffuse interstitial lung disease [244]) are often treated with a course of steroids. The limits of clinical experience, however, preclude exact therapeutic guidelines for dose and duration in these situations. Myocardial involvement requiring corticosteroid therapy is uncommon and difficult to diagnose antemortem. Resting tachycardia unexplained by other factors and related features of a new-onset cardiomyopathy may warrant a trial of moderate- to high-dose prednisone to control signs and symptoms. Other features of cardiopulmonary involvement such as symptomatic serositis and small effusions may require low- to modest-dose steroid therapy. However, this is usually instituted only after an adequate trial of nonsteroidal anti-inflammatory drugs and observation.

Vasculitic skin lesions may present in a variety of forms, including tender indurated lesions on the finger tips, palpable purpura with a biopsy picture of leukocytoclastic angiitis, ulcerations on the lower leg, and blotchy erythematous lesions on the palms. All may respond to low- or moderate-dose steroids. High-dose therapy is reserved for vasculitis of major organ systems which is often difficult to document. Myositis associated with lupus usually responds to corticosteroids. Although muscle enzyme abnormalities may vary with muscle mass, exercise, and other factors [245], improvement in strength and enzyme abnormalities are the usual guide to adequate therapy.

Many features of systemic lupus do not require corticosteroid therapy. Arthritis is usually controlled by appropriate nonsteroidal antiinflammatory drugs. Constitutional symptoms may respond to rest and either nonsteroidal anti-inflammatory drugs or antimalarials. While low-dose steroids may play a role on occasion, adequate trials of other management approaches are always warranted.

High-Dose Intravenous Corticosteroids

Large intravenous doses of corticosteroids came into common usage for the management of renal transplant rejection [246, 247]. Such regimens were used as an essential component of immunosuppressive therapy to manage, and perhaps even to prevent, rejection. Because of the similarity of the histologic lesion on renal biopsy specimens from renal transplant rejection to the lesions seen on several renal biopsies from patients with lupus nephritis, Carthcart and colleagues

tried this mode of therapy in a group of seven lupus patients with renal disease [248]. The improvement in some immunologic parameters and in renal function in this group led to the use of short courses of high-dose intravenous corticosteroid therapy in additional patients with SLE and other glomerulonephritides [249]. Interest in "pulse" steroid has focused on attempts to provide an episodic treatment regimen for episodic disease manifestations and on attempts to minimize side effects while providing a therapeutic increment not achieved through other more conventional therapies.

Primary interest regarding high-dose intravenous pulse steroid therapy has centered on lupus nephritis. Glomerular filtration rate and serum creatinine are the most common measures of renal outcome in response to high-dose intravenous methylprednisolone (IV-MP). Rapid improvement in renal function, often within a few days of therapy, has been noted both in lupus nephritis [232, 233, 249–263] and in other glomerulonephritides [231, 264–271]. This dramatic improvement in an *ad hoc* situation, although not observed uniformly in all patients, has stimulated and sustained interest in the clinical value of high-dose intravenous corticosteroids. The lack of recognition of and discussion about such a pattern of rapid spontaneous improvement in renal function in previous reports suggests a direct therapeutic effect of the IV-MP [249]. Although some comparative data are available [233, 260, 261, 263, 271], controlled studies comparing the efficacy of IV-MP to that of conventional-dose oral corticosteroids are unavailable.

Several features may characterize renal disease patients who have an apparent response to high-dose intravenous corticosteroids when used for new onset of or a flare of renal disease. Ofuji *et al.* [256] have suggested the patients with a shorter mean duration of abnormal urinary protein excretion prior to therapy may show greater improvement. Kimberly *et al.* [232] have demonstrated the association between recent deterioration in glomerular filtration rate and the probability of subsequent improvement. The pattern of change in serum creatinine rather than the absolute level of serum creatinine seemed to be the more sensitive predictor of therapeutic responses. In addition to a single course of high-dose intravenous corticosteroids given on an *ad hoc* basis, alternative dosage regimens have been employed including monthly maintenance doses for 1 year [272] and monthly doses until immunologic improvement occurs with the final assessment at 6 months [256]. Each paradigm suggests that IV-MP may provide a therapeutic increment, but controlled trials indicate that monthly maintenance IV-MP is not superior to cyclophosphamide [273, 274]. However, a long-term follow-up study of patients with proliferative lupus glomerulonephritis enrolled in a randomized, controlled trial suggests that intravenous pulse methylprednisolone in addition to pulse cyclophosphamide may further reduce the risk of renal insufficiency over the effect of pulse cyclophosphamide alone [275].

Attempts to treat the nonrenal manifestations of lupus with high-dose intravenous corticosteroids have met with variable success [255, 276–283]. Fessel [255] described three patients with pulmonary manifestations who did well after IV-MP. Reports of several patients with thrombocytopenia suggest that platelet counts may improve in situations refractory to more conventional doses [255, 276, 278]. Other manifestations including fever, vasculitis rash, and polyserositis may also improve with IV-MP [279, 282, 283]. Experience with central nervous system involvement is limited [276, 278, 280, 281]. Case reports suggest, however, that IV-MP is often used for serious disease manifestations, refractory to conventional steroid regimens, before proceeding (if necessary) to other therapeutic regimens.

Dose Reduction and Alternate-Day Therapy

Fulminant systemic lupus requires daily corticosteroid in divided doses. Once the disease is adequately controlled, the therapeutic goals expand to include reduction of dose to minimize side effects while maintaining adequate suppression of disease. Since hypothalamic–pituitary–adrenal axis suppression and many side effects of steroid therapy are less on an alternate-day schedule of medication, many physicians attempt to establish such a regimen. However, others feel that truly active disease requires daily corticosteroids and that an alternate-day schedule is primarily an approach for tapering the total dose of steroid after disease control is achieved.

The first step in tapering is the gradual consolidation of the divided daily doses into a single morning dose to coincide with the normal peak cortisone level. Without changing the total daily dose, four divided doses are consolidated to three, then three to two, and finally two to a single morning dose. The tempo of this process must be individualized and may take from several weeks to several months. When a satisfactory remission of signs and symptoms has been established on a constant single daily dose of steroid, reduction in that dose can proceed. Starting at levels of 60 mg of prednisone per day, the dose can usually be tapered 5 mg per week. However, all patients must be monitored closely for signs of exacerbation and the schedule modified accordingly.

An alternate-day regimen can be approached by various management strategies. The rationale of alternate-day administration is that the anti-inflammatory

effects last longer than the catabolic and ACTH-suppressive effects [284, 285]. Daily steroids can be tapered to approximately one-half of the desired alternate-day dose. Double the daily amount is then given on alternate days and the amount on the "off" day is tapered. Another strategy involves doubling the daily amount for alternate-day use soon after consolidation of the divided daily doses into a single morning dose. This approach may allow a lower "off" day dose to be established more rapidly. The most important aspects of any strategy for tapering corticosteroid therapy and for establishing an alternate-day schedule, however, are to attain adequate disease control before tapering, to maintain adequate control during dose reduction, and to monitor the patient closely so that adjustments in the therapeutic plan can be made should signs of exacerbation become evident.

Supplemental Corticosteroids for Adrenal Suppression with Steroid Therapy

Adrenal suppression during glucocorticoid therapy and subsequent to treatment is highly variable. Some suggest that for acute illness and for elective surgery maintenance of the current dose of steroid is sufficient [286–288]. However, several days of supplemental steroids add essentially no harm and may avoid complications. Salem *et al*. have recommended supplementation based on the previous dose of steroid and the severity of the physiologic stress: (a) for minor stress, 25 mg of hydrocortisone or its equivalent is recommended for 1–3 days; (b) for moderate stress, 50–75 mg is recommended; and (c) for major stress, 100–150 mg is recommended [289]. During the year following long-term high-dose therapy, similar supplementation for physiologically stressful situations would seem prudent.

Dose Response Modifiers: Genetics, Disease States, and Drug Interactions

Genetic factors, various disease states, and environmental influences, including medications and dietary nutrients, can affect drug metabolism in humans. While most attention has been directed toward drug–drug interactions, genetic and dietary factors may also play a role in drug disposition.

Genetics

Genetic effects are evident in the substantial interindividual variability in the rates of drug metabolism [290] and in individual differences in the response of metabolic rates to environmental factors [291]. Differences in phenobarbital metabolism, for example, can in turn influence cortisol metabolism. It is likely that glucocorticoid "sensitivity" and "resistance" also reflect genetic factors [292]. Naturally occurring human glucocorticoid receptor variants do have different biologies although currently recognized ones do not seem to explain "resistance" [293, 294]. Nonetheless it is likely that genetic factors will underlie many of these differences. In occasional patients, glucocorticoid insensitivity leads to unchecked progression of disease. The presence of high levels of GR-β, a splice variant of the classic GR-α, has been associated with corticosteroid-insensitive asthma. Although GR-β does not bind glucocorticoid, it can inhibit the transactivating effects of activated GR [295]. Proinflammatory cytokines may stimulate the production of this receptor [296, 297]. The clinical impact of GR-β induction on the clinical response to corticosteroid therapy for SLE has not been formally investigated.

Diet and Disease States

Dietary protein, carbohydrate, and cruciferous vegetables can alter drug metabolism in humans. Oxidative drug metabolism, studied with the test drugs antipyrine and theophylline, is influenced by high protein intake. Subjects on a high protein diet show shorter plasma half-lives and higher metabolic clearance rates of these test drugs [298]. Similarly, dietary protein can alter the metabolism of the major sex steroids in humans with increased 2-hydroxylation of estradiol and decreased 5α-reduction of testosterone [299]. Glucuronide conjugation and oxidative metabolism of acetaminophen is enhanced by feeding the cruciferous vegetables, brussel sprouts and cabbage [300]. The extent to which these nutrient interactions influence glucocorticoid metabolism and excretion remain to be defined.

The potential for disease states to alter the metabolic handling of and response to glucocorticoids is recognized but often not clearly defined [301]. Hyperthyroidism accelerates deactivation of glucocorticoid activity via 11-dehydrogenation. Liver disease has a variable influence on the hepatic metabolism of drugs [302]. For glucocorticoids the multiple effects are probably off-setting and do not usually require changes in drug dosages. The pharmacokinetics of prednisone in chronic active liver disease do not appear to be significantly altered [303]. Initial studies of the impact of active systemic lupus per se on glucocorticoid metabolism are interesting [301], but the basis for the clinical observation that some patients appear to be steroid resistant and free of the common side effects of high-dose therapy remains an important question for continuing investigation.

Drug Interactions

The drug interactions involving glucocorticoids fall into several major categories: those resulting from the anticipated actions of glucocorticoids and a second drug, those resulting from the induction of hepatic microsomal enzymes, and those for which the mechanism is uncertain. Among the effects in the first grouping, glucocorticoids elevate blood glucose and may increase the dose of insulin or oral hypoglycemics required for optimal control of blood sugar. Glucocorticoids may also cause sodium retention due to a mineralocorticoid effect and increase the optimal dose of antihypertensive agents. A drug-induced increase in intraocular pressure may increase the medications needed for management of glaucoma. Since glucocorticoid administration can lead to hypokalemia from increased urinary excretion of potassium, digitalis toxicity secondary to hypokalemia can occur in a previously stable patient.

Hepatic microsomal enzymes participate in the metabolism of glucocorticoids. Drugs, such as barbiturates, phenytoin and rifampin, which induce these enzymes accelerate metabolism and may increase the steroid requirement [14–21]. Ketoconazole and mitotane can alter cortisol synthesis. However, the basis for some drug interactions is not well understood. Administration of glucocorticoids reduces the serum salicylate level achieved with a fixed dose of salicylate [182, 304]. Accordingly, reduction or withdrawal of steroids in a patient receiving salicylates often leads to an increase in the salicylate level. The neuromuscular blockade induced by pancuronium may also be altered by steroids [305]. An acute paralyzing myopathy may develop in mechanically ventilated, critically ill patients managed with neuromuscular blockade and treated with systemic corticosteroids. This syndrome has been termed critical care myopathy or acute relaxant-steroid myopathy. It appears to develop as a result of the combined effect of corticosteroids and pharmacologic denervation of muscle and usually occurs in patients treated for severe exacerbations of asthma [306, 307]. It is distinguished from chronic steroid myopathy by elevated serum muscle enzyme levels and significant myopathic changes on electromyogram. Troleandomycin, a macrolide antibiotic, reduces methylprednisolone elimination but apparently does not alter prednisolone disposition [308].

Side Effects

Systemic Corticosteroid Therapy

A wide range of adverse reactions to glucocorticoids have been observed during their clinical usage. These include some manifestations of spontaneous Cushing's syndrome, some manifestations more characteristic of iatrogenic Cushing's and hypothalamic–pituitary–adrenal suppression. While some features are shared by both spontaneous and iatrogenic Cushing's syndrome, the clinical manifestations may differ (Table 3). Part of this difference is explained by increased adrenocortical androgens and mineralocorticoids present in spontaneous Cushing's syndrome.

Several complications appear more commonly with exogenous administration of glucocorticoids. Posterior subcapsular cataracts, glaucoma, and benign intracranial hypertension (pseudo-tumor cerebri) can occur with protracted use of glucocorticoids. Aseptic necrosis of bone is often a debilitating complication of glucocorticoid therapy. Studies have failed to consistently show an association with total glucocorticoid dose [309–312] or with pulse corticosteroids [312–314]. However, several investigators have demonstrated an increased risk of aseptic necrosis in SLE patients treated with high-dose steroids [309–317]. In a prospective study of aseptic necrosis in the hip and knee, consecutive SLE patients started on high-dose glucocorticoids underwent magnetic resonance imaging (MRI) scans at the start of therapy and at 1, 3, 6, and 12 months of treatment [318]. A total of 72 patients received the equivalent of 50 mg/day of prednisolone, and after follow-up, 32 patients (44%) developed lesions on MRI consistent with aseptic necrosis. The lesions developed early after initiation of treatment (mean 3.1 months).

TABLE 3 Cushing's Syndrome: Iatrogenic vs Spontaneous

	Iatrogenic	Spontaneous
Hormones involved	Glucocorticoids	Glucocorticoids Adrenocortical androgens Mineralocorticoids
Shared clinical features	Obesity Osteoporosis Psychiatric symptoms Poor wound healing	Obesity Osteoporosis Psychiatric symptoms Poor wound healing
Distinctive clinical features	Glaucoma Osteonecrosis Posterior subcapsular cataracts Benign intracranial hypertension (pseudo-tumor cerebri) Pancreatitis Panniculitis	Hypertension Hirsutism, virilism Altered menses Impotence in men

Differential Diagnostic Problems in SLE

Several complications of exogenous glucocorticoid therapy may be difficult to distinguish from manifestations of active lupus per se. These clinical situations present a special challenge to the clinician.

Central Nervous System Manifestations

Cognitive and emotional changes ranging from irritability and difficulty in concentration on mental tasks to severe depression, confusion, or even frank psychosis may occur with glucocorticoid administration [319–321]. In addition, convulsions have been infrequently associated with such therapy. The central nervous system manifestations of systemic lupus include the same range of clinical symptomatology thus making determination of the etiology of the central nervous system signs and symptoms problematic. The concomitant expression of signs of organicity or of focal neurologic findings favors central nervous system lupus. Similarly, an abnormal cerebrospinal fluid (CSF) examination with either elevated protein or cells supports lupus as the underlying cause. However, an explicit diagnostic conclusion may not be possible and an empiric modification of drug dosage may be necessary. Steroid-induced psychiatric disturbances usually respond to reduction or discontinuation of corticosteroid and phenothiazine treatment [320, 321].

Myopathy

Glucocorticoid administration may lead to muscle wasting and weakness. On biopsy this adverse effect is evidenced by a decrease in both Type 1 and Type 2 fibers without signs of inflammation [322, 323]. In systemic lupus inflammatory muscle disease with weakness and atrophy may also occur. Although this may be associated with tenderness of the muscles and elevations of the creatinine phosphokinase, these additional manifestations are not uniformly present. Muscle biopsies may be entirely normal or show drop-out of Type 1 and Type 2 fibers as in steroid myopathy. The presence of perivascular infiltrates of lymphocytes, plasma cells, monocytes, and neutrophils help to establish a diagnosis of lupus myositis; however, the presence of these findings cannot be relied on. Vacuolar myopathy, which is characterized by swollen sarcolemmal nuclei and prominent central nuclei within a muscle fiber and often within a vacuole, also occurs both with lupus and with steroid therapy [324, 325]. The pattern of serial change in muscle enzymes may be helpful in differential diagnosis [323, 326].

Chronic steroid myopathy has been associated with increased glutamine synthetase activity in skeletal muscle [327–329]. Increased enzyme activity has been attributed to a glucocorticoid response element in the glutamine synthetase gene [330]. Endurance training leads to a reduction in enzyme activity and improvement in skeletal muscle atrophy [331]. Kimura *et al.* [332] have shown that insulin-like growth factor-I decreases glucocorticoid-induced glutamine synthetase activity in rat myocytes while others have demonstrated a similar effect in animal models and humans treated with growth hormone [333, 334]. Pending further study, these agents may be treatment options for patients with steroid myopathy unable to discontinue corticosteroids due to persistent or recurrent lupus activity.

Pancreatitis

Patients with SLE may present with gastrointestinal crises including pancreatitis [335]. The occurrence of pancreatitis in lupus patients either prior to the use of glucocorticoids or during a period without steroid therapy has demonstrated that pancreatitis may result from active lupus. Glucocorticoid therapy has also been implicated as a cause of pancreatitis [336, 337]. Among lupus patients with documented pancreatitis, however, recovery has occurred despite continued glucocorticoid therapy [335]. A series of eight patients treated with glucocorticoids for lupus-associated pancreatitis recovered clinically and biochemically without complications related to the steroids [338].

Specific Problems in Systemic Lupus Erythematosus

Because of the multisystemic and protracted nature of systemic lupus erythematosus, several side effects of glucocorticoid therapy represent specific clinical challenges.

Gastrointestinal Manifestations

The controversy over the association of glucocorticoid therapy in peptic ulcer disease continues [339]). Conn and Blitzer reviewed data from 42 randomized controlled trials and concluded that short-term steroid administration was not ulcerogenic [340]. However, steroid use for more than 30 days for a total dose of 1000 mg of prednisone equivalent appeared to be associated with a small increase in the frequency of peptic ulcer disease. Reexamination of similar data has suggested that corticosteroids do increase the risk of peptic ulcers and gastrointestinal hemorrhage [341]. This analysis, however, excluded trials in which antacids were used since they might serve to prevent or neutralize any ulcerogenic potential.

In systemic lupus the potential concomitant administration of nonsteroidal anti-inflammatory drugs raises the important possibility that NSAID and glucocorticoids together may have a significantly greater risk for

ulcers than steroids alone. Some data, gathered in patients 65 years of age or older, support this possibility [342]. A meta-analysis which reviewed studies of the association between NSAID use and serious adverse gastrointestinal events found an increased the risk among NSAID users taking corticosteroids in comparison to NSAID users not taking steroids (odds ration 1.83) [343].

Infections

Glucocorticoids enhance susceptibility to infection [344]. The basis for this clinical effect is multifactorial and includes alteration of the leukocyte traffic within the circulation, modification of leukocyte function, and decreased inflammatory responses. Patients with systemic lupus also appear to have an intrinsic propensity to infection [345, 346]. Azathioprine does not appear to enhance the rate of infection in SLE patients receiving steroids [345], but other evidence suggests that combinations of steroids and cytotoxic agents may be synergistic in enhancing the risk of infection. For example, the risk of *Pneumocystis carinii* pneumonia may be higher for patients receiving both steroids and cytotoxic agents than either agent alone [347–349]. The true risks, and the applicability of these observations to other organisms, remain to be determined.

Osteonecrosis

Osteonecrosis occurs as a complication of exogenous glucocorticoid therapy in lupus patients [350–352]. Although total steroid dose probably is related to the incidence of osteonecrosis [353], the influence of other factors modifies the potential for any direct relationship. Osteonecrosis can occur with minimal steroid use, but high-dose intravenous methylprednisolone does not seem to increase the risk of its occurrence [354, 355]. It is unclear whether osteonecrosis is part of the natural history of systemic lupus erythematosus in the absence of steroid therapy. The potential for long-term steroid therapy in SLE, however, emphasizes the urgency for use of the smallest amount of steroids consistent with the clinical picture.

Osteoporosis

Glucocorticoids cause severe bone loss both in spontaneous Cushing's syndrome and in many patients receiving exogenous therapy [356–361]. The mechanism of glucocorticoid-induced osteoporosis (GIOP) includes reduced intestinal calcium absorption [362]. Reduction of osteoblastic cell activity including collagen biosynthesis and stimulation of bone resorption by osteoclasts may also contribute. Although lupus patients do not have any known intrinsic predisposition to osteoporosis other than joint inflammation and immobility, the prolonged use of corticosteroids which characterizes most therapeutic regimens probably provides a risk for significant osteoporosis [315]. Of interest, glucocorticoid-induced osteoporosis is reversible [363], but alternate-day steroid treatment may not offer an advantage over daily therapy in avoidance of osteopenia [364].

Dietary calcium and vitamin D have received substantial attention as prophylactic and therapeutic agents for glucocorticoid-induced osteoporosis (GIOP) [365, 366]. Fluoride, sex steroids, calcitonin, and bisphosphonates have also been studied. The bisphosphonates etidronate, alendronate, and risedronate have been shown to effectively prevent and treat GIOP in randomized, controlled trials [367–372]. Both risedronate and alendronate reduce the rate of incident vertebral fractures in patients with GIOP [369, 372, 373]. Bisphosphonate efficacy relates, in part, to a potent reduction in glucocorticoid-induced osteoblast apoptosis [374]. Current recommendations from the American College of Rheumatology suggest treatment with calcium and vitamin D in all patients receiving glucocorticoids. In addition, prevention of bone loss with a bisphosphonate is recommended for all postmenopausal women and men being started on long-term glucocorticoid therapy (≥5 mg/day prednisone or equivalent). Consideration should be given to bisphosphonate treatment for premenopausal women initiating prolonged corticosteroid therapy, with appropriate counseling regarding contraception [375].

Arteriosclerosis

Patients with systemic lupus erythematosus are susceptible to premature atherosclerosis, which is now recognized as a leading cause of mortality in SLE [376]. Epidemiologic studies have shown that young women with SLE have a marked increased risk of myocardial ischemia in comparison to age-matched controls [377]. Ultrasound studies demonstrate that SLE patients with higher damage scores and prolonged use of corticosteroids are at greater risk of developing carotid plaque and intimal thickening [378]. Cumulative corticosteroid dose has been associated with an increased risk of symptomatic coronary atherosclerotic disease and exposure to high-dose prednisone may increase the risk of cerebrovascular ischemia [312, 379]. Any association between corticosteroid use and arteriosclerosis in SLE is likely to be due in part to disease severity, for which increased steroid exposure is an intermediate variable. However, corticosteroids may adversely impact CAD risk factors by elevating serum levels of atherogenic lipids including LDL, apolipoprotein B, and triglycerides, particularly in patients with SLE [380–385]. An

aggressive approach to monitoring and managing hyperlipidemia in addition to other atherosclerosis is an integral component of medical care for SLE patients.

Pulse Corticosteroid Therapy

Since one goal of intravenous methylprednisolone pulse therapy is minimization of side effects attributable to long-term high-dose oral steroids, substantial attention has been focused on side effects of IV-MP. Minor transient events including facial flushing, metallic taste, acute arthralgias, hyperglycemia, irritability, and elevation of blood pressure have been recorded. More important are case reports of anaphylactic reactions [386, 387], seizures [388], arrhythmias [389–392], and sudden death [389, 390, 393]. The occurrence of such reactions must be rare but the true incidence cannot be determined from available data. Among renal transplant patients fewer infections have been found in the IV-MP treatment groups [394–397] but nonetheless serious infection may occur [396, 398], especially, if more than 5–6 g of methylprednisolone are given per course [399, 400]. Among patients receiving oral corticosteroids, IV-MP does not appear to increase the risk of aseptic necrosis [351, 352, 401, 402] although definitive data are lacking.

Topical Corticosteroid Therapy

Topical preparations may cause side effects which are related to both the potency and the absorption of the given preparation. Local atrophy, telangiectasia, purpura, and striae can occur especially with extended use of occlusive dressings or with natural occlusion in the groin or axilla. These effects are attributed to local catabolic effects leading to degeneration of collagen. Atrophy may occur on the face even without occlusion [403]. An eruption similar to rosacea, as well as steroid acne characterized by papules and comedones, may also occur on the face with the use of potent topical preparations.

Unusual side effects of topical corticosteroids include the precipitation of latent glaucoma and production of cataracts when the preparation is applied around the eye. The clinical appearance of superficial infections caused by pathogens such as *Candida* and dermatophytes may be altered. Bacterial superinfection may be expressed as a folliculitis. Intradermal injection at the proximal nail fold may cause a dystrophic nail. Systemic side effects may result from systemic absorption of topically applied corticosteroids. This is not usually a clinically significant problem unless there are extensive eruptions treated with occlusive dressings.

Intra-articular Therapy

Significant untoward effects of intra-articular corticosteroids are uncommon. From a systemic perspective, intra-articular steroids can have a variety of effects [185, 186]: facial flushing [180], suppression endogenous hydrocortisone levels [181], change in plasma salicylate levels [182], induction of hyperglycemia [183], and precipitation of a sickle-cell crisis in susceptible individuals [184]. Local problems usually reflect the cumulative effects of recurrent injections. Altered cartilage metabolism, decreased tensile strength of tendons, and soft tissue atrophy may occur with repeated use. Uncommonly, a single injection may result in an immediate flare of symptoms probably due to a crystal-induced arthritis. Rarely arthrocentesis and injection of corticosteroids may be associated with iatrogenic infection.

Steroid Withdrawal Syndrome

Reduction and withdrawal of corticosteroid therapy can lead to an array of symptomatology ranging from frank adrenal insufficiency to pseudo-rheumatic complaints to flares of the underlying disease [404, 405]. The primary challenge to the clinician is to determine the nature and etiology of the symptoms so that an appropriate adjustment in medication can be made [404–408]. Patients usually respond to reinstitution of the lowest previous dose of steroids.

ANTIMALARIALS AND IMMUNOSUPPRESSIVE THERAPIES

John C. Davis
John H. Klippel

Drug therapies currently used in the treatment of systemic lupus have not been specifically developed for lupus. Most of the agents have been adopted from transplant medicine or oncology and used based on the basis of: (1) known immune modulating properties, (2) efficacy in murine models of lupus, or (3) reported clinical observations. The principal noncorticosteroid agents currently used in lupus management derive from empiric experiences or small studies (antimalarials, methotrexate, and leflunomide), the observed effects of cancer chemotherapies on immune function (cyclophosphamide), and immunosuppressive drugs developed for the prevention of rejections of allogenic transplanted organs (azathioprine, cyclosporine, and mycophenolate mofetil). Although the exact mechanisms by which these drugs mediate improvement in lupus have not been defined with certainty, it is generally accepted that modulation or suppression of immune functions contribute to their modes of actions.

Antimalarials and immunosuppressive agents have a therapeutic role that spans the clinical spectrum of lupus (Table 1). Practical use of the agents is based on evidence from clinical trails, and efforts to match the risks of toxicities from the drugs with the potential for disease morbidity.

ANTIMALARIALS

The earliest clinical reports of antimalarials described improvements in discoid skin lesions following empirical treatment with quinine[1] and quinacrine.[2] Of the antimalarials, hydroxychloroquine is most commonly used (Table 2). There are few contraindications to these agents, although they should be used with caution in patients with G6PD deficiency, underlying hepatic disease, or porphyria.

Antimalarials are rapidly and completely absorbed in the gastrointestinal tract with peak plasma concentrations 2–8 hours following a single dose. A small percentage of antimalarials undergo deamination in the liver to inactive metabolites. The majority of the drug is bound to plasma proteins and is avidly concentrated within certain tissues particularly the liver, pituitary, skin, and adrenal glands. Metabolites and unchanged drug are renally excreted which may be enhanced by acidification of the urine. Equilibrium plasma levels are achieved at 4 weeks for chloroquine and quinacrine, and at 6 months for hydroxychloroquine. Therefore, the onset of action in lupus may require up to 4 to 6 weeks of therapy.

Both immunomodulatory and anti-inflammatory properties have been ascribed to antimalarials.[3] The high affinity of antimalarials for DNA with intercalation of the drug between adjacent base pairs inhibits cellular division as well as RNA transcription and translation.[4] In vitro drug effects on both macrophage and B-cell function have been described.[5,6] There is conflicting data in humans, however, as to whether antimalarials actually suppress antibody responses.[7,8] Antimalarials are highly concentrated within mononuclear cells and inhibit phagocytosis, migratory properties,

TABLE 1 Principal Indications for Disease-Modifying Drugs in Lupus

Drug	Principal Indications
Antimalarials	
Hydroxychloroquine	Rashes, Constitutional Symptoms, Arthritis, Arthralgias, Serositis
Chloroquine	
Quinacrine	
Alkylating Agents	
Cyclophosphamide	Major Organ Involvement (particularly nephritis and neurologic disorders)
Antimetabolites	
Azathioprine	Major Organ Involvement (particularly nephritis)
Mycophenolate mofetil	Nephritis
Methotrexate	Arthritis, Serositis
Leflunomide	Arthritis
Macrolide Immunosuppressants	
Cyclosporine	Nephritis (particularly membranous nephropathy
Tacrolimus	

and the metabolism of membrane phospholipids.[9–11] Hydroxychoroquine has been shown to induce apoptosis in peripheral blood lymphocytes.[12] Inhibition of the secretion of cytokines including interleukin-1 (IL-1), intereukin-6 (IL-6), and tumor necrosis factor alpha (TNF α) by mononuclear cells is thought to occur as a result of interference with posttranslational events. A number of effects of antimalarials on platelets have been described including cyclic gmP interactions and antiphospholipase inhibition. These combine to inhibit fibrinogen binding, thrombin-induced platelet responses, and platelet aggregation.[13]

Quinacrine and hydroxychloroquine are the best studied of the antimalarials; the clinical experience with chloroquine is substantially less.[14–20] It is generally believed that antimalarials have little role in the management of lupus involving major organs, although this has not been specifically studied. Antimalarials have a prominent role in the management of chronic cutaneous lupus, especially discoid lupus.[22] Combinations of antimalarials have been shown to be useful in patients with treatment-resistant subacute or chronic cutaneous lupus.[23,24] Hydroxychloroquine has been shown to provide subjective pain relief of musculoskeletal symptoms in lupus patients.[25] A 12-month double-blind, placebo-controlled trial of chloroquine diphosphate (250 mg daily) revealed that chloroquine led to improvements in non-major organ manifestations, reduced corticosteroid requirements, and prevented disease exacerbations.[26] Additional clinical benefits from hydroxychloroquine therapy in SLE may include the prevention of thromboemboloic events in patients with anti-phospholipid antibodies[27] and as a cholesterol-lowering agent. [28]

The efficacy of hydoxychloroquine as a disease-modifying agent in lupus has been most convincingly demonstrated in a prospective, double-blind trial in which patients on stable doses of hydroxychloroquine were randomized to continue drug therapy or be changed to a placebo.[29] The discontinuation of low-dose hydroxychloroquine in patients with clinically stable lupus was associated with significant increases in the risks of both clinical flares as well as severe exacerbations of the disease including vasculitis, transverse myelitis, and nephropathy. The study has led to reluctance to completely discontinue antimalarials in stable lupus patients who have clearly benefited from the drug.

The use of quinicrine remains less than that of hydroxycholorquine, but has been advocated as a second line substitution for hydroxychloroquine in patients with preexisting macular degeneration or those unable to tolerate hydroxychloroquine. [1] It also may be used in combination with hydroxychloroquine in patients with refractory skin manifestations of lupus. [1]

In general, antimalarials are well tolerated and rarely need to be discontinued for an adverse reaction (Table 2). Of the various toxicities associated with low-dose antimalarial therapy, gastrointestinal intolerance, cutaneous eruptions, dizziness, and nonspecific constitutional complaints are most frequent. Although hematologic toxicities are distinctly uncommon, complete blood counts should be obtained periodically.

Much of the concern regarding antimalarials has focused on potential ocular toxicities. Deposition of the drug in the cornea may be associated with complaints of blurred vision, photophobia, focusing difficulties, and visual halos. This side effect is most commonly seen within the first several weeks of starting the drug and typically resolves with the continuation of therapy. In the retina, antimalarials bind to the melanin of the pigmented epithelial layer and may damage rods and cones. Early retinal changes are typically first detected in the macula with findings of macular edema, increased pigmentation and granularity, and loss of the foveal reflex. Although patients with early macular disease (so called premaculopathy) generally have no visual complaints, on testing a paracentral scotomata to a red, but not white, test object may be detected. These types of retinal changes are entirely reversible upon discontinuation of the antimalarial drug. Advance macular disease is characterized by a central area of patchy depigmentation of the macula surrounded by a concentric ring of pigmentation ("bull's eye" lesion). Narrowing of the

TABLE 2 Dosage Guidelines and Potential Toxicities of Antimalarial Therapy in SLE

Agent	Brand Name(s)	Recommended Dose*
4-Aminoquinolones		
Hydroxychloroquine	Plaquenil	200–400 mg/day
Chloroquine	Aralen/Avloclor	250 mg/day
Chloroqune9-Aminocridines		
Quinacrine	Atabrine	100 mg/day
Potential Toxicities		
Constitutional	Malaise, irritability, weight loss	
Gastrointestinal	Anorexia, nausea, vomiting, diarrhea, abdominal pain, bloating flatulence	
Dermatologic	Pruritis, urticaria, multiple forms of rash, skin discoloration (particularly quinacrine), alopecia, bleaching of hair	
Opthalmologic	Keratopathy, preretinopathy, retinopathy, cycloplegia, extraocular muscle palsy	
Neuromuscular	Headache, dizziness, insomnia, tinnitus, psychosis, seizures, peripheral neuropathy, myopathy of proximal muscles, cardiomyopathy	
Hematologic	Leukopenia, agranulocytosis, aplastic anemia	

* Dose reduction required for patients less than 45 kg; 5–7 mg/kg/day for hydroxychloroquine, 4 mg/kg/day for chloroquine, and 1–2 mg/kg/day for quinacrine.

retinal vessels, optic atrophy, and diffuse depigmentation of the peripheral retina are very late changes. Patients with retinal pathology from antimalarials may be entirely asymptomatic or may complain of nyctalopia and scotomatous vision with field defects of paracentral, pericentral ring types and typical temporal scotomas.

The risks of retinal damage from antimalarials are increased with doses that exceed 6 mg/kg daily, cumulative doses greater than 800 g, and patient age, the latter presumably due to the increased prevalence of macular disease with age.[30–32] In addition, retinal toxicity may be more common with chloroquine as opposed to hydroxychloroquine.[33] Although the risks of retinal toxicity in patients with lupus treated with low does of antimalarials are extremely low, rare cases of retinal damage in lupus patients have been described.[34] Routine ophthalmologic examinations including slit lamp, funduscopic, and visual field testing should be performed at baseline in patients over the age of 40 and every 6–12 months during drug treatment. Patients with impaired renal function or those who have received antimalarials for more than 10 years may require more frequent monitoring.[32] An Amsler grid test, which can be self-administered, is a reliable and useful screening instrument for antimalarial retinal toxicity.[35]

Antimalarials cross the placenta and rare instances of congenital defects including cleft palate, sensorineural hearing loss, and posterior column defects have been reported with the use of chloroquine given for malarial prophylaxis. This poses a dilemma in lupus patients on antimalarial therapy in which there is the clear potential for disease exacerbation if the antimalarial is discontinued. It is generally recommended that antimalarials be avoided in pregnancy and ideally, because of the long drug half-life; they should be stopped several months in advance of an anticipated pregnancy (FDA Use in Pregnancy Rating Category C, Table 3), On the other hand, the safety of antimalarials in pregnancy has been noted in several small series of patients with lupus.[36–38] Although opinions vary widely, there appears to be increasing acceptance that the risks of flaring lupus exceed the risks of fetal congenital

TABLE 3 FDA-Use in Pregnancy Rating for Agents Used in SLE

Category	Evidence and Risks
A	Controlled clinical trials demonstrate no risk to the fetus
B	No evidence of risk to fetus in humans, either (1) human studies are lacking but animal studies show no risk, or (2) animal studies show risk but human studies do not
C	Human studies are lacking and animal studies are either positive for risk or lacking, potential benefits may justify potential risk
D	Evidence of risk to the fetus, however potential benefits may outweigh the risk
X	Definitely contraindicated in pregnancy—either human or animal studies have shown clear risk to the fetus

abnormalities and that antimalarials should be continued throughout the lupus pregnancy.

ALKYLATING AGENTS

There is a clinical experience with three nitrogen mustard alkylating agents in lupus—mechlorethamine, chlorambucil, and cyclophosphamide. For all practical purposes, mechlorethamine and chlorambucil are of historical interest only and infrequently used to treat lupus. Cyclophosphamide has become the standard of care for the drug management of most severe forms of lupus, particularly lupus nephritis.

Mechlorethamine

Mechlorethamine hydrochloride (mustargen, nitrogen mustard) is highly unstable and must be reconstituted from a powder immediately before use. A dose of 0.2–0.4 mg/kg body weight is infused rapidly through an indwelling venous catheter. Typically, the dose is repeated on a monthly basis. The drug is highly irritating, and great caution must be taken to avoid extravasation or drug contact with skin or mucous membranes. Following infusion, the drug rapidly undergoes transformation and is essentially undetectable within the bloodstream within several minutes. In comparison with other nitrogen mustard alkylating agents, mechlorethamine is considered to have relatively weak effects on immune factions.

A number of studies have documented benefits of mechlorethamine combined with corticosteroids in lupus, particularly in patients with lupus nephritis[39–42] For all practical purposes, nitrogen mustard has been replaced by the alkylating agent cyclophosphamide, which is easier to use. However, rare case reports of diffuse proliferative lupus nephritis with nephritic syndrome resistant to treatment with intravenous cyclophosphamide, but responsive to nitrogen mustard, have been noted to suggest that there may be a continued limited role for the drug.[42]

Cyclophosphamide

Substitution of a cyclic phosphamide for the N-methyl group of mechlorethamine yields an inert, stable alkylating agent, cyclophosphamide (Cytoxan, Endoxan). Activation of the drug required oxidation by hepatic microsomes to yield a number of metabolites. The key intermediate metabolite, aldophosphamide, is nonenzymatically cleaved to carboxyphosphamide and the potent alkylating compound phosphoramide mustard. These metabolites, in addition to alkylation, also have the capacity to phosphorylate molecular structures of the cell.

Cyclophosphamide is well absorbed following oral administration with peak plasma levels occurring one hour following the dose. Pharmacokinetics of oral and intravenous routes are comparable with a serum half-life of approximately 6 hours. Drug metabolism may be theoretically affected by drugs that enhance (corticosteroids, sex hormones, barbiturates) or inhibit (allopurinol, chloroquine, phenothiazine) hepatic mixed-function oxidase microsomal enzymes. However, the practical consequences of these influences in the clinical use of the drug are minimal. Alkylating metabolites circulate bound to plasma proteins and are renally excreted. Thus, plasma levels may be significantly increased in patients with compromised renal function and appropriate reductions of the drug dose are necessary.

Cyclophosphamide may be given by oral or intravenous routes (Table 4—not typed but is Table 4 from previous edition of book). Although there is no clear evidence that oral and intravenous regimens differ in clinical efficacy, in clinical practice oral cyclophosphamide has largely been abandoned in lupus in favor of intermittent, intravenous bolus therapy.[43,44] Drug schedules are empiric and largely based on acceptable levels of bone marrow suppression. The most commonly used intravenous regimen consists of monthly infusions (0.5–1.0 gm^2 body surface area) for a course of 6 months. Studies in patients with lupus nephritis suggest that continuation of bolus cyclophosphamide infusions every 3 months reduces the likelihood of disease relapse (see below). Studies of intravenous doses of 500 mg given

TABLE 4 Dose Guidelines and Monitoring of Cyclophosphamide Therapy

Dose	Routine Monitoring Studies
Oral: 1–3 mg/kg/day[a]	Hematocrit, white blood cell count/differential, and platelet count every 1 to 2 weeks with change in dosage and every 1 to 3 months thereafter. Urinalysis and urine cytology every 6 to 12 months[b]
IV: 0.5–1.0 mg/kg in 150 ml saline given over 60 minutes	Hematocrit, white blood cell count/differential days 7, 10, and 14 postdrug. Urinalysis and urine cytology every 6–12 months[b]
IV fluids (2–3 liters)/24 hr following dose	

[a] Drug should be taken in the morning in a single dose. Dose needs to be decreased in patients with impaired renal function.

[b] Urine cytology/cystoscopy for unexplained hematuria.

weekly have been reported to show comparable clinical improvements with fewer adverse effects.[45–48] In addition, high-dose oral administration has been shown to have a pharmacokinetic profile that is similar to that observed following intravenous administration.[49] Although the clinical experience with high dose bolus oral cyclophosphamide is limited, it appears to be well tolerated and most likely has an important role in outpatient management.[49,50]

Randomized controlled trials in lupus nephritis have demonstrated that cyclophosphamide retards progressive scarring within the kidney, preserves renal function, and reduces the risk for the development of end-stage renal failure requiring dialysis or renal transplantation.[51–56] Most recent studies have emphasized an important role for intermittent monthly boluses of intravenous cyclophosphamide in the preservation of renal function in lupus nephritis.[57–59] Studies suggest a similar important role in children with lupus nephritis.[60–64]

Variables such as drug dose, interval between boluses, and duration of intravenous cyclophosphamide therapy in lupus nephritis have not been well studied so as to define the optimal regimen for treatment. The relapse rate after 6 months of continuous monthly therapy is approximately 50% with some evidence to suggest that chronic maintenance therapy with less frequent infusions of cylophosphamide[53,54] reduces the likelihood of relapse.

There are no good studies that provide guidelines to indicate when cyclophosphamide should be discontinued. It is commonly recommended that cyclophosphamide be continued for a period of one year after the nephritis has been judged to be in remission; however, there are no data to support the recommendation. The relapse rate following even chronic therapy appears to be substantial,[65–67] and a further course of intravenous cyclophosphamide may be needed for patients who relapse.[68] In addition, a number of patients with severe nephritis fail to show any evidence of improvement with cyclophosphamide therapy.[69] Recent studies suggest that African-American lupus patients,[70] as well as patients with an elevated serum creatinine and advanced interstitial fibrosis[71] respond less well to drug treatment.

Although less rigorously studied, there is convincing evidence from case reports that intravenous cyclophosphamide has an important role in the management of most other forms of serious, major organ lupus. Improvements in a variety of neurologic or psychiatric manifestations have been reported following cyclophosphamide including transverse myelitis,[72–75] mononeuritis multiplex,[76] organic brain syndrome,[37] and optic neuropathy.[78] Other major organ lupus manifestations that have been reported to have responded to treatment with intravenous cyclophosphamide include hematologic abnormalities,[79–82] vasculitis,[83–85] myositis,[86] interstitial lung disease[87], pulmonary hemorrhage,[88] pulmonary hypertension,[89] and cardiomyopathy.[90]

There has been limited experience with combining cyclophosphamide with other therapeutic approaches. Combination regimens of oral cyclophosphamide and azathioprine have been studied in lupus nephritis.[51,91] A metaanalysis performed on a small number of patients reported that the drug combination was more effective than prednisone alone in reducing the incidence of end-stage renal disease.[92] Studies have shown that the sequential use of oral cyclophosphamide followed by maintenance oral azathioprine may preserve renal function and prevent disease relapses.[93,94] The use of combination methotrexate and cyclophosphamide has not been studied in adult SLE; however, there have been reports of its use in pediatric populations with beneficial results.[95] The combination of intravenous methylprednisolone and cyclophosphamide has been reported to increase the likelihood of remission in patients with lupus nephritis.[54,56] Recent evidence suggests that the combination of intravenous cyclophosphamide with plasmapheresis has little role in the management of severe, major organ lupus.[96,97]

Recent interest has focused on the use of higher-doses of cyclophosphamide as 'immunoablative' therapy followed by the infusion of autologous stem cells[98–102] or bone marrow growth factors.[103,104] The clinical experience with this approach is limited, although marked improvements in patients with severe forms of lupus have been well documented. Whether the improvements are a result of the cyclophosphamide alone or occur as a result of a readjustment of the immune system due to the replacement or growth of autologous stem cells is unknown. Studies are currently in progress to determine how the therapy compares with conventional monthly intravenous therapy in patients with nephritis and treatment—resistance cutaneous lupus. The risks of toxicities increases with high-dose cyclophosphamide.

The potential toxicities of cyclophosphamide administration are substantial (Table 5), and serve as a major deciding factor in patient selection of immunosuppressive therapy in lupus.[105] Nausea and vomiting from stimulation of central nervous system vomiting receptors are common, particularly after intravenous infusions, and occur approximately 12 hours after drug administration. In most patients, premedication with antiemetics such as oral ondansetron combined with dexamethasone[106] effectively minimizes gastrointestinal side effects. Hair loss is common with cyclophosphamide therapy and may occasionally be severe so as

TABLE 5 Potential Toxicities of Cyclophosphamide

Constitutional	Malaise, irritability, weight loss
Gastrointestinal	Anorexia, nausea, vomiting, diarrhea, abdominal cramps
Dermatologic	Alopecia, nail changes
Cardiopulmonary	Myocardial necrosis, pulmonary fibrosis (high dose only)
Genitourinary	Hemorrhagic cystitis, bladder fibrosis, bladder carcinoma, gonadal failure
Metabolic	Inappropriate antidiuretic hormone syndrome
Hematologic	Leukopenia (dose dependent), aplastic anemia with chronic therapy
Malignancy	Gladder, skin, cervical (?), and vulvar (?) carcinoma

to require a wig for cosmetic purposes. Patients need to be reassured that the hair will regrow even with continued therapy. Cyclophosphamide is a well established teratogen,[107,108] and effective birth control during therapy is essential.

The cytotoxic action of cyclophosphamide is most commonly expressed by its effects on bone marrow function, particularly while blood cells.[109] Peripheral leukopenia is dose dependent with the nadir of the depression occurring from 8 to 12 days after intravenous drug administration or increase in oral drug dose. During this period, serial white counts should be obtained several times to document the effect and to alter the drug does accordingly. As a general rule, the absolute white blood count should not be depressed below 2000 cells per cubic milliliter and the drug dose should be adjusted accordingly to maintain counts above this level.

Cyclophosphamide increases patient susceptibility to bacterial, fungal, and viral infections.[110–114] Several drug-induced effects such as leukopenia, depressed antibody synthesis, and altered cellular immune function likely contribute to this increased susceptibility. Risk factors shown to be associated with serious infection following cyclophosphamide include multiple organ involvement, concomitant high-dose corticosteroid administration, and white blood cell count nadirs below 3000 cells/mm^3.[111,115] Prophylaxis with low-dose trimethoprim/sulfamethoxazole to prevent *Pneumocystis carinii* has been recommended in non-sulfa-allergic patients with vasculitis treated with the combination of cyclophosphamide and high-dose daily corticosteroids.[114]

Damage to gonadal tissue follows prolonged cyclophosphamide administration and leads to ovarian failure and oligo/azoospermia.[116–124] During cyclophosphamide treatment serum levels of follicle-stimulating and luteinzing hormones are increased, and estradiol levels are reduced. The deficiency of estrogens produces signs and symptoms of menopause with amenorrhea, hot flashes, endometrial hypoplasisa and atrophy of vaginal epithelium. Pathologic examination of ovaries following prolonged cyclophosphamide treatment reveals destruction of follicles and fibrosis of the interstitial areas. In men, the primary damage is to the germinal epithelial lining layer of the seminiferous tubules. Clinically, there is a decrease in testicular volume and oligo or azoospermia leading to infertility. This associated with marked elevations of serum follicle-stimulating hormone, a measurement that might be useful in monitoring cyclophosphamide effects on the testes. Libido and sexual function are generally unaffected. Recovery of spermatogenesis or ovarian function following cyclophosphamide is unpredictable, although has been observed even months or years after the drug has been discontinued. Several studies have shown that patient age and cumulative drug dose are the two major factors that determine the risk of ovarian failure.[121–125] Cumulative drug dose also appears to be a factor in menstrual disorders that occur in adolescent girls with lupus treated with cyclophosphamide.[123] Recent evidence suggests that testosterone may prevent azoospermia in men treated with oral cyclophosphamide.[126] Theoretically estrogen supplementation or the use of gonadotropin-releasing hormone agonists[127] should help prevent ovarian failure, however neither strategy has been well studied. Ova or sperm banking prior to cyclophosphamide administration might be considered in selected patients.

Several forms of bladder toxicity, a complication unique to cyclophosphamide and not apparent from other alkylating agents, are evident including hemorrhagic cystitis,[128] fibrosis,[129] and transitional and squamous cell carcinoma.[130–133] Bladder complications appear to be associated with oral drug administration with no evidence, at least to date, that intermittent, intravenous therapy causes bladder problems. The drug metabolite acrolein has been shown to be the irritant responsible for acute cystitis.[134] Daily oral cyclophosphamide should be taken in the morning with attention to generous fluid intake throughout the day to reduce concentrations of acrolein in the bladder to minimize the risk of bladder toxicities. In patients treated with intravenous bolus cyclophosphamide, mesna (Mesnex) which binds acrolein is increasingly being used in conjunction with intravenous bolus cyclophosphamide therapy as a way to further protect the bladder, particularly in patients with know cyclophosphamide-induced bladder damage in whom continued drug administration is required.[135,136] The dose of mesna used is 20% of the total cyclophosphamide dose given either intravenously or orally start-

ing immediately before cyclophosphamide administration and every 3 hours thereafter for a total of 4 doses. In lupus patients with urinary retention, for example a neurogenic bladder secondary to transverse myelitis, catheterization with bladder irrigation using a three-way Foley catheter should be used for 24 hours following the cyclophosphamide infusion.

Patients treated with prolonged courses of cyclophosphamide probably should be screened indefinitely for malignant changes in the bladder. Urine cytology is useful if abnormal but has a poor sensitivity to detect low-grade cancers. Nonglomerular hematuria has been found to be the most useful marker to identify patients at risk for developing bladder cancer and urinalysis should be done every 3–6 months even after cyclophosphamide has been discontinued.[128] The development of gross or microscopic hematuria, particularly of new onset and after prolonged drug administration, should be assessed by cystoscopy for possible malignant changes of the bladder. Patients treated with cyclophosphamide who develop evidence of reduced bladder capacity, such as frequency and small urinarv volumes, should undergo cystometric evaluation.

Cyclophosphamide is a well-documented carcinogen in animals and a number of case reports have documented the development of malignancies in patients treated with cyclophosphamide.[133] A United Kingdom-Australasian collaborative study of immunosuppression in nontransplant patients suggests an increased overall risk of malignancy following cyclophosphamide (13 observed versus 5.86 expected, $P < 0.03$).[137,138] By comparision, the relative risk of bladder cancer was found to be 10.3 ($P < 0.01$). Malignancies of hematopoietic or lymphoreticular origin have been of particular concern. Although the quantitative risks of these malignancies in lupus patients treated with cyclophosphamide are unknown, case reports of reticulum cell sarcoma,[139] lymphoma,[140] and leukemias[140–145] have been observed. It is encouraging that follow-up studies of large series of lupus patients treated with cyclophosphamide have failed to detect evidence of increases in malignancies with the possible exception of cervical and vulvar malignancies.[146,147]

Unusual rare complications of cyclophosphamide therapy that have been reported include interstitial pneumonitis,[148] myocardial necrosis with doses,[149] liver damage,[150] inappropriate antidiuretic hormone syndrome, [151,152] and various hypersensitivity reactions.[153,154]

Chlorambucil

Chlorambucil (Leukeran) is an aromatic bifunctional alkylating agent with substitution of the N-methyl group of mechlorethamine with phenylbutyric acid. The drug is given orally (0.1–0.20 mg/kg body weight daily) with good absorption. Serum half-life is approximately 90 minutes with drug metabolism involving both methylation and beta-oxidation. Drug effects on immune functions are comparable to those described from cyclophosphamide.

There are few clinical studies of chlorambucil in systemic lupus, but improvements in nephritis as well as manifestations such as central nervous system signs, vasculitis, and multisystem involvement have been reported.[155–157] Recent studies in idiopathic membranous nephropathy have shown that combined methylprednisolone and chlorambucil significantly alters the long-term course of the renal disease.[158–159]

Side effects of chlorambucil are similar to those observed with cyclophosphamide with the exception that there is no bladder toxicity associated with chlorambucil. Drug monitoring is the same as that described for cyclophosphamide (see Table 4). Bone marrow suppression, including irreversible marrow failure, may be more severe and less predictable that with cyclophosphamide. There is a markedly increased risk of leukemia, in particular acute myeloblastic leukemia, with chlorambucil.[160,161]

ANTIMETABOLITE IMMUNOSUPPRESANTS

Azathioprine

Early clinical experience with purine analogs in the treatment of lupus included studies of 6-thioguanine and 6-mercaptopurine.[162–165] The only purine analog that continues to be widely used in lupus management is azathioprine, an involves enzymatic conversion by sulfhydral compounds into 6-mercaptopurine. Metabolism of azathioprine involves two major pathways. Direct oxidation by the enzyme xanthine oxidase yields 6-thiouric acid that is eventually converted to uric acid. This pathway can be blocked by the xanthine oxidase inhibitor allopurinol. Metabolism is then shifted to the second major pathway which involves methylation of the sulfhydral group and subsequent oxidation. Mono-, di-, and triphosphate nucleosides of the methylthiopurine products accumulate, which leads to alterations of cellular purine biosynthesis as well as DNA function. Because metabolites from this latter pathway produce the immunosuppressive and toxic effects of 6-mercaptopurine, the shift of drug metabolism produced by allopurinol significantly enhances drug effects.[166] Therefore, it is important that the dose of azathioprine be decreased in patients receiving concomitant treatment with allopurinol. Generally, a reduction of the standard

TABLE 6 Dosage and Potential Toxicities of Azathioprine

Dose	Monitoring Recommendations
Oral 1–3 mg/kg/day*	Complete blood count every 1–2 weeks with changes in dose and every 1–3 months thereafter. Liver enzymes every 4 months.
Toxicities	
Constitutional	Malaise, weight loss, fever
Gastrointestinal	Anorexia, nausea, vomiting, diarrhea, abdominal pain, hepatotoxicity
Dermatologic	Hypersensitivity skin eruptions
Hematologic	Leukopenia, macrocytic anemia
Neurologic	Aseptic meningitis
Maligancy	Cervical atypia, non-Hodgkin's lymphoma, leukemia

* Reduce dose in patients concomitantly treated with allopurinol

dose to approximately one-third is sufficient to produce comparable effects achieved by full dose in most patients.

Initial oral doses of between 25 and 50 mg/day of azathioprine are suggested to determine acute toxicity/sensitivity; in addition drug metabolism varies widely in individual patients and may account for both efficacy and toxicity. (Table 6) The dose can be increased by 0.5 mg/kg/day every 4–6 weeks with the goal of achieving a range between 2 and 3 mg/kg/day. Monitoring should include full hematologic testing every 1–2 weeks while the dose is being adjusted and every 1–3 months thereafter.[167] Liver function tests and serum creatinine should be performed every 4–6 months.

There have been multiple clinical studies of azathioprine in patients with lupus that have documented improvements in various nonrenal manifestations, stabilization or improvement of impaired renal function, reduction of proteinuria, and corticosteroid-sparing properties of the drug.[168–179] A serial histologic study in lupus nephritis reported a decrease in cellular proliferation and electron dense deposits as well as a transition from proliferative to membranous disease following azathioprine treatment.[173] Exacerbations of disease observed in the several month period following azathioprine withdrawal have been regarded as further evidence of efficacy.[174]

A number of controlled trials have evaluated the effects of azathioprine in patients with lupus nephritis.[180–187] Although the studies themselves reached different conclusions as to whether azathioprine modified the course of lupus nephritis, a meta-analysis combining the data from these trials concluded that azathioprine was a valuable drug in the management of lupus nephritis.

Other approaches using azathioprine in the treatment of lupus have included combination with low-dose cyclophosphamide,[182,188] heparin,[184] bolus methylprednisolone,[189] and antilymphocyte globulin.[179] The efficacy of any of these combinations remains to be proven.

The most common side effects of azathioprine that limit therapy involve various forms of gastrointestinal intolerance and bone marrow toxicity (Table 6).[190] Azathioprine affects both erythroid and myeloid elements of the bone marrow. Macrocytosis often with megaloblastic erythroid changes of the marrow develops in the absence of vitamin B_{12} or folic acid deficiency. Rarely, patients with severe macrocytosis have progressed to selective erythroid hypoplasia. The onset of leukopenia may be abrupt and blood counts should be monitored regularly to detect any changes early.[167,191] Bone marrow toxicity is generally reversible with reduction of the dose or discontinuation of the drug.

Azathioprine increases patient susceptibility to infections from common bacterial and opportunistic organisms. Azathioprine can produce elevations of liver enzymes, particularly the pyruvic and glutamic oxaloacetic transaminases. On liver biopsy hepatocellular necrosis and mild biliary stasis have been seen. Hepatotoxicity is thought to result from drug hypersensitivity and may be accompanied by clinical features such as fever, diffuse abdominal pain, diarrhea, and maculopapular skin rash.[192] Hepatic abnormalities are typically reversible upon stopping the drug. There are a number of well-documented reports of azathioprine-induced pancreatitis.[193–197] In addition, a severe hypersensitivity reaction with fever, hypotension, and oliguria has been described.[198,199]

Although uneventful pregnancies have been documented in transplant recipients, lupus patients, and patients with other inflammatory conditions treated with azathioprine,[200–205] it is generally recommended that birth control be used during azathioprine therapy and that the drug not be given during pregnancy or periods of breastfeeding (FDA Use in Pregnancy Rating D, Table 3).[206] Both congenital defects and evidence of severe immune deficiency have been described in infants born to mothers treated with azathioprine during pregnancy.[207,208] Azathioprine is known to induce chromosome abnormalities as well as increases in sister chromatic exchanges. The relationship of chromosomal defects to teratogenicity is unknown.[209]

There is strong evidence to suggest that azathioprine is carcinogen in humans. Case reports of the development of solid tumors, lymphoma, and leukemia[210–215] and a fourfold increase in cervical atypia[216] in lupus patients treated with azathioprine have been documented. An epidemiologic survey identified statistically increased frequencies of non-Hodgkin's lymphoma and reticlum

cell sarcomas in patients treated with azathioprine for indications other that organ transplantation.[217,218]

Mycophenolate Mofetil

Mycophenolate mofetil has been used in the prevention of renal allograft rejection. It is a potent inhibitor of inosine monophosphate dehydrogenase, an enzyme critical for *de novo* synthesis of guanine nucleosides. Therefore, it has similar functional consequences as the purine analogs. Mycophenolate mofetil is rapidly hydrolyzed to its active form mycophenolic acid. The functional selectivity of mycophenolic acid for T and B-lymphocytes derives from the reliance of these cells on the *de novo* purine pathway rather than the hypoxanthine-guanine phosphoribosyl transferase salvage pathway for purine biosynthesis. Its effects on immune function include suppression of T and B lymphocyte proliferation, monocyte activation, antibody formation, and recruitment of leukocytes into inflammatory sites.

Both oral and parenteral preparations are available. The drug has excellent bioavailability and has a half-life of seventeen hours. It is metabolized to its active form which is excreted in urine and bile. Dosage adjustment is recommended for patients with impaired renal function. There have been no studies performed in pregnant women, but the drug has shown teratogenic effects in animals. Therefore, it is recommended that pregnancy be avoided in patients taking mycophenolate mofetil (FDA Category C Table 3).

Mycophenolate mofetil has been used extensively in the prophylaxis of organ rejection concomitantly with cyclosporine and corticosteroids in patients receiving allogenic solid organ transplantation. It has been shown to be more effective than azathioprine in the prevention of acute rejection of transplanted organs.[219] The drug is given orally (1–2 gm twice daily) on an empty stomach with rapid absorption and hydrolysis to free mycophenolic acid in the liver and gastrointestinal tract. The most common adverse reactions reported are gastrointestinal intolerance, leukopenia, and infection which appear to improve with lower doses.

Recent studies have begun to assess its role as an immunosuppressive agent in immunologic disorders, including lupus. In murine models, mycophenolate mofetil has been shown to inhibit the development of nephritis and increase survival.[220,221]

Mycophenolate mofetil has been used with some success in rheumatoid arthritis and psoriasis. Studies in patients with lupus have reported benefit in patients with cyclophosphamide refractory nephritis.[222,223] A more recent study reported that treatment with mycophenolate mofetil in combination with corticosteroids was as effective as an oral regimen of cyclophosphamide for six months followed by azathioprine for six months.[224] Relapse rates were similar in both groups as well. Mycophenolate mofetil was generally well tolerated with infections being the most common adverse event.[225] Common side effects are leukopenia and diarrhea. A randomized controlled trial is underway comparing monthly intravenous cyclophosphamide with mycophenolate mofetil in lupus nephritis.

Methotrexate

Clinical experience with methotrexate (MTX) in SLE has been until recently limited to case series and open-label trials.[225–235] Most dose schedules have involved low-dose, weekly oral or parenteral doses with escalations and dose ranges (7.5–15 mg/week) similar to those used in rheumatoid arthritis. Because MTX is eliminated by both glomerular filtration and active tubular secretion, reductions in dose are necessary in patients with impaired renal function. Absorption appears to be dose dependent and peak serum levels are reached within 1–2 hours. In general, doses of 30 mg/m^2 or less are well absorbed of which 60% is bioavailable.

After oral or parenteral administration, MTX is present either in its native state or an active metabolite 7-hydroxy-MTX for only a few hours. These compounds are taken up by Kupfer cells and converted intracellularly to their polyglutamate forms, which are both biologically active and have longer half-lives than the parent compound. It is thought that it is the accumulation of MTX polyglutamates that is, in part, responsible for both the therapeutic and toxic effects of the drug. Although the mechanism of action is unknown, the therapeutic effects of MTX have been attributed to properties: (1) the inhibition of methylation reactions and (2) the promotion of adenosine release.[236]

Analogs of folic acid inhibit cellular single-carbon transfer reactions necessary for the biosynthesis of purine nucleotides, thymidilate, and ultimately DNA and RNA. Normally, folic acid is actively transported in the cell, converted to dihydrofolate, and reduced to tetrahydrofolic acid by the enzyme dihydrofolate reductase. The tetraphydrofolate serves as a coenzyme onto which single carbon fragments are added and then transferred as part of multiple specific cellular biosynthetic reactions. Folic acid analogs, all of which are 4-amino folate derivatives, have an affinity for the dihydrofolate reductase, which is much greater than the natural substrate and prevents the formation of tetrahydrofolate. Folate metabolism is thus blocked at the level of dihydrofolate, a metabolically inactive product, a cellar synthetic reactions involving single carbon transfer are prevented.

Methotrexate polyglutamates inhibit the enzyme 5-aminoimidazole-4-carbonxamide ribonucleotide (AICAR) transformylase leading to the intracellular accumulation of AICAR. Intracellular accumulation of AICAR inhibits AMP deaminase leading to the accumulation of adenosine and its subsequent release of adenosine into the extracellular space. Interaction of adenosine with it's A2 receptor on cell surfaces has been reported to inhibit release of toxic oxygen metabolites, inhibit lymphocyte proliferation to mitogens, and induce suppresser phenotype and function. Adenosine has also been demonstrated to inhibit the production of TNF_{α} IL-8, and increases in IL-10 production. Although these studies have largely involved animal models of rheumatoid arthritis, MTX has also been shown to produce the same effects in murine models of SLE.[237] This has let to the hypothesis that promotion of adenosine release mediates at least in some part the anti-inflammatory effects of low-dose MTX therapy in several autoimmune diseases.

Clinical studies have emphasized improvements in polyarthritis, skin rashes, serositis, fever, and leukocytoclastic vasculitis in lupus patients treated with MTX. In addition, MTX has also been reported to have a steroid-sparing effect and to lower overall measures of disease activity such as the SLEDAI score.[233] Reports of improvement in renal manifestations have been conflicting and most series have excluded patients with either renal or central nervous system manifestations.[231] MTX in low, weekly doses has been shown to be useful as adjunctive therapy for selected cases of childhood SLE.[225] Prompt recurrences of disease activity with discontinuation of MTX have been documented in most reports, while others have described sustained benefit over a period of months when used for severe, refractory cases of lupus.

One controlled trial reported suppression of disease activity with doses ranging from fifteen to twenty milligrams per week over a six month period.[238] As with the open label studies, articular and cutaneous manifestations appear to be the most responsive to therapy.

Toxicities of MTX have consisted mainly of gastrointestinal intolerance, malaise, transient elevations of transaminases, mucositis; no instances of pulmonary toxicities have been described in SLE. Administration of folic acid may reduce some of these adverse events without decreasing efficacy. MTX can cause teratogenic effects and fetal death and should not be used in women considering pregnancy. Pregnancy should be avoided if either partner is receiving therapy with MTX during treatment and for a minimum of 3 months after discontinuation for males and one ovulatory cycle for females (FDA Category D Table 3).

Overall, studies of the use of MTX in SLE are encouraging and suggest that MTX may be used as an alternative to antimalarials or low-dose corticosteroids for the management of musculoskeletal manifestations, serositis, and constitutional symptoms. Furthermore, in view of its relatively less severe long-term side effects when compared to cyclophosphamide therapy, further evaluation of the use of MTX in lupus involving major organs appears to be warranted.

Leflunomide

Leflunomide is an isoxazole derivative that has been approved for the treatment of rheumatoid arthritis to reduce symptoms and reduce structural damage.[239–241] The drug is rapidly absorbed after oral dosing and converted into the active metabolite A77–1726 (a malononitrilamide). The half life of the metabolite is approximately 15 days. There is extensive enterohepatic recirculation of the drug and it is strongly bound to plasma proteins. The mechanism of action is by inhibition of pyrimidine synthesis thereby resulting in anti-inflammatory effects. This occurs through inhibition of the enzyme dihydroorrotate dehydrogenase leading to decreased production of rUMP in lymphocytes. Low levels of rUMP in lymphocytes prevent further cellular activation. This leads also to decreased production of inflammatory cytokines.

Because of its long half life, leflunomide requires a loading dose of 100 mg/day for three days followed by 20 mg/day thereafter. The drug is eliminated through the feces and urine. Leflunomide is teratogenic and is contraindicated in patients trying to become or are pregnant. To accelerate the elimination of the drug, cholestyramine (8 gm orally for 8–11 days) is recommended.

Animal models have shown that leflunomide is effective in preventing (1) the development of autoantibodies in the MRL/lpr mouse, and (2) development of tubulointerstitial nephritis in rats.[242,243]

Leflunomide has been reported to be safe and efficacious in patients with rheumatoid arthritis.[239–241] Results from a pilot study of eighteen patients with lupus treated with leflunomide would seem to suggest efficacy and safety.[244] Patients were treated with standard doses and evaluated after two to three months of therapy. Two thirds of the patients treated had reported improvement despite failing other conventional therapy. Large placebo controlled trials will be needed to confirm the role of this agent in the treatment of lupus.

MACROLIDE IMMUNOSUPPRESSANTS

Studies in murine models of lupus suggest an important role for the macrolide immunosuppressive agents in the prevention and treatment of nephritis.[245–247] To date, however, clinical information is limited to a small number of trials done with cyclosporine and tacrolimus.

Cyclosporine

Cyclosporine has been widely used to prevent rejection in patients with kidney, liver and heart transplantation. It has also been studied in severe rheumatoid arthritis and less frequently in lupus. It is a cyclic, lypophilic polypeptide produced as a metabolite by the fungus *Beauveria nivea*. The lipid solubility of the drug requires that it be given in a liquid oil base; however, the newer preparation form a microemulsion in aqueous environments. The absorption of the drug from gastrointestinal tract in incomplete and highly variable, although newer microemulsion formula is reported to have better bioavailability and less intrasubject variability. Oral preparations have about 30% bioavailability compared to that of intravenous administration, and peak serum levels are achieved in 3–4 hours. The biliary tract is the major pathway of drug excretion. Neither dialysis nor renal failure appears to significantly alter clearance of the drug. The pharmacokinetic properties vary widely with age of the patient, the presence of concomitant diseases, and the use of many other medications. Serum cyclosporine levels are possible to monitor; however, levels reflect neither the potential for toxicity nor efficacy. The minimal effective daily dose has not been established but is probably less that 5 mg/kg body weight. The two forms of cyclosporine are not bioequivalent, and dose adjustments are required when changing to the microemulsion formulation. A 1:1 dosage is usually started with adjustments made to attain preconversion trough concentrations.

The mechanism of action of cyclosporine has been reported to be the inhibition of T-cell-receptor-induced IL-2 transcription through inhibition of the calcium/calcineurin induced nuclear translocation of NF-ATc.[248] It inhibits the production of Interleukin-2 and multiple other inflammatory cytokines by lymphocytes. Generation of cytotoxic T cells is also suppressed. In animal studies, improvements included survival of skin grafts, reduced swelling of adjuvant arthritis, and modulation of a cell-mediated model of autoimmune uveitis.

Most of the literature on cyclosporine in the treatment of SLE consists of brief reports with small numbers of patients treated in an open-label fashion with short periods of follow-up.[249–253] Although improvements in lupus nephritis have been noted in several series, other studies have failed to document any clinical benefits. Cyclosporine appears to produce remission in adults and children with nephritic syndrome associated with minimal-change disease. It also has been reported to produce remission in children with focal and segmental glomerulosclerois; however, it has been less effective in adults and in individuals resistant to steroids. It appears to reduce proteinuria and to slow progression of renal insufficiency in membranous forms of glomerulonephritis. There have been several reports of the effectiveness of cyclosporine in patients whose disease was either poorly responsive or unresponsive to treatment with steroids, cytotoxic agents, or both.[252,253]

Most improvement in disease activity has been reported with 4–8 weeks of drug initiation, and it has been suggested that prolonged treatment should be aimed more at consolidating clinical results rather than achieving further improvements. Relapses are common after drug discontinuation. Adverse drug reactions encountered included hypertrichosis, paresthesias, gastrointestinal symptoms, tremors, gingival hyperplasia, and a peculiar angioedema with reduction of C1 esterase inhibitor levels. It is the side effects of hypertension[254] and direct nephrotoxicity[255] of cyclosporine that appear to limit the usefulness of the drug in the management of lupus. In particular, studies have shown a clear dose-dependent reduction in renal function that was only partially reversed upon discontinuation of the decrease in dosage of cyclosporine. Risk appears to be increased with initial or maximal doses greater than 5 mg/kg/day; however, even in lower doses nephrotoxicity and hypertension have been reported.[256,257] Toxicity appears to be additive when cyclosporine is used in combination with nonsteroidal anti-inflammatory drugs.[238] Cyclosporine-induced hypertension is generally treated by angiotensin-converting enzyme inhibitors or B-blockers. Metabolism of cyclosporine is reduced with concomitant diltiazem, ketoconazole, rifampin, and phenytoin use. Cyclosprine is rate Category C for use in pregnancy (Table 3)

A review of over two hundred patients (in twelve studies) reported that treatment with doses of 2.5 to 5.0 mg/kd/day were well tolerated.[258] Improvement in the following parameters were reported: proteinuria, cytopenias, complement, double stranded DNA antibody, and general disease activity scores.[258] Adverse events reported were mild nephrotoxicity, hypertension, gingival hyperplasia, and hypertrichosis—most of which improved with discontinuation of the drug. One group has reported efficacy of cyclosporine particularly in patients with membranous nephropathy.[259]

Cyclosporine should be considered in patients with SLE and major organ involvement (especially membranous nephritis) whose disease is either poorly responsive or unresponsive to steroids, cytotoxic drug, or both.

Tacrolimus

Tacrolimus is a potent macrolide immunosupressant, 10–100 times as potent as cyclosporine.[260,261] It is chemically unrelated to cyclosporine, however has a similar mechanism of action in the inhibition of T cell activation.[262] It appears to be efficacious in the treatment of autoimmune, inflammatory, and allergic skin diseases through at least three distinct mechanisms. First, Tacrolimus suppresses the activation of T cells by inhibiting the expression of early T-cell response genes. It binds to a cytosolic FK binding protein, forming a complex which inhibits the ability calcineurin to dephosphorylate a subunit of the transcription factor NF-AT. Thereby preventing the subunit of NF-AT from translocating across the nuclear membrane and associating with its nuclear counterpart, thereby diminishing transcription and expressing of all genes activated by NF-AT (including IL-2) (Figure 1. Second, Tacrolimus possesses strong anti-pruritic activity, and has been shown to inhibit IgE mediated histamine release from mast cells, diminish transcriptional activation of IL-3 & IL-5, and downregulate the expression of leukotrienes.[263] Finally, Tacrolimus has also been demonstrated to inhibit the expression of IgE on Langerhans antigen presenting cells in the epidermis and inhibit their ability to stimulate autologous lymphocytes.[263,264]

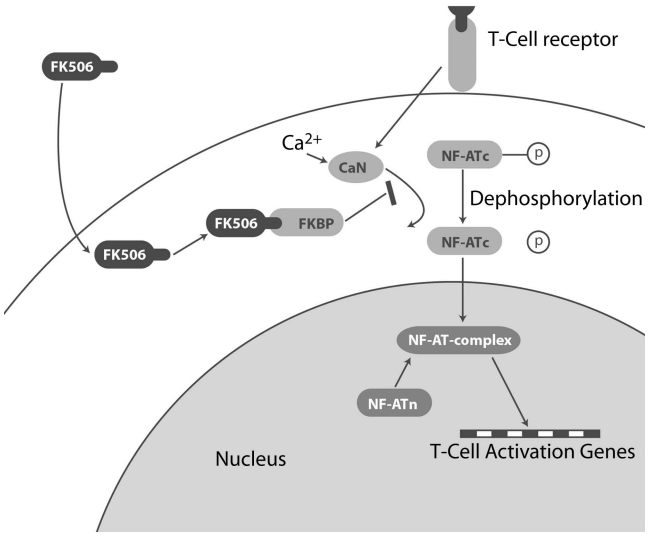

FIGURE 1 Mechanism of action of tacrolimus. Tacrolimus suppresses the immune response by preventing dephosphoralyation of the nuclear transcription factor NF-Atc which is required for nuclear translocation NF-AT. This action then bocks the expression of early T-cell activation genes.

A single oral dose, tacrolimus reaches peak blood levels within 30 to 180 minutes, with a mean bioavailability of 16–22% and half-life of 40 hours.[265] Oral doses of 0.10, 0.15, and 0.20 mg/kg lead to maximum blood levels of 19, 24, and 48 ng/ml respectively in renal transplant recipients.[265] Tacrolimus is strongly bound to plasma proteins and red blood cells. Hepatic metabolism represents the major route of elimination.[265]

As with cyclosporine, the clinical use of systemic tacrolimus has been associated with a dose-dependent and reversible nephrotoxicity as demonstrated in kidney transplant recipients.[260] Following liver transplantation, tacrolimus has also been shown to lead to a lower incidence of hypertension than cyclosporine.[260] Less frequent reported side effects of systemic use of tacrolimus include cardiomyopathy in children, anxiety, seizures, delerium and tremor, diabetes, and hyperlipidemia.[260,261]

Both oral and topical forms of the drug have been studied. To date, with over 5,000 patients studied, the use of topical tacrolimus has not been associated with glucose intolerance, hypertension, nephrotoxicity, or neurotoxicity.[262] In a clinical trial of topical tacrolimus conducted in 180 children 7–16 years of age with atopic dermatitis, no systemic side effects were reported. The most common local adverse events noted were increased pruritis and burning only during the first four days of application.[266] There were no significant changes in laboratory values throughout the 22 days of the study, and no increase in skin infections was observed.[266] These results in pediatric patients were confirmed earlier this year in a long-term safety trial conducted in children ages 2–15 with atopic dermatitis.[267] In the European Tacrolimus Ointment Study Group, 316 adult patients greater than 18 years of age were studied for 6–12 months. The study revealed no significant change in laboratory parameters, with minimal systemic levels of tacrolimus detected (76% with less than 1 ng/ml).[268] Adverse events reported were local irritation, pruritis, erythema, and burning which tended to occur during therapy initiation.[268]

Recently, topical tacrolimus was approved by the FDA for use in atopic dermatitis. In numerous studies, topical tacrolimus has been found to be superior to placebo in improving symptom scores and reducing the skin scores of patients with atopic dermatitis, including several patients with disease refractory to topical cyclosporine and steroids.[260-263,266–268] Doses of 0.03%, 0.1%, and 0.3% were used in one trial for atopic der-

matitis and all doses found to be equally efficacious.[261] Other applications of topical tacrolimus to treat autoimmune skin disease include its successful use for erosive mucosal lichen planus.[269,270] In one series of 6 patients with severe refractory disease, application of topical tacrolimus 0.1% resulted in improvements in all patients, with 3 showing complete resolution of disease.[269] Treatment successes with topical tacrolimus have also been reported for pyoderma gangrenosum and the bald-rat model of alopecia areata.[260,261,271]

Although showing positive results with oral tacrolimus, the treatment of psoriasis has been less impressive than topical preparations. However it was shown to be effective in patients in whom the ointment was applied under occlusion after removal of psoriatic scale. Oral tacrolimus has been found to be effective in several cases series to treat the skin and mucosal manifestations of Behçet's disease.[261,272]

To date, there have been no reports of clinical trials involving the use of oral or topical tacrolimus to treat the manifestations of lupus. In animal models, the intraperitoneal administration of tacrolimus has been found to be effective in reducing the incidence of skin lesions in the MRL/lpr mouse model of SLE.[272] Finally a case series of 3 patients with severe, refractory SLE has been reported showing a benefit in 2/3 patients in controlling manifestations of the disease, including vasculitis. A recent case series reported the efficacy of topical tacrolimus in patients with lupus.[273] Further controlled studies are needed to assess the role of tacrolimus in the treatment of lupus.

UNPROVEN AND EXPERIMENTAL THERAPIES

Ronald F. van Vollenhoven

INTRODUCTION

While established therapies are successful in many patients with systemic lupus erythematosus (SLE), there is still a great need for more effective and safer treatments, particularly with respect to the long-term outcomes and quality of life. New data continue to emerge regarding unproven but widely employed therapies, such as intravenous gammaglobulin and plasmapheresis, while several immunosuppressive and immunomodulatory agents originally developed for use in other diseases are being evaluated for their potential in SLE, in particular, the agent mycophenolate mofetil that in one study showed promising results in the treatment of lupus nephritis. Appropriately, a large number of entirely new therapies for SLE are currently being tested in animal models and in human clinical trials. These include the hormonal agent dehydroepiandrosterone (DHEA) which has gone through extensive clinical trials with positive results. A number of biological agents, such as monoclonal antibodies targeting B lymphocytes (rituximab), various "second signal" inhibitors (including CTLA4-Ig), and anti-IL10 have also been tested in humans, with varying results. The B-cell toleragen LJP394 is being evaluated for its ability to prevent nephritis flares. In addition, a range of "alternative" treatments including herbs and nutritional supplements are available to the general public. Thus, while the proper evaluation of new treatments for SLE remains a formidable challenge, the prospects are excellent for more successful treatments in the not too distant future.

> All who partake of this remedy recover in a short time except those whom it does not help, who all die. Therefore, it is obvious that it fails only in incurable cases.
>
> [Galen, second century A.D.]

OVERVIEW

Evaluating New Therapies for SLE

Numerous potential new treatments for SLE have been proposed in both the scientific and the lay literature over the past decades. A survey of these treatments might easily leave one bewildered and wondering where they are now, given the time that has elapsed. While evaluation of new treatments for any disease engenders certain difficulties and pitfalls, it is particularly challenging in the case of SLE, because of several characteristic features of this disease.

1. SLE is a chronic disease, and treatments must be evaluated based on their ability to bring about a meaningful change in the long-term rather than the short-term outcome.
2. SLE is characterized by morbidity as well as mortality. In most patients the main focus is on improving quality rather than length of life; thus, longer-term outcomes and quality-of-life issues play a major role.
3. SLE is highly heterogeneous. In view of this, some clinical trials single out one specific organ manifestation of SLE, most often nephritis, to investigate the efficacy of an intervention. However, it is not necessarily true that a treatment for one such organ manifestation is also

effective for other symptoms or for the disease as a whole. In order to deal with this problem, a number of indices for *global* disease activity have been developed [1, 2], that are now being used in therapeutic trials.

4. SLE has a variable and unpredictable course. Any clinician can attest to the fact that some patients with very severe disease have made remarkable recoveries, while others have succumbed to what appeared to be manageable disease severity. In view of this, case reports and small series of 'successful' interventions need to be regarded with caution, and controlled studies of sufficient size are critically important.

Challenges in SLE Therapy

The currently available therapies for SLE fall considerably short of achieving the desired objectives in many patients. Some patients still die of lupus, and organ damage accrues over time in many patients. Moreover, therapy for SLE often does not achieve control of persistent "smoldering" disease activity, and the patients who attain complete remissions of disease activity, even when treated aggressively, may well be in the minority. Clinical lupus practice is frequently dominated by patients who, despite adequate treatment for the most serious, organ-threatening manifestations of SLE, remain symptomatic, often with "minor" or "systemic" manifestations of the disease. While lupus therapeutics has been dominated for many years by the emphasis on preventing death, renal failure, and other end-organ damage, a number of more recent studies have deliberately focused on agents and treatments that may improve the less severe but more common symptoms of SLE, such as UV-A1 light, bromocriptine, and DHEA.

Unproven and Experimental Therapies: An Overview

Unproven and experimental therapies for SLE are found in various stages of development (Table 1). Many new biological and pharmacological therapies have been studied in mouse models of SLE only, while some have been used in small numbers of patients with SLE; and a few such novel therapies are currently in controlled clinical trials. Some "new" treatments, such as the immunosuppressive mycophenolate mofetil or the hormonal agent bromocriptine, are established in the treatment of other diseases, and are being tested in clinical trials involving patients with lupus. These types of treatment are, therefore, available to physicians for use in individual patients (although insurance coverage may not be extended for their use). Finally, most "alternative" treatments, such as nutritional interventions, herbs, and acupuncture, are generally available to the patient without having received any kind of formal regulatory approval.

NONIMMUNOSUPPRESSIVE IMMUNOMODULATORY TREATMENTS

Intravenous Immunoglobulin

Intravenous infusion of pooled human donor-derived immunoglobulin (IVIG) has become a well-established treatment for several human diseases with immunological mechanisms, but remains controversial in the therapy of SLE [3]. The most successful roles for IVIG are in the management of idiopathic thrombocytopenic purpura (ITP) where rapid and dramatic, albeit transient, improvements of platelet counts are almost invariably seen [4]; and in Kawasaki's disease, where significantly improved long-term outcomes are observed following such therapy [5]. In the wake of these successes, IVIG has been used in various autoimmune diseases, but with few controlled data so far.

In SLE, the use of IVIG in patients that manifest lupus-associated thrombocytopenia is generally accepted. The mechanism of this therapy is believed to be blockage of Fc receptors in the reticuloendothelial system, thereby preventing the phagocytosis of antibody-coated platelets [6]. Whether IVIG is useful for the treatment of SLE other than in this specific setting remains controversial. In 1984, Gaedicke *et al*. [7] reported on 2 patients with juvenile SLE, 1 of whom showed impressive improvement of multiple SLE manifestations following IVIG administration. Francioni *et al*. [8] reported on 12 patients with moderately severe lupus who were treated with monthly IVIG infusions for up to 2 years; 11 of their patients had progressively improving disease courses during the trial. Several case reports suggested remarkable benefits in patients with CNS-lupus [9–12]. Other reports have stressed benefits for lupus nephritis [8, 13]. While most reports in the literature describe patients with severe disease who have failed conventional therapy, Schroeder *et al*. [14] reported on 12 patients with mild to moderate disease, who were treated with two series of IVIG infusions (approximately 2 g/kg × 2 total) in lieu of standard therapy; 9 of the 12 patients improved, and 3 had sustained responses for 5–12 months. Successful treatment with IVIG has also been reported for lupus-related myelofibrosis [15], lupus-related acquired factor VIII inhibitor [16], lupus-related cardiomyopathy [17], and lupus-related polyradiculoneuropathy [18]; but treatment failures, which are far less likely to be reported in

TABLE 1 Unproven and Experimental Therapies: An Overview

Studied in mouse models	Studied in patients with SLE; uncontrolled data	Studied in controlled clinical trial(s)	Available to treating physician	Available to public
	IVIG	IVIG	IVIG	
LJP394	LJP394	LJP394		
	Plasmapheresis	Plasmapheresis[a]	Plasmapheresis	
	Selective immunoadsorption		Selective immunoadsorption[b]

[a] Controlled trial(s) with *negative* results.
[b] Available only in specialized centers.
[c] FDA is reviewing new drug application for DHEA (Prasterone, Aslera). Physicians can prescribe DHEA to be compounded by specialized pharmacies.
[d] Non-prescription products labeled as containing DHEA have been found to contain inconsistent and variable amounts of DHEA and may contain other hormones.
[e] Possibly some benefits in male patients with testosterone but worsening disease with nortestosterone; doubtful if any efficacy in females.
[f] *Negative* study.
[g] One small negative study, other study terminated due to serious side effects.
[h] development halted due to severe, life-threatening side effects.
[i] effective in *cutaneous* lupus.

the literature, were also noted [19, 20]. No controlled trials have been performed of IVIG in SLE. Because IVIG is not immunosuppressive, its use could be considered in patients with concurrent infection, particularly with encapsulated organisms where IVIG may have additional therapeutic benefit [21]. IVIG appears to be safe during pregnancy, and its use in this setting has engendered significant interest, particularly when SLE was accompanied by the anti-phospholipid antibody syndrome [22].

Various therapeutic mechanisms of IVIG in SLE have been proposed (reviewed in Ref. 23), including down-regulation of autoantibody production, dissociation and/or increased clearance of immune complexes; RES blockade; and blockade of autoantibodies by anti-idiotypic antibodies in the IVIG [24]. However, most of these possibilities remain to be formally tested.

IVIG is perceived as safe, but some toxicities have been noted. Mild to moderate infusion reactions are fairly common. Leukopenia and other hematological side effects occur in 2–3% of patients. Acute renal failure is an uncommon but potentially serious side effect [25]. A 6-year-old patient with SLE developed severe vasculitis following IVIG therapy [26]. The most notable side effect of IVIG is "pain in the pocket book": the retail cost of a single treatment course of IVIG (2 g/kg) ranges from $2000 to $3500, and the additional expenses involved in the administration of an intravenous drug, such as nursing time and equipment use, add substantially to this figure. One would hope that the considerable financial gains posted by the manufacturers of commercially available IVIG will to some extent be used to support well-designed clinical trials of IVIG in appropriate clinical settings.

Thus, IVIG remains an as yet unproven but interesting therapeutic option in SLE. In clinical practice, one might consider IVIG particularly in those situations where the patient is critically ill despite appropriate corticosteroid and immunosuppressive therapy; in cases of severe CNS disease; in patients with concomitant SLE and infection, particularly with encapsulated organisms; and in pregnant women with severe SLE.

LJP394: DNA-Toleragen

Anti-(double-stranded) DNA antibodies are unique among the autoantibodies associated with human autoimmune diseases in that they are virtually pathognomonic of SLE, are seen mostly in patients with nephritis, and in that their levels may mirror or even predict SLE disease activity [27]. Moreover, anti-DNA may play a pathogenetic role in lupus nephritis through formation of immune complexes with circulating native DNA, through binding of DNA within the glomeruli, or through cross-reactivity with glomerular structures. Thus, the objective of lowering anti-DNA antibody levels in patients with SLE is scientifically appealing. The most straightforward approach to this problem, removal of anti-DNA antibodies from the circulation by plasmapheresis, has met with limited success (discussed elsewhere in this chapter). An approach that would selectively down-regulate the anti-DNA producing B cells is therefore a logical goal.

Experimentally, B-cell tolerance can often be achieved through the administration of antigens intravenously [28–30]. One of the mechanisms for such tolerance is the binding of soluble antigen by the B cell in the absence of a costimulatory signal provided by T cells, resulting in B-cell anergy [31]. The molecule LJP394 was engineered for this purpose. LJP394 is a triethylene glycol-platform with four 20-mer oligonucleotides, consisting of alternating deoxycytidine and deoxyadenosine nucleotides, covalently attached. This molecule was shown to have high affinity for anti-DNA antibodies and to decrease anti-oligonucleotide antibody formation in oligonucleotide immunized mice [32]. Moreover, LJP394 reduced anti-DNA antibody formation in the BXSB mouse model of SLE, and decreased glomerulonephritis, nephrosis, and death in these mice [33]. In human SLE patients treated with LJP394 50-mg IV once weekly for 16 weeks, anti-DNA titers were decreased by more than 50%, and levels of anti-DNA remained suppressed during an additional 2-month follow-up period without further treatment [34]. In a similar but larger dose-finding study the reduction in anti-DNA was around 40% at the highest dosage level [35]. In a subsequent multicenter randomized placebo-controlled clinical trial the ability of weekly intravenous injections with LJP394 to *prevent* flares of lupus nephritis was evaluated. While the results of this trial have not yet been published, the main findings have been made public and indicate that a meaningful reduction of nephritis flares was seen in those patients who had anti-DNA antibodies with high binding affinity for LJP394. A subsequent phase III clinical trial to confirm this possibility is currently underway. If successful, LJP394 may become the first in a new class of drugs, designed to reduce the burden of pathogenic autoantibodies and thereby prevent disease relapses. This principle could then be applied to other diseases as well.

It is as yet unclear if LJP394 would exert its effects by binding circulating anti-DNA, facilitating clearance of these antibodies, or by actually down-regulating autoreactive anti-DNA producing B lymphocytes (as originally intended). While the former mechanism might be equally effective, only the latter possibility would suggest that a major treatment benefit could be

maintained after therapy is discontinued. And even if anergy is in fact induced, it is unknown how long such anergy might persist following cessation of the treatment.

NONPHARMACOLOGICAL IMMUNOSUPPRESSIVE APPROACHES

Plasmapheresis

Conventional Plasmapheresis

Plasmapheresis or plasma exchange for the treatment of SLE appears to have gone through several cycles of enthusiasm and disappointment. The assumption that removal of harmful autoantibodies would be beneficial to patients with lupus could not be more straightforward, and uncontrolled observations in the 1970s suggested that plasmapheresis was indeed an important therapeutic tool for the management of this disease.[1] However, several controlled studies failed to show benefit for plasmapheresis. A 2-year randomized trial in 18 patients showed similar outcomes with or without plasma exchange [36]. In a pivotal clinical trial of this treatment, the Lupus Nephritis Collaborative Study Group randomized 86 patients with severe lupus nephritis to receive either corticosteroids plus cyclophosphamide, or corticosteroids plus cyclophosphamide plus plasmapheresis three times a week for the first 4 weeks [37]. After a mean follow-up of 136 weeks, there were no statistically significant differences between the two groups in terms of mortality, progression to renal failure, or improvements in creatinine clearance and proteinuria.

Plasmapheresis can engender a rapid "rebound," an increase in antibody levels that even exceed the previous ones, due to expansion of autoreactive B cells after withdrawal of the negative feedback exerted by the antibodies in the circulation. Therefore, plasmapheresis is almost exclusively used in settings where strong immunosuppressive therapy can be given as well (most often cyclophosphamide). Some studies even suggested that it might be beneficial to "synchronize" plasma exchange with cytotoxic therapy. However, in an ambitiously designed, multicentered, randomized clinical trial by the Lupus Plasmapheresis Study Group (LPSG), patients with severe SLE (including a majority of patients with nephritis, but not excluding other lupus manifestations) were randomized to regimes of monthly infusions with cyclophosphamide vs synchronized plasmapheresis followed by cyclophosphamide, for 12 months. Contrary to expectations, the results of the trial showed that the treatment with synchronized plasmapheresis plus cytotoxic therapy was *not* superior to cytotoxic therapy alone with respect to the primary outcome of interest, improvement in systemic lupus activity measure (SLAM; Ref. 1) score, or to organ-specific outcomes (reported in abstract form, Ref. 38. An analysis of the subset of patients with nephritis was also published with similar results [39]. From a scientific point of view, it would be important to determine if the synchronized treatment did, in fact, decrease the numbers or activity of autoantibody producing B cells, in order to determine if the negative results of this trial were due to an incorrect premise (i.e., anti-DNA producing B cells are not critical for the outcome of SLE), or due to an inadequate treatment (i.e., inability to down-regulate such cells with this type of therapy).

Thus, plasmapheresis given in a variety of manners does not appear to improve the outcome of lupus overall or of severe lupus nephritis. However, there may still be a role for plasmapheresis in the management of certain patients with SLE, especially since it has become increasingly recognized that some patients with SLE exhibit features of thrombotic microangiopathy [40, 41], such as thrombotic thrombocytopenic purpura (TTP), or hemolytic–uremic syndrome (HUS).

Because of the established role of plasmapheresis in the treatment of these disorders, it would seem reasonable at this time to include plasmapheresis in the therapeutic regimen for severely ill patients with SLE who have evidence for TTP or HUS [42]. Furthermore, patients with SLE who exhibit concomitant conditions amenable to treatment with plasmapheresis, such as cryoglobulinemia, or the catastrophic anti-phospholipid syndrome [43] are also reasonable candidates for such therapy.

Plasmapheresis is not without potential risks. Side effects during the procedure itself include hemodynamic complications, electrolyte disturbances, access-related complications such as bleeding and infections, and others. A small retrospective comparison of lupus patients treated with or without plasmapheresis unexpectedly suggested a significantly higher mortality due to infectious causes for patients given plasmapheresis [44].

Selective Immunoadsorption

A variant of plasmapheresis is immunoadsorption, whereby specific subsets of antibodies can be extracted from the patients' blood. Various methodologies

[1]So much so that, when the Lupus Nephritis Collaborative Study Group proposed doing a controlled trial of plasmapheresis, some prospective participants argued that it was unethical to withhold this treatment from a group of patients for the purposes of this study.

employing membranes and columns have been used over the years [45–52] and the fact that they accomplished the desired reduction in specific antibody titers has been demonstrated. For example, immunoadsorption using a dextran sulfate column effectively removed anti-DNA antibodies from the circulation of patients with SLE [46]. Only individual cases and small series of patients with SLE have been reported [47–50]. Immunoadsorption with a protein A column was effective in the treatment of a patient with SLE-related thrombocytopenia, presumably by binding the antiplatelet antibodies [51]. Successful treatment in a patient with SLE and transverse myelitis was also reported [52].

The complement component C1q has a central role in immune complex mediated inflammation. In a pilot study, treatment with a C1q immunoadsorption column gave excellent responses of long duration in three of eight treated patients [53]. Similarly, rapid improvement of cutaneous lupus was seen in one patient with the same treatment [54].

Total Lymphoid Irradiation (TLI)

X-ray irradiation of the lymphoid tissues results in dose-related immunosuppression [55], and suppresses lupus-like disease in NZB/NZW mice [56, 57]. Total lymphoid irradiation (TLI) in humans resulted in long-lasting immune suppression, reflected by decreased mitogen and antigen responses, and reductions in peripheral blood T-cell counts, particularly $CD4^+$ T cells [58]. TLI with 2000 rads administered to all the lymphoid tissues above and below the diaphragm over a period of around 6 weeks, and with mantel-field shielding of the bone marrow and lungs analogous to the treatment of Hodgkin's disease, has been used in small numbers of patients with SLE at Stanford University over the past 20 years. In the initial description of 15 patients, favorable 1–2 year results were reported [59, 60]: most patients attained significant improvement of renal disease, and many were able to discontinue corticosteroid therapy. However, 2 patients with SLE treated at another institution did not do well [61]. It was also noted that, in patients with rheumatoid arthritis who were treated with TLI, encouraging 2- to 5-year results were followed by 10-year outcomes that were significantly less favorable than with cytotoxic therapy [62]. Long-term follow-up of the Stanford TLI cohort was more recently published [63]. Out of a total of 21 patients treated with TLI for lupus nephritis, 6 died after an average of 6 years. Nine patients (43%) survived >10 years without progressing to renal failure. Of these, 4 patients did not require additional cytotoxic therapy. Inasmuch as these patients were characterized by high severity and, in most cases, failure to achieve disease control with conventional agents, these results may be viewed as favorable. Infections seen among the 21 patients treated with TLI included herpes zoster in 5, and fungal infections in 2. Four malignancies were seen (two lymphoma, one thyroid cancer, one cervical cancer), all of which were successfully treated.

In summary, TLI has been used to date primarily in patients with severe and/or refractory lupus with nephritis. In this group of patients, overall results and toxicities were similar to those seen with aggressive immunosuppressive drug therapy (e.g., with cyclophosphamide). It is unclear at present how TLI would compare if used instead of, rather than in those patients who have failed, cytotoxic therapy. Long-term benefits in a small number of patients who had failed standard cytotoxic regimens suggest that TLI may have a role in the management of patients with refractory lupus nephritis.

HIGH-DOSE AND MYELOABLATIVE CHEMOTHERAPY

It is a rather striking fact that, whereas the chemotherapy agents cyclophosphamide and azathioprine have become mainstays of lupus therapeutics, their usage has been as single agents (along with corticosteroids) and at dosage levels much below those used in oncology.[2] However, there has been a surge of interest in various forms of high-intensity chemotherapy for SLE.

Higher-Than-Conventional Dosages of Cyclophosphamide

A treatment protocol for severe SLE was developed in Kiel, Germany, consisting of plasma exchange, IVIG, and cyclophosphamide at 1200–2100 mg/m^2 given over 3 days, followed by oral cyclophosphamide for 6 months. The initial results with this protocol showed a remarkable percentage of patients with durable treatment-free remissions [64]: of 14 patients treated with this regimen, 8 were in remission without treatment for 4–8 years. A later update on the use of this protocol in a number of centers [65] shows that overall results were somewhat less impressive: while 16 of 52 patients attained treatment-free remissions, toxicities were severe, including a >10% mortality, frequent major infections, hemorrhagic cystitis, severe thrombocytopenia, and major hemorrhage.

[2]The historical reason for this may be the success of low-dose daily cyclophosphamide in the treatment of Wegener's granulomatosis.

Petri and colleagues [66] treated 14 patients with severe and refractory SLE (9 with nephritis) using cyclophosphamide 50 mg/kg daily for 4 days followed by G-CSF. Global disease indices improved significantly. Five of the 14 patients were considered complete responders and 7 partial responders. After up to 4 years of follow-up, some patients had durable responses but others had relapsed. No deaths and no premature ovarian failure were seen. Inasmuch as these results were obtained in patients previously treated with conventional immunosuppressive regimens with inadequate responses, the results are impressive. However, the lack of response in some, and the occurrence of relapses in others, underscores the need for better ways of identifying those patients most likely to benefit from aggressive therapeutic strategies. A trial randomly assigning patients with severe lupus to conventional cytotoxic therapy vs high-intensity chemotherapy, is currently underway.

Bone-Marrow and Stem-Cell Transplantation

The use of allogeneic bone-marrow transplantation for a range of malignancies has been associated with a few scattered reports of remissions in patients who also suffered from autoimmune diseases, for example, rheumatoid arthritis (RA) [67]. However, the 20–30% mortality associated with allogeneic transplantation precludes it from being considered as a reasonable therapeutic option in SLE. In contrast, autologous stem-cell transplantation (ASCT), having a much lower mortality, is under intense investigation for the treatment of autoimmune diseases [68–70]. The rationale for ASCT is based on two separate premises: First, it can be postulated that diseases such as SLE might respond better to very high-dose, myeloablative chemotherapy, which must then be followed by "rescue" ASCT. This premise would follow logically on the demonstration that better results can be obtained in SLE with higher-intensity chemotherapy. Second, it can be argued that ASCT reestablishes the immune system, replacing the malfunctioning lymphocytes with a freshman class of soon-to-be-educated B and T cells. Whether either of these two rationales is correct remains to be seen. In one reported series, five patients with autoimmune diseases, one of whom had SLE, were given ASCT with unmanipulated grafts [71]. In all five patients the serological and clinical evidence for autoimmune disease persisted or recurred after the transplant. The lack of success in these patients was interpreted as underscoring the need for "purging" of the graft from mature lymphocytes prior to reintroduction, but it is also conceivable that more intensive treatment of the host in order to eradicate autoreactive lymphocytes may be necessary to accomplish better results. Several reports of ASCT with purged grafts for SLE were published, including in childhood SLE [72, 73]. A larger series was reported by Traynor *et al*. [74]. Of nine patients with SLE selected for treatment with ASCT, two patients underwent stem-cell mobilization but could not be transplanted due to infections, and both died. Of the remaining seven, after a follow-up of 12–40 months, all were reported to be free of signs of active lupus and to require no other immunosuppressive therapy than small dosages of prednisone.

The overall experience worldwide with ASCT for SLE was reviewed by Tyndall [75]. Thirty-two patients with SLE have now been treated with ASCT, mostly receiving myeloablation with cyclophosphamide plus anti-thymocyte globulin. Three procedure-related deaths occurred (9%), 19 patients improved after treatment, and of those, 5 relapsed. Currently, several centers in the United States as well as in Europe are actively pursuing these types of therapies. A centralized registry has been formed by the European Group for Blood and Marrow Transplantation (EBMT) and the European League against Rheumatism (EULAR) [76].

In conclusion, high-intensity immunosuppressive therapy, with or without stem-cell transplantation, appears to have the potential of achieving treatment response in those few patients with very severe SLE that are refractory to conventional immunosuppressive treatments, and of achieving long-lasting treatment-free remissions in some but certainly not all patients. Whether such high-intensity regimens have advantages over conventional immunosuppressive treatment, for example, by shortening the duration of immunosuppression or by attaining more "remissions," remains to be seen. Remarkably, a more recent study by Gunnarsson *et al*. [77] did *not* show a clear dose response relationship for cyclophosphamide dosages and renal outcome. Moreover, the risks and side effects of high-intensity treatments are formidable obstacles. Most importantly, the main challenge with these extremely aggressive and high-risk therapeutic options for pa-tients with SLE remains the selection of appropriate patients for such treatment. The identification of more reliable prognostic indicators in SLE [78] will be of great importance in order to implement successfully the more aggressive therapies for SLE that will become available.

HORMONAL THERAPIES

The role that sex hormones play in the etiology and pathogenesis of SLE remains incompletely understood. Because of various observations suggesting important

roles for such hormones, including the female-to-male predominance in SLE and the changing disease patterns during periods of hormonal alteration, a potential therapeutic role for sex steroids has been discussed [79].

Dehydroepiandrosterone (DHEA)

The adrenal androgen DHEA (prasterone) appeared attractive as a candidate hormonal therapy for SLE based on a number of considerations. The use of androgens in general was appealing based on the relative abundance of the immunologically active 16α-hydroxylated estrogen metabolites [80], and the faster oxidative elimination of testosterone seen in this disease [81]. The fact that DHEA is known to have only mild intrinsic androgenic properties suggested that it might be much better tolerated by female patients than androgens such as testosterone. Moreover, serum levels of DHEA, as well as of the principal metabolite DHEA-sulfate, are lower than normal in patients with SLE, even in the absence of corticosteroid treatment or disease activity [82, 83]. Interestingly, studies done at Stanford also suggested a potentially important immunomodulatory effect of DHEA on human T cells [84]. Specifically, it was shown that *in vitro* IL-2 production by stimulated peripheral blood T cells (from healthy individuals) was enhanced by DHEA. Similar results in murine systems had been obtained by Daynes and others [85], who also reported additional effects on other cytokines, suggesting that DHEA might effect a shift in T-cell phenotype from the Th2 type (characterized by production of IL-4, IL-5, and the enhancement of humoral immune responses), to Th1 (characterized by production of IL-2 and γ-interferon (IFNγ) and the enhancement of cellular immune responses) [86]. Juxtaposed to the finding that patients with SLE exhibit lower-than-normal IL-2 production by peripheral blood T cells [87, 88] and that, in general, humoral immune responses might be most pivotal in the immunopathogenesis of SLE, these results suggested that the administration of exogenous DHEA to patients with SLE might restore a fundamental abnormality of immunological functioning. More recently, it has been demonstrated that the defective IL-2 production in patients with SLE is due to deficiency of endogenous DHEA, and that *in vitro* supplementation with exogenous DHEA is sufficient to restore normal levels of IL-2 secretion [89]. Lucas *et al*. [90] showed that DHEA was beneficial in the NZB/NZW mouse model of SLE, and we subsequently showed that this benefit could be attained at lower dosage levels and was associated with normalization of lymphocyte proliferative responses in such mice [91].

Based on these observations a number of studies of DHEA in patients with SLE were done at Stanford. In an uncontrolled trial, 10 premenopausal women with mild to moderate SLE received DHEA 200 mg/day for 6 months [92]. Average systemic lupus erythematosus disease activity index (SLEDAI) scores (a composite measure of lupus activity based on clinical symptoms, signs and laboratory values; Ref. 2) decreased significantly, while prednisone dosages also decreased. Subsequently, a randomized, double-blinded, placebo-controlled clinical trial was performed [93]. Twenty-eight female patients with mild to moderate SLE were randomized to receive either DHEA 200 mg/day or placebo for 3 months. During the trial period, corticosteroid dosages were adjusted as clinically indicated. At the end of the trial period, a decrease was seen in the SLEDAI scores of patients who had received DHEA, along with a reduction in prednisone dosage; whereas a slight increase was noted in patients on placebo, both in terms of lupus activity by SLEDAI and prednisone dosage. Correcting for the baseline imbalance, the patients on DHEA did achieve a statistically significant reduction in patients' global assessment compared to the control group. In addition, SLE flares occurred less frequently in the DHEA-treated group (three flares vs eight in the controls, $p < 0.06$). DHEA appeared safe in this study and was tolerated well.

Data on 50 patients treated with DHEA 50–200 mg/day for periods up to 1 year [94] suggested that in some patients who show initial responses to DHEA after 3 months, further improvement of lupus scores and reductions of prednisone dosages are seen when treatment is continued for 6–12 months. Side effects with DHEA in this dosage range are generally minor and include mild to moderate acne, changes in skin texture, and mild hirsutism.

In our patients, serum levels of DHEA and DHEA-sulfate while in the study showed wide variability and corresponded only weakly to clinical benefits, although a trend was seen toward optimal clinical responses at serum DHEA-sulfate levels of around 1000 μg% [95].

We also conducted a 6-month trial of DHEA vs placebo in patients with *severe* SLE [96]. In this group of patients, which had not been included in any other studies of DHEA to date, the trial drug was added to a conventional regimen of high-dose corticosteroids and immunosuppressives. The primary outcome was stabilization or improvement in the principal target organ involvement in each patient's disease. After 6 months, 7 of 9 patients on DHEA and 4 of 10 patients on placebo achieved the primary outcome ($p < 0.10$). An additional trend in SLEDAI scores favoring DHEA was observed but baseline imbalances impeded further interpretation of these findings.

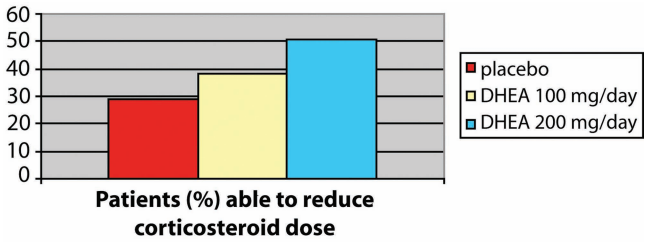

FIGURE 1 Results of the GL94-01 corticosteroid-sparing clinical trial of DHEA in SLE. Treatment with DHEA at 100–200 mg/day for 7–9 months allowed corticosteroid dosage reductions in a higher percentage of previously corticosteroid-dependent patients. Analyzed for those patients who at baseline hae disease activity (SLEDAI > 2). The difference between the DHEA 200 mg/day and placebo group is statistically significant ($p < 0.05$). Reformatted from published data [97].

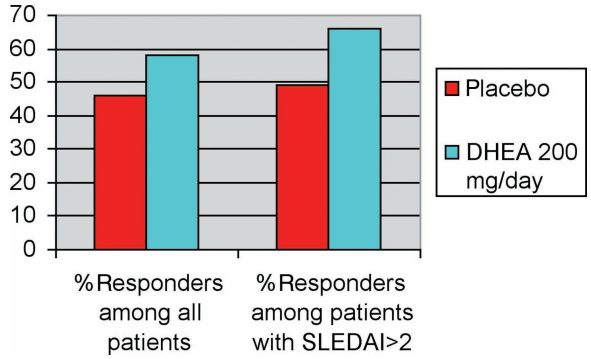

FIGURE 2 Treatment with DHEA 200 mg/day for 1 year in female patients with mild–moderate SLE. According to a predefined responder definition, a significantly higher percentage of patients on active treatment were responders ($p < 0.02$ for all patients, $p < 0.01$ for patients with SLEDAI > 2 at baseline). Reformatted from published data [98].

Based on these small studies, two large-scale, multicentered, randomized, placebo-controlled clinical trials of DHEA (prasterone, GL701) in SLE were conducted. The first of these two trials (the GL94-01 study) investigated the possible corticosteroid-sparing role of DHEA in patients with SLE who had been unsuccessful in attempts to taper prednisone dosages below 10 mg/day [97]. The results indicate that, in patients with at least some degree of disease activity (i.e., SLEDAI scores >2), among the patients on DHEA a significant and clinically meaningful increase was seen in the percentage who achieved the prospectively defined goal of a sustained reduction of corticosteroid dosage to ≤7.5 mg/day of prednisone. Moreover, a dose–response effect was seen, with patients on DHEA 200 mg/day showing higher rates of success than those on 100 mg/day (Fig. 1).

The second large-scale clinical trial of DHEA in SLE (the GL95-02 study) represents, in fact, the largest randomized placebo-controlled clinical trial to date in SLE [98]. Approximately 300 female patients were randomized to receive DHEA 200 mg/day for 1 year vs placebo. At the end of this year, the proportion of responders was determined for each group. In order to be qualified as a responder, patients had to have improved or stabilized with respect to all four of the following: SLAM score, SLEDAI score, patient's visual analog scale for disease activity, and a scale for fatigue. In addition, any lupus flare during the treatment year would also make the patient a nonresponder. Using this predefined criterion, 58% of patients in the DHEA group were responders, compared to 46% in the placebo-treated group (Fig. 2). For patients with disease activity at baseline (SLEDAI > 2) the difference was even more pronounced, 66% vs 49% ($p < 0.005$). Thus, DHEA treatment during 1 year imparted a statistically significant benefit with respect to global SLE activity.

An additional study of DHEA by Chang *et al.* [99] in 119 patients with SLE showed that during 6 months of treatment with DHEA 200 mg/day, the number of SLE flares was significantly reduced, from 34% in the placebo group to 18% in the treatment group ($p < 0.05$).

In addition to the overall benefits with respect to SLE activity, two separate analyses indicated that DHEA might have important benefits for bone metabolism in SLE as well. Thus, in the study of severe lupus [96], the placebo group showed significant reductions in bone mineral density at the lumbar spine after 6 months of treatment (with high-dose corticosteroids), whereas the group of patients receiving both high-dose corticosteroids and DHEA had no such decrease. In the GL95-02 study [98] a subset of patient underwent bone mineral densitometry: here a significant improvement was seen in the patients treated with DHEA compared to placebo.

In all these clinical studies, DHEA was generally well tolerated. Acne was a frequent but rarely problematic side effect. Hirsutism and other androgenic side effects occurred rarely. A decrease in HDL cholesterol was seen in some patients. There were no increases in infections, endocrinological disturbances, thromboembolic complications, or malignancies. Importantly, all these studies were limited to female patients with SLE.

In summary, several smaller studies, both controlled and uncontrolled, and three large clinical trials provide support for the hypothesis that DHEA may have therapeutic benefits for female patients with SLE. The significant gains in outcomes over intermediate periods of time coupled with good tolerability suggest that DHEA is likely to have an important role as a therapeutic

option in the long-term management of SLE, with improvements in overall disease activity, corticosteroid sparing effects, reductions in SLE flares, and beneficial effects on bone mineral metabolism.

The results of these trials have been under review by the FDA for approval of DHEA/prasterone as a prescription drug under the brand name Aslera. Meanwhile, in the United States, a number of products claiming to contain DHEA are being sold as nutritional supplements. In one study, these products were found to contain amounts of DHEA differing considerably from those indicated on the labels, and some such products did not contain DHEA at all [99a].

Other Hormonal Therapies

Besides DHEA, a variety of hormonal interventions have been employed in animal models as well as in patients with SLE, with different degrees of success.

Androgens

Danazol is a semisynthetic androgen with therapeutic efficacy in ITP, through a mechanism that is not well understood [100]. Not surprisingly, it also appears beneficial in patients with SLE-associated thrombocytopenia [101, 102], and it may be of benefit in lupus-related hemolytic anemia as well [103]. The possibility that danazol might be of benefit for nonhematological lupus manifestations was addressed in several papers. Case reports suggested benefits in patients with oral ulcers [104] and with discoid lesions [105]. A cross-over study in seven patients suggested modest clinical improvement with minimal side effects [106]. A 1-year controlled clinical trial in 40 patients showed fewer SLE flares in the patients randomized to danazol and lower corticosteroid requirements, but limiting side effects were common in this study, particularly gastrointestinal ones [107]. Thus, it appears that danazol may benefit patients with hematological lupus, and can perhaps ameliorate milder, generalized symptoms; but danazol is often not tolerated well by patients with SLE.

Treatment with the androgen 19-nortestosterone decanoate did not improve SLE in seven female patients and worsened disease in three male patients [108]. The disappointing results in the latter group may have been explained by down-regulation of endogenous androgen production. Moreover, 19-nortestosterone was not well tolerated by the female patients, resulting in severe masculinization.

One patient with Klinefelter's syndrome (XXY) and SLE showed sustained improvement on testosterone treatment [109]. In my own experience, many male patients with SLE have some degree of hypogonadism, most likely secondary to the chronic disease, and testosterone supplementation into the physiological range can bring about improvements in subjective well-being, muscle strength, and sexual function. Dyslipidemias, mood changes, and erythrocytosis can be limiting side effects.

GnRH Agonists and Antagonists

Continuous administration of gonadotropin releasing hormone (GnRH) suppresses ovarian estrogen production. A GnRH analog appeared to have short-term benefit in several patients [110], and a study of the GnRH agonist leuprolide showed improvement during 6 months of therapy with respect to SLAM scores, joint count, and lymphocytopenia [111]. Side effects in this study included hot flashes, decreased libido, and vaginal dryness. Moreover, a case report describing an SLE nephritis flare while receiving the GnRH agonist leuprorelin was also reported [111a]. GnRH *antagonists* were investigated in (SWR × NZB):F1 mice and had beneficial effects independently of regulation of gonadal steroid secretion [112].

Bromocriptine

Because of the proinflammatory and immunostimulatory properties of prolactin [113–116] it has been suggested that the prolactin-antagonist bromocriptine would be beneficial for patients with SLE. In an open-label study of seven patients, bromocriptine therapy led to significant decreases in SLAM and SLEDAI scores over a 6-month trial period. After discontinuation, however, prolactin levels appeared to rebound to levels above baseline, and lupus activity increased concomitantly in most of the patients [117]. One patient was found to have a pituitary microadenoma after the trial. Bromocriptine therapy was associated with few side effects in this study.

Subsequently, a double-blind, placebo-controlled, randomized clinical trial of bromocriptine for SLE was conducted [118]. Sixty-six patients with mild to moderate disease were randomized to receive bromocriptine 2.5 mg/day or placebo and followed for a mean of 12.5 months. After 1 year of follow-up, the bromocriptine-treated patients had significantly better SLEDAI scores than controls, and significantly fewer SLE flares had occurred in the treatment group. Headaches and nausea were treatment-limiting side effects in five patients.

In an additional randomized trial, 24 patients with mild to moderate SLE were randomized to receive bromocriptine or hydroxychloroquine for 1 year. A preliminary analysis revealed that over this period similar

treatment effects (improvements in SLAM scores) were seen in both groups [119].

These results point to a potential role for prolactin-antagonism in mild to moderate SLE. Bromocriptine therapy does not appear to carry major risks, but nausea, headaches, and mood changes can be treatment-limiting side effects for 10–20% of patients. Moreover, the significant rebound activation of SLE after discontinuation of bromocriptine noted in one study would limit the applicability of this treatment [120]. However, for patients with SLE who have prolactin-secreting microadenomas with hyperprolactinemia, the use of bromocriptine can be recommended.

Estrogen and Estrogen Antagonists

Carlsten *et al*. [121] showed that estrogen aggravates the immune complex disease in MRL/lpr mice—but also that it slows down the cell-mediated components of the autoimmune disease in the same mice, vasculitis and sialadenitis, pointing out the ambiguous role played by this hormone. A selective estrogen receptor modulator LY139478 was beneficial in MRL/lpr mice [122]. The estrogen antagonist Tamoxifen, was effective in the 16/6 Id [123] and the MRL/lpr [124] mouse models of lupus, but a small study in patients with SLE failed to show benefit [125].

MONOCLONAL ANTIBODIES AND OTHER BIOLOGICAL TREATMENTS

The availability of a number of biological agents including monoclonal antibodies (mAbs) as therapeutic agents for a variety of diseases, and most notably the spectacular therapeutic results seen in the treatment of rheumatoid arthritis with the anti-TNFα agents etanercept and infliximab, has fueled hopes that some such agents will assume a major role in the treatment of SLE as well. To date, many biological interventions have been employed in animal models of SLE, and increasingly, human trials are being conducted to explore these exciting possibilities.

Cell-Directed Biological Therapies

Earlier efforts utilized mAbs targeting subsets of lymphocytes. After the initially promising reports regarding successful treatment of murine lupus with anti-T-cell antibodies [126], anti-CD4 [127–129], and anti-B-cell antibodies [130, 131], human trials were eagerly awaited. In five patients with severe cutaneous lupus, anti-CD4 did appear to show some benefit [132]. However, the disappointing results with anti-CD4 in rheumatoid arthritis [133] put a serious damper on these efforts. More recently, nondepleting anti-CD4 mAbs have been developed and are being tested in various clinical settings. A non-depleting anti-CD4 mAb had modest benefits in MRL/lpr mice [134]. The T-cell specific immunoconjugate anti-CD5-ricin was given to six patients with SLE, of whom two improved clinically [135]. This treatment proved very toxic and is not being studied further in SLE.

The B-cell specific monoclonal anti-CD20 antibody rituximab (Rituxin, Mabthera), is used widely for the treatment of B-cell lymphomas [136, 137]. Logically, its use has now been reported in isolated cases of patients with other B-cell driven diseases [138–140]. In a small dose-escalation trial, 12 patients with SLE were given relatively low dosages of rituximab [141]. Significant depletion of circulating B cells was seen, and no adverse experiences occurred. Improvement in disease activity was seen in some patients.

At our institution, we treated two patients with highly refractory SLE, using a combination of pulse-dose corticosteroids, conventional-dose cyclophosphamide, and rituximab at the full lymphoma dose of $375\,mg/m^2$ weekly $\times$ 4. Both patients tolerated the treatment well. One of these patients had severe lupus nephritis and had received a prior 6-month course of cyclophosphamide without improvement; 4 months after the combined therapy, the nephritis was shown by biopsy to have nearly resolved. The other patient had persistent hypocomplementemia, active nephritis, and multiple other active lupus manifestations despite standard therapy with cyclophosphamide. After the combined treatment, her disease parameters improved dramatically, whereas repeat renal biopsy showed modest improvement. We continue to evaluate the efficacy and safety of combined cyclophosphamide plus rituximab as a salvage therapy for patients who fail conventional immunosuppressive treatment.

Cytokines and Cytokine Antagonists

The roles and interactions of the multitude of identified cytokines in the pathophysiology of SLE are being increasingly unraveled, but major gaps in our knowledge to date preclude accurate predictions of which cytokines or cytokine-antagonists would be most likely to benefit patients with lupus. Unfortunately, results from cytokine manipulation in animal models of lupus have not always provided clear answers to such questions, and as more and more cytokines/cytokine-antagonists are being developed for use in patients with other diseases, it is likely that the main advances in our understanding of these aspects of SLE will come from

carefully conducted observational studies or controlled clinical trials. For instance, antagonism of the broadly proinflammatory cytokines IL-1, IL-6, and IL-15 might be theoretically appealing in SLE. A recombinant form of the IL-1 receptor antagonist has more recently been approved for the treatment of rheumatoid arthritis [142], but there are no published data concerning its potential in SLE. Likewise, anti-IL6-receptor mAbs and anti-IL15 mAbs are being tested in rheumatoid arthritis, and may eventually be tried in SLE as well; anti-IL6-receptor was effective in MRL/lpr mice [143].

Levels of the pleiotropic cytokine IL-10 are known to be increased in SLE and to correlate with disease activity, playing an important role in the pathogenesis of the disease [144, 145]. Anti-IL10 was shown to be beneficial in NZB/NZW mice [146]. In a pilot study, six patients were treated with a murine mAb against IL-10 [147]. The intravenous treatment was given daily for 3 weeks and the patients followed for 6 months. During the entire follow-up period improvements were seen, and after 6 months, five of the six patients were considered to have inactive disease. These encouraging results will most likely have to be duplicated with humanized anti-IL10 before further progress can be made. In a case report, the platelet growth factor IL11 was effective for SLE-related thrombocytopenia [148].

Antagonism of TNFα has been established as a treatment for RA and other inflammatory disorders [149, 150]. However, in SLE the role of TNFα remains controversial. Some studies showed that in NZB/NZW mice, the administration of TNFα rather than its antagonist was beneficial [151, 152]. On the other hand, other studies have suggested a pathogenetic role for TNFα even in human SLE [153–155]. In the 16/6 Id mouse model of SLE, TNFα blockade with a mAb or with pentoxiphylline attenuated disease [156]. Interestingly, in some rheumatoid arthritis patients treated with anti-TNFα therapy, anti-DNA antibodies develop, and a few have developed transient SLE-like symptoms.

Other cytokines have been studied in murine models only. Gene transfer of IL-12 using a plasmid ameliorated disease in the MRL/lpr mouse [157]. Studies point to an important role for the α-interferon (IFNα) system in SLE [158]. Disease in NZB/NZW mice is suppressed by mAb to IFNα [159]. The role of IFNγ is less clear: soluble IFNγ receptor was beneficial in NZB/NZW mice [160] whereas anti-IFNγ mAbs did not appear beneficial in MRL/lpr mice [161].

Several case reports have documented the onset of SLE following thymectomy for myasthenia gravis [162–164]. It was assumed that defective thymic immune education was responsible. Interestingly, a case was described of one such patient who was successfully treated with thymosin [165]. An older report suggested that three out of four patients with SLE improved after receiving thymosin [166], although details were sketchy.

Second Signal Blockade

A new and fertile area of interest is the possibility to target therapeutically the cell-surface molecules responsible for cell–cell interactions. Thus, it has been recognized that *de novo* T-cell activation not only requires the recognition of an antigenic peptide in the context of an appropriate MHC molecule, but also the delivery of a "second signal": without the second signal, anergy rather than activation will result. There are, in fact, several different surface molecules that can mediate the "second signal," most importantly the interaction between CD40 and CD154 (CD40-ligand), and the one between B7 and CD28. Both sets of interactions can be blocked by mAbs directed at the individual molecules, and the B7–CD28 interaction can also be blocked by the fusion protein CTLA4-Ig. CTLA4-Ig was beneficial in BXSB mice [167] and particularly in NZB/NZW mice [168], where significant survival benefits were seen even when treatment was delayed to the point when severe nephritis was already established. In a remarkable study, the combination of CTLA4-Ig and cyclophosphamide was much more effective than either agent alone [169]. Likewise, in MRL/lpr mice, adenovirus mediated gene transfer of the CTLA4-Ig gene gave excellent results [170]. Clinical trials with CTLA4-Ig are currently underway for a variety of diseases other than SLE (RA, psoriasis). Similarly, an anti-CD154 mAb was effective in NZB/NZW mice [171, 172]. In human SLE, clinical trials of two different mAbs targeting CD154 (CD40 ligand) were reported. The first study [173] showed good tolerability but little to suggest efficacy in this small group of patients. The second study was prematurely terminated when a high frequency of thromboembolic events was noted in the treatment group [174]. A mechanism for this observation was suggested in that CD154 is expressed on platelets as well.

Conceptually, second-signal blockade may be of interest, yet it remains an antigen-nonspecific, broadly immunosuppressive strategy. Moreover, as the "second signal" is mostly involved in the activation of naive T lymphocytes, it remains to be seen whether established autoimmune responses can be down-regulated sufficiently, and if so, whether treatment must be continued indefinitely.

Other Biological Agents

An interesting study showed that polyclonal dextran-conjugated anti-IgD delays autoimmunity in MRL/lpr mice [175]. It was hypothesized that the anti-IgD treat-

ment prevented class switching of pathogenic autoreactive B cells, thus leading to production of the relatively nonpathogenic IgM isotype rather than more pathogenic IgG. This suggests that the elevated serum IgD levels found in NZB/NZW and other autoimmune-prone mice [176] may have pathogenic significance. In addition, it is conceivable that the interaction between IgD on B cells and the Fcδ receptor on T cells described by Coico *et al*. [177] mediates a "second signal" analogous to the ones discussed previously.

Anti-idiotypic antibody therapy has been investigated for its potential immunomodulatory role, but an anti-Id against anti-DNA only temporarily suppressed anti-DNA and disease activity in NZB/NZW mice [178]. Nine human patients were treated with the anti-idiotypic anti-DNA "vaccine" 3E10. In five, an anti-idiotypic response was seen. Inasmuch as the patients had quiescent disease at the onset, no conclusions regarding efficacy could be drawn [179].

Evidence has accumulated implicating dysregulation of apoptosis in the pathogenesis of SLE. It was therefore of interest that a mAb against the Fas ligand attenuated disease in the NZB/NZW mice [180] and that a synthetic apoptosis inhibitor ameliorated an SLE-like disease in IFNγ transgenic mice [181]. In other approaches, mAbs against complement C5 [182] were beneficial in NZB/NZW mice, and similar antibodies are being tested for use in rheumatoid arthritis. Antisense oligonucleotides were used to target the p50 subunit of NFκB, a regulatory protein of immune response genes and the primary target of corticosteroids. In the BXSB model this therapy reduced anti-DNA antibodies by 90% [183].

NOVEL IMMUNOSUPPRESSIVE AND IMMUNOMODULATORY PHARMACOLOGICAL AGENTS

Spurred by the spectacular growth of organ and bone-marrow transplantation, a number of novel immunosuppressive agents are currently in early or advanced development, or have become available for use in patients, while not specifically approved or recommended for use in SLE.

Mycophenolate Mofetil

The immunosuppressive agent mycophenolate mofetil (MMF) was effective in NZB/NZW mice [184] as well as in MRL/lpr mice [185]. In an uncontrolled study [186] 10 patients with SLE were treated with MMF 1500–2000 mg daily for 8–16 months. During the first 6 months, significant improvements were seen in SLAM scores, and prednisone dosages were significantly reduced. Side effects in this trial were minor. Subsequently, a controlled study was done in patients with diffuse proliferative lupus nephritis [187]. Forty-two patients were randomized to receive either cyclophosphamide for 6 months followed by azathioprine for 6 months, or MMF for 12 months. All patients received prednisone as well. After 1 year, the percentages of patients achieving a complete (renal) remission were similar in the two groups (81% on MMF and 76% on conventional therapy), and other efficacy parameters were also nearly identical. The side effects with cyclophosphamide/azathioprine were generally more severe, including two deaths. Thus, the results after 1 year suggested therapeutic equivalence and a more favorable side-effect profile. However, it is important to note the limitations of this study: the 1 year duration was too short to establish equivalence between treatments for this particular disease, and this group of patients appeared to have an overall better prognosis compared to other such studies, possibly suggesting milder disease. Moreover, in a study of 11 children with juvenile SLE and nephritis [188], significant global improvements were seen, but renal disease improved only in those patients who had membranous (WHO class V) nephritis and not in those with membranoproliferative disease (WHO class IV). Moreover, infections and other adverse events were a major concern.

Other Immunosuppressive Agents

The transplantation agent tacrolimus (FK506) is a fungal-derived complex molecule with immunosuppressive properties. Highly specific for T lymphocytes, it inhibits the production of several cytokines including IL-2 and IFNγ [189]. Tacrolimus is effective in the treatment of lupus-like disease in NZB/NZW and MRL/lpr mice [190–192], and was synergistic with cyclophosphamide in MRL/lpr mice [193]. In one report, 2 of 3 patients treated with tacrolimus for up to 9 months had good clinical responses [194]. Tacrolimus has toxicities similar to cyclosporin A.

Other immunosuppressives that are in development but not (yet) generally available include frentizole, which was successfully used in NZB/NZW mice [195]. In human patients, it resulted in modest improvements of SLE activity, but resulted in severe, and sometimes life-threatening, side effects [196–199]. Mizoribine was beneficial in MRL/lpr mice [200], and a case report showed a favorable response to treatment with mizoribine alone (i.e., without corticosteroids) in a patient with mild SLE [201]. Several immunosuppressive agents have been used with favorable results in murine lupus, but without human data so far. These include linomide

[202, 203], rapamycin [204], deoxyspergualin [205–208], cholera toxin [209], and OK-432 [210].

Immunomodulators

Thalidomide possesses immunomodulatory therapies and may down-regulate TNFα. It has shown benefits in various cutaneous autoimmune disorders, including E. nodosum and vasculitis, and is approved for use against oral aphthous ulcers in HIV infected patients [211]. Several large observational studies [212–216] have consistently shown that this agent can benefit many patients with severe and/or refractory cutaneous lupus. The agent does not appear to have major efficacy with respect to other lupus manifestations. Moreover, sedation, neuropathy, and devastating teratogenicity pose significant limitations on the use of this otherwise interesting agent.

Dinitrochlorobenzene (DNCB) administered topically to the skin appears to boost Th1 type immune responses [217]. An elderly patient with SLE was treated with topical DNCB with excellent clinical and immunological results [218]. Levamisole, an antihelminthic agent with immunostimulatory properties, was unsuccessful in a controlled trial [219]. The antiviral ribavirin appeared beneficial in NZB/NZW mice [220].

Arachidonic Acid Derivatives and Their Inhibitors

Prostaglandins and leukotrienes are important modulators of the inflammatory cascade, and selective inhibition or augmentation of such molecules is a logical target for intervention. Specifically in SLE, it was shown that intrarenal production of PGE2 and thromboxane was elevated in mice as well as in humans [221, 222]. In NZB/NZW mice, iloprost (a prostacyclin analog) and thromboxane were beneficial [223]. In patients with lupus nephritis, infusion of a selective thromboxane antagonist for 48 h was shown transiently to improve renal function [224].

Prostacyclin analogs are used increasingly in the treatment of pulmonary hypertension, and several reports suggest that patients with SLE who suffer from this complication can benefit from these as well [225, 226].

The 5-lipoxygenase (5-LO) inhibitor Zileuton was tried in an 8-week, double-blinded study of 40 patients with SLE [227]. Modest improvement in SLAM scores were seen in the treatment group with slight worsening in the controls ($p < 0.05$ for comparison of the two groups). 5-LO inhibition appears to be safe, but it is not clear whether the small effect size in this study would translate into a meaningful clinical benefit.

PROPHYLACTIC USE OF CORTICOSTEROIDS

Although corticosteroids are the most well-established agents in the treatment of SLE, a novel approach to using corticosteroids was suggested by Bootsma *et al*. [228]. ter Borg *et al*. [229, 230] demonstrated that rises in anti-DNA titers preceded the development of SLE flares, suggesting that by treating patients who exhibited rising anti-DNA titers even prior to any change in symptoms, lupus flares might be preventable. To put this hypothesis to the test, a total of 156 patients with stable SLE were monitored with serial anti-DNA determinations, and patients who showed a 25% rise in their titer were randomized to receive "early" therapy with prednisone 30–60 mg/day vs conventional therapy (watchful waiting). The trial showed that, indeed, a significant proportion of SLE flares could be prevented by such treatment: a total of 20 flares occurred in the patients under conventional treatment, and only 2 flares occurred with "early treatment." However, this success came at a price: the total amount of corticosteroids used in the patients receiving the "early" treatment was significantly higher (median prednisone dose 15.3 vs 10.0 mg/day) than that received by the conventionally treated patients (who did, of course, receive corticosteroids as treatment for their flares). These intriguing results suggest that monitoring of anti-DNA levels in patients with SLE, and treating the patients with rising titers even before any symptoms develop, could prevent many flares of SLE. However, it is an interesting question whether patients would actually prefer this, that is, would they be bothered more by having to take corticosteroids when feeling well as opposed to when feeling ill. Moreover, a study by Esdaile *et al*. [231] did not confirm the most important underlying assumption for this treatment, namely, that rising anti-DNA titers predict SLE flares. Clearly, more studies are needed before this treatment strategy can be adopted widely.

UV-A1 LIGHT THERAPY

The use of UV-A1 light therapy for SLE, as counterintuitive as it may seem, has been proposed based on specific immunomodulatory properties of electromagnetic waves in the 340–400 nm range [232]. Uncontrolled observations suggested possible benefits [233, 234]. In a double-blind, crossover study of 26 women with SLE, 3 weeks of treatment with UV-A1 appeared superior to placebo treatment with visible light [235]. Similar results were seen in a double-blinded, randomized, controlled crossover study in 11 patients [236]. Modest effect sizes,

technical details, and cost of the treatment have tempered enthusiasm for this therapy. It should be emphasized that UV light sources in commercial use (i.e., solariums) do not adequately filter out UVB to make them safe for patients with SLE.

"ALTERNATIVE THERAPIES"

During the past decade, interest has burgeoned in the use of "alternative" treatments, such as nutritional supplements, vitamins, antioxidants, herbs, acupuncture, homeopathy, and many others. A more recent study [237] found that nearly half of all lupus patients (whether it be in the United States, in Canada or in the United Kingdom) utilize alternative therapies.

Chinese Herbs and Other Herbal Therapies

IN VITRO AND ANIMAL STUDIES

Traditional Chinese medicine employs a great variety of herbal treatments. Efforts are underway to characterize some of the complex mixtures used in such treatments and analyze the active ingredients. Not surprisingly, varied biological effects have been found. For instance, "chi-han" was found to contain several immunomodulatory ingredients, some with opposite effects on IL1 or TNFα secretion *in vitro* [238]. Solamargine, extracted from the Chinese herb *Solanum incanum*, was shown to trigger expression of the TNFα receptor and to increase apoptosis [239]. Similarly, Saiboku-To, an herbal mixture used in Japan, was found to inhibit 5-lipoxygenase [240]. Some Chinese herbs were found to enhance IL2 production, and to decrease anti-DNA antibody titers and prolong the life of NZB/NZW mice [241]. More recently, an extract of the fungus *Ganoderma tsugae*, commonly used in traditional Chinese medicine, was shown to decrease proteinuria and anti-DNA antibody formation and prolong survival in NZB/NZW mice [242]. The Japanese herbal therapy ren-shen-yang-rong-tang was effective in MRL/lpr mice, but only when given in combination with corticosteroids [243]. In the same model, stagalin was shown to decrease immune complex depositions in the glomeruli [244], and the Japanese traditional herb hachimi-jio-gan was shown to decrease autoantibody formation and IL12 expression [245].

Experience in SLE

In a remarkable blend of traditional Chinese medicine and Western approaches, traditional Chinese herbal medicine was used in 41 patients with active lupus nephritis in conjunction with cyclophosphamide. These patients were compared with 35 patients treated with cyclophosphamide alone [246]. The patients receiving both conventional and traditional therapies were found to have significantly better outcomes after 6 months of treatment. However, this was not a randomized clinical trial, and details of the treatment regimens are unclear. The traditional Chinese medical diagnosis in these patients was a "deficiency of liver-kidney Yin."

Tripterygium Wilfordii Hook F

In Chinese herbal medicine, rheumatoid arthritis and other inflammatory conditions are frequently treated with extracts from the vinelike plant *Tripterygium wilfordii* Hook. f. (TW). Such an extract was found to inhibit animal models of arthritis [247] and, in a controlled study, to be efficacious in the treatment of rheumatoid arthritis [248]. Studies of this compound revealed that it had powerful immunomodulatory properties, inhibiting transcription of cytokine genes, including IL-1, -2, -4, -6, -8, and TNFα [249, 250]. Unfortunately, TW is associated with significant gastrointestinal side effects. A slow-release form of TW was shown to be equally efficacious but less toxic [251]. The active ingredients in TW are most likely the diterpenoid triepoxides, triptolide and tripdiolide [252]. TW has not been systematically studied in SLE. Benefit was shown in the MRL/lpr model of lupus [253, 254]. A single case report indicated improvement of severe lupus nephritis after treatment with TW [255].

Toxicities

Unlike a commonly held perception, Chinese herbs are not at all harmless. It stands to reason that any mixture with significant immunomodulatory effects would also engender potential risks, and it is becoming clear that this is indeed the case. The most significant risk appears to be a unique interstitial nephropathy, characterized by a relatively rapid progressive course, without much proteinuria, but with severe anemia [256, 257]. A severe but reversible dilated cardiomyopathy was linked to treatment with Chinese herbs in one patient [258].

Nutritional Therapies

Caloric restriction was shown to ameliorate murine lupus [259–261] but has not been studied in humans. Likewise, dietary modulation of fatty acid content has resulted in attenuation of murine lupus, for example, by

limiting essential fatty acids [262], or by supplementation with eicosapentaenoic acid [263, 264], or with other unsaturated fatty acids [265]. In a small pilot study, fish oil, which contains ω-3 fatty acids including eicosapentaenoic acid, was given to 12 patients with SLE [266], but no benefits with respect to SLE disease activity were seen.

Flaxseed contains α-linolenic acid, which has antiatherogenic properties, and lignans, which are antagonists of platelet activating factor. Flaxseed was beneficial in MRL/lpr mice. In an uncontrolled study, flaxseed was given to 9 patients with SLE and nephritis [267]. The creatinine clearance and proteinuria improved while on dosages of 30 or 45 g/day for 4 weeks. However, in a subsequent 1-year controlled trial in 23 patients with lupus nephritis, no clear benefits were seen [268]. The lignan precursor SDG was studied in the MRL/lpr mice and exerted a modest renoprotective effect [269]. The wheat germ-derived fermentation product Avemar attenuated the aberrant immune responses in the 16/6 Id model of lupus [270].

Antioxidants

The broad hypothesis that antioxidants can be of benefit in inflammatory diseases goes back to the original discovery of vitamin C by Pauling and Szent-Györgyi. More recently, a number of other antioxidants have become popularized in the health food and nutritional supplements arena. Only a few scientific studies relate to the use of antioxidants specifically in SLE. In one study, NZB/NZW mice were treated with the antioxidants *N*-acetylcysteine and cysteamine [271]. While *N*-acetylcysteine reduced anti-DNA antibodies and nephritis severity, cysteamine increased anti-DNA and kidney inflammation; however, both agents prolonged survival. Thus, these two antioxidants appear to have different immunomodulatory properties, while the effects on the overall inflammatory response appear to be favorable for both. The antioxidant Pycnogenol was reported to improve SLEDAI scores in a small controlled study [272]. The antioxidant Lobenzarit [273] was well tolerated and appeared beneficial in an uncontrolled 1-year trial in 15 patients with SLE [274].

Acupuncture

Acupuncture was reported to be of value in discoid lupus in one series of 15 patients [275]. However, a review of acupuncture for the treatment of various rheumatic diseases concluded that the 17 surveyed studies were all of such poor quality that "acupuncture cannot be recommended for treatment" as of yet [276].

Other Alternative Therapies

The list of therapies suggested for use in SLE is nearly endless. In addition to those discussed previously, various vitamins, plasma-derived proteins, various kinds of electromagnetic radiation, pulsed magnetic fields [277], heavy metals, photoferesis [278], and other more or less bizarre treatments have been proposed. It would seem prudent to exclude from consideration those treatments that lack a scientific rationale and are not supported by animal data and are successful only in uncontrolled circumstances.

CONCLUSION

During the first years of the third millennium, many significant developments in the area of new treatments for SLE are taking place. From bench work through animal studies and all the way into large clinical trials, promising novel approaches are being explored. It is unprecedented in the history of SLE that several novel therapeutic agents are in large-scale clinical trials at the same time. Among the new treatments, DHEA and high-intensity chemotherapeutic regimens illustrate approaches to opposite poles in the spectrum of lupus, the former of potential benefit for patients with mild or moderately active lupus, the latter for those with severe and refractory disease. These and many other new treatments, if successful, may herald in a new era in the treatment of SLE.
