Robert G. Lahita

LIST OF CONTRIBUTORS

Numbers in parentheses indicate the chapter numbers of the authors' contribution.

GYÖRGY ÁBEL (6), Clinical Immunology Laboratory, Lahey Clinic Medical Center, Burlington, Massachusetts 01805-0001.

VINCENT AGNELLO (6), Department of Immunology Research, Lahey Clinic Medical Center, Edith Norse Rogers Memorial Veterans Affairs Hospital, Burlington, Massachusetts 01805-0001.

DONATO ALARCÓN-SEGOVIA (3), National Autonomous University of Mexico, Department of Immunology and Rheumatology, Instituto Nacional de Ciencias Médicas y Nutrición Salvador Zubirán, 14000 Mexico, D.F.

MARTA E. ALARCÓN-RIQUELME (3), Department of Genetics and Pathology, Rudbeck Laboratories, Uppsala University, Uppsala, Sweden.

HOWARD AMITAL (1), Center for Autoimmune Diseases and Department of Medicine "B," Affliated with Sackler Faculty of Medicine, Sheba Medical Center, Tel-Aviv University, Tel-Hashomer 52621, Israel.

RONALD A. ASHERSON (41), Rheumatic Diseases Unit, Department of Medicine, University of Cape town School of Medicine, Cape Town 8001, South Africa.

JOHN P. ATKINSON (5), School of Medicine, Washington University, St. Louis, Missouri 63110.

TATSUYA ATSUMI (39), Department of Medicine II, School of Medicine, Hokkaido University, Sapporo 060-8638, Japan.

HOWARD A. AUSTIN (30), National Institutes of Health, Bethesda, Maryland 20892-1818.

ROBERTO BACCALA (8), Centre Hospitalier Universitaire Vaudois, Lausanne, Switzerland.

JAMES E. BALOW (30), National Institutes of Health, Bethesda, Maryland 20892-1818.

DIMITRI BOUMPAS (30), National Institutes of Health, Bethesda, Maryland 20892-1818.

ROBIN L. BREY (26), Department of Medicine, Division of Neurology, University of Texas Health Science Center, San Antonio, Texas 78229.

JILL BUYON (17), Department of Rheumatology, Hospital for Joint Diseases, New York, New York 10003

EDWARD K. L. CHAN (13), Department of Oral Biology, University of Florida College of Dentistry, Gainesville, Florida 32610–0424.

RICARD CERVERA (41), Department of Autoimmune Diseases, Hospital Clinic, 08036 Barcelona, Catalonia, Spain.

WENDY S. COHEN (27), School of Medicine, New York University, New York, New York 10016.

JOHN C. DAVIS (47), Clinical Trials Center, Lupus Clinic, San Francisco, California 94143.

CRAIG J. DELLA VALLE (37), Department of Orthopaedic Surgery, Rush-Presbyterian-St. Lu8ke's Medical Center, Chicago, Illinois 60612.

PAUL J. DEMARCO (18), Department of Psychological and Brain Sciences, University of Louisville, Lousville, Kentucky 40292.

JUDAH A. DENBURG (28), Department of Psychiatry and Behavioural neurosciences, McMaster University, Hamilton, Ontario L8N 3Z5, Canada.

SUSAN D. DENBURG (28), Department of Psychiatry and Behavioural neurosciences, McMaster University, Hamilton, Ontario L8N 3Z5, Canada.

BETTY DIAMOND (10), Albert Einstein College of Medicine, Bronx, New York 10461.

PAUL E. DICESARE (37), Department of Orthopaedic Surgery, Hospital for Joint Diseases, New York University, New York, New York 10003.

Iris Dotan (34), Division of Clinical Immunology, Mount Sinai Medical Center, New York, New York 10029-6574.

Barri Fessler (32), Division of Clinical Immunology and Rheumatology, University of Alabama, Birmingham, Alabama 35294.

Martin J. Fritzler (13), University of Calgary, Calgary ALB T2N 4N1, Canada.

Dafna D. Gladman (23), Centre for Prognosis Studies in the Rheumatic Diseases, Toronto Western Hospital, Toronto, Ontario M5T 2S8, Canada.

Oscar S. Gluck (38), Department of Medicine, College of Medicine and Arizona Rheumatology Center, Phoenix, Arizona.

Richard E. W. Halliwell (9), Veterinary Field Station, University of Edinburgh, Easter Bush, Rosling, Midlothian EH25 9RG, Scotland.

Evelyn V. Hess (45), Division of Immunology, University of Cincinnati Medical Center, Cincinnati, Ohio 45221.

Gary S. Hoffman (32), Department of Rheumatic and Immunologic Diseases, Cleveland Clinic Foundation, Cleveland, Ohio 44195.

Robert W. Hoffman (24), Division of Rheumatology and Immunology, University of Miami, Miami, Florida 33101.

Graham R. V. Hughes (40), Lupus Research Unit, Department of Rheumatology, Rayne Institute, St. Thomas Hospital, London SE1 7EH, England.

Munther A. Khamashta (40), Lupus Research Unit, Department of Rheumatology, Rayne Institute, St. Thomas Hospital, London SE1 7EH, England.

John Klippel (47), NIAMS, Arthritis Foundation, Atlanta, Georgia 30309.

Robert P. Kimberly (46), Division of Clinical Immunology and Rheumatology, University of Alabama, Birmingham, Alabama 35294.

Takao Koike (39), Department of Medicine II, School of Medicine, Hokkaido University, Sapporo 060-8638, Japan.

Dwight H. Kono (8), Department of Immunology, Scripps Research Institute, La Jolla, California 92037.

Robert G. Lahita (7, 16), Department of Medicine and Rheumatology, LibertyHealth, Jersey City, New Jersey 07304.

Lynne Larocque (28), department of Psychiatry and Behavioural Neurosciences, McMaster University, Hamilton, Ontario L8N 3Z5, Canada.

James L. Levenson (27), Liaison Psychiatry, Medical College of Virginia, Virginia Commonwealth University, Richmond, Virginia 23298.

Jeffrey Laurence (36), Weill Medical College, Cornell University, New York, New York 10021.

E. Clinton Lawrence (33), McKelvey Lung Transplantation Center, School of Medicine, Emory University, Atlanta, Georgia 30322.

Matthew Liang (20), Department of Medicine/Rheumatology/Immunology/PBB-B2, Brigham and Women's Hospital, Boston, Massachusetts 02115.

Michael D. Lockshin (22), Barbara Volker Center, Hospital for Special Surgery, Weill-Cornell Medical College, New York, New York 10021.

Lisa A. Mandl (20), Department of Medicine, Weill Cornell Medical College, Hospital for Special Surgery, New York, New York 10021.

Mart Mannik (14), Department of Medicine, University of Washington, Seattle, Washington 98195.

Michael J. Maricic (38), University of Arizona, Southern V. A. Health Care System, Tucson, Arizona 85723.

Eiji Matsuura (39), Department of Cell Chemistry, Graduate School of Medicine and Dentistry, Okayama University, Okayama, Japan.

Lloyd Mayer (34), Division of Clinical Immunology, Mount Sinai Medical Center, New York, New York 10029-6574.

FOREWORD

"One small step for man . . ." Neal Armstrong's intended first utterance when he stepped onto the surface of the moon on July 20, 1969 can indeed be the motto of every researcher and clinician involved in the investigation of systemic lupus erythematosus, which also blossomed in the late 1960s. Each can point to their contribution as one small piece of the puzzle in the understanding of the etiology, pathogenesis, clinical presentation and treatment of lupus. In the last three decades the puzzle has indeed begun to take shape! The immune system abnormalities and their pathogeneic consequences have been extensively elaborated and are now serving as guides for the development of new therapies. Prognosis has improved dramatically from less than 50% at 5 years in the 1950s to 70% at 20 years today.

Quality of life has also improved as we learn to modulate our therapies more appropriately. At the same time, new clinical presentations have come to the forefront, either as unrecognized features of the disease itself or as a consequence of our therapies, including accelerated atherosclerosis, cognitive dysfunction, osteoporosis/osteonecrosis, and antiphospholipid antibody syndrome. The intensive investigations of these new features in lupus will give insights into their underlying mechanisms in people in the general population with atherosclerosis, dementia, osteoporosis, and clotting disorders. However, the etiology section of the puzzle still continues to elude us. Although investigations in many laboratories and clinics around the world continue to probe the genome, no clear understanding of susceptibility genes or disease expression genes has yet emerged. Similarly, the putative viral or hormonal etiologic factors remain elusive. Systemic Lupus Erythematosus, Fourth Edition, brings together the many pieces of the lupus puzzle to allow the researcher, clinician, teacher, and student to begin to see the puzzle coming together. Researchers, physicians, and patients look forward to the day when the puzzle will come together as a clear picture . . . *"one giant leap for mankind."*

Murray Urowitz, MD
University of Toronto

PREFACE

A book about the disease systemic lupus erythematosus (SLE) has to be remarkable. As we have heard many times, patients who acquire this illness are young, in the prime of life, surprised, and often diagnosed on average of five years after their first symptoms. Moreover, this is a deadly disease, even though patients look well. More and more people develop related autoimmune diseases like lupus, and the disease shares many clinical characteristics with these other maladies. In fact, I will reiterate the notion held by some that SLE is more than one illness. This notion is likely based on the varied presentation, organ selectivity, and waxing severity even after therapy is complete. Understanding this complexity, this book is designed to explore both the clinical and basic aspects of immunology as it applies to lupus. The book is divided into sections, which deal with the basic immunology, the overall clinical presentations, system analysis, and then treatment options. However, it is not that easy, since conditions like fibromyalgia and the antiphospholipid syndrome have to be included. I have attempted to make the division of sections and the grouping of chapters logical and easy to follow.

It is a book directed to both the student of immunology and the experienced clinician. In addition, it is a book that includes work by some of the most experienced clinicians and researchers among us. Each chapter is a compelling treatment of a specific area in exhaustive detail, and the authors of these detailed chapters have taken great time to write for this book. For them we are grateful.

This fourth edition of *Systemic Lupus Erythematosus*, a book born at the Rockefeller University in the laboratory of the late Professor Henry G. Kunkel, serves as a testimony to his dedication and work in immunology. It is an inspiration for all who take the findings at the patient's bedside and bring it to the laboratory in order to understand. Wherever possible, I have taken the progeny of the many investigators who passed through the Kunkel laboratory and included their work between these covers. Dr. Kunkel wrote the first Foreword for this book and encouraged me to include as much science as possible in the first edition. The inclusion of science continues. Eng Tan, Graham Hughes, and now Murray Urowitz followed Dr. Kunkel's tradition and wrote forewords for the next three editions. Dr. Urowitz, author of the current Foreword, is the director of the successful Toronto Center for Lupus Research and is a guiding force in the current thinking of the science of SLE.

Many authors from the last edition have revised their chapters, and much new material has been added. By necessity, overlap has occurred in some of the chapters. Purposefully, Some material is presented in different ways in different chapters. Some newer additions to the book include George Tsokos, who covers the molecular aspects of cellular immunology as it applies to lupus in great detail. James Levenson and colleagues chapter on the psychiatry of SLE, which places some perspective on the variant forms of behavior that can occur either because of the effects lupus has on a patient due to the severity of the illness or the actual production of psychosis by the effects of the immune dysfunction on the brain. Robin Brey and colleagues present the latest information on all aspects of the nervous system and lupus, a particularly challenging area. Carlos H. Nousari, Department of Dermatology, Cleveland Clinic Florida, details the dermatologic aspects of lupus, a system that was studied at Johns Hopkins by William Osler more than 100 years ago. John Winfield, in a new chapter, carefully dissects

fibromyalgia in association with SLE. Finally, Oscar Gluck presents osteoporosis and lupus in a chapter that covers both the steroid-treated patient and the effects of natural loss of bone in a patient with a chronic disease.

Lupus is a complex illness that often requires a physician's considerable time and effort. It is not an easy disease to diagnose or manage. This book is written as an aid to help the physician understand the subtle nuances of this enigma and use knowledge herein to manage the patient. It is written with the idea that new knowledge is urgently needed to diagnose and treat those patients for whom this illness is nothing short of a major catastrophe—a life emergency that deserves all our efforts and attention.

Numerous worldwide groups of patients dedicate their time and effort to social programs and funding of basic and clinical research, in the hope of an eventual cure. I salute the patients and their families for their efforts on behalf of our knowledge. I hope that the accuracy of the information given here in this book will educate and inform until the fifth edition comes forward. It is always the hope of this editor that subsequent editions might include both the cause and cure of this devastating illness.

Finally, I thank my publisher Elsevier for its patience and high standards of excellence and dedication to helping the sick. I specifically note my developmental editors Tari Paschall and Judy Meyer for sticking with the project and enduring my many letters, telephone calls, and emails regarding the authors and their materials included in the book.

INTRODUCTION

OVERVIEW

As I have noted in previous editions of this work, systemic lupus erythematosus (SLE), known to the public as *lupus*, is not a rare disease, but it is not common either. It is a chronic disease of unknown etiology that is very difficult to diagnose, not easy to treat, and yet sometimes over diagnosed. Since the last edition of this book, major advances have been noted in the treatment of illnesses like rheumatoid arthritis using biological therapy but still nothing that is able to completely reverse the ravages of a autoimmune diseases like lupus. This absence of therapeutic agents is the subject of discussion by a host of groups established to look at criteria for diagnosis, biomarkers of severity, and instruments of clinical activity. The establishment of clear indices that would allow regulatory agencies to see some consistency of response is lacking because lupus is a disease that often does not respond to either therapy or conventional wisdom.

I am unsure that lupus is really only one illness, and that may be one of the difficulties. I am more convinced that lupus is a series of illnesses that has, as its basis, an autoimmune response that devastates the whole body or destroys a single organ. Its classification and drugs for treatment might be better designed if it were a simple organ-specific entity that had consistency of presentation.

This protean illness presents in a variety of ways. It really depends on the organ chosen by the immune system for attack. The diagnostic difficulty revolves around the standard issues surrounding all illnesses, namely, the factors associated with the disease. This disease favors women, has a genetic association, and has an elusive trigger. Although we get closer to a cause by looking at many different possibilities, the problem is not easily solved because the immune system seems to become more complex by the year. In this fourth edition, the issues remain the same for clinicians and investigators. Reading the chapters in this book will not solve the mystery, but it will give you the impression that we are closer to understanding the illness. Most importantly, you will understand the disease better. The newer association of fibromyalgia and phospholipid antibody with this illness and the presence of cognitive disability apart from any gross neurological findings would seem to indicate the lupus is also evolving as time goes on. The limited numbers of drugs available to treat lupus despite years of research speak for the difficulty the scientific community has with understanding the biology of lupus.

In this fourth edition, we have revised every chapter. It includes new chapters on fibromyalgia and certain aspects of treatment. New authors write older topics like the dermatology of lupus. Older chapters such as the imaging of lupus are considerably enhanced with a thorough discussion of the current and future roles of the different modalities for imaging each organ system of patients with SLE. The section on the overview of the cellular and molecular aspects of lupus is probably the most comprehensive treatment of this area in print. The central nervous system and psychiatric aspects of lupus are written by new authors and are new and exciting. Apart from books dealing solely with the antiphospholipid syndrome, there is no better discussion of this topic and all of the aspects of the syndrome from clinical presentation to theories about pathogenesis. All in all, the book is enhanced in all areas to provide the reader with the latest information about SLE, its science, presentation, and treatment.

We have also produced a CD-ROM of the illustrations in this book in hopes that you might use it

to teach students and young physicians who may delight in a new frontier in medicine. Lupus gives us a handle on molecular biology, insight into common ailments like atherosclerosis, and a better understanding of the way the brain works. I have said before that it is a disease of the twenty-first century, and this book is testimony to that statement.

HISTORY OF LUPUS

The history of the disease SLE is colorful. The term *lupus* is attributed to the thirteenth century physician Rogerius, who described the facial lesions that were reminiscent of a "wolf's bite"(1). In 1851, Cazenave applied the term *lupus erythematosus* for the first time to a disease described by his teacher Laurent Biett (2). In 1845, von Hebra, a Viennese physician, used *butterfly rash* to describe the familiar malar rash of the disease. For most of the nineteenth century, lupus was thought to be a dermatologic disease. Von Hebra, in his 1856 book, published the first illustrations of the disease in the *Atlas of Skin Diseases*. However, when Moretz Kaposi described the visceral forms of the disease in 1872, physicians began to suspect that this disease was a more generalized form of the illness and the term *acute disseminated* was included in the description (3). Kaposi proposed two types of lupus: disseminated and discoid. In his early writings, he supposed that the disseminated form consisted of (1) subcutaneous nodules, (2) arthritis, (3) lymphadenopathy, (4) fever, (5) weight loss, (6) anemia, and (7) central nervous system involvement. In 1904, William Osler described two women who developed renal failure within 10 months of the appearance of a facial erythema, which in retrospect was the facial rash of von Hebra (4). Osler described a number of other illnesses at the time, among them, Henoch Schoenlein purpura and disseminated gonococcemia, which could be confused with the lesions on the two women. In Vienna at this time, Jedasson described similar syndromes in a few patients. Both he and Osler therefore established SLE as a distinct entity by the turn of the century, even though many practitioners still thought of SLE as a form of skin tuberculosis (5). Very typical cases of SLE were reported under a variety of names (6), and it was not until the 1920s and 30s that the disease was well defined. The disease, at that time, was carefully described by pathologists who studied the morbid anatomic changes that so characterized someone with lupus. The atypical bacterial endocarditis of Emmanuel Libman and Benjamin Sacks, described in 1924, was a classic example of the pathology found in some patients with SLE and were likely lesions associated with antiphospholipid antibody (7). Following that description, George Baehr, published a series of 23 autopsied cases of the renal *wire loop* lesions of lupus nephritis and described the solar sensitivity we know so well. Thus, pathologists further elucidated the disease known as lupus. In 1936 Frieberg, Gross and Wallach autopsied a young woman with lupus and no skin lesions, indicating that the disease was not primarily a skin condition and was even less associated with tuberculosis. Klempner, Pollack, and Baehr in 1941 suggested that collagen was a part of the disease because of the many instances of fibrinoid necrosis that they found with the disease. This gave rise to the name *collagen disease* as a grouping for all of the diseases that affected connective tissue, a term that is not used widely today.

Hack and Reinhart were the first to describe the false-positive syphilis test in SLE, and in 1940 Keil similarly reported ten cases of SLE with false-positive syphilis tests. Haserick and Lang wrote about an additional series of cases where the presence of the false-positive syphilis serology predated the clinical lupus by up to eight years. In all of these cases, the false-positive syphilis tests probably resulted from the presence of antiphospholipid antibodies, the discovery of which was to take an additional 30 years. In 1955, Moore (8) studied another 148 patients who were positive for syphilis and found that some 7% developed lupus with time, whereas 30% had symptoms relegated to *collagen vascular disease.* In 1949, Phillip Hench (9) discovered cortisone, and the future of the connective tissue diseases changed. Rheumatoid arthritis patients and those with lupus erythematosus (LE) were manageable, and "cures" were reported.

In 1948 Hargraves, Richmond, and Morton described the LE cell in the bone marrow of SLE patients (10). The test was later adapted to peripheral blood. This discovery laid the foundation for our confirmation of the disease lupus as an autoim-

mune disease. These were phagocytes eating cells coated with autoantibody. Until it was described in other illnesses like rheumatoid arthritis (RA), it was thought to be pathognomonic of lupus. Dubois in 1953 and Harvey in 1954 (11, 12) sought to set the record straight by stressing the chronicity of SLE and stressed the diagnostic importance of the LE test. However, its presence in only 50% to 70% of lupus cases made it a useful adjunct to the diagnosis of SLE, but the discovery later of more sensitive and more specific tests made its use limited. Meanwhile, other serum abnormalities such as hypergammaglobulinemia, detected in newly discovered techniques like immunoelectrophoresis, suggested that gamma globulins were present in great numbers that behaved like antibodies that reacted with normal tissues. These were later called *autoantibodies.* George Friou in 1957 (13) applied the indirect immunofluorescent test of Coons to the study of these autoantibodies. The fluorescent antinuclear antibody test (FANA) is positive in some 95% to 98% of SLE cases. At about the time of the Friou discovery, Deicher, Holman, and Kunkel (14), along with three other groups, described antibodies to DNA. In 1956, Eng Tan and Henry Kunkel described an antibody to a glycoprotein called SM after the first two initials of the patient's name, Smith (15). This was a practice that would follow over many years after for several new antibodies. Although present in only 30% of patients with lupus, this antibody would be one of the few that is found with relative specificity to SLE.

Many more antibodies were described after the findings of the antiDNA and the antiSM. Among these were the discovery of Gordon Sharp of an overlap syndrome characterized by high titers of anti ribonucleoprotein antibody, a syndrome that we now call *mixed connective tissue disease (MCTD).* Moreover the discovery of countless autoantibodies to cellular components such as the signal proteins of the nucleus, high molecular group proteins, and others have in large part helped the foment revolution in molecular biology by providing reagents with which to study cell function.

Dixon and colleagues (16) assisted with the development of many murine strains that develop diseases like lupus and afford models for genetic study. Leonhardt in 1954 described the familial nature of lupus, something studied later by Shulman and Arnett at Hopkins (17) and more deeply by Hahn, Harley, and others in recent years (18). Such studies allowed for the description of large multiplex families, identical twins, and again the application of these studies to molecular biology. From this came our knowledge of the role of the MHC class II and III in lupus and other related illnesses, work which goes forward today.

Finally, the work of Hughes, Harris, Gharavi, Asherson, and Alarcón-Segovia (19) to name a few opened the door to our understanding of the antiphospholipid antibody as an important aspect of lupus. The frequency of this unusual syndrome, which can be secondary to SLE, is one of great curiosity and the subject of intensive research much as the early studies of autoantibody were. The role of these antibodies in lipid metabolism and biological processes such as atherosclerosis again places lupus in the knowledge "revolution" and makes this global scourge known as SLE relevant to the most common causes of morbidity and mortality, something that the early researchers found implicit in the urgency of their work.

This brief history of lupus does not give justice to the countless investigators who make history every day with small steps. In this book, you will find that many of the historical discoveries that provided data and added terms to our immunological lexicon are discussed within the cover of this book in great detail. Moreover, the academic progeny of those who I mention previously are those who write about lupus and this disease as it applies to modern medicine. I am among those progeny. We write with humility and eloquence, since our knowledge of lupus and all of medical science is very young and evolving for the good of all humanity.

AUTOIMMUNITY AND AUTOIMMUNE DISEASES SUCH AS SYSTEMIC LUPUS ERYTHEMATOSUS

Howard Amital
Yehuda Shoenfeld

THE NATURE OF AUTOIMMUNITY

Autoimmune disorders affect approximately 5% of the population in the Western world and there are about 80 different autoimmune diseases [1]. Autoimmunity develops when an individual mounts an anti-self response. This reaction is signaled by the presence of self-reactive antibodies (e.g., humoral-mediated autoimmune diseases) or self-reactive T cells (e.g., cell-mediated autoimmune diseases). An autoimmune disease is a condition in which injury to the organs or tissues is caused by autoreactive antibodies or cells. According to these definitions, it is clear that these two entities usually coexist; however, a milieu of autoimmunity can exist without an overt autoimmune disease. Various clinical conditions of diverse etiologies may express autoimmune phenomena, e.g., malignant tumors, infections, and immune deficiencies (IgA or complement component deficiencies). Many are not accompanied with a substantial loss of organ function or body impairment, which can be classified as a sign or symptom. In all of these conditions one can find an increased incidence of autoantibody production with a great diversity of ligand-binding characteristics. Nevertheless, in most of these conditions it is not possible to link the affinity of the autoantibodies to the clinical expression of the patients [1–12]. This phenomenon is demonstrated most clearly in patients with monoclonal gammopathies, a group of diseases in which an uncontrolled proliferation of plasma cells takes place [9–13]. The outcome of the monoclonal proliferation of these cells is the production of an extremely high amount of immunoglobulins with a concomitant decline in the concentration of the other polyclonal immunoglobulins, usually only with minimal autoimmune phenomena, if at all. In a series of studies, approximately 8–10% of serum monoclonal immunoglobulins were found to be autoreactive with antibodies that bound to DNA, histones, Sm/RNP, Ro SSA, and La SSB [9–11]. By and large, only a minority of these patients develop signs that are related to the binding characteristics of the monoclonal immunoglobulins as a bleeding diathesis or as a peripheral neuropathy [12, 13]. Autoimmune features are associated with monoclonal gammopathies clarify several important principles.

1. The existence of an autoantibody is not sufficient in order to evoke an autoimmune disease. Even huge amounts of such an autoantibody may fail to induce an autoimmune disorder. For an autoimmune disease to be clinically apparent, additional genetic, hormonal, and environmental parameters are essential [14, 15]. Interestingly, Marmont [16] demonstrated four decades ago that the transfer of lupus LE cells to human recipients stimulated the generation of similar cells but no clinical signs or symptoms.
2. For decades it was accepted that the clonal deletion theory elucidated the maintenance of healthy

immune equilibrium, leaving a repertoire of T and B cells that recognize foreign antigens. Today we hold the view that a certain degree of autoreactivity is essential to the normal function of the immune system. Yoles *et al*. [17] inserted the term "protective autoimmunity" to the scientific vocabulary. They have shown that active or passive immunization with central nervous system (CNS) myelin-associated self-antigens reduced secondary neuronal loss. Autoantigens help form the repertoire of mature lymphocytes that secrete natural autoantibodies. These autoantibodies are generated in minute amounts, usually of the IgM isotype being polyspecfic in nature, with low avidity to autoantigens. Several physiological and regulatory roles have been attributed to these natural autoantibodies. Grabar [18] was the first to postulate that natural autoantibodies fulfill the role of biological scavengers binding to catabolic end products, cleansing the circulation from debris and other degraded tissue components. Concomitantly, these complexes facilitate opsonization and phagocytosis. Others stressed their role in achieving self-tolerance and balance of the idiotypic network [19–21]. Because autoreactivity is physiological, the challenge is to understand the mechanisms that divert normal function to pathological processes that lead to tissue injury.

What Leads from Autoimmunity to an Autoimmune State?

Many individuals remain in an "autoimmune state" throughout their entire lives without a subsequent "autoimmune disease." Others are destined to develop a full-blown disease. We believe that alteration of the delicate equilibrium that distinguishes physiological from harmful effects of autoantibodies may be caused by infections, sunshine, drugs, and smoking [14, 15, 22–25]. The concept of the "kaleidoscope of autoimmunity" describes this concept in a virtual manner. Any change in the immune system may induce remission or cure from one autoimmune disease but may set the foundation to the emergence of another [26–29].

Which Diseases Are Really Autoimmune Ones?

The list of diseases in which autoimmune pathogenesis is implicated has grown to embrace diverse disorders such as cataracts, peptic diathesis, and alopecia [30, 31]. Several indications even pointed that schizophrenia has an autoimmune "flavor" [32–34].

In most cases, there is no explicit evidence of autoimmunity except than the presence of an autoantibody or an autoreactive cell. By strict application of the criteria set out in Table 1, very few diseases would be regarded as truly autoimmune (e.g., myasthenia gravis, autoimmune thyroiditis, autoimmune hemolytic anemia, Lambert–Eaton's syndrome, idiopathic thrombocytopenic purpura, pemphigus vulgaris). In addition, autoimmunity can be transferred by T cells as in the case of experimental antiphospholipid syndrome. In this syndrome, the passive transfer of autoreactive T cells to naive mice induced the disease [35].

TABLE 1 Criteria for Autoimmune Diseases

A defined circulating antibody or cell-mediated immunity to autoantigens
The ability to generate the autoantibody or self-reacting cells following immunization with the self-antigen (with complete Freund's adjuvant)
The ability to produce the disease in an experimental animal by passive transfer of the antibody or the self-reacting cells
The ability to produce the disease in an experimental animal by immunization with the self-antigen (with complete Freund's adjuvant)
Definition of a specific autoantigen

Paradoxically, even systemic lupus erythematosus (SLE), the subject of this book, does not fulfill the strict criteria required for a disease to be classified as autoimmune (Table 1): passive transfer of various autoantibodies (e.g., anti-DNA, anti-Sm antibodies) was not followed by disease development [36]. Indeed, some antinucleic acid autoantibody specificities could be achieved by immunization of experimental animals with protein–nucleic acid complexes (nucleosomes). However, it is almost impossible to stimulate an immune response to intact native DNA, ribosomal RNA, or tRNA unless certain biochemical modulations are carried out [37–39]. However, despite these interesting attempts to generate immunogenic DNA, no one has been able to induce SLE following immunization of naive animals with either DNA or another autoantigen emulsified with adjuvant [40]. Furthermore, most passive transfer experiments employing either monoclonal or polycolnal anti-DNA antibodies failed to induce manifestations of SLE [41, 42]. According to the most recent data, it is inconceivable that anti-DNA antibodies are ascribed to all the actual organ damage of SLE. Anti-DNA antibodies probably cross-react with antiheparan sulfate, antiproteoglycans, or antilaminin antibodies, hence evoking renal and placental injury [43–45]. Nevertheless, SLE remains one of the classical autoimmune diseases due to several reasons.

- It is associated with the appearance of more than a hundred different autoantibodies (Table 2) [46, 47].
- It is associated with other parameters characteristic of the classical autoimmune conditions, e.g., human lymphocyte antigen (HLA), sex hormone influence, Gm allotypes, T-cell defects in apoptosis and

TABLE 2 Autoantibodies in SLE[a]

No.	Target of autoantibody
1	Antinuclear antibodies (ANA)
2	Nucleosomes
3	Deoxyribonucleic acid (DNA) Double-stranded (native) DNA (dsDNA) Single-stranded (denatured) DNA (ssDNA) Z-DNA
4	Telomeres
5	Nucleosides, nucleotides
6	Histones (H) (H2A-H2B)–DNA complex H1, H2A, H2B, H3, H4
7	DNA-dependent ATPase
8	DNA polymerase α
9	Replication protein A (RPA) RPA-70 RPA-32
10	Ku
11	Poly(ADP-ribose) polymerase (PARP)
12	Poly(ADP-ribose)
13	Topoisomerase-I (Scl-70)
14	High-mobility group protein HMG17
15	DEK oncoprotein
16	Centromere proteins CENP-A CENP-B
17	Antisense to the ERCC-1 DNA excision repair enzyme gene (ASE-1)
18	Proliferating cell nuclear antigen (PCNA)
19	RNA polymerase (RNAP) I, II, III
20	Transcription factor TFIIF (Rap74 subunit)
21	Transcription factor TFIIB
22	Protein kinase NII
23	Ro (SS-A)
24	La (SS-B)
25	Nuclear poly(A) polymerase (polynucleotide adenyltransferase)
26	Nucleolar RNA helicase (Gu) protein
27	SR proteins SRp20, SRp30a, SRp30b, SRp40, SRp55, SRp75
28	Alu RNA–protein complex
29	Small nuclear ribonucleo-protein particles (snRNP) spliceosomal Sm-B/B′, D1, D2, D3 proteins and E-F-G protein complex U1 snRNP-70K, A, C polypeptides U2 snRNP-A′, B″ polypeptides nonspliceosomal P ribonuclease (RNase P)
30	Heterogeneous nuclear ribonucleoprotein particles (hnRNP) Protein A1 Protein A2 (RA33)
31	Fibrillarin
32	Nucleolin
33	B23/nucleophosmin
34	90-kDa protein of the nucleolus organizer region/human upstream-binding factor (NOR-90/hUBF)
35	Interferon-inducible protein IFI 16
36	Mitotic spindle apparatus Type 1 nuclear mitotic apparatus protein (NuMA-1, MA-I) Spindle kinesin-like protein HsEg5 (NuMA-2, MA-II)
37	Ki-67
38	p53
39	c-myc oncogene product
40	Proteins phosphorylated during apoptosis
41	Ki [probably identical to sicca lupus (SL) system]
42	Nuclear lamins B-type lamins B1 and B2
43	Su
44	Prothymosin α
45	DA1, DA2
46	MA
47	Me
48	Outer ring subunit HC9 (α3) of 20S proteasome
49	Ribosomal P proteins (P0, P1, P2)
50	Ribosomal protein S10
51	Ribosomal protein L12
52	28S ribosomal RNA (rRNA)
53	JA
54	Eukaryotic protein L7
55	Golgi apparatus proteins Golgin-95/gm 130, golgin-160, golgin-67
56	Transfer RNA (tRNA)
57	Cytoskeletal antibodies Microfilaments Actin Fimbrin T- and L-isoforms (T-f, L-f) α-Fodrin (α-f) 135-KDa antigen microtubuli Tubulin Intermediate filaments Vimentin Neurofilaments (NF) Cytokeratins (CK)
58	Calpastatin
59	Follistatin-related protein

(*continues*)

TABLE 2 (*continued*)

No.	Target of autoantibody
60	Heat shock protein 90 (HSP 90)
61	FK506-binding protein 12
62	Carbonic anhydrase (CA) I,II
63	Pyruvate dehydrogenase (mitochondrial antibodies of M2 type)
64	Profilaggrin (perinuclear factor)
65	CD45
66	CD4
67	FcγR FcγRI (CD 64) FcγRII (CD 32) FcγRIII (CD16)
68	Insulin receptor
69	Gangliosides (Gang) GM_1, GD_{1a}, GD_{1b}, GT_{1b} Galactocerebrosides (Gal)
70	Cell membrane-associated DNA (cmDNA)
71	Cell membrane DNA-binding protein
72	Lipocortin-1
73	β_2-Microglobulin
74	Lupus anticoagulant (LAC)
75	Anionic phospholipids Cardiolipin (CL)
76	Zwitterionic phospholipids Phosphatidylethanol-amine (PE) Phosphatidylcholine (PC) (including bromelain-treated erythrocytes) Platelet-activating factor (PAF)
77	β2-Glycoprotein I (β2GPI)
78	Prothrombin (PT, factor II)
79	Annexins (Anx) Anx IV Anx V (placental anticoagulant protein I) Anx XI [calcyclin-associated protein (CAP-50)]
80	Protein S
81	Protein C
82	Thrombomodulin (TM)
83	Factor XII
84	Tissue type plasminogen activator (t-PA), bound to fibrin
85	High and low molecular weight kininogens (HMWK, LMWK) Kininogen-binding proteins: factor XI and prekallikrein
86	Thromboplastin (tissue factor)
87	Vascular heparan sulfate proteoglycan
88	Oxidized low-density lipoprotein (ox-LDL)
89	Malonaldehyde (MDA)-modified lipoprotein (a) (MDA-Lp[a])
90	Antimitochondrial antibodies of M5 type (AMA5)
91	Lysophosphatidylcholine (LPC)
92	Platelets Glycoprotein (GP) IIb-IIIa GPIb-IX CD36 (GPIV)
93	Antineutrophil cytoplasmic antibodies (ANCA) with cytoplasmic staining pattern Proteinase 3 (PR3) ANCA with perinuclear staining pattern (pANCA) Myeloperoxidase (MPO) ANCA with specificity other than MPO and PR3 Lactoferrin (LF) Cathepsin G (CTG) High mobility group proteins HMG1, HMG2 Lysozyme (LZ) Elastase (EL) α-Enolase (EN)
94	Endothelial cells (EC) candidate antigens: Ribosomal P protein P0 Endothelial cell-specific plasminogen activator inhibitor (EPAI) Ribosomal protein L6 (L6) Elongation factor 1α (E1α) Adenyl cyclase-associated protein (CAP 1) DNA replication licensing factor (LF) Profilin II Tubulin Vimentin Human endothelial-associated putative lupus antigens HEAPLA 1, HEAPLA 2
95	Nervous system (neuronal antibodies) Gangliosides Galactocerebrosides 50-kDa antigen 97-kDa antigen Ribosomal P protein Neurofilaments
96	Lymphocytes T cells, B cells CD45 CD4 T-cell receptor (TCR) Major histocompatibility complex (MHC) class I and II antigens Ribosomal antigens including P protein
97	Red blood cells (RBC) "Warm" autoantibodies (WA) Rh family antigens p34 and gp37-55 Glycophorin A Band 3 anion transporter Other blood group system antigens Wr^b, LW, U, K, Kp^b, K13, Fy "Cold" autoantibodies (CA)
98	Collagen-like region of C1q

[a] SLE, systemic lupus erythematosus; SS, Sjogren's syndrome; SSc, systemic sclerosis; RA, rheumatoid arthritis; MCTD, mixed connective tissue disease; UCTD, undetermined connective tissue disease; PMR, polymyalgia rheumatica; APS, antiphospholipid syndrome; PM, polymyositis; ANA, antinuclear antibodies; aCL, anticardiolipin; LAC, lupus anticoagulant; CNS, central nervous system; CSF, cerebrospinal fluid.

cytokine production, and association with IgA and complement component deficiency [14, 15]. Therefore, we have to accept the definition of several clinical conditions as autoimmune because they are associated with those typical characteristics of SLE, although they do not fulfill the criteria listed in Table 1.

Classification of Autoimmune Diseases

For practical reasons, autoimmune diseases can be classified according to how the damage is induced: humoral-mediated autoimmune diseases (e.g., myasthenia gravis and immune thrombocytopenic purpura) and cell-mediated autoimmune diseases (e.g., insulin-dependent diabetes mellitus, thyroiditis, and rheumatoid arthritis). The division between the two is not distinct, and evidence for the involvement of T cells in induction of the damage in antibody-mediated disease and *vice versa* has been documented. Another classification is based on the number of organs afflicted. Thus, autoimmune diseases may be categorized according to organ-specific diseases and multisystemic diseases (Table 3).

Autoimmune diseases have also been sorted according to the type of the immunodysregulation that evokes the disorder. Diseases that originate from a reactive immune system, mainly composed of an excess of T-cell

TABLE 3 Classification of Autoimmune Diseases

Disease	Target organ/tissue
Multisystemic	
SLE	Skin, joints, kidneys, brain, heart, lungs
Rheumatoid arthritis	Joints, lungs, skin, pericard
Sjogren's syndrome	Exocrine glands (particularly lacrimal and parotid)
Diffuse systemic sclerosis	Skin, joints, kidneys, gastrointestinal tract, lungs
Goodpasture's syndrome	Kidneys, lung
Organ specific	
Graves' disease	Thyroid
Hashimoto's disease	Thyroid
Myasthenia gravis	Muscles
Polymyositis	Muscles
Pernicious anemia	Stomach
Addison's disease	Adrenal
Insulin-dependent diabetes	Pancreas
Primary biliary cirrhosis	Liver
Autoimmune hemolytic anemia	Red blood cells
Idiopathic thrombocytopenic purpura	Platelets
Pemphigus	Skin, mucosal membranes

TABLE 4 Primary versus Secondary Autoimmune Diseases (AID)

Primary AID	Secondary AID
Cause unknown	Cause known or suspected
Autoantigens normal	Autoantigens altered or mimicry with exogenous antigens or leakage of sequestered autoantigens
Excess of T-cell help	Immune system normal
Permanent disease	Transient autoimmune phenomena
Can be treated	Curable autoimmune phenomena
Mainly women	Both sexes
Rarely in children	All ages
Clinical overlap with other primary AID	No clinical overlap with other AID
Serological overlap with other primary AID	No serological overlap with other AID
Familial predisposition	Rarely familial predisposition

activity, are often termed "primary autoimmune diseases." They should be distinguished from autoimmune diseases that develop in a completely normal immune system, often called "secondary autoimmune diseases." These latter diseases are probably triggered by certain autoantigens that were altered, by certain exogenous antigens that resemble autologous antigens leading to cross-reactions, or by certain previously well-sequestered autoantigens that broke out of the tolerance. Table 4 gives differences between primary and secondary autoimmune diseases [48].

The Mosaic of Autoimmunity or Why Are Autoimmune Diseases so Diversified?

The etiology of autoimmune diseases is multifactorial [49, 50] (Table 5). It is interesting to note that in almost all autoimmune conditions there are familial tendencies and an increased incidence of autoantibodies among healthy first-degree relatives of affected patients [49]. This trend is very familiar with diabetes type 1 patients [51]. Most autoimmune diseases are multigenic, with multiple susceptibility genes working in concert ending with an abnormal manifestation or disorder [52]. In many of the different disorders an increased incidence of B8 or DR2 and DR3 or DR4 is found [49]. Some HLA alleles protect against the development of autoimmunity even when a susceptibility allele is present. For example, the HLA-DQB1*0602 allele protects against type 1 diabetes even if the HLA-DQB1*0301 or DQB1*0302 susceptibility gene is present [53]. There is hardly an autoimmune disease in

TABLE 5 Major Pieces of the Mosaic of Autoimmunity[a]

Genetic
- Increased incidence of the disease in families
- Increased incidence of autoantibodies in first-degree relatives of the patients
- Increased incidence of the disease in monozygotic twins
- HLA studies: increased incidence of HLA-B8, -DR2, -DR3, and -DR4 in some diseases. A protective effect (e.g., HLA-DR2 in type 1 diabetes noted in others or aspartic acid in position 57 in HLA-DQ3β)
- Increased incidence of common idiotype of autoantibodies in patients and first-degree relatives
- Gm allotypes
- Complement component deficiencies

Defects in immune system
- IgA deficiency
- Complement component deficiencies (e.g., C1q, C2, and C4)
- Qualitative and quantitative defects in suppressors
- Defects in natural killer cells
- Defects in secretion, response to, and receptors for IL-2 and other lymphokines (including interferons and tumor necrosis factor)
- Defects in phagocytosis
- AIDS

Hormonal
- Increased prevalence of disease among females
- Increased prevalence of disease in Klinefelter's syndrome
- Increased prevalence of autoantibodies among females
- Exacerbation of diseases during puberty, pregnancy, and postpartum periods and while taking contraceptives
- Association between hyperprolactinemia and autoimmunity
- The protective effects of testosterone-like drugs

Environmental
- Infecting agents: viruses, bacteria, parasites
- Drugs (e.g., in idiopathic thrombocytopenic purpura, myasthenia gravis, SLE)
- Toxins (e.g., scleroderma)
- Ultraviolet light (e.g., SLE)
- Smoking (Goodpasture's syndrome)
- Stress (e.g., SLE)
- Nutritional influence (e.g., rheumatoid arthritis)

[a] Based on Shoenfeld and Isenberg [49].

which a defect in T suppressor cells has not been reported with an associated natural killer cell function impairment [54]. Many of these diseases have been reported in conjunction with an interleukin-2 deficiency [55] or IgA deficiency [56]. Complete deficiencies of the early components C1q, C2, and C4 in the classical pathway of complement are associated with the most striking risk to the development of SLE. Deficiency of C4A is probably the most common inherited complement deficiency, occurring at varying frequency in different population groups [57]. Hereditary homozygous deficiencies of C1q, C1r and C1s, and C4 are each strongly associated with susceptibility to SLE, with respective prevalences of 93%, 57% (because deficiencies of C1r and C1s are usually inherited together), and

75%. The hereditary C1q deficiency therefore represents the most powerful susceptibility gene identified for the development of SLE in humans. In some populations, 50–80% of SLE patients have the C4A deficiency. C2 deficiency is associated with SLE at a lower frequency and with a mild clinical presentation than other complement deficiencies [58, 59] (discusses further in Chapters 5 and 6).

The high concentration of immune complexes detected in the blood of SLE has raised the suspicion that Fcγ receptor polymorphism might be associated with SLE. Fcγ receptors are active natural immune complex scavengers; therefore, low-affinity-binding characteristics of these molecules to circulating immune complexes might result in excessive deposition of such complexes in various organs. Low-affinity variants of both Fcγ IIA and IIIA have been shown to be associated with lupus nephritis [57, 60]. The mannose-binding protein is a serum acute-phase reactant that activates the classical and alternative pathways of the complement independently of antibody. An allele of this protein shown to be incapable of activating the classical pathway of the complement was found to have a moderate association to SLE [60].

External modulations of the immune system by drugs or by allogenic bone marrow transplantation (causing a graft-versus-host response) evoke autoimmune phenomena [58, 61, 62]. D-Penicillamine is eminent among drugs known to induce autoimmune disease: this compound was used to treat patients with severe rheumatoid arthritis, diffuse systemic sclerosis, and primary biliary cirrhosis but was reported to induce autoimmune conditions as SLE, rheumatoid arthritis, pemphigus, myasthenia gravis, polymyositis, thrombocytopenia, systemic sclerosis, and Goodpasture's syndrome. Similarly, the induction of graft-versus-host disease in animal models and even in humans is associated with various autoimmune conditions, such as SLE, systemic sclerosis, and polymyositis. In graft-versus-host disease, T cells of the donor collaborate with recipient B cells to secrete autoantibodies [49, 62].

Thus, it seems that the different clinical presentations of autoimmune conditions stem from various combinations of factors. In the propositus, a particular setup will evoke a certain manifestation, whereas in another member of even the same family, a different constellation will be associated with an involvement of completely different organs. This phenomenon has been referred to as the *mosaic of autoimmunity* [25, 49, 61] using the definition of mosaic in the shorter "*Oxford English Dictionary:*" "the process of producing pictures or patterns by cementing together small pieces of stone, glass, etc." This definition implies that by reassembling the same pieces in a different order, another pattern or picture will emerge. We share this concept in a similar manner concerning diseases of the immune system; hence by rearranging much of the same parameters, diverse patterns of autoimmune diseases become evident. The integration of many factors into the etiology of one autoimmune disease and the association of the same defects with different diseases may explain some clinical phenomena.

TABLE 6 Association between Autoimmune Diseases[a]

First disease	Associated disease
Multisystemic	
Systemic lupus erythematosus (SLE)	SSc, mixed connective tissue disease (MCTD), SS, HT, MG, PM
Rheumatoid arthritis (RA)	SS, HT
Systemic sclerosis (SSc)	SLE, RA, SS, PM, PBC
Sjogren's syndrome (SS)	SLE, RA, SSc, MCTD
Organ specific	
Immune thrombocytopenic purpura	SLE, CAH
Myasthenia gravis	SLE, SS, HT
Hashimoto's thyroiditis	SLE, SS
Pernicious anemia	Graves' disease, HT, Addison's disease
Chronic autoimmune hepatitis	SS
Insulin-dependent diabetes mellitus	Thyroiditis and pernicious anemia
Primary biliary cirrhosis	SLE, RA, Ssc, SS, HT

[a] The first disease preceded or occurred concomitantly with the associated disease.

- The most prevalent autoimmune disorders are multisystemic.
- There are overlapping syndromes.
- Many organ-specific autoimmune diseases are associated in the same patient with other autoimmune diseases or with other conditions that affect the immune system as malignancies or primary and secondary immunedeficiency syndromes [6, 7, 28, 29, 58–64].

These associations are summarized in Tables 6 and 7. Remarkably, these phenomena go beyond the individual patient. Family members of patients suffering from autoimmune diseases have increased levels of autoantibodies [65, 66] and of similar or other autoimmune conditions [48, 51–53].

The Kaleidoscope of the Autoimmune Mosaic

The origin of autoimmunity is complex and stands probably above all the assumptions and speculations that are prevailing today. Several reports have raised the

TABLE 7 Association between Autoimmune and Malignant Diseases

Autoimmune disease	Malignant disease
Systemic lupus erythematosus	Few cases of lymphomas, thymoma, multiple myeloma
Rheumatoid arthritis	Hodgkin and non-Hodgkin lymphoma, multiple myeloma, leukemia
Systemic sclerosis	Lung cancer (especially the bronchoalvaeolar type), breast cancer
Sjogren's syndrome	Lymphoma, Waldenström's macroglubulinemia, pseudolymphoma
Dermatomyositis, polymyositis	Malignancies of breast, lung, ovary, stomach, uterine, colon, Hodgkin lymphoma
Chronic lymphocytic thyroiditis	Thyroid lymphomas, extrathyroid lymphoma, myeloproliferative diseases
Vasculitis	Hairy cell leukemia, lung cancer (mainly nonsmall cell)
Autoimmune hemolytic anemia and thrombocytopenia	Chronic lympocytic leukemaia, B-cell lymphoma
POEMS syndrome (polyneuropathy, hepatosplenomegaly, endocrinopathy, M protein and skin changes)	IgA plasmacytoma
Hypertrophic osteoarthropathy	Nonsmall cell lung cancer, metastasis to lungs
Sweet's syndrome (fever, neutrophilia, tender erythematosus cutaneous plaques of the arms, neck, and head. Pulmonary, hepatic and musculoskeletal involvement may be seen)	Acute myeloblastic leukemia
Lambert–Eaton myasthenic syndrome	Small cell carcinoma of lung
Stiff man syndrome	Small cell carcinoma of lung, breast cancer, thymoma
Peripheral neuropathy	Waldenström's macroglobulinemia

attention to another aspect, namely that amelioration of one disease "opens the door" for another autoimmune disorder. Levine *et al*. [64] described two patients with immune thrombocytopenic purpura who, following a successful splenectomy, developed chronic active hepatitis, probably of an autoimmune origin. From an etiological viewpoint, one can interpret these events as follows: factors associated with autoimmunity were deranged and in a combination that "favored" the development of immune thrombocytopenic purpura. Subsequently, one or more of the surrounding conditions were altered (in these patients the spleen was removed), bringing about a rearrangement to the antecedent immune equilibrium, leading to the emergence of a different autoimmune condition this time, autoimmune hepatitis. There is an additional report of a patient with immune thrombocytopenic purpura who developed chronic active hepatitis after a splenectomy [67]. Other occurrences reported are of patients with myasthenia gravis that developed aggressive SLE and antiphospholipid syndrome (APS) after thymectomy [28, 68–70]. Gerli *et al*. [68] were uncertain what had more impact on the development of SLE in these patients: the history of myasthenia gravis or the immunomodulation that was caused by the thymectomy. Rodrigue *et al*. [71] described six patients in whom SLE and thyrotoxicosis coexisted. In three of them, hyperthyroidism preceded the SLE, but the cause for the change remained obscure. Interestingly, Krause *et al*. [72] were able to block the development of diabetes in nonobese diabetes (NOD) mice (a model that develops insulin-dependent diabetes mellitus spontaneously) by inducing a lupus-like syndrome by their immunization with an anti-DNA idiotype. The mice developed clinical features of SLE instead of the classical clinical and pathological presentation of diabetes. It seems that the clinical shift in this animal model resulted from a change in the immune milieu after this idiotypic manipulation.

We refer to such a switch from one abnormal immune balance to another as the ***kaleidoscope of the autoimmune mosaic*** [73]. We prefer to use the term kaleidoscope because it gives emphasis to the notion that new emerging autoimmune conditions can not be attributed to a novel exposure to a presumed autoantigen, whereas shuffling of the perturbed self and environment results in a new autoimmune disease.

Why does the kaleidoscope phenomena occur? As suggested earlier, it is probably due to an additional change in one or a few of the factors that compose the autoimmune mosaic. For instance, the spleen is a major regulator of immunocytes, and its removal in predisposed patients undoubtedly modifies the immune function. Similarly, following thymectomy, the loss of thymic T-cell regulation contributes to the subsequent occurrence of SLE. In a similar manner, in patients in whom a certain disease was treated by certain drugs or by immunomodulation, an autoimmune disorder might develop consequently (Table 8). Many other environmental factors known to affect the immune system may play a role in the kaleidoscope phenomenon, such as

TABLE 8 Association between Autoimmune Diseases and Drugs

Disease	Drugs
Drug-induced lupus	Hydralazine, isoniazide, procainamide, captopril, acebutalol, chlorpromazine, labetolol, methyldopa, carbamezapine, phenytoin, lithium, D-penicillamine, propylthiouracyl
Drug-induced myasthenia gravis	D-Penicillamine, trimethadione, long-term therapy with diphenylhydantoin, "unmasking" by therpay with quinidine, propanolol, and lithium
Drug-induced myositis	Amiodorone, clofibrate, enalapril, colchicine, cyclosporine, chloroquine, ε-aminocaproic acid, glucocoticosreoids, vincristine, amphotericin B, salbutamol, D-penicillamine, penicillin, hydralazine, phenytoin, procainamide, propylthiouracyl, lovastatin
Drug-induced hemolytic anemia	Methyldopa, quinidine, quinine, sulfonylurea, phenacetin
Drug-induced thrombocytopenia	Quinidine, quinine, gold salts, D-penicillamine, heparin, digitoxin, methyldopa, carbamezapine
Drug-induced pemphigus	D-Penicillamine, captopril
Drug-induced systemic sclerosis	D-Penicillamine, bleomycin, carbodopa, pentazocine, ergotamines, mazindol, amphetamines

infections and nutrition. For instance, James *et al*. [74] showed that exposure to the Epstein–Barr virus (EBV) is highly associated with the development of SLE. Of the 196 lupus patients they tested, all but 1 had been exposed to EBV, while 22 of the 392 controls did not have antibodies consistent with previous EBV exposure, implying that this viral infection might tilt the kaleidoscope to be more autoimmune.

A certain degree of heresy is needed to accept the inevitable fact that autoantigens are not essential for the induction of the autoimmune process. It is difficult to depart from the role that anti-DNA antibodies have as a tragic hero playing in this scene called SLE and to refer to them as spectators accompanying the performance. These data led us to the comprehension that the classical anti-DNA reaction in SLE is due merely to the fortuitous selection of DNA from a *"shelf"* rather than plainly indicating DNA as a true *self-target antigen*.

Is it possible that there is no true autoantigen in SLE? We probably have to acknowledge the distinction between classical, organ-specific autoimmune disorders (Graves' disease, Hashimoto's disease, myasthenia gravis, pernicious anemia, insulin dependent diabetes, etc.) and multisystemic autoimmune diseases. However, these distinctions do not shed light on the autoimmune kaleidoscope puzzle.

Why Do Patients Differ from Each Other?

It remains ambiguous why two patients with SLE with the same antidouble-stranded DNA (anti-dsDNA) may tremendously differ from each other. In one patient, convulsions may be the first expression of CNS affliction, which may develop into chronic renal failure, whereas another patient may experience a mild butterfly rash with an increased erythrocyte sedimentation rate with slight arthralgia. We would like to offer an additional mechanism to resolve this enigma: the pathogenic potential of different idiotypes. Thus, although two patients may both have anti-dsDNA autoantibodies, one idiotype may induce CNS damage and renal failure and the other may be deposited in the skin or joints [75, 76].

One of the possible solutions to this puzzle may rise from various autoimmune models. It has been shown that immunization of animals with a given antigen can lead to spreading or the antibody response to include not only the targeted antigen but also related epitopes. This "epitope spread" was noticed in various animal autoimmune models, such as experimental allergic encephalomyclitis in which the immunization of mice with the myelin basic protein peptide 1-11 led to the breakdown of T-cell tolerance to three other endogenous peptides [77]. Similarly, immunization of healthy mice with individual protein components of the La/Ro ribonucleoprotein (RNP) targeted in primary Sjogren's syndrome and in SLE induced autoantibodies recognizing Ro60 (SSA), Ro52 (SS-A), and La (SS-B) and, in some cases, the molecular chaperones calreticulin and Grp78 [78]. The endogenous antigen driving determinant spreading might be derived from physiological apoptosis, which could explain the involvement of some chaperone proteins in the autoimmune response. In has been shown that active immunization of mice with a given autoantibody may lead to the production of murine self-autoantibodies and certain autoimmune disease expression. The concept, initially proposed by Jerne [79], suggests that the immune response may be governed by unique antigenic determinants of the immunoglobulin variable regions (idiotypes). These idiotypes are regulated by other antibodies, comprising a dynamic and balanced idiotypic network with intrinsic regulatory properties. Interestingly, when immunizing mice with a given antibody, the generation of murine self-antibodies is often accompanied by the production of apparently unrelated autoantibodies. For instance,

immunization with the anti-DNA antibody 16/6 idiotype leads to the production of antibodies to Ro (SSA) and histones. Additionally, immunization with the anti-Sm idiotype led to the production of anti-dsDNA and ssDNA, as well as anti-RNP antibodies [75, 80, 81]. Thus, immunization with a given antibody can drive spreading of the autoantibody response toward associated molecules as well as to apparently unrelated antigens. Therefore, *autoantibody spreading* may be one of the mechanisms by which heterogeneous autoantibodies emerge in autoimmune conditions. Fluctuating levels of autoantibodies may be one of the mechanisms that determine the clinical presentation of a patient at a certain time.

Physiologic and Pathologic Autoimmunity

Autoimmune diseases are conditions in which the immune system damages normal components of the individual. Initially, it was thought that autoimmune diseases were an inevitable outcome of the presence of clones of lymphocytes with receptors that recognize self-antigens. Thus, tolerance to self, or nonautoimmunity, was due to the absence of autoreactivity, the "forbidden" culprit of autoimmune diseases. As a bacteriologist, Burnet knew that lymphocytes proliferate in response to antigenic stimulation as microbial infections, thus somatic mutations occur in lymphocytes just as they do in bacterial populations. According to his hypothesis, antibodies and lymphocytes may have a myriad of affinities to innumerable antigens. However, because of the random element in the somatic mutation, sometimes clones with autoreactive traits will arise. Burnet referred to such clones as "forbidden clones." In order to be born free of autoimmune diseases, the fetus has to destroy or persistently suppress any expression of clones reactive with host antigens [82]. In "a normal" individual, self-reactive clones are automatically eliminated following their appearance. Furthermore, any case of autoimmunity could be attributed to the failure of suppression or exclusion of a particular autoreactive lymphocytic clone. Proliferation of such a clone with time entails danger due to the emergence of an autoimmune condition.

In contrast to the "Burnetian" theory, it is now known that lymphocytes are produced throughout life, namely their clonal segregation is not only confined to developmental stages of a fetus surrounded by self-antigens. This fact introduces an entirely new concept that tolerance is acquired along with the development of the organism. We believe that it is evident that self-recognition is vital for the maintenance of normal physiology. Grabar [18] argued that the presence of a large variety of autoantibodies in the blood may be required for scavenging effete molecules and cells. Furthermore, autoreactivity is essential for the sustenance of immune tolerance. Thus, cells that "protect" autologous tissues from immune attack must be per definition. This last statement does not negate the concept of clonal deletion, but it does raise the necessity of certain clones to escape it [69].

It has been suggested that a certain degree of autoreactivity is essential to the maintenance of normal immune behavior. Self-recognition has a seminal role in the detection of major histocompatibility complex antigens on most of the cell membranes and, as mentioned earlier, self-recognition is the cornerstone of the binding properties within the idiotypic network. It has been suggested that autoimmune conditions result from many foci of prematurely aging cells. Those inherently damaged cells adapt to *in vivo* challenges by beginning to transform into cancer cells. However, as long as those stressed cells have not fully transformed, they will continue to signal "danger" to the innate immune system. The clinical outcome of that struggle between incipient neoplasia and immunity will vary depending on the degree of tumor proneness and resistance of the individual. This hypothesis is in concordance with the frequent association between neoplasia and autoimmunity [83, 84].

MECHANISMS OF AUTOIMMUNITY

Breaking Peripheral Tolerance

As a consequence of constant reshuffling of the genes that encode T- and B-cell receptors, theoretically more than 10^9 different antigen-binding sites can be generated, some of them with affinities to autoantigens. Tolerance is the process that eliminates or neutralizes autoreactive cells. Whenever a breakdown in the process occurs, autoimmunity might evolve. Distinguishing self from nonself is fundamental to the normal function of the immune system. For T cells, this discrimination is a dangerous balancing act, swaying between extremes of nonresponsiveness and autoimmunity. Several mechanisms are involved in order to preserve this equilibrium. Clonal deletion of immature B cells takes place in the bone marrow, whereas the deletion of autoreactive B cells occurs in the T-cell zones of the spleen and lymph nodes [85, 86]. Tolerance of B cells can be obtained *via* the lack of T-cell assistance and by "receptor editing," a mechanism that changes the specificity of the B-cell receptor when an autoantigen is encountered [87]. However, the relative importance of these mechanisms to the prevention of autoimmunity remains to be determined [88].

The main mechanism of T-cell tolerance is the deletion of self-reactive T cells in the thymus. Immature T

cells migrate from the bone marrow to the thymus, where they bind to peptides derived from autoantigens bound to MHC molecules. Only T-cell clones with an intermediate affinity for such complexes avoid apoptosis. The induction of central tolerance requires the presence of autoantigens in the thymus [89]. Because not all self-antigens exist in the thymus, peripheral mechanisms complete other aspects of peripheral T-cell tolerance by inhibitory mechanisms or deletion of autoreactive clones (*via* the Fas receptor) [90]. The importance of the thymus to the acquisition of a stable degree of tolerance was demonstrated by Saoudi *et al*. [91], who showed that thymectomy or split-dose irradiation to the thymus of adult mice induced latent insulin-dependent diabetes mellitus (IDDM) in a normally resistant strain of mice. Moreover, administration of $CD4^+CD8^-$ thymocytes prevented the development of IDDM in thymectomized and irradiated recipients, indicating that the thymus generates a T-cell repertoire that is highly effective in preventing tissue-specific autoimmune diseases. This process occurs in humans with multisystemic diseases as we learned from patients with myasthenia gravis who underwent thymectomy and developed aggressive SLE afterward [69–71]. Nevertheless, a normal thymus does not render us "autoimmune proof." In the thymus, complexes of self-peptides and self-MHC molecules delete one subset of autoreactive clones and select another subset of T cells. The second group leaves the thymus, enters the circulation, and can encounter complexes of MHC molecules with peptides derived from self-proteins not found in the thymus. T cells that react with such complexes are not destroyed but are tolerated by inactivation (anergy) or suppression by other cells [92].

One idea is that this state of peripheral tolerance is broken because of changes in immune response to environmental antigens and microorganisms. Structural similarity between microbial and self-antigens ("molecular mimicry") probably plays a key role in activating autoreactive T cells [90]. Considerable evidence ties infections with autoimmunity as in multiple sclerosis, catastrophic antiphospholipid syndrome, type 1 diabetes mellitus, and many other disorders [2, 23, 93, 94]. Some T cells recognize both microbial peptides and self-peptides with similar amino acid sequences. Additionally, the release of sequestered autoantigens following tissue damage and the activation of a large fraction of the T-cell population by superantigens consequently induce the secretion of inflammatory cytokines and costimulatory molecules, enhancing the autoimmune reaction [95–98]. Interestingly, infections are crucial for the development of protective T-cell clones, and depriving the immune system from combating infectious agents has also been associated with a higher frequency of autoimmune phenomena. Sasazuki *et al*. [99] reported that diabetes in NOD mice was increased by keeping the animals pathogen free and was decreased by a variety of treatments that activate T-cell responses. A similar finding was also reported in humans, multiple infections during the first year of life are associated with a significant reduction in the risk of autoimmune diabetes [100].

While class I molecules are expressed on all nucleated cells, the expression of MHC class II molecules is normally restricted to cells of the immune system. Not only the genetic composition of the MHC class II, but also changes in the amount of surface molecules determine the type and magnitude of antigen presentation, and hence the consequences of the immune response [101]. Therefore, their expression is tightly regulated. The appearance of such antigens can be induced *in vitro* mainly by interferon-γ (IFN-γ), and synergistically with tumor necrosis factor (TNF)-α, on a wide variety of nonimmunological cells, such as astrocytes, keratinocytes, melanocyte, and many other cell types. Expression of MHC class II molecules can be induced on tissue cells, including thyrocytes, during viral infection, independent of cytokine effects [102]. *In vivo* aberrant expression of MHC class II molecules has been observed on autoimmune and malignant tissue cells, including autoimmune and neoplastic thyrocytes [101].

Reovirus and cytomegalovirus have been demonstrated to induce MHC class II expression on cultured thyrocytes in the absence of T cells [103, 104]. A direct correlation between the high expression of MHC class II and the degree of the inflammatory response has been observed in autoimmune thyroiditis [105].

Population studies have demonstrated that Graves' and Hashimoto thyroiditis, as well as type 1 diabetes mellitus and many other autoimmune disorders, are associated with specific MHC class II alleles [101, 106]. The efficiency with which certain MHC classes II allotypes present autoantigens may affect either failure or success to mount a productive immune response, thereby determining the fate of the patient whether normal immune homeostasis will prevail or an autoimmune reaction will emerge.

Autoimmunity Induction by the Idiotype–Anti-idiotype Interaction

In the past decade a growing body of evidence has accumulated suggesting that the idiotype network may play an important role in the development of autoimmunity. The roots of this concept lie in the initial hypothesis postulated by Jerne (79) in 1974, stating that the immune response may be modulated via unique antigenic determinants of the immunoglobulin variable

region, e.g., its idiotype. We referred to it earlier in an attempt to explain the diversity of manifestations in SLE as dependent on the appearance of different idiotypes of autoantibodies.

One mechanism by which anti-idiotypes could become pathogenic and induce autoimmune diseases involves antireceptor antibodies as experimental myasthenia gravis, IDDM, and Graves' disease [15, 107]. An anti-idiotype that combines with the ligand-binding site at the variable region of the autoantibidy can mimic the ligand by specifically combining with their receptors. Such anti-idiotypic/antireceptor antibodies have been produced that bind to receptors for insulin [108], acetylcholine [107], thyroid-stimulating hormone [109], adrenergic catecholamines [110], and other ligands.

Consequently, the development of receptor-binding anti-idiotypic autoantibodies can be harmful to the host and initiate autoimmunity. Data support the idea that anti-idiotypes bearing an internal image of viral antigens participate in the induction of several autoimmune disorders. Indeed, it has been shown that myasthenia gravis developed in five individuals a few weeks after rabies virus vaccination [111]. Because the rabies virus has been shown to bind to the acetylcholine receptor [112], the antiviral response can induce anti-idiotype antibodies and bind to the acetylcholine receptor, thus indicating an autoimmune process.

The idiotypic network may be involved in the induction of autoimmunity in yet another mechanism, namely bypass of the suppressor arm of the immune system. The bypass mechanism is based on the demonstration that antigenic stimulation can induce the production of antibodies not directed against the challenging antigen, but sharing a cross-reactive idiotype (CRI). If the antibody sharing the CRI with the antigen-specific antibody is an autoantibody, an autoimmune response may result. Autoimmune reactions may be initiated by anti-idiotype antibodies triggered by environmental agents that share a CRI with autoantibodies. Anti-DNA antibodies and antibodies to *Klebsiella* have been shown to share a CRI, namely the 16/6 idiotype. Patients with *Klebsiella* infections have an increased incidence of high titers of 16/6 idiotype, and both the 16/6 idiotype and anti-*Klebsiella* antibodies can be absorbed by the *Klebsiella* K30 antigen [113].

It has been shown that immunization of different mice strains with either murine or human anti-DNA carrying the pathogenic 16/6 idiotype or with their anti-idiotypes resulted in the production of a wide array of lupus-associated antibodies (anti-ssDNA, anti-Sm, and anti-Ro/SSA antibodies). In parallel, the mice developed clinical findings consistent with human SLE, including an increased erythrocyte sedimentation rate, leukopenia, thrombocytponia, proteinuria, alopecia, and paralysis [75, 114, 115]. Another interesting animal model we developed was the experimental anti-phospholipid syndrome (APS) [116]. We demonstrated that immunization of naive mice with either human or mouse monoclonal or polyclonal anticardiolipin antibodies led to the production of anticardiolipin antibodies 3–4 months following administration of the antibody. Concomitant with the serological parameters, the immunized mice developed a prolonged activated thromboplastin time, thrombocytopenia, and a low fecundity rate with increased fetal resorptions upon mating. The hypercoagulable state was also manifested by the detection of multiple thrombi in some of the fetuses [116]. Idiotypic manipulation enabled us to produce an animal model of Wegener's granulomatosis-like disease as well [117]. This disease is a granulomatous disease that affects the upper respiratory tract, lungs, and kidneys. The disease is considered autoimmune due to its association with the antineutrophil cytoplasmic antibodies (ANCA), which is primarily detected against proteinase-3, a serine protease in neutrophil azurophil granules. Immunization of naive mice with ANCA-enriched IgG led to the production of mouse ANCA. Starting from 6 months following immunization, the mice developed signs of vasculitis, focal mononuclear infiltrates within the lungs, and granular deposition of immunoglobulins with glomeruli detected by immunofluorescence studies [117].

By immunizing mice with idiotypes of antithyroglobulin and antiglomerular basement membrane antibodies, we were able to produce clinical characteristics of a compatible autoimmune diseases as decreased thyroid hormone secretion and the appearance of erythrocyturia and proteinuria, respectively [118, 119]. These studies emphasize the important role that idiotypes play in the induction and pathogenesis of autoimmune diseases; however, this finding may also be used in order to divert the progression of one autoimmune condition to another.

As mentioned previously, we succeeded in preventing the development of diabetes in NOD mice by immunizing them with an anti-DNA antibody carrying the 16/6 id. Only 25% of the immunized mice developed diabetes in comparison to 90% of the control animals. Interestingly, the mice acquired a lupus-like syndrome regardless of their "usual" proneness to develop diabetes, pointing out that the "kaleidoscope phenomenon" can also be recruited by idiotypic manipulation and harnessed in order to avert the development autoimmune conditions [72].

Role of Cytokines in the Induction of Autoimmunity

Although both $CD4^+$ and $CD8^+$ T cells secrete cytokines, $CD4^+$ cells secrete them in significantly larger

quantities. $CD4^+$ T cells can be further subdivided by the patterns of cytokine released: Th1 cells produce interleukin-2 and IFN-γ, which are critical for cell-mediated immunity and acute allograft rejection, whereas Th2 cells produce IL-4, IL-5, IL-6, IL-9, and IL-10, which promote antibody production and humoral immunity [120]. IFN-γ and IL-12 are thought to be the most potent cytokines that enhance Th1 cell differentiation but they do not exert any effect on Th2 cells [122, 123]. However, IL-4 is a potent inducer of Th2 cells and is essential for their maturation, whereas the major role of IL-10 is to suppress the synthesis of Th1 cytolkines [124].

When naive T cells first exit the thymus they secrete both Th1 and Th2 cytokines (at that maturational phase they are termed Th0). After an antigen activates Th0 cells they turn into memory cells and become committed to a certain T-cell type. Both low and high antigen concentrations tend to induce Th2 responses preferentially, whereas intermediate doses induce Th1 responses. These mechanisms are likely part of the tolerance mechanisms mentioned in detail earlier; these pathways probably favor specific T-cell type responses.

The discovery of this polarized immune response is of great significance in the understanding of autoimmunity, and many efforts have been carried out in order to immunomodulate autoimmune disorders by tilting one T-cell type response to the other. Autoimmune conditions can be classified according to their dependence on Th1 or Th2 responses (Table 9). Th1 responses are involved primarily in the pathogenesis of organ-specific autoimmune disorders (experimental autoimmune encephalomyelitis, autoimmune thyroid disease, and type 1 diabetes mellitus) and acute allograft rejection. In contrast, allergic reactions involving IgE production and mast cell activation are typical Th2 responses. However, "classical" autoimmune diseases such as SLE and rheumatoid arthritis (RA) share Th1 and Th2 response characteristics [125].

Many abnormal cytokine concentrations were measured in SLE patients. Elevated concentrations of IL-2, IL-4, IL-6, IFN-γ, and TNF-α serum levels were detected [126]. A heterogeneous cytokine profile (high levels of IL-1β, TNF-α, and IL-10 and low levels of IL-2, IL-4, IL-6, and IFN-γ) was also reported in murine SLE models [125, 127]. We have described that repeated administration of IFN-γ to an experimental lupus model that was induced by the immunization of BALB/c mice with the 16/6 anti-DNA intensified the degree of clinical, histological, and serological parameters. All the laboratory parameters reflected acceleration of the disease in the IFN-γ-treated animals. An elevated sedimentation rate, a decreased white blood cell court, and the development of massive proteinurea meant worsened disease. IFN-γ unregulated the levels of typical Th2 cytokines and increased the number of IL-4 and IL-6 secreting splenocytes [128].

TABLE 9 Association between Autoimmune Diseases and T Helper Subtype

T helper subtype	Associated disease
Th1 cells	
	Autoimmune thyroid disease (Hashimoto's thyroiditis, Graves' disease)
	Multiple sclerosis (and experimental allergic encephalomyelitis)
	Insulin-dependent diabetes mellitus
	Crohns' disease
	Primary biliary cirrhosis
	Lyme's arthritis
	Recurrent abortions
	Yersinia reactive arthritis
	Contact dermatitis
	Acute allograft rejection
Th2 cells	
	Hypereosinophilic syndromes
	Allergic reactions
Heterogeneous Th1 and Th2 cytokines	Systemic lupus erythematosus
	Rheumatoid arthritis
	Primary systemic vasculitis
	Myasthenia gravis
	Sjogren's syndrome

Llorente *et al*. [129] assessed the clinical efficacy of administering an anti-IL-10 monoclonal antibody to six SLE patients with active steroid-dependent disease. In all the patients, cutaneous lesions and joint symptoms improved with the beginning of anti-IL-10 administration and a decrease of the steroid dosage continued during the 6 months of follow-up. The SLE disease activity index decreased markedly from a mean ± SEM of 8.83 ± 0.91 on day 1 to 1.33 ± 0.80 with only one of the six patients remaining clinically active.

Abnormal IFN production has been found in SLE patients. This cytokine has a role in the upregulation of major histocompatibility complex class II molecules and in this way contributes to the pathogenesis of autoimmunity [130]. The B-cell hyperactivity found in SLE and in other autoimmune diseases may be related to a generic increase in Th2 cytokines. However, it has been shown that IL-6 production in SLE can take place in cells other than T cells and that excessive IL-10 levels are actually produced in monocytes and B cells rather than in T lymphocytes [131].

Success in diverting the course of autoimmune models was achieved with recombinant IL-4 in rat experimental autoimmune uveoretinitis [132] and with anti-IFN-γ in experimental autoimmune thyroiditis and collagen-induced arthritis [133, 134]. Nowadays, many efforts are made in attempts to develop medications

that target cytokines that are seminal to the formation of the autoimmune process.

Inobe *et al*. [135] unraveled some of the complexity of this cytokine equilibrium using experimental allergic encephalomyelitis (EAE) as a model. They showed that T cells generated from gut-associated lymphoid tissue can suppress the eruption of EAE following oral administration of the myelin basic protein (MBP). These regulatory T cells (also termed Th3 cells) are known to produce TGF-β with various amounts of IL-4 and IL-10. Interestingly, treatment of (PLJ × SJL)F1 mice with intraperitoneal or oral IL-4 with low-dose oral MBP reduced the severity of EAE, whereas injection of IL-4 alone or oral MBP alone given in these suboptimal doses showed no protection. Spleen cells from protected mice produced increased amounts of TGF-β and reduced IFN-γ upon stimulation with MBP *in vitro*. Moreover, mucosal MBP-specific IgA production was increased significantly in IL-4 plus MBP-fed animals. Their findings demonstrated that IL-4 is a differentiation factor for TGF-β-secreting Th3 cells.

Similar results have been obtained employing oral tolerance in our mouse model of APS [induced by immunizing with β2-glycoprotein I (β2GPI)] [136]. Promising outcomes have been reported on the administration of TNF-α inhibitors to patients with long-standing refractory RA [137, 138]. In the near future, similar agents will be part of the therapeutic arsenal of many autoimmune conditions.

Autoimmunity and MHC: Dissecting the Molecular Basis

The susceptibility to many autoimmune conditions was mapped to genes of the human and murine MHC [14, 15, 139].

Some autoimmune diseases are tightly related to a genetic defect such as an autoimmune lymphoproliferative syndrome, the syndrome of autoimmune polyglandular endocrinopathy with candidiasis and ectodermal dysplasia (APECED) [140, 141].

However, most autoimmune disorders are polygenic by nature with multiple susceptibility genes working in concert to produce the autoimmune condition. Mostly the diseases manifest with the presence of other predisposing factors. Some genes confer a higher risk than others, whereas others are protective by nature; e.g., the major histocompatibility complex makes an important contribution to disease susceptibility or protection [14, 15]. Tissue typing was first confined to class 1 HLA molecules, and in type 1 diabetes mellitus, it was initially correlated with HLA-B8 and B-15 antigens. A subsequent discovery of class II MHC antigens revealed stronger associations with HLA-DR3 and -DR4 class II antigens with the disease. It is now known that the HLA-DQB1*0602 allele protects against type 1 diabetes even in individuals with coexisting HLA-DQB1*0301 or DQB1*0302 genes that act as predisposing genes [142, 143]. There is a variance between HLA alleles and a particular disease in relation to different ethnic populations and that may vary among different populations. SLE in Europeans is associated with allele B8 at the HLA-B locus, allele *0501 at the DQA1 locus, and with alleles DR2 and DR3 at the HLA-DR locus. Risk ratios associated with DR3 loci are generally similar in African-Americans (2.7) to the risk ratios in Europeans (2.4) [143].

Studies in transgenic mice have led to the discovery of numerous genes that contribute to the pathogenesis of autoimmune conditions. These genes encode cytokines, antigen coreceptors, cytokine ligands, molecules involved in pathways that promote apoptosis, and other important molecules. Because they have either stimulatory or inhibitory effects, their deletion or overexpression results with either amplification or amelioration of the autoimmune cascade. These research outcomes will join other biological therapies that find their place in the treatment of autoimmune diseases.

Apoptosis and Its Role in Autoimmunity

Apoptosis is an active cell death process essential for a large spectrum of physiological functions, including T-cell—mediated cytotoxicity and immunosurveillance. Whenever normal apoptosis function is impeded, deviation from normal immune homeostasis may emerge, manifesting as neoplasm or autoimmunity. Concentrations of self-antigens depend, among other factors, on the clearance rate of apoptotic cells. During apoptosis, the cell membrane forms cytoplasmic blebs, some of which are shed as apoptotic bodies. Casciola-Rosen *et al*. [144] and Rosen and Casciola-Rosen [145] have shown that UV-induced apoptosis of keratinocytes leads to a redistribution of several autoantigens to apoptotic blebs. Phosphatidylserine, an acidic phospholipid autoantigen that normally resides on the inside of the cell, flips outward while the cell undergoes apoptosis [146]. Interestingly, immunizing mice with apoptotic cells induced autoantibody formation [147]. The hypothesis that apoptosis is one of the mechanisms that lead to the development of SLE provides a possible solution to some long-standing enigmas. The traditional intracellular boundaries in apoptosis lose their significance as nuclear, cytosolic, and membranous materials undergo structural modification blebs, which are partially presented to the outer surface [148]. The acceleration of apoptotic processes following viral infections

and sunlight exposure may also elucidate their linkage to SLE [149]. Association between the lupus-like syndromes of patients or mice and inherited deficiencies of complement components (particularly Clq and C4) may be explained by their impaired capability to clear apoptotic cells [150].

The presumed linkage between apoptosis and SLE has led many investigators to unravel this association via genes that take part in this apoptosis. Analysis of the genetic background of Mexican-American lupus patients disclosed a synergistic effect between alleles of the IL-10 and bcl-2 genes in determining the susceptibility to SLE [151]. However, it seems that this finding has ethnic correlates, as similar results were not obtained in Italian patients [152].

Apoptotic cells were initially regarded as anti-inflammatory because they inhibit the liberation of proinflammatory molecules by macrophages; it is now well known that some forms of apoptosis can be inflammatory and can induce dendritic cell maturation, particularly when apoptotic cells are coated with antibodies [153].

One of the most important antigens involved in apoptosis is Fas. Fas is a transmembranous receptor belonging to the TNF/nerve growth factor receptor superfamily [154]. The Fas ligand is also a transmembranous protein that induces apoptosis by binding to the Fas receptor. Suzuki *et al*. [155] reported that 33% of SLE patients have anti-Fas ligand antibodies in their sera. This interaction has an inhibitory effect on Fas–Fas ligand-mediated apoptosis. This finding might be one of the mechanisms that promote autoreactivity by Fas-positive lymphocytes from apoptosis observed so commonly in SLE [155].

USING THE PRINCIPLES OF AUTOIMMUNITY TO DESIGN THERAPEUTICS

Modulation of the Idiotypic Network as a Possible Treatment Approach to Autoimmune Diseases

The realization that the expression of idiotype-bearing antibodies is regulated by anti-idiotypes [79] has led to a new approach to the treatment of autoimmune diseases via manipulation of idiotype–anti-idiotypes interactions. Essentially, the idea is very simple; to suppress the production of autoantibodies bearing pathogenic idiotypes by immunizing with specific anti-idiotypes. This in turn can prevent the damage produced in target organs by the pathogenic idiotypes. Kim *et al*. [156] demonstrated that anti-DNA production by anti-DNA-secreting hybridomas can be inhibited by the addition of anti-idiotypes to anti-DNA. Anti-idiotypic therapy has been shown to suppress autoantibody synthesis in various experimental models of autoimmune diseases, including autoimmune thyroiditis and autoimmune tubulointerstitial nephritis [157, 158]. In lupus mice, models of unequivocal findings were reported. Immunization of MRL mice with an anti-idiotype directed against H-130 (a dominant idiotype of MRL anti-DNA antibodies) augmented the production of the H-130 idiotype and anti-DNA antibodies, whereas others abrogated anti-DNA production, immunizing them with another anti-idiotype carried by an anti-DNA natural autoantibody [159, 160]. This conflicting evidence can be elucidated if we accept that diverse anti-idiotypes regulate idiotype-bearing autoantibodies in various ways: some acting to suppress idiotype expression, whereas others amplify its production.

Another method used to manipulate the idiotypic network is to produce anti-idiotypes by active immunization with the idiotype instead of passive administration of the anti-idiotype. As mentioned previously, we have generated a lupus-like mouse model by immunization with an anti-DNA antibody carrying the 16/6 idiotype. In order to potentiate the effects of anti-idiotypes, we have conjugated a widely used toxic compound termed saporin to an anti-idiotype to the 16/6 id. The suppressive impact of this treatment was specific: *in vitro* the idiotype synthesis was halted and *in vivo* therapy diminished the clinical manifestations and decreased the level of the autoantibodies in the mice sera [161].

Although anti-idiotypic therapy has not been accepted as a therapeutic modality for human disease, it is believed that an abundance of idiotypes within preparations of intravenous γ-globulin infusion (IVIG) is one of the mechanisms that confer an inhibitory effect on autoimmunity.

Intravenous Gamma Globulin Infusion

Intravenous immune globulin has been used to treat primary and secondary antibody deficiencies since the mid-1970s. It is composed of IgG pooled from plasma originating from a large number of blood donors. This pooling of intact antibodies entails the basic characteristics of the IVIG preparation [162].

1. *Fc receptors.* An intact immunoglobulin ensures appropriate interactions of all the components of the molecule, e.g., the Fc portion can bind to complement components or with the Fcγ receptor and it may block Fc receptors on macrophages and

effector cells and induce antibody-dependent cellular toxicity.
2. *Inflammation.* IVIG attenuates and decreases the damaged caused by complement-mediated processes, it has the capacity to induce anti-inflammatory cytokines and abrogates the activation of endothelial cells, and it neutralizes microbial toxins.
3. *B-cell regulation.* IVIG can control the B-cell repertoire via the idiotypic network. Selectively, it can down- or upregulate antibody production by specific B-cell clones. In mice, IVIG administration controlled the migration of B-cell populations from the bone marrow to secondary lymphoid organs.
4. *T-cell regulation.* IVIG plays a role in the modulation of T-cell cytokine synthesis. IVIG was shown to selectively decrease the production of IL-2 and IFN-γ by antigen-reactive T cells. IVIG also has the ability to restore the balance between Th1 and Th2 responses various autoimmune conditions.
5. *Cell growth.* As mentioned earlier, IVIG via antibodies to antigens that have key roles in apoptosis can modulate cell proliferation. This mechanism implies that IVIG therapy may have be promising in cancer therapy [163].

Since this primal report of Shulman *et al*. [164], who reported on a positive response to fresh frozen plasma infusions in patients with chronic thrombocytopenia, IVIG therapy has been studied extensively and found to confer significant benefits to patients with autoimmune conditions such as idiopathic thrombocytopenic purpura (ITP), Guillian–Barre syndrome, myasthenia gravis, Kawasaki's syndrome, corticosteroid-resistant polymyositis, autoimmune uveitis, multiple sclerosis, and vasculitis [165–172].

Rheumatoid Arthritis

RA remains the most controversial indication for IVIG. Despite a few encouraging open study reports, results from controlled trials have not shown a significant effect. However, none of these studies were carried out with high-dose IVIG (2 g/kg). More impressive results were achieved in adult Still's disease and in juvenile rheumatoid arthritis [173, 174].

SLE

Corvetta *et al*. [175] described successful treatment with IVIG in three patients with life-threatening manifestations of SLE (encephalitis, nephritis) unresponsive to conventional high-dose corticosteroids or immunosuppressive therapy. We reported on various manifestations of SLE that responded favorably to treatment with IVIG: 7 patients with lupus nephritis that failed on therapy with cyclophosphamide and prednisone had good responses to six courses of IVIG [176]. We measured the effect of IVIG therapy on 20 patients with SLE. A beneficial clinical response following IVIG treatment was noted in 17 out of 20 patients (85%). Few clinical manifestations responded more favorably to treatment: arthritis, fever, thrombocytopenia, and neuropsychiatric lupus. In 9 of the patients that were evaluated before and after IVIG, a significant decrease in the mean systemic lupus activity measure (SLAM) score was recorded [177].

Antiphospholipid Syndrome

The employment of IVIG in the treatment of antiphospholipid syndrome was considered after demonstration of the potential of IVIG to neutralize lupus anticoagulant LA activity *in vitro* [178]. As IVIG appeared less toxic in pregnant women than prednisolone, most of the reports focus on the use of IVIG in the obstetric complications of antiphospholipid syndrome. The use of IVIG either alone or in combination with aspirin or heparin resulted in a successful pregnancy outcome in the vast majority of patients with antiphospholipid syndrome who had previously had recurrent abortions. Also, IVIG was beneficial in antiphospholipid antibody-positive patients undergoing *in vitro* fertilization. We have reported on the favorable outcomes of treatment with IVIG in our experimental models of APS and lupus [179].

Other Diseases

IVIG therapy was reported to favorably affect patients with insulin-dependent diabetes mellitus; however, the results were not based on large population studies and the reported follow-up was of short duration [180]. Successful reports indicate that IVIG therapy may have a pertinent role in the treatment of thyroid ophtalmopathy even in cases in which immunosuppressive therapy failed [181]. Similar tendencies have been documented after IVIG treatment of patients with chronic inflammatory demyelinating polyneuropathies and multiple sclerosis [182]. IVIG is a safe therapeautical agent; we reported that among 56 patients with various autoimmune diseases treated with IVIG, 20 (36%) had at least one adverse reaction (headache, low-grade fever, chills, anemia, low-back pain, transient hypotension, nausea, diaphoresis, and superficial vain thrombosis). These reactions were mostly mild and transient and were not correlated with the patients' response to the therapy [183].

Oral Tolerance

Oral tolerance refers to the observation that oral administration of an antigen followed by immunization might evoke a state of hyporesponsiveness to the specific antigen. Low doses of antigen administration favor the induction of active cellular regulation, whereas higher doses favor the induction of clonal anergy or deletion [184–186]. Active suppression is mediated by the induction of regulatory T cells in the gut-associated lymphoid tissue (GALT). These cells migrate to the systemic immune system and secrete Th2-type cytokines as TGF-β, IL-4, and IL-10 that suppress the immune reaction [187]. Benson *et al.* [188] demonstrated the downregulation of T-cell receptors as an immediate but reversible effect following high-dose feeding of mice with myelin basic protein (MBP). Carrying a detailed analysis of cytokine responses following a single high-dose feeding, they found that on day 1 there was an increase in the number of cells expressing IL-2, IFN-γ, IL-5, and IL-4, followed by their subsequent decrease and apparent deletion by day 14, a consequence of apoptosis. Cells secreting TGF-β, referred to as Th3 cells, have been implicated in the maintenance of oral tolerance [189]. These cells were distinctive in that they were not deleted following oral exposure to MBP. This effect was associated with protection from experimental autoimmune encephalomyelitis [188].

The promising prospects of oral tolerance in the treatment of autoimmune conditions were shown in our mouse model of APS (induced by immunizing with β2GPI [136]. Oral tolerance was induced in BALB/c mice by feeding low-dose β2GPI. β2GPI-fed mice did not develop serologic or clinical markers of experimental APS upon immunization with the autoantigen. β2GPI given orally before priming with β2GPI resulted in complete prevention of experimental APS development; β2GPI given at an early stage of the disease reduced clinical manifestations, whereas administration of β2GPI 70 days postimmunization conferred a less significant effect. Tolerized mice exhibited a diminished T lymphocyte proliferation response to β2GPI in comparison with β2GPI-immunized mice fed ovalbumin. When nontolerant β2GPI-primed T lymphocytes were mixed with T lymphocytes derived from tolerized mice, a significant inhibition of proliferation upon exposure to β2GPI was observed. Furthermore, $CD8^+$ T cells adoptively transferred the tolerance from the tolerized mice into naive mice.

Several teams worldwide have reported on successful trials suppressing animal models of EAE, collagen-induced arthritis, experimental autoimmune uveoretinitis, myasthenia, and diabetes in NOD mice by the oral administration of the inducer autoantigen [188, 190, 191].

Human trials have shown some success in patients with juvenile rheumatoid arthritis, rheumatoid arthritis, and uveoretinitis [192–194]. However, in multiple sclerosis and type 1 diabetes, patients' oral administration of a myelin preparation and insulin using different doses, respectively, failed to block progression of the disease [195, 196].

Despite the preliminary phase in which clinical trials seem to appear very challenging due to the simplicity of administration and lack of adverse effects, further progress in this field is expected in the near future.

HEMOPOIETIC STEM CELL TRANSPLANTATION IN AUTOIMMUNE DISEASES

Almost a decade ago Yin and Jowitt [197] described two patients with a long history of psoriasis and ulcerative colitis who received allogenic bone marrow transplantation (BMT) for leukemia. Four years posttransplantation they remained in full remission of psoriasis and ulcerative colitis and their leukemia.

The ability to transfer autoimmune disease to normal animals by the infusion of hemopoietic stem cells opened new avenues for investigating the pathophysiology of autoimmunity, as well as for altering this modality into an optional therapeutic intervention in established autoimmune processes. The substantial risk of morbidity and mortality associated with allogeneic BMT has so far prevented its application in the treatment of patients with severe autoimmune disease. In contrast, the lower complication rate (3–5% mortality risk) of autologous transplants justified trying this approach in patients with severe autoimmune disease who were refractory to current treatments, particularly among those with a severe and refractory course [198].

It is believed that BMT confers its effect by the following mechanisms.

1. Eradicating autoreactive mature and progenitor cells that contribute to the autoimmune condition, replacing them with a normal immune system.
2. Reducing the number of autoreactive cells to low levels that allow self-tolerance to overcome.
3. Altering immunoregulatory circuits by the use of cytotoxic agents to reestablish more efficient immune control mechanisms.

Several individual cases and a phase I study including patients with severe SLE treated with autologous stem cell transplantation have been published. SLE remained clinically inactive in all cases, sometimes after

more than 2 years [199, 200]. Tyndall and Gratwohl [201] reviewed the outcome of BMT in around 350 patients with multiple sclerosis, systemic sclerosis, rheumatoid arthritis, juvenile idiopathic arthritis, idiopathic thrombocytopenic purpura, and SLE. The procedure-related mortality was around 9% (being higher in systemic sclerosis and juvenile idiopathic arthritis). A benefit has been recorded in around two-thirds of cases.

Peptide Immunotherapy

$CD4^+$ helper T lymphocytes and $CD8^+$ cytotoxic T lymphocytes play major roles in the normal activation of the immune system to foreign antigens. These cells are triggered when their specific T-cell receptors (TCRs) recognize foreign antigenic peptide fragments hound to MHC molecules. $CD8^+$ T cells usually recognize peptides complexed to class I MHC molecules, whereas $CD4^+$ T cells usually recognize peptides complexed to class II MHC molecules. The activated T helper cell consequently secretes diverse cytokines that conduct the type of the immune reaction. The current understanding of the role of T cells in the immune response has led extensive research in attempts to modulate these steps and to alter disease outcome.

One of the major breakthroughs that was accomplished with peptide immunotherapy was obtained with copolymer I (cop 1, glatiramer acetate, *Copaxone*). Cop I, a synthetic amino acid copolymer, synthesized randomly from a pool of four amino acids—L-glutamic acid, L-alanine, L-lysine, and L-tyrosine—immunologically simulates myelin basic and was shown to suppress experimental autoimmune encephalomyelitis in mice when administered parenterally [203]. The beneficial effect of oral cop I was associated with specific inhibition of the proliferative and cytokine secretion responses of Th1 cells to MBP. The tolerance induced by cop I was adoptively transferred with spleen cells from cop I-fed animals and cop I-specific T-cell lines that inhibited EAE induction. These T-cell lines secreted IL-10 and TGF-β in response to both cop I and MBP. Therefore, oral cop I has a beneficial effect on the development of EAE that is associated with the down-regulation of T-cell immune responses to MBP [204]. In MS patients, a 29% reduction in attack frequency was observed over the 2 years of treatment with cop I, which became a 32% reduction when a 6-month extension of the trial was taken into account [205].

Singh *et al*. [205] examined the possibility that in mice with SLE, autoantibody molecules may be upregulating their own production by autoactivation of self-reactive T cells to their own processed peptides. They demonstrated that lupus-prone (NZBINZW)Fl (BWFl) mice developed spontaneous T-cell autoimmunity to peptides from variable regions of heavy chains (VH) of syngeneic anti-DNA MAbs. Tolerizing young BWFl mice with intravenous injections of autoantibody-derived determinants substantially delayed the development of anti-DNA antibodies and nephritis and prolonged survival. Thus, in such an autoantibody-mediated disease, the presence of autoreactive T cells against VII region determinants of autoantibodies may represent an important mechanism involved in the regulation of autoimmunity, hence tolerizing such autoreactive T cells might postpone the development of SLE.

In the (SWR x NZB)F1 mouse model of lupus, treatment with peptides corresponding to the critical autoepitopes (localized in the core histones of nucleosomes) markedly delayed the onset of severe lupus nephritis. Chronic therapy with the peptides injected into older mice with established glomerulonephritis prolonged survival and even halted the progression of renal injury [206].

Waisman *et al*. [207] employed a model of murine SLE induced by active immunization with a pathogenic anti-DNA MAb bearing the 16/6 idiotype. Strain-dependent differences were observed in the proliferative responses of lymph node cells of mice immunized with two peptides based on the sequences of the complementarity-determining region (CDR) I and 3 of a pathogenic anti-DNA monoclonal antibody. Immunization of high responder strains with the CDR-based peptides led to the production of autoantibodies and clinical manifestations characteristic of experimental SLE. The CDR-based peptides, however, could prevent autoantibody production in neonatal mice that were immunized later with either the peptide or the pathogenic autoantibody. Furthermore, the peptides inhibited specific proliferation of lymph node cells of mice immunized with the same peptide or with the pathogenic anti-DNA monoclonal antibody.

We have three hexapeptides that react specifically with anti-β2GPl MAbs that elicited endothelial cell activation and induced experimental APS. The peptides specifically inhibited both *in vitro* and *in vivo* the biological functions of the corresponding anti-β2GPl MAbs. Exposure of endothelial cells to anti-β2GPl MAbs and their corresponding peptides led to the inhibition of endothelial cell activation, as shown by a decreased expression of adhesion molecules and monocyte adhesion. *In vivo* infusion of each of the anti-β2GPl MAbs into BALBIc mice, followed by administration of the corresponding specific peptides, prevented the peptide-treated mice from developing experimental APS [208].

Five prospective clinical studies in lupus patients have shown that the LJP 394 peptide can reduce circulating anti-dsDNA antibody levels without causing gen-

eralized immunosuppression. The compound is currently being evaluated in a phase III clinical trial for the prevention of renal flares in patients with high-affinity antibodies to LJP 394 and a history of lupus nephritis [209]. These studies reflect that the use of synthetic peptides that focus on neutralization of the immune response may entail new avenues to the therapy of autoimmune diseases [210].

What Are We Expecting in the Future?

Despite the complexity of the mechanisms that are engaged in the induction of autoimmunity, this decade will be remembered as the period in which modern therapeutic modalities, mainly those impeding seminal steps of the immune response, have emerged. IVIG and the exploitation or the principles of oral tolerance seem promising. However, other novel therapeutic avenues such as bone marrow transplantation, immunomodulation by drugs and peptides, and utilization of MAbs directed against essential components of effector cells are undergoing great change and are encountered more commonly as medications seen at the patient bedside. We believe that all these advances will lead to more progress in the comprehension and combat against autoimmune diseases, turning the therapeutical measures we employ today more specific, targeting precise steps of the autoimmune reaction [211].

OVERVIEW OF CELLULAR IMMUNE FUNCTION IN SYSTEMIC LUPUS ERYTHEMATOSUS

George C. Tsokos

INTRODUCTION

Systemic lupus erythematosus (SLE) is considered a prototypic human autoimmune disease, which manifests itself with a variety of fascinating clinical and immunological features. Although the causes of SLE, and autoimmunity in general, remain unknown, considerable evidence has been accumulated on the pathophysiologic mechanisms, which lead to the failure of distinction between self and self +X and the production of autoantibodies. Genetic, hormonal, and environmental factors have been attributed certain roles in the etiology of autoimmunity. Both cellular and hormonal abnormalities have been identified and participate in the pathogenesis of SLE. Our understanding of the nature of these abnormalities has advanced along with our perception of the complexity of the immune system. In human autoimmune disease, immune aberrations vary from the production of a single autoantibody in the absence of any other detectable immune abnormalities to the production of multiple autoantibodies accompanied by universal derangement of the immune system. An example of the former case is membranoproliferative glomerulonephritis, which is characterized by the production of a unique antialternative pathway C3 convertase [1]. The latter is typified by SLE.

Our concept of autoimmunity has evolved gradually over the past century. The immune response against self was considered harmful ("horror autotoxicus") at the turn of the century [2]. In an effort to explain the prevention of self-reactivity, Burnet formulated a hypothesis according to which autoreactive clones ("forbidden clones") are eliminated during the ontogenic process [3]. Data have provided evidence that the autoimmune response is part of the normal immune response [4].

Current concepts on the cellular basis of autoimmunity include a deficit in the active process of immune regulation [5–7], participation of oligoclonal (restricted) T-cell populations [8], selection or exclusion of parts of the T-cell receptor (TCR) repertoire, which leads to the expression of "forbidden," autoreactive TCR genes [9, 10], genetic factors [11–13], defects in apoptosis [14, 15], aberrations in costimulation [16–19], abnormalities in lymphokine production [7, 20–23], and abnormalities in immune cell signaling and gene transcription [24–26].

Our efforts to understand the contribution of cellular abnormalities in the immunopathogenesis of SLE are further complicated by (a) the clinical heterogeneity of the disease; (b) patient sampling, which is particularly true when most reports are made on one or two dozens of patients; (c) the heterogeneity in the nature of the prevailing autoantibodies and their presumed ability to alter immune cell function; (d) the fact that the deranged immune response may become normalized during periods of disease inactivity; and (e) drugs that are frequently used in the treatment of SLE patients modulate the immune response and thus complicate patient sampling and interpretation of the results that are obtained from *in vitro* studies.

This chapter attempts to provide the reader with a complete systematic description of the cellular immune defects and aberrations that have been reported in SLE and discusses their relative contribution to the pathophysiology of the disease.

MONOCYTE/MACROPHAGE FUNCTION

Macrophages/monocytes serve, along with B lymphocytes and dendritic cells, as antigen-presenting cells (APC). Macrophages express major histocombatibilty genes (MHC) class II molecules that are recognized by the helper/inducer T cells in conjunction with processed antigen fragments.

Monocytes from patients with SLE display diminished phagocytic activity that does not increase upon stimulation *in vitro* with lipopolysaccharide [27]. Serum factors and particularly circulating immune complexes may be responsible for the deficient phagocytic function in lupus patients.

Monocytes from patients with SLE produce decreased amounts of interleukin (IL)-1 [28]. This defect can be corrected by indomethacin, indicating that excessive prostaglandin production suppresses the production of IL-1. Production of IL-1β by stimulated and nonstimulated SLE monocytes is decreased regardless of disease activity [29]. Activated monocytes produce prostaglandins (PGE2), which inhibit IL-1 production [30], mononuclear cells produce a glycoprotein inhibitor of the action of IL-1 [30], and immune complexes stimulate monocytes to produce IL-1 and the IL-1 inhibitor [31]. It is unclear why in the presence of huge amounts of circulating immune complexes SLE monocytes do not produce the IL-1 receptor antagonist. Molecular data are needed to interpret the role or the cause of deficient IL-1 production in monocyte dysfunction in SLE.

The percentage of monocytes in Ficoll-isolated peripheral mononuclear cells (MNC) from patients with SLE is higher than that from normals (detected by staining with α-naphthylesterase, unpublished experiments [27]). Removal of monocytes from culture systems that were set up to test a number of cellular immune functions *in vitro* has led to the amelioration of defective responses [32]. Reduction of the percentage of monocytes improves the proliferative response of lupus MNC to PHA [33, 34], the proliferative response in autologous mixed lymphocyte reaction (AMLR) [35], the pokeweed mitogen-induced immunoglobulin (Ig) synthesis by SLE MNC [36], the mixed lymphocyte reaction proliferative response and T lymphocyte-mediated lympholysis [37], the pokeweed mitogen-induced plaque-forming cell responses of peripheral SLE MNC [38], the anti-DNA antibody synthesis [39, 40], and the Ig production by lupus B cells [41]. SLE monocyte-derived culture supernatants inhibit profoundly normal T-cell responses [34]. These experiments indicate that *in vivo*-preactivated monocytes secrete prostaglandins and/or other inhibitory molecules that interfere with the *in vitro* function of lymphocytes. Adjustment for optimal numbers of monocytes in various culture systems is hence mandatory to avoid improper evaluation of experimental data. Indeed, the production of eicosanoids such as PGE_2 and thromboxane B_2 by SLE monocytes is increased [42].

Peripheral blood monocytes from patients with active disease exhibit decreased expression of surface human leukocyte antigen (HLA)-DR antigens and decreased accessory function for T-cell activation [43–46]. *In vitro*, SLE sera reduce the accessory function of normal monocytes. This suggests the existence of circulating factors (anti-macrophage antibodies [47], immune complexes, or other) that are responsible for the impaired macrophage function in patients with SLE. Does SLE serum affect the function of monocytes? Some reports indicate that SLE serum is toxic to monocytes and prohibits its function and differentiation [46], whereas others have suggested that SLE serum promotes monocytes differentiation to dendritic cells [48]. The latter report attributed the effect of the SLE serum on the presence of interferon (INF)-α. The production of INF-α has been claimed to be increased by earlier reports [49] and the previously mentioned report and decreased by others [50]. Reasons for the diversity in the reported levels of interferon-α are many, including technical and patient cohort differences. Reasons for the reported increased differentiation or lack thereof are unclear. The most obvious explanation may relate to the fact that the report by Blanco *et al*. [48] included only pediatric patients with SLE.

SLE monocytes cultured in optimal percentages with allogeneic or autologous T lymphocytes express a decreased ability to induce a proliferative response. Prothymosin-α, a thymic preparation, normalizes these responses by direct action on monocytes [51]. A similar defect, also correctable by prothymosin-α, has been described in patients with multiple sclerosis. Monocytes from patients with multiple sclerosis have decreased numbers of surface membrane HLA-DR molecules. Decreased HLA-DR expression on the surface membrane of monocytes from patients with multiple sclerosis is associated with decreased AMLR [52]. Preculture of monocytes from multiple sclerosis patients with prothymosin-α enhances DR expression and normalizes the AMLR response [53]. More definitive data are needed to establish the status of expression of DR

TABLE 1 Macrophage Function in SLE

Decreased MHC class II surface expression
Decreased expression of costimulatory molecules (CD80)
Decreased expression of CD44 and Fcγ receptors
Increased production of eicosanoids
Decreased production of IL-1β and receptor antagonist
Increased spontaneous apoptosis
Decreased ability to stimulate in AMLR
Increased propensity to differentiate to dendritic cells
Increased suppressor cell function of *in vitro* immune cellular responses
Decreased phagocytosis

molecules on the surface of lupus monocytes and their role in the development of the disease. Defects in the expression of costimulatory molecules (CD80, B7-1) are discussed later. Peripheral blood monocytes from lupus patients display increased rates of spontaneous apoptosis [54]. Apoptosis of lupus cells is also discussed later.

In conclusion (Table 1), lupus monocytes produce less IL-1 and express decreased amounts of surface HLA-DR antigens and possibly costimulatory molecules. These abnormalities may interfere with their ability to process and present antigen and provide appropriate costimulation to lymphocytes. Decreased phagocytic function may contribute to the established [55] increased susceptibility of lupus patients to infections.

The expression of CD44, a molecule believed to participate in the clearance of apoptotic cells, is decreased in patients with SLE [56]. Decreased clearance of apoptotic debris can contribute to excessive stimulation of immune cells in SLE. Decreased expression of Fcγ receptors (II and III) may also account for the decreased clearance of immune complexes [57] and antibody-covered apoptotic bodies.

DENDRITIC CELLS

The numbers and function of dendritic cells have been studied in patients with SLE. Two studies present opposing results. In the first one, dendritic cell numbers, defined as $Lin^{-}DR^{+}CD4^{+}$ cells, and function, evaluated in a mixed lymphocyte reaction, were decreased in patients with SLE. In addition, the surface expression of B7 and CD40 was reduced in SLE dendritic cells [58]. In the second study, both the numbers and function of dendritic cells were found to be increased [48]. Besides methodological differences, the fact that the first study used adults whereas the second one used children with SLE may account for the differences. If dendritic cell function proves to differentiate pediatric and adult lupus SLE, then more studies will be needed to understand the differences between the two disease subsets.

TABLE 2 Overview of T Cell Abnormalities in Patients with SLE

T-cell numbers
T lymphopenia
Increased numbers of $DR^{+}CD4^{+}$ and DR^{+} $CD8^{+}$
Increased numbers of $CD3^{+}CD4^{-}CD8^{-}$ cells
$CD4^{+}$ T-cell epitope deficiency
T-cell function
Increased helper cell activity expressed by both $CD4^{+}DR^{+}$ and $CD3^{+}CD4^{-}D8^{-}$ cells
Normal concanavalin A suppressor cell function of polyclonal B-cell responses
Deficient concanavalin A-induced suppressor cells of antigen-specific responses
Deficient EBV-associated suppressor/cytotoxic cell function
Anti-T-cell antibodies
Anti-$CD4^{+}$ antibodies
Anti-$CD8^{+}$ antibodies
Antiblast T-cell antibodies
Anticytotoxic T-cell antibodies
Anti-NK cell antibodies
Anti-lupus-associated membrane protein (LAMP)
Anti-CD45 antibodies

T LYMPHOCYTES

T-cell abnormalities are multiple and prominent in patients with SLE. T-cell abnormalities are crucial in the pathogenesis of the disease because T cells regulate B-cell function and the production of most of the pathogenic autoantibodies is T cell dependent. T lymphocyte abnormalities in patients with lupus are summarized in Table 2.

Lymphocyte Numbers

Lymphopenia is common in SLE and its severity relates to disease activity [59–61]. Peripheral B lymphocytes are present in normal numbers, whereas the absolute number of T lymphocytes is decreased. The decrease is often marked in the suppressor/cytotoxic lymphocyte subpopulation as defined by the presence of cell surface markers recognized by monoclonal antibodies or appropriate functional assays. The number of circulating helper T lymphocytes (Tμ, $OKT4^{+}$, $Leu\text{-}3A^{+}$, $CD4^{+}$) is less affected. A preferential loss of a subset of

T lymphocytes with the higher density of cell surface markers has been reported [62]. Anti-T lymphocyte antibodies have been found in SLE sera and may be responsible for the elimination of T cells [63–66]. The ratio of helper/suppressor cells in SLE has been reported to be increased in a nonconsistent manner. In one of the studies, low, normal, and high ratios were found in 25, 50, and 25% of patients, respectively [67]. Other investigators have reported that the most commonly observed abnormality in untreated patients with active SLE is a relative decrease in $CD4^+$ (helper/inducer) lymphocytes, whereas decreased percentages of $CD8^+$ (suppressor/cytotoxic) cells were observed in less than 10% of more than 100 patients with SLE [68].

The OKM1 monoclonal antibody recognizes an epitope of the CR3 (receptor binding iC3b). CR3 is expressed on macrophages, monocytes, glanulocytes, and natural killer (NK) cells [69, 70]. A subpopulation of $CD3^+$ lymphocytes also carries an antigen recognized by the OKM1 monoclonal antibody [71]. Ficoll-prepared MNC from healthy individuals that express CR3 may be classified in those carrying a receptor for the Fc portion of IgG (FcR^+) and those carrying CD3. In healthy individuals, 60% of the $CR3^+$ cells are FcR^+ and 18% are $CD3^+$ [71]. In patients with SLE, only 33% are FcR^+ and 50% coexpress CD3 antigen. Of the $CD3^+CR3^+$ cells, only 14% were $CD4^+$ and 44% were $CD8^+$. This expanded $CD3^+CR3^+$ lymphocyte subpopulation in SLE does not contain precursors for NK cells because stimulation of this subpopulation with either IL-2 or IFN-γ does not induce the generation of NK activity [71]. Interestingly, $CD3^+CR3^+$ cells do not fluctuate with the degree of lymphopenia and disease activity in patients with SLE. In contrast, $CD3^+CD4^+CR3^+$ cells increase during periods of disease activity and might provide help to B cells to produce Ig [72].

In conclusion, various T-cell subsets have been described to be decreased in lupus patients. Lymphopenia correlates with disease activity. The major controversy regarding lymphocyte subset numbers in SLE relates to whether they contribute to immunoregulatory imbalances or whether they represent secondary effects of autoantibodies against various cellular antigens.

T Lymphocyte CD4 Epitope Deficiency

Expression of the CD4 molecule on the surface of T cells demonstrates heterogeneity. Expression of CD4 molecules on the surface membrane of T cells from African-Americans but not Caucasian individuals may be normal, intermediate, or deficient. The mode of inheritance of the expression of CD4 molecules is autosomal dominant [73, 74]. Stohl and Kunkel [75] described three black Jamaicans with SLE who lacked $CD4^+$ T cells. A culture of peripheral MNC cells from these patients in the presence or absence of antigens did not facilitate CD4 expression among T cells. Lymphadenopathy was part of the lupus syndrome [75]. Subsequently, another patient with thymoma, hypogammaglobulinemia, and red blood cell aplasia was described who lacked the $CD4^+$ epitope from peripheral blood T cells [76]. Ten more patients with CD4 epitope deficiency were reported from Saudi Arabia [77]. Eight patients had SLE and two had rheumatoid arthritis. Of the patients with SLE, two had IgA deficiency and one had C4 deficiency. The CD4 epitope deficiency is not associated with any HLA haplotype. The CD4 epitope deficiency in the rare patients who were described earlier implies genetic basis for the disease.

Functional Features of Anti-T-Cell Antibodies

Antilymphocyte antibodies found in SLE patient sera are heterogeneous because they recognize different T-cell subsets, B cells, monocytes, and NK cells. Some lymphocytotoxic antibodies are directed against thymocytes [64]. Circulating anti-T-cell antibodies were first found to inhibit concanavalin A-induced suppressor T cells [80]. A T-cell subset, which was identified by gradient centrifugation, was found to be missing from patients whose sera contained IgM anti-T-cell antibodies [62]. Subsequently, Sakane *et al*. [81–83] reported studies that documented that anti-T-cell antibodies were responsible for the decreased suppressor cell function in these patients. In further studies in which murine monoclonal antibodies were used to identify human T-cell subsets, anti-T-cell antibodies in SLE sera were further characterized and were found to target the suppressor–inducer CD4 subpopulation [84]. However, other studies using highly purified peripheral $T4^+$, $T8^+$, autologous rosette-forming cells, or $T4^+$ and $T8^+$ clones as targets in cytotoxicity assays showed almost no difference in killing between SLE and normal sera [85–87].

More definitive studies [79, 88] have shown that SLE sera-derived IgM antilymphocyte antibodies recognize different isoforms of the CD45 molecule (molecular mass ~200 Da). CD45 is pivotal in T-cell signaling during stimulation because it has protein tyrosine phosphatase activity [89, 90]. Indeed, the protein tyrosine phosphatase activity of anti-CD45 antibody precipitates from lupus lymphocytes was found to be

decreased significantly. Decreased phosphatase activity correlated with disease activity but not with the dose of prednisolone. The CD45 protein content was not decreased, suggesting that enzymatic activity was affected [91].

IgM antilymphocyte antibodies have also been shown to recognize separate specificities on intact or desialylated peripheral T cells [92]. Other experiments demonstrated that antibodies distinct from conventional cold-reactive cytotoxic antibodies target T-cell blasts and interfere with the expression of interleukin 2 receptors [92]. These antibodies might interfere with the development of IL-2-dependent immune responses in patients with SLE. Anti-T-cell antibodies have long been known to inhibit mixed lymphocyte reactions [65] and cytotoxic responses to xenoantigens [93] and alloantigens [37], as well as NK cell activity [94]. IgG antilymphocyte antibodies potentiate antibody-dependent cell cytotoxicity [95]. Antilymphocyte antibodies may bind to lymphocytes by a non-Fc-mediated mechanism and by Fc to antibody-dependent cell-mediated cytotoxicity effector cells and cause lymphopenia. This explains why the presence of antilymphocyte antibodies correlates with both lymphopenia and decreased antibody-dependent cell-mediated cytotoxicity among SLE-derived MNC. The aforementioned discussion indicates that circulating anti-T lymphocyte antibodies in patients with SLE are heterogeneous.

Antilymphocyte antibodies have been found to cross-react with tissue antigens, including nuclear antigens [96–98], human brain tissue [99], and trophoblastic antigens [100]. This information suggests potential cross-reactivity between anti T-cell and other autoantibodies, including anti-DNA.

A murine monoclonal anti-DNA antibody was found to bind to a surface membrane structure (lupus-associated membrane protein, LAMP) of Raji cells [101] and other cell types, including normal human lymphocytes [102]. Similar antibodies were found in the sera of patients with SLE [103]. These findings have led to the formulation of a hypothesis whereby LAMP rather than DNA may trigger the autoimmune response.

Activated T Lymphocytes

Activated but not resting lymphocytes express markers such as DR antigens, IL-2, transferrin, insulin receptors, and other surface molecules that can be identified by monoclonal antibodies. Patients with SLE have been reported to have increased percentages of circulating DR^+ T lymphocytes. We have found increased expression of HLA-DR antigens on T cell from patients with active SLE. Both $CD4^+$ and $CD8^+$ T cells express increased levels of DR antigens. DR^+ cells are slightly larger than DR^- cells and provide help to autologous B cells to secrete immunoglobulin [104]. Another study demonstrated that DR^+ T cells are distributed preferentially among the $CD8^+$ subpopulation [105]. More recently, $CD8^+DR^+$ cells were found to correlate with disease activity [106].

The finding that T cells from patients with SLE express increased amounts of mRNA for protooncogenes (c-*myc,* c-*myb, and* c-*raf*) further supports the presence of activated T cells in these patients and implies a possible role for activated T cells in the expression of SLE [107–109]. Although lupus T cells express more surface DR antigens, they express fewer numbers of IL-2 receptors. The number of intermediate affinity IL-2-binding molecules p70/75 is decreased on the surface of freshly isolated T cells from lupus patients [110]. Lupus T cells do not proliferate *in vitro* in response to IL-2 [110]. Furthermore, stimulation of lupus T cells *in vitro* with phytohemagglutinin causes a decreased expression of high-affinity IL-2 receptors [111]. The cause for the discrepancy between the high levels of DR expression and the low levels of IL-2 receptor expression on the surface of lupus T cells is unknown. It may simply represent an activational arrest of lupus T cells at a phase between cells expressing DR antigens and cells expressing receptors for IL-2 or a basic defect of the transcription and expression of surface IL-2 receptors. Interpretation of decreased IL-2 receptor expression is complicated by the finding (see later) of increased levels of circulating soluble forms of the IL-2 receptors.

T Suppressor Lymphocyte Function

Numerous studies have been performed to test the hypothesis that deficient suppressor cell activity is responsible for the uncontrolled production of autoantibodies by B cells and the subsequent development of autoimmunity. Concanavalin A-induced suppressor cell function in patients with SLE has been reported to be deficient [112–117] or normal [118, 119]. Concanavalin A-induced suppressor cell activity has been tested in a number of systems, including proliferative responses [117, 120, 121] and pokeweed mitogen-induced plaque-forming cell responses [114, 116, 122–124]. Deficient suppressor cell activity has been shown in the aforementioned studies to correlate with disease activity, serum DNA binding, low serum C3 levels, and treatment status. In procainamide and diphenylhydantoin-induced SLE, suppressor cell function is normal [125, 126]. Spontaneous and mitogen-induced nonspecific suppressor cell activity becomes

normal during pregnancy in certain SLE patients [127].

Concanavalin A is a potent stimulus of T cells and, if not used under proper conditions (concentration, cell density, etc.), may not be sensitive enough to detect small differences among responding subpopulations. A number of studies have used more specific stimuli known to induce suppressor cell activity. EBV-associated suppressor/cytotoxic cell function is defective in patients with SLE who were seropositive to EBV [128]. Similarly, concanavalin A-activated T cells in some patients fail to suppress antitrinitrophenyl–*Brucella abortus* responses of autologous B cells [129].

Patients with SLE have severely impaired autologous mixed lymphocyte reaction responses (reviewed in Tsokos and Balow [32]). Deficient responses can be restored to normal levels if the responding cells are treated with exogenous IL-2 [130] or if the stimulatory non-T cells are pretreated with formalin-treated *S. aureus* or phorbol myristate acetate, suggesting that deficient responses may represent in part a failure of SLE non-T cells to present an appropriate stimulus for the generation of T-cell responses [131]. These studies indicate that (a) cellular abnormalities in patients with SLE can be detected when subtle stimuli (EBV, autoantigens) are used instead of more potent mitogens and (b) suppressor cell defects might be involved in the pathogenesis of SLE along with other cellular aberrations [32].

In one study, deficient concanavalin A-induced suppressor cell activity was found not only among SLE patients, but also in one-third of their relatives [115]. A major cross-reactive idiotype (16/6) among monoclonal anti-DNA antibodies has been identified. Antibodies carrying the 16/6 idiotype are increased in sera of patients with SLE and are deposited in the glomeruli and the skin. Schatner *et al*. [132] reported that some patients with SLE and their first-degree relatives have simultaneously defective suppressor cell function and increased levels of the 16/6 idiotype. They also found a correlation between the severity of the suppressor cell defect and the level of 16/6 idiotype carrying serum antibodies. However, increased 16/6 levels were commonly found in the presence of normal suppressor T-cell function. Despite these limitations, which imply that other factors must operate to cause tissue damage and clinical disease, these experiments strongly indicate a genetic input in the expression of cellular abnormalities in patients with SLE.

Impairment of $CD8^+$ function in SLE patients has been attributed to an impaired secretion of IL-6 and IFN-γ and an increased production of IL-12 [133]. In the coculture system that was used to reach this conclusion, IL-6 and IFN-γ are responsible for the suppressor function of the $CD8^+$ cells. These experiments have instigated a line of investigations that may lead to the validation of the earlier described defective suppressor cell function in SLE.

T Helper Lymphocyte Function

Increased helper cell activity has been considered a possible alternative explanation to the defective T suppressor cell function for increased B-cell function. Increased helper cell activity was first shown in the MRL *lpr/lpr* autoimmune murine strain [134]. In human lupus, a number of T cell subpopulations have been identified to provide help to B cells to produce Ig. $CD4^+DR^+$ cells from lupus patients provide help *in vitro* to autologous and allogeneic B cells to secrete more Ig [104]. A newly recognized $CD3^+$ subpopulation in the peripheral blood of patients with SLE, which lacks surface CD4 and CD8 molecules, provides help to autologous B cells to secrete cationic anti-DNA antibodies, which are considered nephritogenic [135]. Linker-Israeli *et al*. [136] showed that $CD8^+DR^+$ T lymphocytes provide substantial help *in vitro* to autologous B cells to produce anti-DNA antibodies. Optimal help to autologous B cells was provided by mixtures of $CD4^+$ and $CD8^+$ cells, $CD4^+$ and $CD16^+$ (NK cells), and $CD8^+$ and $CD16^+$ cells. Although $CD8^+$ and $CD16^+$ [137] are known to act as suppressor cells, they may have a special role in the pathogenesis of human lupus.

It should be noted that defective T helper cell activity in patients of SLE has been reported. SLE T cells have been shown not to support IgM anti-TNP responses [138] and autologous and allogeneic *in vitro* B-cell colony formation [139]. Other studies have reported normal T helper cell activity [140, 141].

Double Negative T Cells in SLE

CD4 and CD8 negative cells populate the thymus and the lymph nodes of MRL lpr/lpr mice and have been shown to provide helper signals to B cells to secrete autoantibodies [134]. Studies by Datta and colleagues [142] have shown that double negative cells ($CD4^-CD8^-$) from the spleens of MRL lpr/lpr, (NZBxSWR)F1 and (NZBxNZW)F1 murine strains provide help to B cells to produce cationic IgG anti-DNA antibodies. These antibodies are considered nephritogenic because they bind to and form immune complexes with positively charged sites of the glomeruli [143–145]. Furthermore, $CD4^-CD8^-$ T cells lines from these animals similarly provide help to syngeneic B cells to produce nephritogenic antibodies that share the cross-reactive idiotype called Id^LNF1 (lupus nephritis idiotypes) [146].

Peripheral lymphocytes from patients with SLE also produce highly cationic IgG class anti-DNA antibodies when cultured *in vitro* [135]. $CD4^+$ cells as well as $CD4^-$ and CD8-depleted peripheral $CD3^+$ cells provide help to syngeneic B cells to produce cationic anti-DNA antibodies. Only T cells from patients with inactive disease provide help, whereas T cells from patients with inactive disease and normal individuals failed to do so. Patients with active disease exhibited a striking expansion of the $CD4^-$ $CD8^-$ lymphocytes that were also $TCR\alpha\beta^+$ (TCR) and $CD3^+$. Two-thirds of these double negative cells were $Dw29^+$ (helper, 4B4), whereas one-third were $CD45R^+$ (suppressor/inducer, 2H4). A similar distribution of $CDw29^+$ and $CD45R^+$ cells has been described previously in $CD4^+$ lupus cells [147]. This $CD4^-CD8^-CD3^+$ $TCR\alpha\beta^+$ subpopulation is novel in humans and was detected by virtue of its expansion in the peripheral blood of patients with SLE [135]. The origin and expansion of this subpopulation in patients with SLE remain to be elucidated. Nevertheless, it represents a novel subpopulation, which is committed to provide help to B cells to produce pathogenic autoantibodies.

Rajagopalan *et al*. [148] established IL-2-dependent T-cell lines from T cells from patients with active lupus nephritis. Only 15% of these lines had the ability to selectively augment the production of pathogenic anti-DNA autoantibodies that were cationic in charge, IgG in class, specific for DNA, and clonally restricted in spectrotype. The majority (5 out of 6) of these lines was $CD4^+$ and expressed the TCRaβ. The remaining 10 were $CD4^-CD8^-$; 3 of them expressed the TCRaβ while 7 expressed TCRγδ. On addition to providing specific help to autologous B cells, all lines responded by proliferation to some endogenous antigen presented by autologous B cells. The DN T-cell repertoire includes cells restricted by CD1 Ag-presenting molecules. Indeed, it was shown that CD1c-restricted $CD4^-$ and $CD8^-$ T cells from SLE patients can provide help to CD1c(+) B cells for IgG production and could therefore promote pathogenic autoantibody responses in SLE [149]. Because neutralizing Abs to CD1c inhibited the ability of DN T cells to induce IgG production from CD1c(+) B cells, CD1c may represent a therapeutic target.

Heat Shock Proteins in Lupus Immune Cell Biology

Autoreactive responses of the $CD4^+$ helper T cell lines, which were discussed in the preceding section, were restricted by MHC class II antigens, whereas the double negative T-cell lines were not. Endogenous heat shock proteins (HSP) of the HSP60 family, which were shown to be expressed by lupus B cells, were responsible for stimulating the autoreactive proliferation of $\gamma\delta^+$ T helper cells. The fact that lupus sera contain IgM and IgG antibodies against the HSP70 family of proteins [150] strengthens the notion that HSP may serve as pathogenic antigens in SLE [151].

HSP have been highly conserved during evolution because of their fundamental importance in cell biology and responses to stressful assaults [152]. HSP proteins have gained interest because they are found in organisms that commonly afflict humans. These organisms elicit immune responses that may later evolve into autoimmune responses and overt autoimmune diseases [153, 154]. HSP from *M. lepra*, *tuberculosis*, *bovis*, and other bacteria are closely homologous to HSP of mammals. TCRγδ-bearing lymphocytes recognize HSP epitopes by a mechanism similar to that of $a\beta^+$ T lymphocytes, i.e., in the form of small processed protein fragments bound to antigen-presenting molecules [155]. HSP proteins have been shown to play a role in the pathogenesis of inflammatory arthritis in animals and human rheumatoid arthritis. Adjuvant arthritis in rats can be initiated by T-cell lines and clones specific for the mycobacterial HSP65 [156]. $a\beta^+$ or γδ T-cell clones from rheumatoid synovial fluid recognize HSP65 [157] and specifically the first 15 amino acid peptide of the NH2 terminus of this protein [158]. Although HSP epitopes may not represent the original antigens involved in rheumatoid arthritis or SLE, HSP certainly contain crucial cross-reactive elements. Research along these lines may identify the "pathogenic" T cells, characterize the circumstances that permit their development and expansion, and finally develop vaccination strategies against the development of T cells that recognize HSP [153].

Studies show that HSP-70 alters the function of kinases and phosphatases that are involved in cell signaling. Using HSP-70-transfected Jurkat T cells, we demonstrated that HSP-70 overexpression offers thermoprotection but enhances TCR/CD3- and Fas antigen-induced apoptotic cell death. This phenomenon was associated with downregulation of the Ag receptor-initiated early signal transduction pathways, including increases in $[Ca2^+]_i$ and protein tyrosine phosphorylation, and with upregulation of Fas-mediated early metabolic events [159]. In addition, HSP-70 inhibits stress kinases that are activated following the exposure of cells to heat shock, strong oxidants, UV irradiation, and other stressors and prevents the programmed cell death that ensues exposure to these stressors [160]. If programmed cell death and exposure to physical, chemical, or psychological stressors are of pathogenic importance in lupus, then a better understanding of the molecular and cellular biology of the HSP-70 is warranted.

TABLE 3 T-Cell Clones in the Study of the Pathogenesis of SLE

A. Expansion of peripheral T cells with IL-2		
	Phenotype:	$CD4^+$, $CD3^+$ $\alpha\beta^+$ $CD4^-$, $CD8^-$, $CD3^+\gamma\delta^+$ $CD4^-CD8^-$
	Function:	Help autologous B cells to produce cationic anti-DNA antibodies
	Genotype:	Vγ1, Vδ5,1,3
B. Expansion of peripheral T cells with IL-2 and autoantigen		
a. snRNP antigen		
	Function:	Proliferate in response to snRNP antigen
	Origin:	$HLA\text{-}DR2^+$ or $HLA\text{-}DR4^+$ patients with SLE, mixed connective tissue disease and normal individuals
b. Proliferation of T cells in response to autoantigen		
	Function:	Respond to P antigen; drive B cells to produce anti-P antibodies
C. Expansion of peripheral T cells in the presence of IL-2-containing medium and 6-thioguanine		
	Frequency:	Increased frequency in the peripheral blood of patients with SLE, multiple sclerosis, and systemic sclerosis. Correlation with disease activity and duration
	Function:	Preferential proliferative response to basic myelin protein (multiple sclerosis) or help B cells produce anti-DNA antibodies

T-Cell Clones in the Study of the Pathogenesis of Lupus

T cells are considered to be responsible for B-cell hyperactivity and autoantibody production, to contribute to the initiation and progression of tissue pathology, and to the inability of patients with SLE to successfully fend off infectious agents [161]. Three major technical approaches have been used to characterize the nature of the specific T cells that are involved in the pathogenesis of SLE. In the first, T cells are being expanded by continuous stimulation with IL-2; in the second, T cells are stimulated *in vitro* by the presumptive antigen; and in the third, T cells are expanded in selective media (Table 3).

One-seventh of the T-cell lines that have been established from patients with lupus nephritis following *in vitro* expansion with IL-2 can help autologous B cells to produce cationic anti-DNA antibodies. The majority of the T helper cell lines were $CD4^+$, whereas a small fraction were $\alpha\beta$ TCR^+ $CD4^-CD8^-$ and $\gamma\delta$ TCR^+ [135, 148]. $\gamma\delta$ TCR^+ clones were able to augment anti-DNA antibody production dramatically and in a non-MHC-restricted fashion [148].

Clones reactive with the presumptive autoantigen small nuclear ribonucleoprotein (snRNP) have been established from both patients with SLE and normal individuals who carry the HLA-DR2 or HLA-DR4 genotypes following stimulation of peripheral blood MNC with IL-2 and snRNP [162]. All clones responded in an MHC-restricted fashion to snRNP. Clones derived from normal individuals frequently used the Vβ6 TCR gene [162].

Study of anti-Sm antigen-derived clones from patients with SLE has revealed that T cells recognize a highly restricted set of Sm peptides, with three epitopes on Sm-B and two in Sm-D. Longitudinal studies revealed that the response is stable and support the concept that T-cell immunity to the Sm antigen is antigen driven [163]. In line with these observations is the fact that these clones use TCR CDR3 in a restricted manner [164].

One-third of lupus peripheral blood MNC responded to recombinant ribosomal P2 protein, despite the fact that the response to the recall antigen tetanus toxoid was diminished. The majority of the responding patients had circulating anti-P antibodies, whereas none of the seronegative patients or normal controls responded. The proliferative response was mediated by $CD4^+$ cells and was MHC class II restricted [165]. Apparently these autoantigen-responsive T cells are responsible for the production of anti-P autoantibodies in patients with lupus.

The identification of putative autoantigens may prove useful in reestablishing tolerance. Indeed, myelin basic protein (MBP) disease-inducing T cells have been deleted successfully by a high dose of MBP antigen in a murine model of autoimmune encephalomyelitis [166]. Additionally, oral administration of chicken collagen II in a double-blinded clinical study to patients with rheumatoid arthritis resulted in significant clinical improvement [167].

Studies of T-cell mutations in the *hprt* gene have provided one approach to better understanding *in vivo* immune activity in patients with autoimmune disorders [168–170]. It is based on the principle that random mutation in any gene would be expected to occur more frequently in proliferating than in resting T cells. This approach was used initially to show that patients with multiple sclerosis have increased numbers of mutated T cells that react preferentially to myelin basic protein *in vitro* [171]. It has been found that many patients with SLE have increased numbers of 6-thioguanine-resistant T cells, presumably due to mutations in the *hprt* gene of those T cells [172]. In that study of 18 patients, it was suggested that patients with many mutant T cells were those with the greatest amount of lupus disease. More recently, it has been found that there is a strong correlation between the number of mutant T cells and the duration and magnitude of past lupus disease activity [173]. In another study, it was determined that the T cells that carry the *hprt* gene mutation are phenotypically similar to wild T cells and may help autologous B cells

produce the anti-DNA antibody in a MHC-restricted fashion [174]. Although T cells that carry the *hprt* gene mutation do not exclusively contain the ability to help the production of autoantibody, they may be useful in producing "autoreactive" T-cell clones in the absence of any antigenic stimulation. An increased frequency of *hprt*-mutated T cells has been observed in the peripheral blood of patients with other systemic rheumatic diseases, such as systemic sclerosis [175] and anti-U1 70-kDa autoantibody-positive connective tissue disease [176]. Systemic analysis of the T-cell receptor repertoire of *hprt*-mutated T cells shall examine the clonal origin of these cells, whereas further testing of their function is needed to test whether they have a pathogenic role in the disease process.

T-Cell Antigen Receptor Gene Repertoire in SLE

Autoreactive T cells that bear TCR gene products recognizing self-antigens are eliminated in the thymus by either positive or negative selection. Deletion of the variable region of the β chain of TCR has been reported in various autoimmune murine strains that develop lupus spontaneously [12, 13]. The relevance of these deletions to the development of the disease is under discussion. An early study of the restriction fragment polymorphism of the a, β, and γ chains of TCR in Australians did not reveal any association with lupus [177]. Also, antibody-recognized epitopes of the variable region of the β chain in peripheral T cells was also similarly distributed between lupus patients and normal individuals [178]. In contrast, another study demonstrated an association between anti-Ro antibody production in American patients with lupus and a constant region of the β chain restriction fragment. The majority of these patients were also DQw1 positive [179]. Tebib *et al.* [180] demonstrated that a restriction fragment (1.3 and 3.0-kb band pairs) of the constant region of the α chain of TCR was predominant among American Caucasian patients with SLE but not among Mexican patients with SLE. The same study showed that in three out of five families with SLE the 1.3/3.0-kb band patern was partially concordant with disease transmission. Differences in these cited data may be due either to ethnic heterogeneity or to differences in the restriction enzymes that were used. Vα24JαQ positive T cells are decreased in patients with active disease and reemerge following treatment [181].

T-cell lines that had been established from the peripheral blood of patients with lupus nephritis and had been shown to provide help to autologous B cells to produce anti-DNA antibodies (see earlier discussion) [148] were further studied to determine the molecular structure of the T-cell receptor chains. Sequencing of α and β TCR chain genes from 42 $CD4^+$ lines from five lupus patients revealed recurrent motifs of highly charged residues in their CDR3 loops. Four of the five patients displayed the Vα8 gene family. Some of the studied clones responded to the nonhistone chromosomal protein HMG and nucleosomal histone proteins [182]. These results are in keeping with previous studies from the same group in murine lupus [183] and suggest that autoimmune T helper cells in patients with lupus expand in response to charged antigens.

Indiscriminate sequencing of γ and δ chains of TCR from the peripheral blood of patients with lupus showed oligoclonal expansion of γδ T cells in lupus [184] similar to that observed by the same group in patients with sarcoidosis and rheumatoid arthritis. Sequencing of γ and δ chains of TCR of T-cell lines from patients with lupus nephritis showed certain biases in the selection of these genes [185].

Clones reactive with the presumptive autoantigen small nuclear ribonucleoprotein (snRNP) derived from normal individuals frequently used the Vβ6 TCR gene [162]. T-cell lines from patients with mixed connective tissue disease that expanded in response to snRNP displayed Vβ1, Vβ3, Vβ5.2, and Vβ14 families at increased frequencies [186] and use the CDR3 gene in a restricted fashion [187]. Characterization of TCR profiles from different patients and different sources (blood and kidney tissues) identified that T-cell clonotypes expand at different times and at different sites [188]. These findings suggest that the sensitizing antigens are changing over time and may be different in various inflammatory sites. Obviously, these studies contribute to our understanding of the pathogenesis of lupus and generate a rationale for specific immunologic interventions (Table 4) [189]. More than a decade ago it was shown that the response to certain autoantigens was highly restricted in the usage of TCR V genes. Specific treatments of autoimmune diseases by targeting the TCR were initiated. At this point the enthusiasm has been decreased

Vβ1, Vβ3, Vβ5.2, Vβ14	

[a] These data follow the murine lupus paradigm and stress the importance of charge in the production of anti-DNA antibodies that can bind to the charged glomerular basement membrane.

and the approach is criticized because the autoimmune response spreads intra- and intermolecularly over time, the autoimmune infiltrate (in diseases such as thyroiditis and multiple sclerosis) is extremely diverse, and autoimmune cells represent only a small fraction and do not regulate the function of the vast majority of nonspecific cells [190].

LYMPHOKINES

IL-2

SLE T cells have been shown to produce decreased amounts of interleukin-2 [191, 192]. Both $CD4^+$ and $CD8^+$ cells are responsible for the deficiency [193]. This is in agreement with the inability to detect IL-2 receptors on the surface of activated (DR^+CD3^+) lupus cells [104]. The fact that lupus T cells proliferate *in vitro* spontaneously more than normal T cells, particularly in the presence of the phytohemagglutinin-stimulated normal T-cell supernatant, suggests the presence of functionally activated T cells and indicates that DR^+CD3^+ lupus T cells carry low-affinity IL-2 receptors or receptors for other growth factors [104].

Decreased IL-2 secretion, *in vitro*, by lupus cells correlates with increased disease activity, lack of previous treatment, and increased numbers of spontaneously immunoglobulin-secreting B cells [191, 192]. Despite the fact that lupus T cells fail to produce IL-2 *in vitro,* the serum levels of IL-2 were increased, indicating the presence of activated cells *in vivo* [194]. A decreased production of IL-2 by lupus MNC *in vitro* is the product of regulatory action exercised by cells or soluble factors. This statement is supported by several lines of experimental evidence. (A) Removal of $CD8^+$ cells increases IL-2 production by *in vitro*-stimulated SLE MNC to normal or above normal levels [195, 196]. These $CD8^+$ cells, which suppress IL-2 production by lupus MNC, are radiosensitive [197]. In addition to $CD8^+$ T cells, which suppress IL-2 production by SLE MNC, another cell, which is $CD3^-CD8^-CD16^+$, also suppresses IL-2 production [198]. (B) Phorbol myristate acetate, which activates protein kinase C directly, restores IL-2 production to near normal levels. This indicates that the IL-2 production defect is distal to protein kinase C [197, 199]. Phorbol myristate acetate restores IL-2 production in both $CD4^+$ and $CD8^+$ T cells [200, 199]. (C) Culture of SLE MNC *in vitro* without a stimulus for 2–3 days restores their ability to produce normal amounts of IL-2 in response to mitogens [194, 201, 202, 203] and increases significantly the IL-2-producing precursor frequency *in vitro* [204]. Although *in vivo* exhaustion of T cells due to continuous activation may be responsible for this observation, elimination of suppressor cells during the preculture period may also contribute. (D) Culture of lupus MNC under proper cell concentration conditions affects IL-2 production. Lupus MNC cultured at low cell densities overproduced IL-2 [205]. (E) Circulating autoantibodies directed against IL-1-producing adherent cells or IL-2-producing cells may interfere with IL-2 production [206].

Evidence that is discussed later in this chapter has revealed that the two sets of transcriptional defects, i.e., decreased expression of the enhancing transcription factors NF-κB [207] and AP1 [208] and increased expression of the transcriptional repressor CREM [209], are responsible for the decreased expression of IL-2 in patients with SLE.

IL-2 Inhibitor

The activity of IL-2 *in vivo* is regulated by the presence of a 60–70,000 MW, heat-stable, IL-2 inhibitor [210]. Patients with SLE and other autoimmune disorders lack this inhibitor, leaving thus uncontrollable the action of the increased IL-2 amounts [210, 211].

Soluble IL-2 Receptors

Activated T cells produce a soluble form of IL-2 receptor. Sera from patients with SLE have increased levels of circulating IL-2 receptors that correlate with disease activity and several immunologic parameters [212–216]. Increased levels of circulating soluble IL-2 receptors are present in the sera of autoimmune murine strains [217] and other autoimmune human diseases [216, 218]. Because soluble IL-2 receptors bind IL-2, circulating soluble IL-2 receptors may regulate IL-2 levels in patients with SLE. The type and the location of the IL-2 receptor-producing cell, which is responsible for elevated serum IL-2 receptor levels, are unknown. Freshly isolated T cells from peripheral MNC from patients with SLE have decreased levels of the intermediate affinity IL-2-binding molecules p70/75 [110].

The levels of IL-2 are regulated at different levels.

1. Regulation at the level of production: decreased numbers of IL-2-producing precursor cells, unresponsiveness to exogenous antigens, or action of regulatory cells. Because the promoter region of the IL-2 gene is known along with the various transcription factors that bind to it, it should be easy to characterize completely the molecular basis of the decreased production of IL-2 in lupus patients.

2. Regulation at the level of circulation: neutralization by binding to the soluble IL-2 receptor and neutralization by binding of IL-2 inhibitors.
3. Regulation at the level of action: mitogen-activated lupus B and T cells express decreased amounts of IL-2 receptors, which will interfere with the action of IL-2, or *in vivo*, lupus lymphocytes may express more IL-2 receptors [219] and facilitate the action of IL-2. Deficient interleukin production accompanies and at least partly explains the obviously decreased levels of various forms of cellular cytotoxicity in SLE patients [220].

IFN-γ

Peripheral MNC from patients with SLE exhibit deficient production of IFN-γ upon stimulation with PHA or IL-2 [221]. Stimulation of SLE MNC with Newcastle disease virus, polyinosinic, propionolactone-inactivated measles virus [222], and Sendai virus [223] also resulted in diminished IFN-γ production. Another study has shown normal IFN-γ production by mitogen-stimulated SLE MNC [224]. The significance of IFN-γ in the pathogenesis of SLE relates to its antiviral activity and to its ability to enhance cytotoxic activity and suppress antibody production [129]. Decreased IFN-γ may contribute to a higher incidence of infections and autoantibody production in patients with SLE.

These findings contrast reports of patients with rheumatoid arthritis who developed lupus following a systemic administration of IFN-γ [225, 226], suggesting that IFN-γ may promote autoimmunity. Lymphocytes from lupus-prone mice express increased levels of IFN-γ mRNA [227], and IFN-γ may promote autoimmunity by enhancing the expression of autoantigens [228]. Additional studies have shown clearly that IFN-γ promotes autoimmunity. Specifically, NZB/NZW mice treated with an anti-IFN-γ antibody [229] and MRL/lpr mice deficient in IFN-γ (IFNγ-/-) [230, 231] or MRL/lpr [232, 233] and NZB/NZW lacking the IFN-γ receptor (MRL/lpr γR -/-) [234] have less or no glomerulonephritis and other autoimmune manifestations.

IL-6

IL-6 is produced by different cell types, including monocytes and T cells. The most important function of IL-6 is the promotion of Ig production by activated B cells and EBV-transformed B cells [235]. SLE MNC were found to express high levels of mRNA for IL-6 [191]. IL-6 mRNA is also increased in patients with SLE because its half-life is increased, indicating decreased decay [236]. Although the possibility that this is the result of increased transcription has not been tested formally, promoter polymorphisms that are more prevalent in SLE patients may contribute to increased transcription [237]. The production of IL-6 is not autonomous and it can be downregulated in the presence of exogenous IL-10, which increases the decay of the IL-6 mRNA [236].

Increased levels of Il-6 have been found in the cerebrospinal fluid of patients with SLE and central nervous system involvement [238]. Successful treatment of the central nervous system disease in these patients resulted in significant reduction of the IL-6 levels [238]. The possible role of IL-6 in the pathogenesis of SLE is further supported by the finding that mesangial cells from rats with proliferative glomerulonephritis express increased levels of mRNA for IL-6. Because recombinant IL-6 promotes the *in vitro* growth of mesangial cells, it can be speculated that IL-6 acts as an autocrine factor in amplification of the proliferative process of glomerulonephritis [239]. IL-6 is also present in involved kidneys of SLE patients [239]. Factors leading to the constitutive expression of IL-6 in SLE have not been elucidated yet, but they may involve other regulatory cytokines. B cells from patients with SLE express constitutively high numbers of receptors for IL-6 and secrete spontaneously large amounts of IL-6 [240]. These observations establish an autocrine pathway of B-cell activation that may further promote the production of autoantibodies. Finally, IL-6 has been shown to promote disease expression on NZB/NZW F1 mice [241].

IL-10

Lymphokines are responsible for driving or prohibiting various B-cell activation and differentiation phases. The relative role of IL-10 in driving human autoantibody production was studied. IL-10 is produced by monocytes and B lymphocytes and it has been shown to suppress monocyte function on the one hand and promote antibody production on the other [242, 243]. Llorente *et al*. [244] showed that recombinant IL-10 enhanced the ability of peripheral blood lupus mononuclear cells to produce spontaneously IgA, IgM, and IgG. The role of IL-10 in the production of anti-DNA antibodies was also tested in mice with severe combined immunodeficiency that were reconstituted with peripheral MNC from lupus patients. In these chimeric animals, production of the human anti-DNA antibody was blocked by anti-IL-10, but not by anti-IL-6 antibodies. Although IL-10 was given the leading role in the aforementioned experimental system, we should consider that other lymphokines, particularly IL-6, may play significant roles [245, 246]. An autocrine pathway similar to that of IL-6 can be claimed for IL-10, which

is produced by B lymphocytes and promotes autoantibody production [244].

Single nucleotide polymorphisms (SNP) of the IL-10 promoter determine the levels of IL-10 production in humans. These SNP are significantly associated with SLE in African-Americans and may define one component of genetic susceptibility to SLE in this group [247]. It should be noted that IL-10 promoter polymorphisms were not found in a Japanese cohort of SLE patients [248]. It is still possible, although not yet tested, that IL-10 promoter polymorphisms are responsible for the transcriptional regulation of the *IL-10* gene.

Neutralization of IL-10 may present another therapeutic option for lupus and other systemic autoimmune diseases. IL-10 is produced at increased levels by non-T cells from patients with rheumatoid arthritis lupus and Sjogren's syndrome [249, 250]. Both serum IL-10 levels and the message for IL-10 correlated with IgM rheumatoid factor levels in patients with rheumatoid arthritis [250]. Continuous infusion of the anti-IL-10 antibody of (NZB/W) F1 mice from birth on improved survival dramatically, indicating either that IL-10 is directly in promoting disease activity by acting on B lymphocytes and other cells or that elimination of IL-10 reversed the cytokine ratio in favor of the type 2 group of cytokines (see later) [251].

IL-12

IL-12, another cytokine in the Th1 group, has also been found to be decreased in the sera of patients with active disease [252]; mononuclear cells from patients with new onset disease [253] and macrophages from NZB/NZW and MRL/lpr mice [254] also produce decreased amounts of IL-12 [255]. Interestingly, IL-12, delivered by means of gene therapy, prevented autoimmune disease development in the graft-versus-host (DBA into F1) model [256], opening the possibility of utilizing IL-12 in the treatment of human disease.

Tumor Necrosis Factor

Jacob and McDevitt [257] presented evidence that the tumor necrosis factor (TNF) gene may be involved in the pathogenesis of murine lupus nephritis. Specifically, they showed that a restriction fragment length polymorphism in the TNF gene correlated with decreased production of TNF and that treatment of these mice with TNF delayed the development of nephritis significantly. Peripheral blood lymphocytes from HLA-DR2- and DQw1-positive normal individuals produce low amounts of TNF upon stimulation with antigens. In contrast, lymphocytes from DR3- and DR4-positive individuals produce high levels TNF. SLE patients who are DR2, DQW1 positive and are associated with an increased frequency of lupus nephritis produce very low amounts of TNF under similar conditions. DR2- and DR4-positive SLE patients, who are associated with a low frequency of glomerulonephritis, produce high levels of TNF [257, 258]. This study presents TNF as the causative link between HLA-DR2, DQw1 positivity and clinical expression of lupus nephritis. Mitogen and phorbol myristate acetate-induced TNF production was found decreased in another study in all patients with untreated lupus. Decreased TNF production was associated with decreased polymorphonuclear cell-mediated phagocytosis. Because decreased phagocytosis can be improved by the addition of exogenous TNF, an association between decreased TNF production and decreased susceptibility to bacterial infections was speculated [259]. Serum levels of TNF in patients with SLE are comparable to those of normal individuals [260]. Lupus patients with bacterial infections have elevated serum TNF levels, as normal individuals do [260]. The similarity between murine and human data strengthens the possibility that TNF may participate in the expression of the disease. The possible role of TNF-α in defective activation-induced cell death (AICD) is discussed later.

TGF-β

Although the phenomenon of immunosuppression is well established, mechanisms involved in the generation of lymphocytes with downregulatory activity are poorly understood. Stimulation of PBL with anti-CD2, but not anti-CD3, generated substantial amounts of active TGF-β. The presence of active TGF-β coincident with $CD8^+$ T-cell activation can condition these cells to mediate downregulatory activity [261]. TGF-β can induce certain $CD4^+$ T cells in the naive ($CD45RA^+RO^-$) fraction in human peripheral blood to develop powerful, contact-dependent suppressive activity [262]. Anti-CD2 antibody-stimulated SLE T cells produced a decreased production of TGF-β in comparison with healthy controls [263]. These experiments have shed light on the claimed decreased "suppressor" cell activity in SLE patients and its role in the downregulation of the autoimmune response [7].

Other Cytokines

IL-4, a Th2 cytokine, cytoplasmic content is increased in NK and double negative SLE T cells [264]. The serum levels of IL-16 are increased in patients with active

TABLE 5 Lymphokines in Patients with SLE

Definite abnormality	
IFN-γ	Decreased production
IL-1	Decreased production
IL-2	Decreased production certain patients; role of stimulus and culture condition
IL-6	Increased levels in sera and cerebrospinal fluid; increased mRNA for IL-6 in SLE peripheral MNC
IL-10	Increased production responsible for decreased APC function and B-cell overactivity in SLE patients
IL-12	Decreased production
Possible abnormality	
IL-3	Treatment with IL-3 prevents fetal loss in animals with antiphospholipid syndrome
Side effects of treatment with lymphokines	
IL-2 or IFN-α	thyroiditis, SLE Anti-DNA antibodies Multiple symptoms usually found in patients with autoimmune rheumatic diseases IFN-γ induction of expression of autoantigens

disease [265]. Serum levels of IL-15, which is functionally related to IL-2, are decreased in SLE [266]. These new preliminary reports add to the complexity of abnormal cytokine production in SLE.

Polarization of the Lymphokine Production Response

The aforementioned studies (Table 5) indicate that SLE is characterized by an imbalance in the ratio of type 1 (IFN-γ, IL-2):type 2 (including IL-4, IL-5, IL-6, and IL-10) cytokine-secreting PBMC. In one study, type 1 and type 2 lymphokines were estimated in the same group of patients. T cells were the major source of IL-2, IL-4, and IFN-γ, whereas monocytes were the primary source of IL-6 and IL-10 in the peripheral blood of lupus patients. Significantly fewer PBMC spontaneously secreted IFN-γ and IL-2, whereas significantly more PBMC produced IL-6 and IL-10 in lupus patients versus controls. The disease severity in lupus patients correlated with an elevated ratio of IL-10:IFN-γ-secreting cells [267]. In contrast, another study, which included only patients with lupus nephritis, a Th1 predominance was found [268, 269]. An imbalance between type 1 and type 2 cytokines is increasingly being recognized in autoimmune disorders, including RA [270].

PROLIFERATIVE RESPONSES

Antigens and Mitogens

Proliferative responses of SLE MNC to a variety of antigens and mitogens are decreased [33, 271–276]. The magnitude of the proliferative response does not always correlate to disease activity. SLE serum factors suppress the proliferative response of normal cells. Some studies have reported normal proliferative responses [277–280]. Antilymphocyte antibodies [274], increased monocytic suppression [33], altered dose kinetics to PHA [281], and treatment of patients with corticosteroids [282] may all contribute to the decreased proliferative responses. One study showed that lupus $CD4^+$ cells do not respond to self-antigen-presenting cells presenting tetanus toxoid or influenza virus [283]. Defects in antigen-presenting cell function (see later) and T cells are responsible for the decreased proliferative responses.

Alloantigens

Proliferative responses of SLE MNC to alloantigens are moderately decreased [37, 65, 284], or normal [279]. Antilymphocyte antibodies are probably responsible for the decreased responses [65, 284]. Decreased responses did not correlate with clinical disease activity and immunologic parameters [37]. Alloantigens may stimulate $CD4^+$ or $CD8^+$ T cells [283]. The pathways of interaction between alloantigen-presenting cells and $CD4^+$ or $CD8^+$ are relatively intact. SLE $CD4^+$ and $CD8^+$ cells stimulated with alloantigen-presenting cells produce normal amounts of IL-2 [283].

Autologous Mixed Lymphocyte Reaction

AMLR is decreased in patients with SLE [285–288]. AMLR is considered important in homeostasis of the normal immune response. Studies of AMLR in identical twins with discordant disease activity have shown that cells from patients with active disease fail both to stimulate and to respond; in contrast, cells from patients with inactive disease may stimulate but they fail to respond in AMLR [289]. In another similar study, the defect was limited to the stimulating cells [290]. The CD45R antigen characterizes a $CD4^+$ subset that is responsible for the induction of suppressor/effector cells. $CD4^+CD45R^+$ cells proliferate maximally during AMLR, and anti-CD45R antibodies (2H4) block the suppressor/inducer function of AMLR-activated $CD4^+CD45R^+$ cells [291]. Patients with SLE, specifically those with renal disease, have reduced percentages of $CD4^+CD45R^+$ cells [147]. Expression of the CD45R

antigen does not increase on the surface of $CD4^+$ T cells from SLE patients following stimulation in AMLR [291].

Skin Tests

Reactivity to a variety of antigens placed intradermally in patients with SLE is decreased. The antigens used include streptokinase-streptodornase [282, 292–294], purified protein derivative [277, 282, 292, 293], mumps, dermatophytin, monilia, trichophytin [295], and candida [277, 282, 293, 294]. Normal skin reactivity was found in a number of the studies [277, 296–298].

Responses to Anti-CD3 Antibody

T cells from SLE patients display increased proliferative responses when stimulated with the anti-CD3 monoclonal antibody (mAb) [299–301]. This increased response is not associated with increased IL-2 production or increased IL-2 receptor expression but rather to a not proven increase in the binding of IL-2 to the IL-2 receptors that are expressed on the surface membrane of SLE T cells [299]. Furthermore, monocytes from these SLE patients expressed normal amounts of receptors that bind the Fc portion of the anti-CD3 mAb (FcRII) [299] . In contrast, many other studies (discussed under IL-2 production and APC function) have shown that the anti-CD3 mAb-mediated proliferative and IL-2 production responses are low in at least half of the SLE patients.

BIOCHEMICAL AND MOLECULAR ABNORMALITIES OF SLE T CELLS

Capping of Surface Molecules

Primary biochemical and molecular defects that affect the signal transduction pathway in lupus lymphocytes could offset the importance of immunoregulatory abnormalities in the pathogenesis of SLE, although the former may give rise to the latter.

Cross-linking of surface membrane molecules with polyvalent ligands forces them to move laterally, accumulate in patches, and finally form a cap at one pole of the cell. Capping of CD3, CD4, and CD8 molecules on the surface membrane of lupus lymphocytes is impaired significantly as compared to normal subjects. Lymphocytes, of both helper/inducer and suppressor/cytotoxic subsets, from patients with active lupus disease fail to initiate the capping process. Furthermore, of the cells that are able to cap, only part of them can regenerate and reexpress new molecules. Patients with inactive disease have a lesser but still significant capping defect. This capping defect is not due to the inhibitory defect of anti-T-cell antibodies [302]. The lateral mobility of CD3, CD4, and CD8 molecules on the surface membrane of T cells is mediated in part by the cAMP-dependent pathway [303, 304]. Cross-linking of surface molecules induces a rapid rise of intracytoplasmic cAMP concentrations. This process is inhibited by antagonists of the cAMP-dependent protein kinase, whereas treatment of cells with agents that increase the intracellular cAMP concentration enhances the rate of capping [304, 305]. Inhibition and induction studies of protein kinase A (cAMP-dependent) in lymphocytes from patients with inactive disease have shown that the activity of this enzyme is defective. This defect was further confirmed by showing that cAMP-dependent protein kinase A-induced phosphorylation of intracellular proteins is defective in SLE [306]. A defect in the adenylate cyclase-dependent mechanisms in SLE lymphocytes has been suggested [307] in view of deficient responses to aminophylline and prostaglandin E_2.

Kammer *et al.* [308] have shown elegantly that T cells from patients with active disease but not from patients with rheumatoid arthritis and normal individuals display impaired protein kinase A-catalyzed protein phosphorylation. Although the T-cell membrane proteins that are phosphorylated routinely by PKA were intact, the amount of the PKA-I isozyme was decreased. Patients with mild or moderate disease activity also displayed, albeit to a lesser extent, PKA-I isozyme deficiency. The importance of these observations is enormous because alterations in the cellular protein phosphorylation pattern may alter cellular homeostasis and eventually disturb immune function.

Oncogenes in SLE

Oncogenes play a major role in the control of proliferation of animal cells. Protooncogenes are harbored in all vertebrate cells and have the potential to become dominant transforming genes. Certain oncogenes have structural similarities with growth factors, i.e., the *v-sis* protein product is almost identical to the β chain of the platelet-derived growth factor, whereas the *k-fgf* is related to fibroblast growth factors. Cells overexpressing *v-sis* and *k-fgf* grow in the absence of growth factors. Other oncogenes are related to growth factor receptors, i.e., *c-kit* to the platelet-derived growth factor receptor, *c-erb* to the epidermal growth factor receptor, *c-fms* to the colony-stimulating factor-1 receptor, and *c-ros* to the insulin receptor. Cellular activation leads to the accumulation of mRNA for a number of oncogenes

known as early growth-regulated *genes* (*c-myc*, *c-fos*) or late growth-regulated genes (*c-myb*, *c-mos*) [309].

Low but detectable levels of the oncogenes *c-myc*, *c-myb*, and *c-raf* have been found in B and T lymphocytes from normal individuals. In contrast, patients with SLE and other autoimmune diseases express significantly increased amounts of mRNA for these protooncogenes. B lymphocytes from these patients express three- to sixfold higher levels of protooncogene RNAs than T lymphocytes. Increased levels of oncogene mRNA expression in SLE cells are due to increased nuclear transcription rates and prolonged degradation rates. The mechanisms that lead to these two abnormalities remain unknown [108]. We and others have explored the possibility that gene amplification, gene rearrangement, or retroviral (HTLV family) infection might cause this oncogene activation, but results have been negative so far [108, 109, 310, 311]. Whether this oncogene activation in patients with SLE is caused by intrinsic and/or extrinsic factors has yet to be determined. The exact role of oncogene activation in lymphocyte activation in autoimmune diseases, as well as its relation to the increased incidence of lymphoreticular malignancies [312–319] observed in these diseases, is not clear at the present time.

T-Cell Signaling Abnormalities

Immune cells respond to external antigens following their engagement to the antigen receptor through a series of biochemical processes involving protein tyrosine phosphorylation, calcium mobilization, and activation of transcription factors known as cell signaling. The antigen receptor, TCR/CD3, is a multisubunit complex consisting of α and β chains, CD3γ, δ, and ε chains, and a ζ–ζ homodimer [320–322] or heterodimer of ζ with the η chain or γ chain of the high-affinity IgE receptor FcεRI . The disulfide-linked α–β heterodimer is responsible for antigen recognition, whereas CD3ε–δ, CD3ε–γ, and ζ–ζ homodimers couple with the α–β chains to initiate intracellular signal transduction. Each subunit of the ζ chain homodimer possesses three immune receptor tyrosine-activated motifs (ITAMs), whereas other CD3 chains contain one ITAM each. Upon TCR activation, the tyrosine residues within the ITAMs become phosphorylated by Lck and Fyn, leading to the association and activation of ZAP-70. Once activated, Fyn, Lck, Syk, and ZAP-70 cooperate in the tyrosine phosphorylation, activation, and juxtaposition of downstream signal transducers that contribute to the initiation of MAP kinase cascades, PI 3-kinase activation, Ca^{2+} flux, and activation of transcription factors. Eventually these transcription factors translocate to the nucleus and modulate the expression of genes that regulate lymphocyte activation, cellular proliferation, anergy or apoptosis, secretion of soluble mediators, and effector functions.

TABLE 6 Molecular Defects of the T-Cell Signaling Pathways in Systemic Lupus Erythematosus

Molecular defect	Functional effect
CD45 tyrosyl phosphatase	Deficient
TCR ζ chain	Deficient, increased lipid raft association
FcεRIγ	Increased
Lck tyrosyl kinase	Deficient
Inositol trisphospate	Increased
Calcium	Increased and more sustained
PKA-I and PKA-II isozymes	Deficiencies
Protein kinase C	Deficiency
NF-κB, p65 Rel A subunit	Deficiency
Elf-1	Deficiency
CREM	Upregulation and increased nuclear binding to—180 site of the IL-2 promoter
Ras-MAP kinase	Deficiency
CD40 L	Increased

Following engagement of the antigen receptor, T and B lymphocytes from SLE patients respond rapidly by hyperphosphorylating a number of cytosolic signaling protein intermediates and increasing their concentration of free calcium [323, 324] (Table 6, Fig. 1). The increased calcium response occurs in patients with SLE in a disease-specific manner and independently of disease activity and treatment [324]. All major T-cell subsets, including $CD4^+$, $CD8^+$, and $CD4^-CD8^-$ cells, display increased responses. Interestingly, short-term T-cell lines [324] and autoantigen-specific T-cell clones [325] display increased calcium responses, suggesting that this molecular defect is central to the pathogenesis of the disease. Increased calcium responses may account for the increased expression of CD40L, FasL, and c-*myc* whose expression is calcium dependent [326]. It should be noted here that the expression of CD40L is inhibited by the calcineurin inhibitor cyclosporin [10]. The substrates that are hyperphosphorylated in SLE T cells following stimulation with anti-CD3 antibodies have not characterized. It appears though that the hyperphosphorylated proteins should be distinct, whereas others are underphosphorylated. An example of underphosphoryalted substrates in *cbl* [10].

In SLE T cells, the more sustained and increased calcium response has faster kinetics and is observed under deficient TCR ζ chain expression [48, 225, 323,

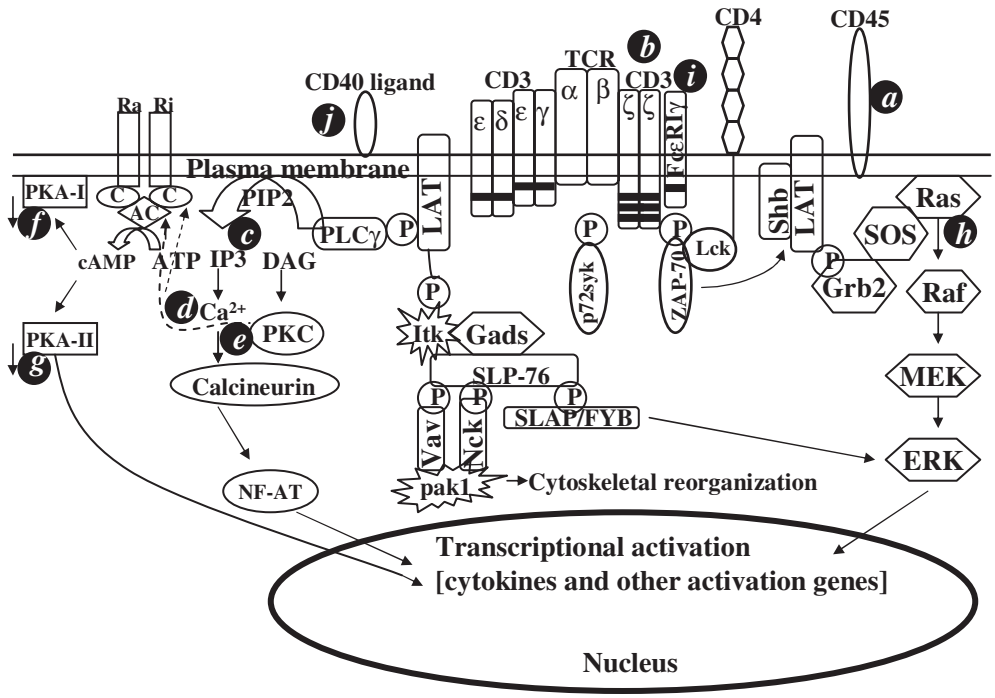

FIGURE 1 Current model of T-cell signal transduction in T lymphocytes depicting the molecular defects identified in SLE. Upon TCR activation by antigen, tyrosine residues within the three ITAMs (-) become phosphorylated by Lck and Fyn, leading to the association and activation of ZAP-70. Once activated, Fyn, Lck, Syk, and ZAP-70 cooperate in tyrosine phosphorylation, activation, and juxtaposition of downstream signal transducers that contribute to the initiation of MAP kinase cascades, PI 3-kinase activation, Ca^{2+} flux, and activation of transcription factors. Eventually these transcription factors translocate to the nucleus and modulate the expression of genes that regulate lymphocyte activation, cellular proliferation, anergy or apoptosis, secretion of soluble mediators, and effector functions. Signaling abnormalities currently identified in SLE T cells are indicated in black circles. *a*, Deficient CD45 phosphatase; *b*, TCR ζ chain deficiency; *c*, moderate increase in inositol trisphosphate; *d*, increased and sustained intracellular calcium levels; *e*, reduced PKC phosphorylation; *f*, deficient protein kinase A I activity; *g*, impaired protein kinase A II activity and increased nuclear translocation of free RIIβ subunit; *h*, reduced Ras-MAP kinase signaling; *i*, increased expression of the FcεRIγ chain that replaces the deficient TCR ζ chain; *j*, increased expression of CD40 ligand.

327]. The deficient TCR ζ chain can explain a number of cellular aberrations that have been observed in patients with SLE, including the defective cytotoxic responses that were described earlier and the reported decreased activation-induced cell death in SLE T cells [328]. The TCR ζ chain is considered to be the limiting factor in T-cell receptor assembly, transport, and surface expression and is crucial to receptor signaling function [320–322]. The TCR ζ chain has also been implicated in the selection of the TCR repertoire and in the prevention of autoimmunity. A vast majority of the SLE patients also display decreased expression of TCR ζ chain mRNA. The TCR ζ chain transcript is generated as the spliced product of eight exons that are separated by distances of 0.7 kb to more than 8 kb [329]. The TCR ζ chain gene is located in chromosome 1q23 [330, 331]. Genes encoded in chromosome 1q have been suggested to contribute to genetic predisposition and susceptibility to SLE by a genome-wide scan of multiplex SLE families [24, 332–334]. Genetic linkage of the TCR ζ chain gene to the FcγRII and FγRIII gene cluster, a candidate locus implicated in genetic susceptibility to SLE, suggests that the TCR ζ chain might play an important role in genetic predisposition to SLE.

Although the precise molecular mechanisms underlying ζ chain deficiency are still being examined, current evidence supports the possibility of a transcriptional defect. In SLE T cells that expressed low levels of TCR ζ chain transcripts, cloning and sequencing revealed more frequent heterogeneous polymorphisms/mutations and alternative splicing of the TCR ζ chain [225, 226, 335, 336]. Most of these mutations are

localized to the three ITAMs or GTP-binding domain and could functionally affect the ζ chain, providing a molecular basis to the known T-cell signaling abnormalities in SLE T cells. Absence of the mutations/polymorphisms in the genomic DNA suggests that these are the consequence of irregular RNA editing. SLE patients also showed a significant increase in the splice variants of the ζ chain. The splicing abnormality included two insertion splice variants of 145 and 93 bases between exons I and II and also several deletion splice variants of the TCR ζ chain resulting from the deletion of individual exons II, VI, and VII or a combined deletion of exons V and VI; VI and VII; II, III, and IV; and V, VI, and VII in SLE T cells [337]. Transfection of a mouse ζ-deficient cell line, MA5.8, with the alternatively spliced isoforms of the TCR ζ chain and TCR/CD3 activation showed functional variation among the splice variants and the wild-type TCR ζ chain. However, the surface expression of the TCR remained similar in MA5.8 cells transfected with the alternatively spliced isoforms of the TCR ζ chain, suggesting that the splice variation does not impair assembly, transport, and surface expression of TCR.

RT-PCR analysis of the TCR ζ chain 3′-untranslated region showed an alternatively spliced 344-bp product with both splicing donor and acceptor sites, resulting from the deletion of nucleotides from 672 to 1233 of TCR ζ chain mRNA. Unlike the normal TCR ζ chain, the expression of TCR ζ chain with the alternatively spliced 344-bp 3′-untranslated region was higher in SLE T cells compared to non-SLE controls. Preliminary studies show that the stability of the TCR ζ chain with the alternatively spliced 3′-untranslated region is more unstable, leading to its downregulation in SLE T cells (G. C. Tsokos *et al.*, unpublished data). Because many of the principal antinuclear antibodies in SLE are directed against spliceosome components, it is not clear whether these autoantibodies play any role in defective mRNA synthesis, splicing, and processing in SLE T cells. Obviously, such a possibility would presume that antibodies can enter the live cells and reach the nucleus. Certain antibodies have been claimed to enter live cells and alter mRNA translation and the production of protein [338].

Abnormalities of Elf-1 Expression

Analysis of the TCR ζ chain transcription factor Elf-1 indicates that the p98 form of the protein was decreased in the majority of lupus patients, whereas the p80 form was increased. Elf-1 is a member of the Ets (E twenty-six specific) transcription factor family. Elf-1 has a calculated molecular mass of 68 kDa; it exists in T cells as both 80- and 98-kDa forms. We determined that the 80-kDa Elf-1 was located mainly in the cytoplasm, whereas the 98-kDa Elf-1 was the major nuclear form. Immunoprecipitation disclosed consistently that the retinoblastoma protein (Rb), which retained Elf-1 in the cytoplasm, displayed higher affinity for the 80-kDa form than the 98-kDa form, indicating that conversion from the 80- to 98-kDa form allows Elf-1 to evade the tethering of Rb and facilitates its nuclear translocation. We found the molecular basis for this conversion involving dual posttranslational processes, i.e., glycosylation and phosphorylation. Specifically, *N*-acetylglucosaminidase, but not the endoglycosidase H, digested the 98-kDa Elf-1 efficiently, whereas actin was not affected. The 98-kDa form was further resolved into three bands, and all bands were either enhanced or suppressed following treatment with okadaic acid or bacteriophage λ phosphatase, respectively. In contrast, only a minor portion of the 80-kDa Elf-1 was in the phosphorylated state subjected to the similar regulation by okadaic acid and phosphatase as the 98-kDa form, indicating that the 98-kDa Elf-1 is the active form. Electrophoretic mobility shift assays and ultraviolet cross-linking studies indicated that the phosphorylated 98-kDa Elf-1 is the functional form that binds to the TCR ζ chain promoter. Nuclear proteins from approximately 40% of SLE T cells displayed decreased production of the 98-kDa form but not the 80-kDa form, which correlates well with their defective TCR ζ chain promoter binding. Another 20% of SLE T-cell nuclear proteins are defective in TCR ζ chain promoter binding, despite normal expression of both 98 and 80 forms of Elf-1. The defective formation of functional 98-kDa Elf-1 thus underlies the defective TCR ζ chain expression in SLE patients [339].

The TCR ζ chain exists in multiple forms and membrane fractions with a distinct function in the Ag-mediated signaling process. Studies on the complete spectrum of expression of various molecular forms of the TCR ζ chain have shown that the phosphorylated 21- and 23-kDa forms of the TCR ζ chain are decreased significantly in SLE T cells compared to normal T cells. In contrast, major ubiquitinated forms of the TCR ζ chain were increased in SLE T cells, suggesting that the TCR ζ chain undergoes an enhanced ubiquitin-mediated degradation in SLE T cells. The level of the TCR ζ chain was also decreased significantly in the detergent-insoluble membranes in SLE T cells. Similarly, expression of the TCR η chain, an alternatively spliced form of the ζ chain, was diminished in SLE T cells. Upregulation of a novel 14-kDa form of the ζ chain, a potential alternatively spliced or degraded species of the TCR ζ chain in SLE T cells, has been identified [340].

Mechanisms of Increased TCR/CD3-Mediated $[Ca^{2+}]_i$ Response in SLE

How the TCR engagement induces hyperphosphorylation of cytosolic proteins and a increased $[Ca^{2+}]_i$ response in the milieu of deficient TCR ζ chain has been a topic of intense research. In addition to the possible gain-of-function mutations of the TCR ζ chain, our investigation has proposed two mechanisms involving increased expression of the FcεRIγ chain and increased membrane lipid-raft association of the residual TCR ζ chain, which could explain the supranormal TCR/CD-mediated $[Ca^{2+}]_i$ response in SLE T cells. Also, the protein tyrosine phosphatase activity of CD45 on peripheral blood lymphocytes is reduced in SLE [91].

FcεRIγ Chain Replaces the Defective TCR ζ Chain

The hypothesis that other members of the ζ chain family may substitute for the deficient TCR ζ chain was first investigated by Enyedy *et al.* [341]. Immunoprecipitation/immunoblotting and confocal microscopy demonstrate that a large proportion of SLE T cells express very high levels of FcεRIγ that functionally associates with the TCR and takes part in antigen receptor-mediated signal transduction. Expression of FcεRIγ *in lieu* of the TCR ζ chain has been reported in mouse large granular lymphocytes [342]. T lymphocytes from tumor-bearing mice expressed TCR that completely lacked the TCR ζ chain and was replaced by the FcεRIγ chain [343, 344]. Also, TCR ζ-deficient mice have been shown to express FcεRIγ as part of the TCR–γδ complex [205, 345, 346]. Unlike the TCR ζ chain, which mediates signaling through ZAP-70, FcεRIγ mediates signaling by associating with the 100-fold more potent phosphorylated protein kinase Syk [347, 348]. At present it is unknown whether Syk is upregulated in SLE T cells and whether FcεRIγ transduces the signal by associating with Syk or other downstream signaling molecules. A high-level expression of Syk and alternative antigen receptor-mediated signaling has been described in T cells of patients with ZAP-70 deficiency [347]. Overexpression of FcεRIγ in normal T cells also shows an increased TCR/CD3-mediated $[Ca^{2+}]_i$ response, suggesting that the single ITAMs in the FcεRIγ compared to the three in the TCR ζ chain do not hinder the level of $[Ca^{2+}]_i$ response (unpublished results). The high-level expression of the FcεRIγ chain could replace the defective TCR ζ chain and contribute to the aberrant antigen receptor-initiated signaling in SLE T cells.

Increased Membrane Lipid Raft Association of the Residual TCR ζ Chain

The TCR ζ chain associated with the detergent-insoluble fraction is distributed between the cytoskeleton and lipid-rich membrane microdomains, composed primarily of sphingolipids and cholesterol, and an enriched subset of proteins that float laterally as "rafts" within the plasma membrane [349]. Lipid rafts are preformed functional modules that serve as platforms for signal transduction and membrane trafficking. Data indicate that lipid rafts are crucial for affecting TCR signal transduction [350–352]. TCR engagement leads to translocation and concentration of the tyrosine-phosphorylated TCR ζ chain and downstream signal transduction molecules within lipid rafts [353]. Conversely, perturbation of the structural integrity of lipid rafts inhibits TCR-induced protein tyrosine phosphorylation and Ca^{2+} flux [351, 354].

Dissociation of the lipid rafts by cholesterol depletion using methyl-β-cyclodextrin showed an increased percentage of the residual membrane-bound TCR ζ chain in lipid rafts in resting SLE T-cell membranes [340]. Fluorescence microscopy indicated that the residual TCR ζ chain is more clustered on the cell membranes of SLE T cells compared to normal cell membranes. Faster kinetics of the TCR/CD3-mediated $[Ca^{2+}]_i$ response in SLE T cells also support the clustering or cross-talk between signaling pathways in SLE. Upon TCR/CD3 activation, ζ chain clusters became more prominent in SLE T cells and they superimpose with LAT, suggesting that they are colocalized to lipid rafts. Increased lipid raft association and surface clustering of the residual TCR ζ chain may explain the supernormal TCR/CD3-mediated $[Ca^{2+}]_i$ response in SLE T cells. Based on these data, a model has been proposed that suggests that although there is a deficiency in SLE T cells, the residual TCR ζ chain is more associated with membrane lipid rafts, resulting in more preformed TCR clustering. Increased membrane TCR clustering, as well as replacement of the deficient TCR ζ chain by the FcεRIγ chain, could lead to a supranormal $[Ca^{2+}]_i$ response under TCR ζ chain deficiency and decreased tolerance in SLE T cells. In support of this view, it has been reported that mice with *N*-acetylglucosaminyltransferase deficiency show decreased glycosylation of T-cell membrane proteins that prevent galectin binding, thereby disrupting the galectin-glycoprotein lattice, increased clustering of TCR [355]. Increased TCR clustering in these autoimmune mice had a very similar phenotype of human SLE, with lowered T-cell activation thresholds and increased TCR signaling [355]. Similarly, it has also been sug-

gested that genetic remodeling of protein glycosylation by mutation of α mannosidase II induces autoimmune disease [356]. As the association among the residual ζ chain with the lipid rafts, TCR clustering, and T-cell effector functions is further explored, it is likely that important new insights will emerge that will explain ζ chain abnormalities and autoreactivity of T cells.

Deficient Protein Kinase A Activity

Studies on the adenyl cyclase/cAMP/protein kinase A (AC/cAMP/PKA) system, a key metabolic pathway integral to cellular homeostasis, identified impaired cAMP-dependent protein phosphorylation in SLE T cells [357]. An abnormal cAMP-dependent signaling pathway is associated with deficient CD8 uppressor T-cell function and altered cytoskeletal regulation of CD3, CD4, and CD8 receptor mobility within the plane of the plasma membrane [302, 358]. It has been demonstrated that the abnormal cAMP-dependent signaling pathway reflects a profound reduction in PKA-I isozyme [308]. Deficient PKA-I activity is the consequence of a reduced type I regulatory subunit. Deficient T-cell PKA-I activity reflects reduction of both holoenzymes $RI\beta_2C_2 > RI\alpha_2C_2$ [359]. Deficient PKA-I activity possibly contributes to altered T-cell effector function by altering the protein phosphorylation that regulates cellular pathways that promote cell growth and differentiation. Similar to the TCR ζ chain, increased mutation/polymorphism of protein kinase A I regulatory subunit α has been reported in a SLE patient [360]. The kinase activity of protein kinase C [361] and Lck is also impaired in SLE T cells [362]. The activity of other kinases, such as protein kinase PKR, which is involved in the phosphorylation of translation initiation factors, is increased in SLE T cells [363].

An interrelationship between the Ca^{2+} and AC/cAMP/PKA pathway raises the possibility that defective PKA activity in part contributes to the impaired Ca^{2+} homeostasis. The TCR/CD3-mediated increase in IP_3 and $[Ca^{2+}]_i$ is downregulated by the inactivation of PLC-γ1 through PKA-dependent phosphorylation [364]. Deficient PKA-catalyzed phos-phorylation may retain the activity of PLC-γ1 and contribute to the supranormal and sustained $[Ca^{2+}]_i$ response in SLE T cells.

Ras-MAP kinase activity is also impaired in SLE T cells and has been connected to decreased DNA methylation (see section on drug-induced lupus).

Abnormalities in Transcription Factor Expression

Early signaling abnormalities are followed by the altered activation of transcription factors and abnormal gene transcription. It is notable that while certain genes are transcribed at low rates (the T-cell receptor ζ chain and interleukin-2 genes), others are transcribed at increased rates (genes for the γ chain of the Fc receptor for IgE and the CD40 ligand) [24]. In addition to the TCR ζ chain, transcription factor Elf-1, described earlier, defects have been identified both in the expression/activation of other transcription enhancers and repressors, including the NF-κB p65-Rel A subunit and p-CREM.

Deficient p65-Rel A Subunit of NF-κB in SLE T Cells

The transcription factor NF-κB plays a profound role in immune and proinflammatory responses and IL-2 production [365]. The possibility that reduced IL-2 production by SLE T cells may be a product of altered NF-κB activity has been analyzed by electrophoretic mobility shift assays (EMSA) [207]. NF-κB activity in the nuclear extracts is decreased significantly in SLE T cells. In the group of SLE patients with decreased NF-κB activity, the transcriptionally active, heterodimeric p65/p50 complex was not formed in the cytosol. The deficiency of the NF-κB heterodimeric complex could be responsible for the downregulation of IL-2 and may have extensive pathophysiological significance in the expression of the disease.

Increased CREM Binding to the –180 Site of the IL-2 Promoter

SLE T cells stimulated *in vitro* in response to antigens or mitogens proliferate significantly less than T cells from normal donors. Activated SLE T cells also secrete low IL-2 *in vitro* that may reflect increased T-cell anergy. Another mechanism for the low IL-2 production by SLE T cells is inhibition of IL-2 enhancer/promoter transcriptional activation. Cyclic AMP response element modulator (CREM) and inducible camp early repressor (ICER) are two transcriptional repressors that bind to camp response elements (CREs) and downregulate genes containing this binding site. It has been demonstrated that phosphorylated CREM (p-CREM) binds to the –180 region of the IL-2 enhance/promoter and contributes to T-cell anergy [209]. This raised the question that p-CREM upregulation may contribute to the downregulation of IL-2 secretion and contribute T-cell anergy. Nuclear extracts from resting SLE T cells showed significantly increased binding of p-CREM/p-CREB to the –180 site of the IL-2 enhancer/promoter [209]. Some patients revealed both p-CREM and p-CREB, although p-CREM was the

main factor. We have found that activated normal T cells increase p-CREB binding by 10-fold in contrast to negligible p-CREM binding to the –180 site. In contrast, activated SLE T cells bound both p-CREM and p-CREB in a 2:1 ratio. Thus, preferential phosphorylation and predominant occupancy of the –180 site of the IL-2 enhancer/promoter by p-CREM during activation may hamper optimum transcriptional activation by p-CREB binding, resulting in very low IL-2 production in SLE T cells. In contrast to the heteromeric complex formation between p-CREB to two nuclear coactivators, CREB-binding protein (CBP) and p300 that initiate transcription in normal T cells [366], SLE T cells mainly form p-CREM/CBP/p300 complexes that may suppress the IL-2 synthesis.

Abnormal Nuclear Translocation of RIIβ Subunit

The RIIβ subunit of PKA II is not classified currently as a nuclear factor, although its translocation to nucleus and binding to CREB support the role of a transcription factor. Upon activation of the PKA-II holoenzyme, RIIα/β_2C_2, by reversible cAMP binding to the RII subunits, releases RIIβ that reversibly translocates to the nucleus. Although it has been suggested that nuclear RIIβ binds CREB, at present its function in the nucleus still remains uncertain. The RIIβ subunit can be constitutively in the nucleus, suggesting an ongoing activation of RIIβ_2C_2 during homeostasis. The mechanism of deficient PKA-II activity in SLE T cells differs from PKA-I and involves increased nuclear translocation of the RIIβ to the nuclear fraction, diminishing the capacity to form a RIIβ_2C_2 holoenzyme [367].

Impaired Protein Translation

PKR is a serine/threonine protein kinase that regulates protein translation [368]. As an inactive holoenzyme, the molecule exists in its dephosphorylated form. However, binding of dsRNA to PKR results in a conformational change, causing autophosphorylation and homodimer formation [368, 369]. Once activated, PKR can phosphorylate several substrates, including those regulating protein synthesis. The initiation of protein translation is regulated at two steps: (a) eukaryotic initiation factor 4e (eIF4e)-mediated binding of the 40S ribosomal subunit to the 5′ end of the mRNA and (b) eIF2α-mediated binding of the initiating methionine (met)-tRNA to the 40S ribosomal subunit [369]. Activated PKR phosphorylates eEF2α, preventing formation of the eEF2α–met-tRNA complex and thereby inhibiting protein synthesis and subsequent cellular proliferation. Interestingly, mice heterozygous for a PKR null mutation exhibit decreased signaling through the p38 MAPK pathway [369]. Stimulation of normal T cells with PMA/IO increased protein translation approximately 90-fold. In contrast, similar treatment of T cells from subjects with active SLE increased protein synthesis only 5-fold, whereas T cells from people with inactive SLE only increased protein synthesis ~20-fold. A comparison of PKR levels revealed that stimulation of SLE T cells caused more rapid and larger increases in PKR than controls, resulting in increased eEF2α phosphorylation. Further, overexpressing PKR in T cells by transfection suppressed protein synthesis. Comparison of PKR mRNA levels in stimulated SLE and control T cells demonstrated no differences, indicating that increased PKR activity in SLE T cells reflects posttranscriptional regulatory differences [363]. The precise mechanism underlying PKR overexpression in SLE T cells is currently unknown.

Abnormal Immune Cell Signaling and Autoimmunity

The aforementioned data, along with those that will be discussed in subsequent sections (B lymphocytes and apoptosis), establish that antigen receptor-initiated signaling is abnormal in SLE. As of now there is no information on the signaling events that are initiated by cytokine receptors or other lymphocyte receptors. It is probable that more abnormalities will be revealed. Aberrant cell signaling is initiated after antigen binds the lymphocyte receptor and is further modulated by signaling events that are initiated by cytokine receptors and other cell membrane receptors. When the quantity and/or the quality of the produced signaling events cross a certain "threshold", then autoimmunity ensues (Fig. 2). Data generated from the study of autoimmune mice concur with this proposition. Break of tolerance in transgenic mice is associated with abnormal (increased) lymphocyte signaling [370], and the expression of cytochrome TCR in MRLlpr mice is associated with increased responses [371].

ANTIGEN-PRESENTING CELL FUNCTION

Abnormal APC function was further suggested by studies that evaluated the response of SLE T cells to the recall antigen influenza virus and alloantigens [372, 373]. Indeed, one-half of the studied patients failed to respond to the MHC self-restricted antigen influenza-A virus while they responded to an alloantigen that can use both MHC self-restricted or unrestricted T-cell activation pathways [372]. Previous reports have shown

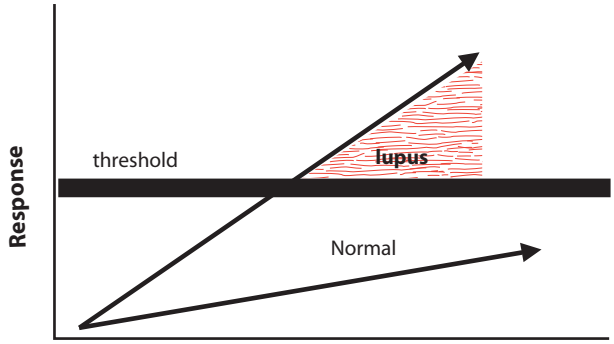

FIGURE 2 Abnormal immune cell signaling and autoimmunity. Aberrant cell signaling is initiated after antigen binds the lymphocyte receptor and it is further modulated by signaling events that are initiated by cytokine receptors and other cell membrane receptors. When the quantity and/or the quality of the produced signaling events crosses a certain "threshold," autoimmunity ensues.

defective IL-1 production [28] and expression of HLA-DR antigens on the surface membrane of monocytes from patients with SLE [43, 44]. Collectively, these studies strongly suggest that the APC function is deficient in the majority of patients with SLE. Defective APC function has also been implied by studies where the need for APC-delivered costimulation is bypassed by effectively cross-linking the CD28 [374] or the CD26 [375] T-cell surface molecules.

Indeed, a defect was found in the induction of B7-1 (CD80) expression by lupus APCs [373]. Resting normal APC do not express B7-1, but treatment with IFN-γ induces the expression of surface B7-1. Lupus APC failed to express surface B7-1 following stimulation with IFN-γ. Interestingly, replenishment of B7-1 in the culture environment by means of adding B7-1-transfected P815 murine mastocytoma cells increased significantly the response of lupus T cells to tetanus toxoid and the anti-CD3 monoclonal antibody. These experiments also revealed that the Fcγ receptor present on the surface of lupus APC is unable to cross-link efficiently the murine monoclonal anti-CD3 antibody and initiate T-cell proliferation (Fig. 3). This function was effectively served by the Fc receptor that is expressed on the surface of P815 murine mastocytoma cells. Reduced expression of CD80 by non-B-cell APC *in vivo* has also been reported in patients with rheumatoid arthritis [376, 377]. In contrast, CD86 was expressed by an increased percentage of lupus B cells [378, 379] and is clearly upregulated in the rheumatoid synovium [377]. Differences in the expression of these two molecules in autoimmune diseases may reflect the fact that each one of them may have different functional attributes or that their molecular requirements for upregulation in disease states are different.

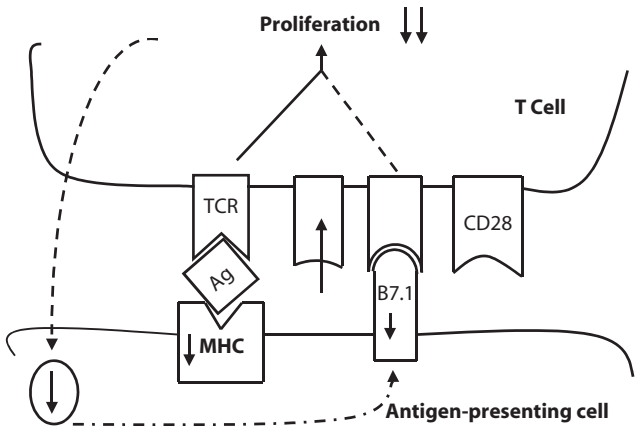

FIGURE 3 Defective upregulation of the B7.1 molecule on the cell surface of antigen-presenting cells (APC) in patients with SLE. Soluble or surface molecules of T-cell origin induce the expression of B7.1 on the surface of APC. An additional signal is thus delivered via the counterreceptor CD28 (constitutively present on T cells), avoiding the induction of a state of anergy, which otherwise would ensue, for the T cell. Recall antigens presented to lupus T cells in a MHC-restricted fashion and in the presence of APC produce subphysiological proliferative responses compared to normal T cells. This is because the important upregulation of B7.1 expression on APCs is decreased significantly.

COSTIMULATION IN LUPUS

B7-CD28

The role of B7-CD28 interaction in T-cell stimulation has been studied extensively. The CD28/CTLA4-B7 family [16] is crucial in IL-2 production and tolerance induction [18]. The CD28/CTLA4-B7 pathway determines tolerance induction and activation of T cells from MRL *lpr/lpr* mice [380]. A B7 binding construct (CTLA4 molecule fused with the heavy chain of Ig to provide decreased plasma clearance rates) was given to mice that develop lupus spontaneously and the rate of survival increased along with a lower titer of autoantibodies and lesser kidney pathology [381]. Because CTLA4 can block both B7-1 and B7-2, effectively it is not known as of yet whether blockage of one or the other or both molecules is necessary for the therapeutic effect. Additionally, it is not known whether B7-1 or B7-2 is the primary molecule involved in the expression of murine lupus. Treatment of animal models for EAE and nonobese diabetic mouse with anti-B7-1 and/or anti-B7-2 antibodies produced opposing results. These observations indicate that (a) the various autoimmune animal models are different diseases with different immunoregulatory requirements; (b) the availability of B7 molecules, and probably others, is mandatory for the

response to the autoantigen; and (c) the autoantigen may be ignored if the appropriate milieu is not available. This proposal is further supported by the following experimental information.

First, constitutive expression of B7-1 alone by keratinocytes does not induce $CD4^+$-mediated autoimmunity but greatly increases and prolongs cutaneous delayed-type hypersensitivity reactions to exogenously applied antigens [382, 383]. Of note, keratinocytes from patients with psoriasis display increased levels of B7 [384]. Transgenic mice that express B7-1 on the surface membrane of pancreatic cells and the appropriate T-cell receptor (double transgenes) develop diabetes [385]. Also, animals that express B7-1 and antigens of the lymphocytic choriomengitis virus (double transgenes) in pancreatic B cells develop anti-self(viral) cytotoxic T lymphocytes and diabetes [386].

Second, endothelial cells from nonsun-exposed areas from lupus patients overexpressed E-selectin, vascular cell adhesion molecule 1 (VCAM-1), and intercellular adhesion molecule 1 (ICAM-1) [387]. Tissue overexpression of adhesion molecules is in accordance with the reported increased levels of soluble adhesion molecules in the sera of patients with lupus (reviewed in Tsokos [388]) and infer their involvement in the autoimmune pathogenic process. Nevertheless, they have not addressed whether the expression of adhesion molecules by APCs or lymphocytes has a primary role in the initiation of the pathologic process. This question has been addressed in a definitive experiment [389]: D10 cloned helper T cells were transfected successfully with the LFA1 (CD18) gene and injected weekly (six times) into syngeneic normal AKR mice. Four weeks after the last injection, the mice produced anti-dsDNA antibodies and pathologic features of glomerulonephritis. Therefore, it can be assumed that circulating T cells that are programmed to recognize DNA pause their ignorance of the autoantigen in the presence of LFA-1. Drugs that cause the overexpression of LFA-1 on the surface of cells [390, 391] can initiate an autoimmune process [392].

CD40-CD40 Ligand

Pathogenic antibodies require cognate interaction between T and B cells. CD40 (expressed on B cells) and gp39 (CD40 ligand, expressed on T cells) have been shown to play important roles in the production of antibody. Patients with CD40 ligand deficiency display increased levels of IgM and deficient responses to antigens. Experiments have shown that signaling through the CD40 ligand (gp39) is necessary for the expansion of antigen-specific helper T cells because mice that lack the CD40 ligand fail to produce an antigen-specific antibody [393, 394]. Interruption of the CD40–gp39 interaction SNF1 autoimmune mice with and anti-gp39 antibody resulted in a decreased expansion of autoimmune memory B cells and long-term improvement of the clinical disease [395]. Experiments that show therapeutic effects in autoimmune mice following interruption of the B7-CD28 and CD40-gp39 paths indicate that these paths are involved in a serial manner in the production of antibody.

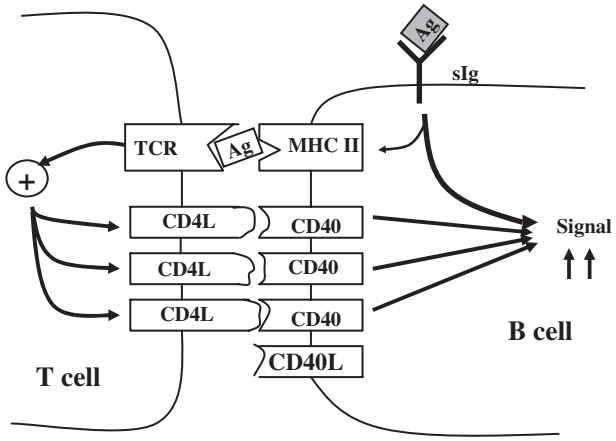

FIGURE 4 Dysregulation of a CD40-CD40L pair of molecules. Antigen presentation to T cells induces the transient expression of CD40L on their surface. This in turn, via its counterreceptor CD40 (constitutively expressed on B cells mainly), delivers an important costimulatory signal to the CD40-bearing cell. In SLE, the upregulation of CD40L on T cells is significantly more intense and more prolonged. This can deliver excessive help to lupus B cells for the production of autoantibodies. B cells in SLE also become $CD40L^+$ upon activation, a finding with unclear significance as of yet.

The CD40-CD40 ligand (CD40L) also appears to malfunction in lupus. The number of circulating $CD40L^+$ T cells of lupus patients is not increased compared to normal individuals; however, the induction of this molecule on lupus $CD4^+$ and $CD8^+$ T cells is both enhanced and prolonged [396]. Moreover, it has been reported that lupus B cells unexpectedly express $CD40L^+$ upon stimulation in an equally intense manner to the T cells. This abnormally regulated molecule on lupus lymphocytes is still functional, as it was shown in two sets of elegant experiments: (1) anti-CD40L mAb was shown to inhibit the production of anti-DNA antibodies [397] and (2) CD40L positive cells induced the expression of CD80 (B7-1) in a B-cell line [396] (Fig. 4).

Although unclear it has become an emerging theme that SLE patients have abnormal RNA splicing processes. Abnormal splicing was discussed earlier for the TCR ζ chain. Abnormal splicing involving the transmembrane region of a molecule will result in the pro-

duction of a soluble form. Both CD40 [398, 399] and CD40L [398] soluble forms have been detected in patients with SLE and they obviously interfere with the interaction of the surface-bound counterparts. Abnormal splicing and increased levels of Fas and FasL are discussed later.

LYMPHOCYTE TRAFFICKING

T lymphocytes that home in various tissues and initiate the pathologic process may express abnormally high levels of receptors that facilitate attachment to endothelial or other cells. Other pairs of molecules are involved exclusively in providing the costimulatory signal to T cells, whereas other pairs of molecules are involved in both cell costimulation and adhesion/homing of cells [16–18].

Several sets of surface molecules participate in the cell–cell and cell–substitium adhesion process. Members of the β1 integrin family of adhesion molecules are major adhesive receptors for the extracellular matrix. Members of the β2 integrin family, VLA4 and VLA3, are involved in both cell–cell and cell–extracellular matrix adhesion [400]. The expression of these molecules is regulated under normal conditions and upregulated in various disease conditions such as atherosclerosis [401], inflammation [402], and rheumatoid arthritis [403]. VLA4 and LFA1 were found to be overexpressed on the surface membrane of lymphocytes from patients with SLE. Interestingly, VLA4 was overexpressed only in lymphocytes from patients who had vasculitis. Lymphocytes from these patients showed increased adhesion to cord vein endothelial cells [58]. Neutrophils from patients with active lupus displayed increased surface membrane expression of β2 integrin CD11b/CD18 [404]. Obviously, these findings shed light on the pathogenesis of vasculitis [405] and other tissue injury in patients with lupus. Increased expression of the VLA4 partner on the surface of endothelial cells may also be present and further facilitates the attachment of lymphocytes to endothelial cells and the initiation of the inflammatory process.

CYTOTOXIC RESPONSES

Cytotoxic mechanisms can be separated into natural cytotoxicity, antibody-mediated cytotoxicity, and specific cytotoxicity. Cytotoxic mechanisms in SLE have been reviewed extensively [32, 406]. Decreased cytotoxic responses are the least disputed abnormalities in SLE. All aspects of cytotoxic responses have always been described to be abnormally low (Table 7).

TABLE 7 Cellular Cytotoxic Function in SLE

Decreased NK cell activity
Decreased allogeneic cytotoxicity
Decreased xenogeneic cytotoxicity
Decreased antibody-dependent cell cytotoxicity
Decreased cytotoxicity function against virus-modified self targets
Decreased IL-2-induced killer cells (LAK cells)
Decreased antigen-nonspecific cell cytotoxicity

Natural Killer Cells

NK cell activity has been described to be low in patients with SLE [407–412]. Low NK activity is associated with disease activity [408, 411, 412]. Serum factors [411], antilymphocyte antibodies [407], and IgM and/or IgG anti-NK antibodies [94] may be responsible for decreased NK activity in lupus patients. In our study, half of the patients with SLE had decreased NK cell activity. Exogenous IFN did not enhance NK activity in the group of patients with low NK activity, although it enhanced NK activity in the group of patients with normal NK activity [412]. Thus, it seems that both decreased IFN production and unresponsiveness to IFN are responsible for low NK activity in SLE patients. Exogenous IL-2 can restore NK activity to normal levels *in vitro* [220, 413, 414].

The importance of decreased NK activity in SLE is severalfold. First, NK cells are known to suppress B-cell function [137] and, therefore, lupus B lymphocytes function in the absence of a suppressor mechanism. Second, NK cells are responsible for carrying out immune surveillance against tumor cells [415]. Patients with lupus have an increased frequency of lymphoreticular malignancies [312–319]. Third, NK cells recognize and kill virus-infected cells [415, 416]. Decreased NK activity may be responsible for the increased frequency of infections in SLE. Deficient elimination of virus-infected cells in lupus patients may be of pathogenic importance should the virus prove to be important in the pathogenesis of the disease. It can be speculated that failure to eliminate EBV-infected B cells may lead to continuous polyclonal B-cell activation. EBV has been considered of pathogenic importance in both rheumatoid arthritis [417–419] and SLE [128, 417]. Because EBV has been implicated, probably among other factors, in the development of non-Hodgkins lymphoma in human immunodeficiency virus-positive individuals [420] and because the frequency of non-Hodgkins lymphoma has been shown clearly to be increased among patients with lupus [421, 422], the significance of deficient cytotoxic responses in the expression of the disease pathology cannot be underestimated.

Other forms of nonspecific cytotoxicity have been found decreased in patients with SLE. Phytohemagglutinin-induced cellular cytotoxicity [423, 424] and IL-2-activated killer (LAK) cell activity [425] are decreased.

Specific Cytotoxicity

Cell-mediated lympholysis directed against xenoantigens (which is considered to be class II MHC antigen mediated) has been found severely depressed in patients with SLE [93]. Cell-mediated lympholysis against alloantigens is also decreased [37]. Cytotoxicity levels correlate with disease activity parameters.

Antibody-Dependent Cell-Mediated Cytotoxicity

Antibody-dependent cell-mediated cytotoxicity is a lytic mechanism mediated by MNC that carries receptors for the Fc portion of IgG [426–429]. Obviously, the specificity of the killing is determined by the specificity of the involved IgG antibody and not the antibody-dependent cell-mediated cytotoxicity effector cell. Killing may be mediated by certain subclasses of IgG and not by others [430].

Antibody-dependent cell-mediated cytotoxicity of SLE MNC has been tested against a variety of targets (Chang cells, chicken erythrocytes, Burro erythrocytes) and found to be decreased [116, 424, 431–434]. Decreased antibody-dependent cell-mediated cytotoxicity correlated with disease activity [435, 436]. Circulating immune complexes and cytophilic IgG molecules may occupy the Fc receptor of the effector cells and inhibit its ability to exercise antibody-dependent cell-mediated cytotoxicity. Overnight treatment of SLE MNC with pronase enhances antibody-dependent cell-mediated cytotoxicity. Also, the SLE-derived IgG antibody suppresses antibody-dependent cell-mediated cytotoxicity exercised by normal MNC [432]. Although antibody-dependent cell-mediated cytotoxicity expressed by SLE MNC *in vitro* is decreased, antibody-dependent cell-mediated cytotoxicity may be enhanced *in vivo*. Antilymphocyte antibodies many bind to lymphocytes through the $F(ab')_2$ fragment and to antibody-dependent cell-mediated cytotoxicity effector cells through their Fc portion. Antilymphocyte antibodies, lymphopenia, and low antibody-dependent cell-mediated cytotoxicity *in vitro* may thus be casually related [95]. Destruction of other cellular elements via antibody-dependent cell-mediated cytotoxicity may be an ongoing process in patients with SLE.

Nonantigen-Specific Cell Cytotoxicity

Finally, nonantigen-specific T-cell-mediated cytotoxicity is decreased in lupus patients [437]. Lupus T cells stimulated with an anti-CD3 monoclonal antibody in the presence of IL-2 displayed decreased cytotoxicity against Daudi target cells. The defect was limited to lupus patients and did not extend to patients with other rheumatic diseases. The cytolytic defect was not affected by disease activity or treatment. Interestingly, the proliferative responses of these expanded cells (in culture for 10–12 days) were normal in lupus cells, which makes the cytolytic defect more prominent in terms of significance [438]. Nonantigen-specific cytotoxicity is mediated by $CD56^+$ cells that include both natural killer and T cells. The percentages and absolute numbers of $CD56^+$ cells are decreased significantly in lupus patients in a disease activity and treatment-independent manner [439]. Subsequent experiments by the same group showed that the cytolytic defect was associated with a low expression of perforin. The Fas antigen-mediated killing was found to be normal [440]. Deficient nonantigen-specific cytotoxic activity could participate in the promotion of the autoimmune response by failing to eliminate autoantigen and polyclonally stimulated B-cells.

B LYMPHOCYTES

B-Cell Repertoire in Lupus

The main immunological event in the pathogenesis of lupus is B cell overactivity. Patients with active disease and mice with lupus have increased numbers of cells that produce anti-DNA and other autoantibodies [32, 441, 442]. Also, the number of B cells that produce antibody against nonself antigens such as TNP-KLH and ovalbumin is increased [443]. Experiments using the chamber ELIspot assay capable of determining the isotype and cross-reactivity of individual *in vivo*-activated lymphocytes [444, 445] in autoimmune mice showed that cross-reactive B cells were utilized at increased frequency in very old animals, which was associated with the production of pathogenic autoantibodies [446]. In patients with SLE, B cells secreting IgM antibodies against DNA or TNP-KLH were no more cross-reactive than those from normal controls. In contrast, IgG anti-DNA antibody-secreting cells from patients with SLE were significantly more cross-reacting than normals. The degree of cross-reactivity correlated with disease activity and serum anti-DNA antibody levels [447]. Epstein–Bar virus-transformed B cells from patients with SLE produce antibodies that do

not differ with respect to antigenic specificities, avidity, isotype, or titer. However, anti-DNA antibodies bearing the anti-DNA-associated idiotype 8.12 [448] were found only in SLE [449]. These findings are in agreement with those of Klinman *et al*. [447] in that they show that the SLE B-cell repertoire is closer to the normal B-cell repertoire than the serum antibody profile. Moreover, SLE anti-DNA antibodies are different with respect to cross-reactivity and idiotype expression.

B Lymphocyte Subsets

Although the number of spontaneously Ig-secreting cells is increased in both peripheral blood and bone marrow in patients with SLE [32], the number of phenotypically defined B cells appears to be within normal limits.

Expression of the T-cell marker CD5 by B cells defined a subset that has been assigned an important role in autoimmunity. NZB and (NZBxNZW)F1 mice have increased numbers of $CD5^+$ B cells [450, 451]. $CD5^+$ B cells are elevated in patients with Sjögren's syndrome [450, 452] and rheumatoid arthritis [453, 454]. In the majority of patients with chronic lymphocyte leukemia, the malignant clone is $CD5^+$ [455, 456]. $CD5^+$ B cells produce most of the polyreactive antibodies with antiself and anti-idiotypic reactivity [450, 451, 457, 458]. In the NZB mouse, $CD5^+$ B cells produce antierythrocyte antibodies. In the (NZBxSWR)F1 mouse, $CD5^+$ cells produce cationic anti-DNA antibodies [10, 459]. In patients with Sjögren's syndrome and rheumatoid arthritis, $CD5^+$ B cells produce IgM rheumatoid factor [452, 458, 460].

Sporadic patients with SLE may have increased numbers of circulating $CD5^+$ B cells [461, 462]. The average percentage of $CD5^+$ $CD20^+$ B cells is comparable to that of healthy individuals [463]. Both $CD5^+$ and $CD5^-$ B cells from patients with SLE produced equal amounts of anti-ssDNA. IgM polyreactive anti-ssDNA antibodies are produced primarily by $CD5^+$ B cells, whereas IgG and IgA anti-ssDNA antibodies are produced by $CD5^-$ B cells [463]. In another study [464], both $CD5^+$ and $CD5^-$ SLE B cells were found to produce comparable amounts of IgG and IgM anti-DNA antibodies. It is unclear why SLE patients do not follow the example of other murine and human autoimmune disorders.

Phenotypic Changes

Desai-Mehta *et al.* [397] described for the first time the appearance of a costimulatory molecule, CD40 ligand (CD40L, CD154), on the surface membrane of lupus B cells, a marker considered to be characteristic of activated T cells. This finding was disease specific. In the peripheral blood of patients with active SLE $CD40L^+$, B cells were 20.5-fold more when compared to healthy donors. In patients with inactive SLE the number of $CD40L^+$ B cells was comparable to those of controls. Nevertheless, activation-induced CD40L expression on the surface of lupus B cells was 17-fold the baseline levels compared to a 7.6-fold increase recorded in control subjects. CD40L was synthesized actively within the lupus B cell as supported by data of CD40L mRNA detection in lupus B cells.

CD40L expressed on the surface of lupus B cells retains full functional properties. The addition of a neutralizing anti-CD40L mAb in *in vitro* cell culture settings decreased cationic anti-dsDNA production. Because not only T cells but also B cells from SLE patients express functional CD40L on their cell surface and because both kinds of lymphocytes express CD40, a bidirectional cognate stimulatory loop may function between lupus T and B cells [465]. Moreover, it was reported that CD40L expressed on the surface of B cells costimulates other B cells as well [466].

In addition to CD40L, CD80 and CD86 are aberrantly expressed on the surface of lupus B cells. Fresh, small, resting, peripheral B cells but also large, activated B cells from patients with SLE were studied for the expression of CD80 and CD86. While CD80 expression was increased only slightly on the surface of large, activated lupus B cells, the expression of CD86 was 2.5- and 7-fold increased on the surface of activated and resting lupus B cells, respectively, when compared to B cells obtained from patients with allergic disorders [378]. While patients in remission only were studied, and the functional integrity of the costimulatory molecules was not assessed, this study provides evidence that B cells from patients with SLE overexpress molecules that belong to the B7 family of costimulatory molecules. Expression of B7 family molecules has been shown to be a prerequisite for the disruption of immune tolerance toward self-antigen [467].

Spontaneously Ig-Secreting B Cells

The number of spontaneously Ig-secreting B cells is increased significantly in patients with SLE [60, 410, 468–471]. Spontaneously activated SLE B cells correlate with disease activity, serum DNA binding, low levels of serum C3, treatment with immunomodulatory drugs [38, 470, 471] and a high RNA/DNA ratio in nuclear chromatin [472]. Unlike B cells from NZB mice, which secrete primarily the IgM antibody [442], B cells from adult patients with SLE secrete Ig of IgG and IgA

classes [38, 473, 474]. It has been reported that B cells from children with SLE secrete primarily IgM [475]. Bone marrow from patients with active or inactive SLE contains large numbers of B cells secreting spontaneously Ig [476].

Mitogen-Induced Ig Secretion

Although the number of spontaneously Ig-secreting B cells is increased in SLE, stimulation of MNC *in vitro* with pokeweed mitogen causes a rapid decrease of Ig production [38, 114, 468, 476–479]. Removal of monocytes from the culture system increases significantly the pokeweed mitogen-induced polyclonal response [38] and the dsDNA-induced specific response [35]. Because pokeweed mitogen is a T-cell-dependent B-cell polyclonal stimulator and anti-DNA production is T cell dependent, these studies do not indicate that B cells from SLE patients have a primary defect. Indeed, stimulation of B cells with the T-cell-independent antigens *S. aureus* Cowan strain I [480] and EBV [128] *in vitro* induces the secretion of normal amounts of Ig.

Lymphokines in Lupus B-Cell Function

Lymphokines are responsible for driving or prohibiting various B-cell activation and differentiation phases. This section addresses the contribution of lymphokines secreted by T cells and macrophages (endocrine or paracrine action) and those secreted by B cells themselves (autocrine action).

B cells from autoimmune mice demonstrate hyperresponsiveness to activating signals and lymphokines promoting B-cell growth and differentiation [481]. Human lupus B cells similarly overrespond to factors produced by T cells [482]. Percoll gradient-separated small resting human SLE B cells show a stronger proliferative response to *S. aureus* Cowan strain I [483]. Addition of the 10- to 12-kDa B-cell growth factor (BCGF) further enhances their proliferative response. *S. aureus* -activated lupus B cells respond with excessive production of Ig if T-cell-derived factors are present [464, 483]. *S. aureus* -preactivated lupus B cells also demonstrate more vigorous responses to IL-1 [484]. Activated B cells express the receptor for IL-2. One-half of *S. aureus* -activated normal B cells express the IL-2 receptor; *S. aureus* -activated SLE B cells express less IL-2 receptors on their surface [485]. This is further corroborated by the finding that *S. aureus* -activated SLE B cells do not respond to exogenous IL-2 [484]. Even in the absence of mitogen SLE B cells proliferate vigorously in the presence of the 50-kDa BCGF, but not in the presence of IL-2 and the 20-kDa BCGF [486]. In an other study [487], enriched SLE B-cell populations were found to respond excessively to recombinant 12-kDa BCGF. Notably, only one-half of the patients responded excessively regardless of disease activity. IL-4 enhanced and transforming growth factor-β suppressed, at expected levels, the BCGF-induced B-cell proliferation. Although IFN-γ suppresses the *in vitro* response of lupus cells to TNP–*B. abortus* [129], IFN-γ increases dramatically the ability of freshly isolated lupus non-T cells to produce Ig [488]. In summary, resting and *S. aureus* -activated lupus cells respond excessively to BCGF-mediated stimulation. IL-2 does not seem to participate in the regulation of proliferation of at least resting SLE B cells, whereas IL-4 and transforming growth factor B regulate the response normally.

EBV-transformed B cells and normal B cells produce lymphokines that may regulate B cell function. SLE lymphocytes [489] and purified B cells [490–494] produce factors that are able to promote proliferation and differentiation in B cells. In one of the studies [494], the factor that was produced by B cells and was acting on B cells had an estimated molecular mass of approximately 18 kDa. This factor promoted both proliferation and differentiation of SLE B cells and did not identify with IFN or IL-2. In contrast, it contained IL-1, IL-4, and IL-6 activity. Lupus B cells respond to IL-1, Il-4, and IL-6 [494].

The relative role of IL-10 in driving human anti-DNA antibody production was shown in mice with severe combined immunodeficiency that were reconstituted with peripheral MNC from lupus patients. In these chimeric animals, production of the human anti-DNA antibody was blocked by anti-IL-10, but not by anti-IL-6 antibodies [244]. A role for IL-10 in the expression of human lupus was inferred by other data, which showed that increased disease activity was associated with a preferential (over IFN-γ) expansion of peripheral cells producing IL-10 [267]. IL-10 may suppress APC function and may be responsible for the defective B7-1 expression [373].

The action of excessive amounts of stimulatory lymphokines is probably facilitated by deficient negative feedback. IgG Fc receptor-mediated signaling delivers a negative signal to B cells [495]. In autoimmune mice, this signaling is defective [496]. There is some indication, yet not direct, that Fc-mediated negative signaling is defective in SLE [497, 498] (see also section on cell signaling). The combination of positive feedback exercised via B cell stimulatory factors as described earlier and the lack of negative feedback provided by Fc receptor ligands contribute to the perpetuation of autoantibody production by lupus B cells.

Aberrant B-Cell Antigen Receptor Signal Transduction

The studies discussed earlier present evidence supporting the view that B cells from patients with SLE have functional as well as phenotypic abnormalities that are at least in part independent of the activity of the underlying disease. It is thus possible that such aberrations represent intrinsic lupus B-cell defects. It is also possible that the heterogeneous defects described previously may have a common underlying central biochemical abnormality. Crucial aspects of lymphocyte function, such as activation, proliferation, cytokine production, effector functions, and apoptosis, are determined by the signaling biochemical pathway initiated following ligation of the surface antigen receptor. Physiologically, the ligand for BCR is the relevant antigen, and for the autoreactive B cell it is the autoantigen.

We currently know that the biochemical cascade triggered in the B cell following the interaction between BCR and antigen can be closely mimicked by anti-BCR antibodies. The question of possible antigen–receptor-mediated signaling aberrations in B cells of lupus patients using anti-Ig antibodies has been addressed [499]. Stimulation of circulating B cells from patients with SLE through their sIgM BCR produced significantly higher fluxes of free intracytoplasmic Ca^{2+} when compared to similarly induced responses of B cells from patients with other systemic rheumatic diseases or to the responses obtained from normal B cells. This phenomenon was not limited to signaling through the sIgM BCR, but was also observed when the sIgD BCR was used for triggering the signaling process. The elevated Ca^{2+} responses were contributed significantly from the intracellular calcium stores. Nevertheless, the production of inositol 1,4,5-trisphosphate (the principal mediator of free calcium release from the intracellular compartment) was elevated only slightly, raising the possibility of either a hypersensitive Ca^{2+} release machinery or of a dominant inositol trisphosphate-independent pathway(s) of Ca^{2+} release.

The earliest known BCR-mediated signaling event is the activation of protein tyrosine kinases, which results in the tyrosyl phosphorylation of cellular proteins [500]. The tyrosyl phosphorylation reaction has numerous substrates; it is only a few of such substrates that have been identified. In lupus B cells, the overall level of sIgM-initiated protein tyrosyl phosphorylation was significantly enhanced and correlated with the augmented BCR-mediated free calcium responses. More specifically, at least four cellular proteins with molecular sizes between 36 and 64 kDa were significantly hyperphosphorylated in anti-IgM-treated lupus B cells compared to the response of B cells from normal controls [499]. The aberrant BCR-mediated signaling process was not associated with disease activity, treatment status, and specific clinical manifestations. Moreover, enhanced tyrosyl protein phosphorylation was disease specific, implying a possible intrinsic lupus B-cell defect, which may have a pathogenic impact. Furthermore, the increased Ca^{2+} responses could represent a biochemical and molecular basis for the enhanced expression of CD40L on the surface of lupus B cells upon stimulation. It was reported previously that CD40L upregulation on the cell surface is predominantly NFAT, and hence Ca^{2+} dependent [25]. Signaling abnormalities encountered in SLE B lymphocytes may provide a biochemical and molecular background for such diverse abnormalities as lymphocyte activation, anergy, and cell death.

It is interesting that similar to the human lupus BCR-initiated signaling, abnormalities were encountered in a study of experimental animal lupus. Feuerstein *et al*. [370] induced systemic lupus-like autoimmunity by inducing graft-versus-host disease in a background of a double transgenic sIg/sHEL murine tolerance model. The induction of autoimmunity correlated with phenotypical as well as with signal transduction changes of B cells similar to the human disease. The B-cell surface expression of CD21 (part of the complement receptor 2, CR2, complex) was decreased significantly in the autoimmune state. In addition, changes in the BCR-mediated protein tyrosyl phosphorylation pattern in B cells developed following the induction of autoimmunity. In the autoimmune but not in the tolerant state, two substrates with apparent molecular masses of 78 and 60 kDa were hyperphosphorylated following BCR cross-linking. The similarity of BCR-induced signaling in patients with SLE and in this particular autoimmunity model underscore the potentially central pathogenic role of aberrantly functioning B cells in both conditions.

B-Cell Surface Receptors That Provide Negative Regulation

There are several different B-cell surface signaling inhibitory receptors. Among them, the functions of CD5, CD22, and FcγRIIB1 are better understood [500]. The ligand for CD5 has been shown to be CD72. The role of $CD5^+$ B cells in SLE and in experimental animal lupus was discussed previously. The role of coreceptor CD22 was incompletely understood until a study using CD22 knockout mice clearly disclosed that CD22 is a signaling inhibitory molecule. Young CD22 knockout mice displayed autoimmunity, increased BCR-initiated cytoplasmic calcium responses, hypergammaglobulinemia, and circulating IgM autoAb [501]. Adult CD22

knockout mice displayed glomerulonephritis, circulating IgG anti-dsDNA, and anticardiolipin autoAb [502]. This is a particularly interesting model of systemic lupus-like autoimmunity because it is monogenic and because a B-cell molecular defect created an autoAb response that included isotype switching and affinity maturation of the (auto)antibody, characters very reminiscent of a T-cell-dependent immune response. Nevertheless, CD22 expression on the surface of B cells from patients with either active or inactive SLE is similar to that of normal controls [503].

A B-cell surface inhibitory receptor with a role that is well appreciated is the one for the Fc fraction of IgG type IIB1 (FcγRIIB1, CD32). When antigen bound to IgG is presented to the BCR, then BCR and FcγRIIB1 are cocross-linked. The net signal is of smaller magnitude than the signal generated by antigen alone. The cytoplasmic-free Ca^{2+} response is of shorter duration and the B-cell response is incomplete, not resulting in full B-cell activation and proliferation. Previous studies have reported that the system of receptors for the Fc fraction of IgG is overall malfunctioning in SLE, resulting perhaps in the production of excess antibodies and the accumulation of immune complexes [504]. Genetically manipulated mice having a B-cell surface FcγRIIB1 deficiency manifested hypergammaglobulinemia [505].

Engagement of CD32 in human SLE B cells fails to suppress the BCR-mediated signaling response by failing to engage SHIP, a molecule that is needed to inhibit the signaling process [341]. Therefore, defective negative regulation may be, at least partially, responsible for the increased B-cell response in SLE. The coreceptors CD22 and FcγRIIB1 bear a signaling inhibitory domain in their cytoplasmic tail called the Immunoreceptor tyrosine-based inhibitory motif (ITIM). ITIM become functional when the tyrosyl residues lying in its context become phosphorylated under the influence of protein tyrosine kinases. Tyrosyl-phosphorylated ITIMs become the docking and activating sites for SH2 domain-containing protein tyrosine phosphatases, particularly SHP-1 and SHIP [150–152]. It is interesting that SHP-1 is absent or dysfunctional in other autoimmunity models, the *motheaten* and the *viable motheaten* mouse, respectively [500].

Phosphorylation of ITIM tyrosyl residues is accomplished by protein tyrosine kinases. The ITIM lying in the cytoplasmic tail of FcγRIIB1 and CD22 coreceptor undergoes tyrosyl phosphorylation by the *src* family kinase *lyn*. In the absence of *lyn* the CD22-initiated signaling inhibitory pathway is not triggered, despite adequate amounts of B-cell surface CD22 expression. In $lyn^{-/-}$ animals, immature B cells developed normally but mature B cells were decreased. Rather unexpectedly it was shown that BCR-initiated signaling events were not only propagated, but in fact were enhanced. $lyn^{-/-}$ mice develop autoimmunity with features quite reminiscent of lupus: they have hypergammaglobulinemia, an increased sensitivity to IL-4, and develop autoAb and glomerulonephritis [506].

It is interesting that one study reported a defective expession of mRNA and protein lyn [507] and another one an abundant presence [508] of lyn in B cells from patients with SLE. It is likely that decreased lyn in SLE B cells contributes to B-cell overactivity by deficiently regulating the BCR-initiating response.

What Causes B-Cell Hyperactivity?

There are several possible explanations, which either alone or in concert may be involved in B-cell overactivity and antibody production.

B cells may be intrinsically abnormal: (a) B-cell subsets secreting autoantibodies may be expanded as discussed earlier. (b) B cells may overrespond after cross-linking of the surface antigen receptor by antigen. (c) B cells may overrespond to lymphokines as discussed earlier. (d) B cells receive aberrant regulatory messages through other cell surface receptors: Deficient negative signaling through the Fcγ receptors, as discussed previously, or excessive help through complement receptors (see discussion under complement receptors).

B cells may receive inappropriate external stimulation: (a) B cells become overactive in the presence of excessive quantities of lymphokines or, more importantly, unbalanced levels of type 1 and type 2 lymphokines, as discussed in the lymphokine section. (b) Excessive help by abnormally expanded helper T cells obviously contributes to B-cell overactivity.

B cells may undergo excessive polyclonal activation. As discussed earlier, lupus patients are characterized by the presence of a wide range of antibodies and generalized hypergammaglobulinemia. In addition, it has been well established that polyclonal activators can break B-cell tolerance. From the clinical point of view it has been well established that infections may exacerbate disease activity.

Autoantigen-specific B-cell stimulation has been classically accepted to drive B cells to produce autoantibodies. The most important antibodies such as anti-DNA (see Chapter 10) undergo isotype switching and affinity maturation.

Hypogammaglobulinemia in SLE

SLE is characterized by hypergammaglobulinemia. Over the past decade 20 SLE patients have been

described who during the course of their disease developed hypogammaglobulinemia. Hypogammaglobulinemia was not associated necessarily by decreased levels of anti-DNA antibodies [509–517]. A number of causes have been claimed in the aforementioned reports to be responsible for the complication, including prolonged treatment with cytotoxic drugs, the absence of phenotypically defined B cells, and increased T-cell suppressor cell activity.

REGULATION OF IMMUNE RESPONSES BY COMPLEMENT

Complement Receptor Expression

CR1 is a cell surface polymorphic glycoprotein present on a variety of cells, including B lymphocytes, certain T-cell subsets, monocytes, and glomerular podocytes [69, 70, 518–520]. It binds the C3b and C4b fragments of complement 3 and exhibits molecular weight polymorphism. CR1 participates in the phagocytic process and provides erythrocytes with the ability to carry and clear immune complexes. The number of CR1 was initially reported to be decreased on the surface membrane of SLE erythrocytes [521]. Genetic studies of the erythrocyte CR1 deficiency in SLE have produced controversial data with numerous studies reporting for or against genetic predisposition [522–532]. An occasional patient with SLE may have circulating antibodies directed against CR1 that are responsible for decreased numbers of erythrocyte CR1 [533, 534]. In addition, it seems that the levels of CR1 on the surface of erythrocytes correlate with disease activity and levels of circulating immune complexes [535–538], which supports that CR1 deficiency is not a primary defect. Conversely, studies have shown that the inheritance of certain alleles of the CR1 does not predispose to lupus [525, 539]. The number of CR1 of the surface membrane of lupus polymorphonuclear cells seems to reflect disease activity [540]. Patients with discoid lupus erythematosus who are completely asymptomatic have normal levels of erythrocyte CR1 [541].

A soluble form of CR1 is detected in the human plasma [542]. A larger form of CR1 is released in the urine bound to immune complexes thought to derive from podocytes and to represent a marker of glomerular injury [543].

On addition to decreased numbers of erythrocyte CR1, the number of CR2 (receptor for C3d and EBV) is decreased on the surface of lupus B lymphocytes [544–546].

Studies in lupus-prone mice have shown a decreased expression of CR on the surface of B cells prior to the clinical initiation of the disease [547]. It is unclear whether loss of CR accelerates or worsens the disease process. Data discussed earlier support either proposal. Treatment of MRL *lpr/lpr* mice with anti-CR anti-=bodies for up to 3 months failed to alter the disease process (G. Tsokos, T. Kinoshita, and F. Steinberg, unpublished results).

Complement Receptor Ligands

Abundant activation of the complement system takes place in patients with SLE. It is manifested by (a) decreased serum levels of several factors of both classic and alternative pathways (C2, C4, etc) [548, 549]; (b) increased levels of complement factor breakdown products, i.e., C3d and C3a [550, 551]; and (c) the formation and tissue deposition of immune complexes [536]. In addition to immune complexes, which clearly are responsible for the activation and consumption of the majority of complement factors, certain patients produce IgG antibodies that have one of the following characteristics: (a) bind to and stabilize the C3 convertase of the classical complement activation pathway (C4b2a), thus promoting a continuous consumption of C3 and C4 [552], or (b) bind to and activate C3 in the absence of antigen (C3-activating factor) [553]. Following any form of activation of the complement, complement factor breakdown products are generated that stay in the circulation for variable time periods, either in monomeric or polymeric (when bound to immune complexes) form [536]. It should be noted that polymorphonuclear cells from some lupus patients produce more C3 than normal cells, which may provide additional breakdown products [554]. Immune cells, particularly B lymphocytess, express receptors for various complement breakdown products, i.e., CR1, which binds C3b and C4b; CR2, which binds C3d; and CR3, which binds C3bi [69]. C3b and C3d can inhibit B-cell function when they are present in monomeric form [555, 556]. This action may serve as a negative "feedback" mechanism to the activated immune system. Polyvalent CR ligands may activate B cells [556, 557] and act synergistically with anti-IgM antibodies in stimulating B cells [555, 557]. Indeed, immunization of mice with genetically engineered molecules that are composed of antigen and multiple copies of C3d displayed a significantly enhanced immune response [558, 559]. A special association between surface immunoglobulin and CR on B cells is probably responsible for these effects [560]. Thus, activation of the complement pathway takes place in patients with SLE and the products of this process interfere with the function of immune cells only to further complicate the interpretation of the observed cellular aberrations. Complement fragments may stay in

the circulation as monomeric CR ligands or may attach to immune complexes [536] and form polyvalent CR ligands. As discussed earlier, polyvalent CR ligands act synergistically with B-cell antigens in amplifying B-cell function. Under this hypothesis, DNA-containing immune complexes will stimulate DNA-specific B cells to produce more anti-DNA antibodies. Monomeric CR ligands may suppress B-cell function and lead to a decreased production of "useful" antibodies. Further studies are needed to clarify the role of CR in the pathogenesis of human lupus.

APOPTOSIS

Biochemistry and Molecular Biology

Apoptosis is an active, signal-dependent cellular process. Cells dying by apoptosis present characteristic morphological changes and fragmentation of genomic DNA into oligonucleosomal bands of approximately 180 bp [561–563]. An endogenous endonuclease that is Ca^{2+}-dependent [564] is involved in this process. Several genes have been associated with apoptosis. The *bcl-2* gene encodes membrane-associated proteins of 26 and 22 kDa (members of the oncogene family), which are present in the nuclear envelope, the endoplasmic reticulum, and the inner mitochondrial membrane [565], and is considered to protect cells from apoptosis. In contrast to this protective function, the APO-1 (Fas) gene encodes a 319 amino acid protein that promotes apoptosis. Cytoplasmic and extracellular domains of the human APO-1 antigen consist of 145 and 157 amino acids, respectively. The proximal 68 amino acid region of the intracytoplasmic domain is responsible for mediating cell killing, whereas the C-terminal amino acid region contains negative regulatory elements [566, 567]. Deletions and/or mutations of the intracytoplasmic domain transfected in L919 cells prevent apoptosis. Apoptosis mediated by the APO-1 receptor is an active process where the action of the APO-1 antigen with its ligand induces apoptotic cell death. The APO-1 gene was identified to be equivalent to the murine Fas gene.

Organization of the human Fas gene is now known. The promoter region contains consensus sequences for AP-1, GF-1, NY-Y, CP-2, EBP 20, and c-myb. The gene consists of nine exons and spans more than 26 kb of DNA in the long arm of chromosome 10 [568]. The expression of Fas antigen gene is regulated by signaling mediators that are produced in response to cross-linking of the CD3 molecule [569]. Reversely, cross-linking of the Fas antigen suppresses the CD3-mediated signaling [570]. It is obvious that in any interaction between T cells and APC that express the Fas ligand a number of functional outcomes may ensue as a result of signaling through multiple cell surface receptors.

Apoptosis in Murine Lupus-Prone Mice

MRL *lpr/lpr* mice carry a mutation at the intracytoplasmic domain of the Fas gene [571, 572]. The mutation has been identified to be a 5.3-kb insertion of homology with a sequence from the 3′ long terminal repeat of the early transposon [573]. These animals develop a lupus-like syndrome with lymphadenopathy, production of large amounts of anti-DNA antibodies, immune complex nephritis, and synovitis. The significance of the *lpr* mutation was tested directly by constructing transgenic MRL-*lpr/lpr* mice using a full-length murine Fas cDNA under regulation of the T-cell-specific CD2 promoter and enhancer. Indeed, early correction of the lpr defect in T cells is sufficient to eliminate the acceleration of autoimmune disease even in the presence of other cells that express the mutant lpr gene [574]. A similar phenotype is also seen in *gld* mice, which have a mutation in the Fas ligand, indicating that the receptor/ligand interaction is necessary for the apoptotic process [575].

Apoptosis in Human Lupus

Freshly isolated B cells and both $CD4^+$ and $CD8^+$ T lymphocyte subpopulations expressed higher levels of Fas antigen when compared to normal cells. Despite the spontaneously elevated levels of Fas antigen, mitogenic stimulation of both T and B lymphocytes from SLE patients resulted in normal Fas antigen upregulation [576, 577]. Freshly isolated and cultured lymphocytes from patients with SLE display higher levels of apoptosis when compared with lymphocytes from normal individuals [578]. Although expression of the Fas antigen did not associate with any clinical parameter [576], the apoptotic rates of lymphocytes correlated significantly with disease activity but not with prednisone treatment [578]. In addition, peripheral blood macrophages display increased rates of apoptosis [54]. T cells but not B cells from patients with SLE were also reported to have increased levels of *bcl-2* protein [577, 579]. These findings were largely reproduced by Lorenz *et al*. [580], and the following useful two points were added: (1) the increased apoptotic rate of lupus cells vanished when the cells were cultured *in vitro* with lymphokines or mitogens or superantigens and (2) these abnormalities extended in patients with other autoimmune disorders (mixed connective tissue disease and various forms of vasculitis). The Fas ligand was also found to be expressed at increased amounts in lupus

T cells and it retains full functional features [581]. Increased apoptosis may contribute to (a) the development of cytopenias and (b) the release of nuclear material in the circulation that may, under certain conditions, stimulate the immune system to produce autoantibodies [582].

Apoptosis of Keratinocytes

Ultraviolet irradiation of cultured human keratinocytes induces changes consistent with apoptosis, and the autoantigens are clustered in two distinct populations of blebs at the surface of apoptotic cells. The smaller blebs contain endoplasmic reticulum, ribosomes, and autoantigen Ro. The larger blebs contain nucleosomal DNA, Ro, and La and the small ribonucleoproteins [583]. Apparently, photosensitivity, i.e., disease exacerbation following exposure to sun, may be explained by the flooding of the immune system with autoantigens that activate T and B cells. Although there is no direct translation of murine lupus data on apoptosis to the human analogue, it is obvious that there is dysregulation of the apoptotic process in human lupus. It remains to be seen whether certain lupus patients and their family members have molecular defects of the Fas gene, its ligand, or other cell proliferation-controlling genes such as *bcl-2*, p53, or *c-myc.*

Soluble Fas Antigen

As discussed earlier, the APO-1/Fas antigen is expressed on the cell surface membrane. Another APO-1 mRNA has been identified in which the exon that encodes for the transmembrane region has been deleted. The deletion does not affect the open reading frame but results in a Fas protein that lacks the 21 amino acid transmembrane region and is secreted in the serum. Patients with SLE have increased levels of soluble Fas protein. Two functions were attributed to the soluble Fas protein: (a) protection of cells from apoptosis by binding to the natural ligand of the cell surface membrane-expressed Fas protein and (b) disturbance of the immune system. The latter was concluded after it was shown that injection of murine-soluble Fas in mice produced redistribution of the thymocyte subsets and an increase in the number of splenocytes [584]. The disease specificity, the levels, and the physiologic significance of soluble Fas molecules in lupus patients have been debated extensively [585–587].

Canale–Smith Syndrome

The human "apoptosis deficiency" syndrome has been recognized as the Canale–Smith syndrome [588]. These apoptosis-deficient patients obviously cannot eliminate any possible autoreactive cells that arise as a "by-product" of all immune responses and display autoimmune manifestations, which nevertheless are not the cardinal features. Interestingly, some of these patients experience cytopenias that cannot be explained by the defective apoptotic cell death [589]. Therefore, it is possible that the lupus cytopenias cannot be explained by the reported increased spontaneous apoptotic cell death.

Structural Defects of Fas and Fas Ligand Molecules in Human Lupus

Lupus patients have been studied for mutations in the known components of the apoptotic machinery that might resemble those of the apoptosis-deficient murine models, and only rare patients with mutations in the apoptotic machinery have been found. One patient with lupus (out of 100 tested) had defective Fas ligand expression [590], whereas another one with treatment-resistant lupus had increased expression of a truncated form of Fas antigen that lacked the transmembrane region. Her lymphocytes were producing large amounts of soluble Fas molecules [591]. Obviously, structural abnormalities of the Fas and Fas ligand genes and their products cannot account for defects in apoptosis in humans as in mice.

Activation-Induced Cell Death

The aforementioned studies have not addressed whether activated T cells from patients with lupus that have been shown to play a crucial role in driving B cells to produce autoantibody display altered programmed death in response to antigen/autoantigen. Activation-induced cell death plays an important role in the regulation of the immune response by eliminating pre-activated and potentially autoreactive cells. To elucidate possible abnormalities of activation-induced cell death in human SLE, activation-induced cell death in activated T cells from patients with SLE was studied [328]. CD3-mediated cell death was determined in short-term T-cell lines by flow cytometry using propidium iodide staining and analysis of DNA subdiploid peak populations. It was found to be significantly lower in T cells from SLE patients compared to cells from normal controls. Anti-Fas mAb-mediated cell death was similar in SLE and control cell lines. CD3-mediated activation-induced cell death could be blocked in control and SLE T-cell lines by an IgG anti-Fas mAB. Indirect immunofluorescence analysis showed statistically significantly less intracellular TNF-α in SLE T cells than in control cells. These data show that activated T cells from

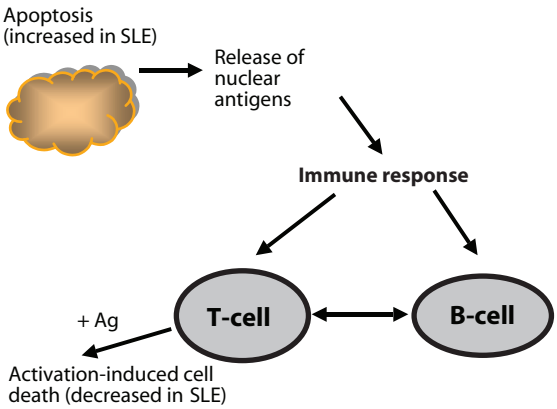

FIGURE 5 Aberrations of apoptosis in human lupus. The increased apoptotic rate of various cell types (monocytes, keratinocytes, etc.) leads to an increased production of nuclear antigens that stimulate the immune system and increase the number of activated lymphocytes. Decreased elimination of activated cells may further contribute to the size of the activated lymphocyte pool.

patients with SLE are relatively resistant to a TCR-mediated death stimulus, although they display intact anti-Fas mAb-mediated cell death. Defective antigen-mediated cell death can contribute to increased numbers of activated autoreactive cells in lupus patients (Fig. 5).

Because death of activated cells involves intracellular TNF-α [166] and because lupus cells produce decreased amounts of TNF-α [257] resulting from a TNF-α polymorphism that is different from that of normal cells [258], it was considered that a decreased expression of intracellular TNF-α may contribute to the decreased CD3-mediated lupus T-cell death. Indeed, permeabilized lupus T cells were found to display significantly lower amounts of TNF-α. Apparently, a functional Fas/Fas-ligand path and adequate amounts of intracellular TNF-α are needed for the CD3-mediated T-cell death. It was concluded that decreased TCR-mediated cell death in T cells from patients with SLE is not due to a dysfunction in Fas expression and function. The possible role of a defective Fas-ligand function needs to be determined. Furthermore, adequate levels of intracellular TNF-α may be necessary for proper execution of the activation-induced cell death cascade. Prolonged survival of autoreactive T cells can lead to increased autoantibody production. The fact that activation-induced cell death is decreased in SLE T cells can be important for the disease process *in vivo*, where engagement of the TCR on the surface of activated T cells, either by circulating or tissue-bound autoantigens, could fail to cause cell deletion, thus supporting the perpetuation of the autoimmune process.

Altered Mitochondrial Hyperpolarization, Reactive Oxygen Intermediates

Disruption of the mitochondrial transmembrane potential ($\Delta\psi_m$) has been proposed as the point of no return in apoptotic signaling [592]. Data indicate that elevation of $\Delta\psi_m$, i.e., mitochondrial hyperpolarization, occurs in the early phase of Fas-, p53-, and H_2O_2-induced apoptosis. Indeed, elevation of $\Delta\psi_m$ precedes caspase activation, phosphatidylserine externalization, and disruption of $\Delta\psi_m$ in Fas- and H_2O_2-induced apoptosis [592–594].

Deviations in key mitochondrial checkpoints of SLE T cells associated with abnormal apoptosis have been identified [595]. $\Delta\psi_m$ and mitochondrial reactive oxygen intermediate (ROI) production were elevated, but glutathione (GSH) levels were diminished compared to healthy or RA controls. A low GSH is consistent with increased ROI production due to the utilization of reducing equivalents. Ongoing oxidative stress *in vivo* may lead to a skewed expression of transcription factors AP-1 and NF-κB [207, 208] and, further downstream, expression of IL-2, TNF, and IL-10 [596]. Of note, increased spontaneous apoptosis of lymphocytes has been linked to increased IL-10 production, release of FasL, and overexpression of the FasR in SLE [597, 23]. Elevated nitric oxide (NO) production may also contribute to increased spontaneous apoptosis [598, 599]. Indeed, increased ROI levels confer sensitivity to H_2O_2, NO, TNF, and Fas-induced cell death [594]. Therefore, elevated baseline ROI and $\Delta\psi_m$ levels may have key roles in the enhanced spontaneous death of SLE PBL.

EFFECT OF TREATMENT ON THE FUNCTION OF LUPUS CELLS

General Considerations

Studies of the cellular immune dysfunction in patients with SLE are criticized by the fact that most, eventually all, patients take some form of immunomodulatory treatment [32]. Careful temporary withdrawal of the treatment prior to the study may not always guarantee the lack of effect of the treatment on the immune function under study. Drugs affect immune functions at differential doses. For example, corticosteroids suppress the autologous mixed lymphocyte reaction at physiological concentrations, whereas they have no effect on the mixed lymphocytes reaction unless they are used in pharmacologic doses [600]. Corticosteroids at nanomolar (subphysiologic) concentrations may enhance the immune system instead [601]. Such will be the situation in a patient from whom the low steroid dose is withheld

for 24 or 48 h. Steroids have pleiotropic effects on the expression of molecules that are involved in T-cell signaling, such as the TCR ζ chain. Specifically, culture of human lymphocytes with 10 n*M* dexamethasone caused increased transcription of the *TCR* ζ chain, whereas culture with 100 n*M* suppressed ζ chain transcription and expression [602]. Interestingly, high concentrations of dexamethasone led to increased TCR-mediated $[Ca^{2+}]_i$ responses [603]. In addition, steroids modulate the expression of IL-2 by suppressing its transcription and destabilizing its message [604], most probably affecting the expression of other cytokines. Unfortunately, there are not any controlled studies on the effect of various treatments on the cellular immune functions in patients with SLE. Patients receiving treatment enter invariably the inactive phase of the disease. Changes in the immune system between active and inactive phases of the disease may well mean drug effect. Treatment of patients with SLE leads inevitably to decreased immunoglobulin production, particularly of anti-dsDNA antibodies. By inference, treatment affects/normalizes B- and T-cell function [322].

Cyclophosphamide

McCune and colleagues [605] administered cyclophosphamide intravenously to patients with SLE in six monthly doses. Patients improved clinically, anti-DNA antibody titers decreased, and serum C3 levels improved along with a decrease in B and T lymphocytes and their CD4 and CD8 subsets. This study was preliminary, uncontrolled, and it would be eventually necessary to know whether the same cellular changes would have taken place in the absence of cyclophosphamide.

Plasmapheresis

Plasmapheresis was proven finally to have no effect on clinical manifestation and cellular immune functions in patients with SLE, despite the rational expectations that had led in its launching in the treatment of lupus [606].

Total Lymphoid Irradiation

Total lymphoid irradiation of patients with severe lupus nephritis seems to have more definitive effects by decreasing the number of peripheral lymphocytes and their major subsets and by their ability to mount proliferative responses *in vitro* [607, 608]. Similarly, *in vivo*, in these patients the levels of antibodies to tetanus toxoid and diphtheria toxin were decreased and rose only sluggishly following immunization [609]. Total lymphoid irradiation exerts its effects by acting on T cells rather than on B cells. Ig production by MNC from patients with SLE who were treated with total lymphoid irradiation was decreased following stimulation with pokeweed mitogen, which is a T-cell-dependent B-cell stimulus, and normal following stimulation with EBV and *S. aureus* Cowan 1, which are T-cell-independent B-cell stimuli [610]. Treatment of an autoimmune murine strain (New Zealand black X New Zealand white)F1 with total lymphoid irradiation resulted in a significant reduction of $CD5^+$ B cells and anti-DNA antibody production [611] and restoration of the thymic architecture [612].

DRUGS IN THE PATHOGENESIS OF SLE

A number of commonly used medications (hydralazine, procainamide, etc.) have been associated with the development of clinical and laboratory features of SLE. Manifestations are characterized by the rarity of vital organ involvement [613]. Peripheral B cells from these patients secrete increased amounts of immunoglobulin while their T cells seem to provide excessive help to B cells [125]. Study of the molecular mechanisms whereby drugs cause increased autoreactivity and autoimmunity is worthwhile, as these drugs represent distinct, identifiable extrinsic factors. $CD4^+$ tetanus toxoid-specific cloned T cells treated with 5-azacytidine (an inhibitor of DNA methylation) proliferate in response to autologous class II MHC gene products in the absence of tetanus toxoid [614]. 5-Azacytidine has also been shown to change the $CD8^+$ phenotype of T cells to $CD4^+$ [391]. Rendering $CD4^+$ cells autoreactive following treatment with DNA methylation inhibitors is an attractive phenomenon, as these cells can go on and induce autoimmunity. Because hydralazine and procainamide cause SLE and are known to bind to DNA [615, 616], they were tested and found to inhibit DNA methylation and induce self-reactivity to tetanus toxoid-specific human T-cell clones [617]. Ultraviolet light, another external factor frequently entertained in the pathogenesis of SLE, also causes extensive DNA demethylation, which is associated with gene (metallothionein-I) activation [618]. Because the methylation status of genes determines their transcription rate in general [619], one can speculate that various inciting factors may lead to autoimmunity by interfering with the methylation of crucial genes. It is difficult at the present time to speculate which are these genes. It was hypothesized that the *c-myc* oncogene and interleukin-2 gene might be involved, and their methylation status was tested using

an enzyme cut approach. Despite these negative results, the hypomethylated gene hypothesis might hold true for other genes that may be more central in the pathogenesis of SLE. Richardson *et al*. [390] found that DNA from T cells from patients with SLE is less methylated than DNA from normal T cells. This conclusion was achieved by measuring the deoxymethylcytosine content of lupus T lymphocyte DNA. DNA methyltransferase activity in lupus T lymphocyte nuclear proteins was decreased and was considered to be responsible for the hypomethylation of lupus T cell DNA. Interestingly, non-T cells from lupus patients expressed normal DNA methylation levels. The significance of these findings is undermined by the fact that T-cell DNA is hypomethylated only in one-half of the patients with lupus and that patients with rheumatoid arthritis share the same abnormality.

Inhibition of DNA methylation in various T-cell lines led to overexpression of LFA-1, which may contribute to T-cell autoreactivity and increased T-cell homing to target tissues as discussed earlier (costimulation) [389].

In mature T cells, DNA methylation is a postsynthetic event mediated by the enzyme DNA methyltransferase 1 (Dnmt1). Dnmt1 levels increase following T-cell stimulation [620]. It was possible that the signaling defects in the proximal and middle pathways might be associated with abnormal signaling in the distal pathways as well, contributing to decreased Dnmt1 levels. Moreover, Dnmt1 levels are also regulated by signals that traverse the JNK and ERK pathways, possibly acting through AP-1 sites in an intronic promoter [621].

The mechanisms underlying deficient Dnmt1 activity in T lymphocytes from subjects with SLE have been studied following stimulation with PMA/IO. The phosphorylation of ERK1/2 and JNK was analyzed. Compared to controls, MEK (MAPK kinase)-catalyzed ERK1/2 phosphorylation in SLE-unfractionated PBMC and CD4 T cells was significantly less, despite normal levels of the ERK proteins. This decrease in ERK phosphorylation was directly proportional to disease activity [622]. The functional significance of decreased signaling was tested by treating normal T cells as well as the leukemic Jurkat T-cell line with PD98059, a selective MEK inhibitor. The MEK inhibitor decreased Dnmt1 mRNA content and enzymatic activity to levels comparable to SLE T cells and caused globally hypomethylated DNA [622]. These observations support the hypothesis that decreased signaling through the ERK pathway contributes to the DNA hypomethylation characteristic of SLE T cells and possibly to the immunopathogenesis of SLE via mechanisms analogous to other DNA methylation inhibitors [623]. The mechanism causing the defect in SLE is presently unknown.

SEX HORMONES IN CELLULAR IMMUNE RESPONSES

The fact that SLE is preponderant among women during their reproductive life and is more frequent among male patients with Klinefelter's syndrome has implicated that hormones have a role in the pathogenesis of autoimmunity. Sex hormone manipulation experiments in lupus-prone murine strains and other *in vitro* experimental evidence have shown that female sex hormones facilitate the development of autoimmunity [624]. Specifically, testosterone enhances suppressor cell activity, whereas estrogens have a direct stimulatory effect on B cells and a suppressive effect on regulator cell activity [625, 626].

Experiments suggest a negative role for estrogens in B-cell proliferation [627]. Hypogonadal female mice display decreased B-cell lymphopoiesis that is restored with estrogen replacement [628]. Estrogens inhibit clonal expansion of B-cell precursors *in vitro* [629] and B-cell lymphopoiesis in pregnant mice [630]. These experiments show clearly that estrogens regulate B-cell biology through binding to the estrogen receptor and contrast previous concepts that estrogens promote autoimmunity. The opposite conclusions may represent the fact that the previous studies were performed in lupus-prone strains, whereas the latter were performed in normal mice.

Studies in human systems have provided indirect evidence on the role of sex hormones in the development of autoimmunity. Lymphocytes from both men and women respond more vigorously to pokeweed mitogen in the presence of estradiol, whereas they show diminished responses in the presence of testosterone [631]. This indicates that estrogen may play a permissive role in B-cell overactivity, provided that other factors are present. In another set of experiments, estrogens were shown to suppress apoptosis in normal and lupus peripheral blood MNC, thus increasing the chances for longer survival of autoreactive cells [632].

Human keratinocytes bind anti-Ro and anti-La antibodies if cultured in the presence of estradiol [633]. This relates to the clinical observation that there is a strong association between antibodies to Ro antigens and cutaneous lupus erythematosus [634]. In addition to estrogens, ultraviolet light induces binding of anti-Ro antibodies to skin cells [635]. Estrogens and ultraviolet light thus represent two permissive factors for the development of skin manifestations in patients with SLE. Pathogenically, both factors could precipitate skin pathology in patients who have anti-Ro antibodies or alternatively they could increase the antigenicity of skin autoantigens and elicit an autoimmune response.

Studies have begun addressing the molecular mechanisms that underlie regulation of the expression of genes that are involved in the pathogenesis of SLE by estrogens. For example, it was shown that estradiol upregulates the expression of the antiapoptotic gene *Bcl-2* in B cells of anti-DNA antibody transgenic mice [636]. In other experiments, it was shown that calcineurin steady-state mRNA levels and phosphatase activity rose in SLE T cells cultured in the presence of estrogen. The increase was dose dependent and hormone specific. T cells have both α and β types of estrogen receptors and, interestingly the exposure of normal T cells or T cells from male SLE patients to estrogen does not lead to the same calcineurin upregulation [637, 638].

FROM PATHOGENESIS TO THE DEVELOPMENT OF NOVEL TREATMENTS

Current therapeutic schemes are directed by individual disease manifestations rather than a general diagnosis of lupus. Involvement of vital organs (kidney, CNS, lungs, heart, severe hematologic disease) usually calls for intense treatment, including high doses of corticosteroids and cytotoxic drugs, whereas manifestations from nonvital organs can be treated with moderate or low doses of corticosteroids, antimalarials, and nonsteroidal anti-inflammatory drugs [639, 640]. Pulse cyclophosphamide has emerged as the treatment of choice for severe visceral involvement [641–644]. Corticosteroids, alkylating agents, or calcineurin inhibitors (such as cyclosporine and FK506) may be used in selected cases of patients with membranous lupus nephropathy [645, 646].

Understanding the processes involved in the pathogenesis of lupus has made possible the design of rational therapeutic approaches (Table 8). The enormous recent progress in the field of cytokines has raised expectations for their use in the management of autoimmune diseases. Indeed, a fusion molecule between the TNF-α receptor and the Fc portion of IgG was shown to significantly improve the clinical course of patients with rheumatoid arthritis [647]. It should be cautioned that lupus is a pathogenically different disease, and treatment with TNF-α-neutralizing biologics may exacerbate it. Patients treated with a humanized anti-TNF-α antibody developed autoantibodies, but not clinical disease [648, 649], an observation that suggests such reagents should not be used in lupus patients.

In an experimental model of antiphospholipid syndrome, an intraperitoneal injection of IL-3 prevented fetal loss [650]. IL-3 has been introduced in clinical trials for the treatment of neutropenias in patients with myelodysplastic and aplastic syndromes [651] and has been noted to have minimal toxicity. Although the justification for use in the prevention of fetal loss originated from the observation that these animals have low serum IL-3 levels, its mechanism of action is not clear.

TABLE 8 Rationalized Therapy for Lupus

Interruption of cognate cell interaction with antibodies or fusion molecules comprising a ligand and the Fc portion of human Ig
CTLA4-Ig
Anti-B7-1 or -2 antibodies
Anti-CD40 ligand antibody
Neutralization of cytokines with antibodies or fusion molecules (cytokine receptor human Ig)
Anti-IL-10 antibody
Anti-TNF-α antibody
TNF-α receptor–FcIgG fusion molecule
Lymphokines
Hormones (DHEA)
Inhibition of complement activation
Bone marrow transplantation
Reestablishment of tolerance (T and B cell)
Modulation of cell signaling
Gene therapy

Neutralization of IL-10 may present another therapeutic option as adjunct therapy for lupus and other systemic autoimmune diseases. Continuous infusion of the anti-IL-10 antibody of NZB/NZW mice from birth improved survival dramatically, indicating either that IL-10 is directly involved in promoting disease activity by acting on B lymphocytes and other cells or that elimination of IL-10 reversed the cytokine ratio in favor of the type 2 group of cytokines [251]. A major concern with all candidate lymphokines is the fact that they are pleiotropic. Patients with various forms of malignancies who have been treated with either IL-2 or IFN-α have developed a wide range of autoimmune diseases, including thyroiditis and SLE [652].

Complement activation is abundant in lupus patients as manifested by the fact that the circulating immune complexes have attached C3 split products [536], and the levels of various complement split products [653] and the membrane attack complex [654] are increased in the sera and urine of lupus patients. The use of biologics that would interfere with complement activation could be of therapeutic value; an anti-C5 antibody was shown to prolong life in NZB/NZW mice [655], and a humanized anti-C5 monoclonal antibody has been considered for use in lupus patients. The use of regulatory surface membrane molecules, such as decay accelerat-

ing factor (DAF), in the treatment of lupus should also be considered. Crry-Ig was shown to inhibit nephritis in a nephrotoxic serum animal model [656]. Crry is the murine analogue of human DAF and CD69 and inhibits both classical and alternative pathways of complement activation. Similarly, a transgenic mouse secreting Crry was resistant to the effects of nephrotoxic serum [657].

Disruption of the cognate interruption between T and B cells has been predicted and proven to be helpful in lupus. A B7-binding construct (CTLA4 molecule fused with the heavy chain of Ig to provide decreased plasma clearance rates) was given to mice that develop lupus spontaneously, and the rate of survival increased along with lower autoantibody titers and reduced kidney pathology [381]. This clinical effect is associated with a suppressive effect on the activated $CD4^+$ cells and the cells that produce anti-DNA antibodies [658].

Interruption of the CD40–gp39 (CD-40L) interaction in SNF1 autoimmune mice with the anti-gp39 antibody resulted in a decreased expansion of autoimmune memory B cells and long-term clinical improvement [395]. Experiments showing therapeutic effects in autoimmune mice following interruption of the B7–CD28 and CD40–gp39 paths indicate that they are involved serially in the production of antibody. These results have instigated ongoing human trials using humanized anti-CD40 ligand antibodies and combined treatments to achieve better and longer lasting effects [659, 660]. Indeed, when CTLA4Ig was combined with anti-gp39, there was sustained inhibition of autoantibody production and renal disease [661].

For patients with severe disease, immunosuppression may be intensified to the point of myelosuppression or hematopoietic ablation. Hematopoiesis and immunity may then be reconstituted rapidly by the reinfusion of $CD34^+$ progenitor cells. This approach has been tried in a limited number of patients with lupus and other autoimmune diseases who had failed standard treatment [662, 663]. Although the number of patients is small and the follow-up period is short, it seems that either the severe immunosuppression or the redevelopment of the immune system with possibly less autoimmune features may have beneficial effects on the clinical expression of the disease.

Hormonal treatment of lupus patients to reverse the effect of endogenous androgens with dehydroepiandrosterone has been tested in double blind controlled studies and found to have a minimal effect, which may justify its use as a steroid-sparing agent or treatment of mild manifestations in selected patients [664–666].

As discussed previously, lupus patients have T cells that respond to defined autoantigens and may display certain TCR selection. These studies helped us understand the pathogenesis of the disease and also provided rationale for specific immunologic interventions [189]. The identification of putative autoantigens may prove useful in reestablishing tolerance. Indeed, myelin basic protein (MBP) disease-inducing T cells have been deleted successfully by a high dose of MBP antigen in a murine model of autoimmune encephalomyelitis [166]. Additionally, oral administration of chicken collagen II in a double-blinded clinical study to patients with rheumatoid arthritis resulted in significant clinical improvement [167]. Histone-defined peptides have been identified in mice [667] and humans [668] that can stimulate T-cell-dependent anti-DNA antibody production and provide the basis for the development of peptide-based tolerogenic therapy for humans similar to that demonstrated in mice with lupus [669].

At the B-cell level, two approaches are currently entertained in clinical trials. In the first, a construct is used that consists of four short DNA fragments conjugated to a backbone. This construct modulates surface anti-DNA Ab of the surface membrane of B cells, which thereupon become unresponsive to further stimulation [670]. In the second one, humanized antibodies were directed against the B lymphocyte stimulator (BlyS). BlyS levels are increased in sera of patients with SLE [671, 672].

The described cellular biochemical abnormalities that characterize lupus cells may become the target of pharmaceutical intervention. The tyrosine kinase inhibitor tyrphostin AG490 was shown to prevent binding of freshly isolated mouse lymph node cells and of i*n vivo* activated lymphocytes to the brain vessel endothelium by inhibiting the expression of adhesion molecules, and systemic administration of the drug in a murine model of experimental allergic encephalomyelitis decreased disease activity [673, 674]. Therefore, drugs that interfere with cell signaling events may prove to be helpful in the treatment of lupus.

GENE THERAPY FOR SLE

The MRL-fas^{lpr} mouse has a mutation in the *Fas* gene that leads to defective lymphocyte apoptosis, lympho-proliferation, distinct immunoregulatory abnormalities, and systemic autoimmune manifestations similar to those of lupus, arthritis, and vasculitis. Reintroduction of *Fas* into these animals corrects the majority of the abnormalities [675]. Because such correction of a single missing gene is of no practical consideration in the treatment of human autoimmunity, attempts should be

made to design and deliver genes whose products can reverse autoimmune pathology. Lawson *et al.* [676] described a chimeric protein consisting of a soluble form of the interferon-γ receptor, which blocks the action of IFN-γ, fused to the Fc portion of IgG, which helps stabilize this bioactive protein in the circulation.

Gene therapy involves the insertion and expression of foreign DNA into the host cell. Viral vectors usually serve as effective carriers to insert DNA into cells by transduction, but each system has unique advantages and disadvantages. In most murine and human studies, modified retroviruses have been used that lack one or more viral structural proteins [677]. Gene therapy has been extensively considered in the treatment of arthritis in animal models [678]. Examples include the intra-articular delivery of IL-4 using a retroviral vector that improved inflammation in a rat model of adjuvant arthritis [679] and retroviral delivery of IL-13 that suppressed collagen-induced arthritis in mice [680]. In one attractive approach [681], human fibroblasts were transduced with a dominant negative form of IκB that blocks the translocation of nuclear factor κB to the nucleus. This transgene results in cell death only in the presence of TNF-α, so if the vector were injected into a human joint, fibroblasts and other cells would die only if TNF-α were present, i.e., if there were active inflammation.

Antigen-specific forms of immunotherapy employ either whole protein antigens or individual immunodominant peptide epitopes. The most important theoretical limitation to such therapies is whether epitope-specific forms of therapy will modulate an immune response directed to multiple epitopes or multiple target proteins. At least in mice, induction of transferable suppressor T cells can indeed regulate polyspecific autoimmune responses, apparently by promoting the release of regulatory cytokines that act on bystander-activated cells with different specificities. For example, nucleosome-defined peptides have been used successfully in the treatment of murine lupus, indicating that it is possible to reestablish tolerance in systemic autoimmune diseases when more than one antigen is involved [669]. The Scott laboratory, which pioneered the use of tolerizing peptides [682] and proteins [683] fused to the N terminus of the IgG heavy chain, found immune suppression to multiple epitopes expressed by the antigenic protein. Gene therapeutics for specific diseases may require this multiple epitope approach if bystander suppression mechanisms are not activated, as in the uveitis model described, in which immune regulation was not transferable by T cells.

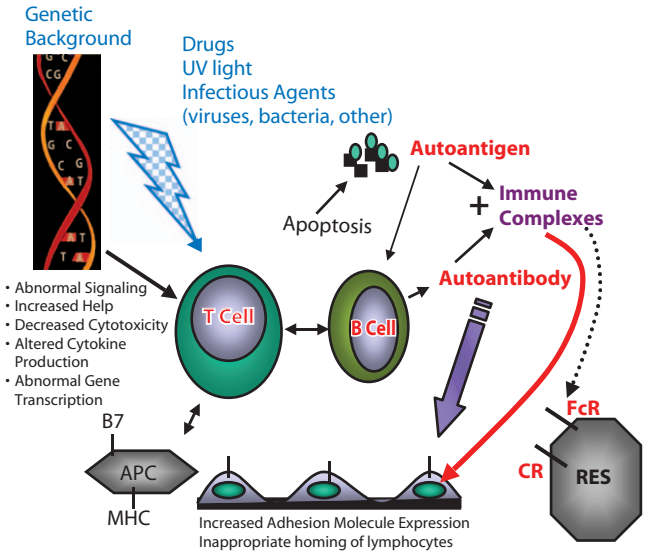

FIGURE 6 Overview of the pathogenetic processes in human SLE. Multiple genetic, environmental, and hormonal factors instigate a number of cellular and cytokine abnormalities. These abnormalities lead to an increased production of autoantibodies, which either directly or after forming complexes with autoantigens and activating complement deposit in tissues and initiate an inflammatory response. Immune complexes are formed in excessive amounts in lupus patients and are cleared at decreased rates because the number and/or the function of Fc and complement receptors is decreased (APC, antigen-presenting cells; RES, reticuloendothelial system).

PATHOGENESIS: AN OVERVIEW

The synthesis of the described cellular and lymphokine aberrations under a unified hypothesis is a difficult task. In the foregoing discussion, multiple recognitive, regulatory, and effector system abnormalities were mentioned (Fig. 6).

The fundamental event in the pathogenesis of SLE is B-cell overactivity, which is responsible for the overproduction of pathogenic autoantibodies, which either alone or in concert with immune complexes is responsible for tissue pathology and clinical manifestations. The relevant pathology and clinical manifestations of each of the produced autoantibodies are described in other chapters of this book. B-cell overactivity is the result of concomitant action of multiple factors. Although human B-cell overactivity has not been associated with a single gene, there is indication that overactive early B-cell receptor-initiated B-cell responses are independent of disease activity [499] and therefore possible inherent. A locus in murine chromosome 4 has been found to harbor a gene that is responsible for B-cell overactivity [684, 685]. Studies on the human

genome are bound to identify genes that contribute to the described cellular aberrations in human lupus. Hormonal factors obviously play a serious role in the expression of human lupus. Although *in vitro* studies suggest that estradiol enhances B-cell function, *in vivo* studies reported by the group of Kincade [627, 629, 630, 686] in normal mice clearly show that B-cell development in normal mice is suppressed by estrogens. Estrogens may "facilitate" the expression of autoimmunity in a more complex manner. Environmental factors have been strongly associated with the clinical expression of disease. Prominent among the environmental factors are drugs that induce lupus and infectious agents. Possible mechanisms for the action of these drugs were discussed earlier. In brief, lupus-inducing drugs may cause demethylation of DNA, possibly of the "lupus"-associated genes. Hypomethylated genes are transcribed at higher rates. Ultraviolet light is strongly associated with the clinical expression of the disease in certain patients. Ultraviolet light may be pathogenic by virtue of (a) causing increased binding of anti-SSA(Ro) antibodies to epidermal cells and (b) causing DNA demethylation. Hypomethylating drugs and environmental factors may directly affect the transcription of relevant genes or indirectly by causing the overexpression of adhesion molecules that are involved in B-cell activation [389]. Finally, immunoregulatory aberrations of the T-cell control or the lymphokine milieu are clearly responsible for increased B-cell function.

T cells play a crucial role in the regulation of B-cell function. Deficient suppressor cell function has a role in B-cell overactivity. Even if someone disclaims a generalized suppressor cell deficiency in the pathogenesis of lupus, antigen-specific suppressor cell deficiency contributes to the production of antibody excess. However, many T-cell subsets have been identified as providing excessive help to B cells to produce antibody in general and pathogenic antibodies specifically [183]. $CD4^+$, $CD8^+$, and abnormally expanded αβ and γδ $CD4^-CD4^-$ $CD3^+$ T cells provide increased amounts of help to B cells to produce antibody. Although not impressive, certain biases in the selection of the TCR repertoire (Table 3) speak for the role of autoantigen-mediated stimulation of T cells and for the potential of specific immunotherapy in lupus [189].

The importance of deficient cytotoxic responses in the pathogenesis of human lupus can not be underestimated. Specific cytotoxic cells able to eliminate EBV, and presumably other virus-infected cells, may be a cornerstone in the pathogenesis of the disease [128]. Similarly, antigen-nonspecific cytotoxic $CD56^+$ cells are vital in the control of the immune response [687]. The latter deficient cytotoxic responses extend to relatives of lupus patients and therefore introduce the possibility of another locus that may contribute independently to the expression of the disease.

The known increased levels of IL-6 and IL-10 in lupus patients may stimulate B cells, whereas decreased levels of IFN-γ and IL-2 to the deficient cytotoxic responses. However, it is difficult to interpret T-cell overactivity. In certain animal autoimmune models and possibly in human disease, the lymphokine response may be polarized in favor of type 1 or type 2 lymphokine production. Although evidence shows that human lupus is a disease with a type 2 lymphokine profile [267], data from a study of lupus-prone mice suggest that lupus may not be a polarized disease in terms of lymphokine production [20]. Study of the regulation of transcription of lymphokines in human lupus [688] has indicated that additional independent genetic defects may contribute to the pathogenesis of human lupus. Is it possible to treat lupus with lymphokines or lymphokine function-interfering agents such as soluble receptors and antibodies? Such possibilities deserve consideration and were discussed earlier in this chapter.

Aberrations in the expression of costimulatory and adhesion molecules have been identified and found to contribute to the pathogenesis of the disease. First, overexpression of adhesion molecules in target tissues may fuel the inflammatory response by causing an inappropriate homing of inflammatory cells [19] or contribute to the abnormal regulation of T- and B-cell function. The role of B7 and CD40, CD40 ligand has been elucidated (see earlier discussion). However, we do not understand what causes the abnormal regulation of their expression on the cell surface membrane.

The role of apoptosis in autoimmunity cannot be overestimated. With the exception of rare cases, structural defects of the apoptosis-involved molecules are not responsible for the aberrant apoptosis in human lupus as it is in certain murine lupus-prone strains. Lymphocytes and monocytes and possibly keratinocytes undergo spontaneous apoptosis at higher than normal rates and contribute to an increased pool of autoantigens, whereas the activation-induced death of lymphocytes is decreased in lupus and contributes to the increased survival of activated T cells.

Abnormalities in antigen receptor-initiated lymphocyte signaling have been identified and characterized. These abnormalities offer a dual purpose: (1) they explain some of the heterogeneous cellular abnormalities and (2) they may lead to the introduction of novel regiments that may help lupus patients by correcting abnormal signaling processes.

The just described synthesis has not taken into consideration all available information and furthermore cannot explain all the immunological abnormalities that have been described in patients with SLE. This does not

belittle their importance in the pathogenesis of the disease. A crucial supposition in understanding the pathogenesis of SLE is the heterogeneity of the disease. Clinical heterogeneity is forerun by etiologic heterogeneity. Each factor mentioned in this discussion may have relative weight in the pathogenesis of the disease in any given patient with SLE.

It is expected that a better understanding of the molecular events that underlie abnormal cellular functions will be found in the near future. Newly characterized molecular aberrations will unify the diverse cellular aberrations. In addition, genes that are associated with these defects will be identified. At this moment it is generally accepted that human lupus, as perceived clinically today, is the result of multiple factors that act in concert to exceed a "threshold" that permits the expression of clinical disease. Many of these factors have a clear genetic origin, and their effect is modified by other genetic factors and/or environmental factors.

ETIOPATHOGENESIS OF SYSTEMIC LUPUS ERYTHEMATOSUS

Itineraries of Three Troikas

Donato Alarcón-Segovia
Marta E. Alarcón-Riquelme

Systemic lupus erythematosus (SLE) results from the interplay of multiple factors that vary in their participation among individuals with the disease, which, in turn makes SLE extremely variable. Actually, in normal individuals some of these factors may be present but are either not enough to cause the disease or have counterbalances or checks that prevent full disease expression. This may be particularly so in relatives of SLE patients.

To discuss the etiopathogenesis of SLE, one needs to subdivide an extremely complex process. We have elected to do this at three consecutive, but separable, levels: etiology, etiopathogenesis, and pathogenesis. The complexity of the subject, however, calls for further subdivision but, at the same time, it must be clear that both the levels and the various factors that compose them are unseparable. Actually, when having reached the third level we may find that some of its factors go back to influence the second or even the first level.

We have previously proposed that in the etiology of SLE there is the interplay of genetic, environmental, and hormonal factors. Because each one of these acts both independently and concurrently we have equated it to a troika, the three-horse Russian carriage where each horse pulls independently, but concertedly, to make it go [1].

The troika analogy has also been useful for the analysis of the subsequent levels of etiopathogenesis and pathogenesis. We therefore decided to present our chapter for the previous edition of this book as a tale of three troikas. The troika analogy continues to be useful to approach the complexity of our subject but many of the nine horses need to be reexamined or somewhat changed in order to keep the troikas tuned to current knowledge. We will now follow the troikas along their itinerary.

THE FIRST TROIKA: ETIOLOGY

As initially proposed [1], the first troika pertaining to the etiology of SLE continues to be pulled by genetic, environmental, and hormonal factors. That environment, hormones, or both have a role in the development of SLE does not exclude that genes are also involved. Thus, genetic factors may determine the way an individual copes with a viral infection or handles a certain drug (i.e., hepatic acetylation of drugs or multidrug resistance genes). In turn, hormonal factors may be modified by genes (i.e., the presence of an allele coding for a hormone receptor with higher affinity for a given hormone or of a mutation that makes estrogens more potent or testosterone less so).

Genetic Factors in SLE

From the genetic point of view, SLE probably results from the effects of a number of genes acting in an additive fashion [2, 3]. This may, however, be simplistic because an individual could have all the gene variants presumably required to develop the disease but still not develop it. This, in genetics, is called *penetrance*. SLE, as many other diseases with complex genetics, has a low penetrance. It can also be that the combination of genes needed to develop SLE in a given ethnic group is different from that required by another ethnic group. This is called *genetic heterogeneity*. A third level of complication in genetic studies occurs when all families studied are linked to a certain locus that is not represented by a single genetic variant of a gene, but by many different variants of the same gene, all of functional importance. This is called *allelic heterogeneity*. Work on the genetics of Crohn's disease [4] has shown that allelic heterogeneity is to be expected in complex diseases. Furthermore, some alleles may be so rare that unless they do affect the function of the protein in an obvious way, it is very difficult to statistically prove their association with the disease. Geneticists have had to find other means of studying the genetics of complex diseases such as SLE. As genes within a locus of interest may be regulated in *cis*, the analysis of haplotypes for association and gene expression may be needed to define the genetics of SLE.

Is SLE a genetic disease? Studies performed on twins suggest so. Comparisons made on the concordance between monozygotic and dizygotic twins revealed that the concordance in monozygotic twins is eight times higher than that in dizygotic twins and that the concordance is even higher if the presence of autoantibodies is considered (concordance may be as high as 92%) [5–7]. The lower concordance for the clinical expression of SLE may be due to the lack of an environmental factor triggering the development of an overt disease, whereas autoantibodies may represent "early" markers of a latent disease. The classical study of Moore and Lutz [8] where they found that patients with false-positive VDRL went on to develop SLE supports this notion. Also supportive is the study on sera stored by the Department of Defense of the United States where they had sera from 130 subjects who subsequently developed SLE. It was found that 62% of them had anti-dsDNA up to 9 years before the disease was diagnosed [9].

SLE is clinically very heterogeneous, but what determines this heterogeneity? Could it be the role of disease-modifying genes or stochastic mechanisms? The described association of the HLADQA1 and DQB1 alleles [10–16] with certain autoantibody specificities and, in turn, with defined clinical manifestations supports the former idea. How different genes play a role in the full-blown expression of SLE is the subject of intense research. What genes act as disease-predisposing genes and what genes act as disease modifiers? What epigenetic mechanisms take place? What genetic interactions are necessary? How do interactions between genes and environmental factors take place? For example, if the Epstein–Barr (EB) virus is indeed involved in SLE [17], what genetic predisposing factors are required for the virus to influence the immune system to promote disease development? Do B cells from some individuals express some type of receptors or molecules that make them handle the EB virus inadequately?

Two main approaches have been taken for studying the genetics of SLE. On the one hand, spontaneous animal models for SLE have been crossed and analyzed in their whole genome for linkage between lupus-related phenotypic traits and chromosomal markers (typically microsatellites). In particular, genome screens were performed on crosses of the NZM2410 recombinant strain (a recombinant of NZB × NZW) with the B6 mouse [18] or on backcrosses performed directly from the NZB × NZW hybrid [19]. Congenic strains have been developed and have led to interesting results. The first (the *nba1* locus) is identification of the susceptible variant of the *Ifi202* gene contributed by the NZB strain [20], and the second (the *sle1* locus) is the identification of a cluster of functionally related genes contributed by the NZW strain [21]. In this strain, however, no individual genetic variant has been detected. It was therefore suggested that as the genes formed by the cluster are all coregulated on lymphocytes, their role in SLE susceptibility could be related to their coregulation. It is therefore possible to hypothesize that the genetic variant could be many kilobases upstream of the gene cluster within an as yet unidentified regulatory element but still within the congenic fragment. Both of the susceptibility factors, the *Ifi202* gene and the cluster, are found close to each other (about 90 cM) in chromosome 1 of mice, but each could only be detected using the particular mouse crosses [18, 19]. This region is syntenic to the human chromosome 1q21–23 cytogenetic region. Previous studies in lupus patients suggested that FcGR genes located in that region were involved in SLE. In particular, the FcGRIIA functional polymorphism H131R was found to be associated to SLE or nephritis in numerous studies, but also as a functional polymorphism in IIIA [22–27]. The allele of IIA containing arginine (R131) has diminished IgG-binding capacity, supporting the hypothesis that FcGRs are involved in immune complex handling and disposal, a mechanism that is defective in

SLE. Researchers are, however, still not completely convinced of the role of this polymorphism. The FcGR family is a cluster of four genes (FcGRIIA, IIB, IIIA, and IIIB) and one pseudogene (FcGRIIC). The four genes vary in their function, and IIA and IIIA have been the main ones found to be associated with SLE, although IIB has not been studied probably because of its great similarity to IIA, despite its having a completely opposite role in cell regulation. Thus, as opposed to IIA, IIB inhibits antigen-specific B-cell activation through a tyrosine-based inhibitory motif in its intracytoplasmic tail. The mechanism leading to autoimmunity could thus be through a lack of inhibition of cellular activation. The close proximity of the mouse loci described earlier to the FcGR genes caused them to be considered important candidates. However, elegant studies by Morel *et al*. [21], together with discovery of the *ifi202* gene, have cast doubt on the role of FcGRs in the disease, at least in the mouse. The question being always whether we can extrapolate the findings made in mouse models to the human disease. Are FcGRs involved in human SLE but not in murine lupus? Alternatively, are *Ifi202* and the *sle1* gene cluster of mice lupus also involved in human SLE? Only intense study can give us answers to these queries, but animal models do give us clues as to pathogenic pathways of the human disease.

The second approach to the identification of genes for human disease is to directly use human material [28]. This implies collecting large cohorts of families with multiple cases of SLE. To date, five human genome scans have been published [29–33]. Table 1 describes the major loci identified in each study. All scans revealed loci in chromosome 1, but only one of these had linkage to the region where the FcGR genes are located (1q21–23). One genome scan performed in Nordic families, a population with little admixture, revealed a locus in chromosome 2q37 (*SLEB2*) [29, 34], whereas a third locus of apparent importance was found in chromosome 16, close to the newly described locus for Crohn's disease [4]. All studies identified the HLA in chromosome 6p also as a locus involved in SLE, as expected [31]. These studies require large numbers of families, and the strategies classically used for monogenic diseases cannot be fully applied for complex diseases. Linkage regions identified usually are many centimorgans in size and may include anywhere from 100 to 600 genes. A candidate gene approach can be taken, but it is difficult to decide what genes to start with. Is there prior evidence for any one gene? Are there many potential candidates? What type of mutations do we expect to find in complex diseases? How frequent are such mutations in the general population? The example of Crohn's disease is interesting [4]. Three rare amino acid substitutions were identified, each of them so rare that genetic association could not be performed and a haplotype test had to be implemented. However, as the polymorphisms were amino acid substitutions that modified the function of the NOD2/CAD15 gene, there was little reason to doubt their role in disease. Are we to expect similar mutations in SLE? We do not know. Each gene is a particular case depending on its function. One of the major problems in complex disease human genetics is the exclusion of genes within a region of linkage.

TABLE 1 Major Loci Identified in Genome scans of SLE

Human chromosome	LOD[a]	Population
1q23-24	3.37	African-American
1q41-42	3.50	African-American
2q37	4.24	Scandinavian
4p15	3.20	Icelandic
6p21-11	3.9	Mixed African-American, European-American
16q13	3.64	Mixed African-American, European-American

[a] LOD score (logarithm of the odds).

One of the approaches discussed in recent years is the identification of disease-associated haplotypes to which a gene expression or function can be related. Use of the publicly available databases of single nucleotide polymorphisms (SNPs) does not solve the issue completely because many of the disease variants we are looking for may be rare among normal individuals. Complete resequencing of genes within susceptibility loci has been proposed as an option with the use of new technologies for the identification of relevant SNPs forming common population haplotypes [35–37].

How different genes play a role in SLE, either through modification of other genes or in disease susceptibility, and what their relation is to disease expression, requires much research. On the one hand, there are germline genes that encode for natural autoantibodies that may become pathogenic when subject to mutation and/or idiotypic switch. On the other hand, there may be genes that predispose to the development of autoimmune disease in general that are evidenced by personal or familial associations with other diseases (e.g., autoimmune thyroiditis, rheumatoid arthritis, pernicious anemia, myasthenia gravis, autoimmune hepatitis).

Genes involved in SLE may participate in different immune pathways, including immune complex handling, B-cell signaling, regulation of apoptosis, antigen processing and presentation, T-cell receptor conformation,

and immunoglobulin structure. Of these, one of the most studied is the one related to inefficiency for immune complex handling by the immune system of lupus patients. Much of this pertains to the study of hereditary complement deficiencies that, when totally affecting the production of a complement component, particularly one of the early phases of complement activation that participate in stabilization and clearance of immune complexes, often result in a lupus-like syndrome.

Partial complement deficiencies cannot by themselves explain the disease but SLE does associate rather strongly with null alleles of C4A (C4AQ0), which in some populations is in linkage disequilibrium with the B8, DR3 haplotype of the HLA. In many instances the association of C4AQ0 has been found without association to DR3, but the reverse has also been found [38–44]. The strength of the role of HLA in SLE is yet undetermined. It should also be remembered that other potentially important genes [e.g., tumor necrosis factor (TNF)] are also located within the major histocompatibility complex (MHC) region.

Also related to immune complex handling are the FcG receptors of macrophages, natural killer (NK) or B cells that bind IgG subclasses with varying affinities. Quantitative differences in the binding of different alleles may be a predisposing factor to disease by influencing either B-cell activation or IgG levels, particularly those of autoantibodies or immune complex-mediated triggering of inflammatory processes. In addition, FcG receptors may participate in the handling of viral or bacterial infections. A strong genetic association has been found in Blacks and other ethnic groups between a polymorphic allele of FcGRIIa and lupus nephritis [45–49]. It could thus be that such association could represent that of a disease severity gene influencing development of nephritis within SLE, but having no role in primary genetic susceptibility to the development of the disease itself [50].

Genes related to the regulation of apoptosis may also be implicated. This has become apparent in the murine SLE model having the lymphoproliferation (*lpr*) that represents a defect in the *fas* gene that regulates apoptosis in lymphoid cells [51]. The *fas* gene has been implicated only in a familial recessive form of human SLE and does not seem to have a role in most SLE cases [52–55]. The *lpr* mutation behaves as an accelerating gene in certain genetic backgrounds. Thus, it seems to influence severe disease in MRL mice whereas it causes only lymphoproliferation in the C57BL/6 strain.

Strain differences provide important clues. The NZB mouse develops two bouts of hemolytic anemia, the second one being usually fatal and due to the interplay of natural autoantibodies to bromelain-treated erythrocytes wall and Coombs' antibody. When NZB mice are crossed with NZW mice, which is a generally normal strain, their F1 hybrids develop severe renal disease akin to lupus nephritis and numerous autoantibodies, including characteristic anti-dsDNA and anti-Sm [56]. Independent laboratories have studied crosses of (NZB/NZW)F1 mice and analyzed their complete genome using anonymous markers looking for loci that predispose to nephritis or to development of autoantibodies. Lupus nephritis, as well as other disease phenotypes, should be seen as a qualitative, dichotomous trait made up of various quantitative traits. When studyng quantitative traits, such as autoantibody titers or immunoglobulin levels of the various isotypes, a large number of loci with smaller effects are revealed. Each locus may act in an additive fashion to render a certain phenotype. However, the various genes may interact, a phenomenon known as epistasis, and modify each other's effects [57, 58] (Fig. 1). An example of this has been provided by crossing MRL-*lpr/lpr* with perforin-deficient mice (*pfp*–) [59]. Survival was reduced and renal IgG deposition was increased in *pfp-/fas-* as compared to *pfp* + /*fas-*,*pfp* + /*fas* +, and *pfp-/fas* + mice. This could indicate a role of the last complement components in disease severity.

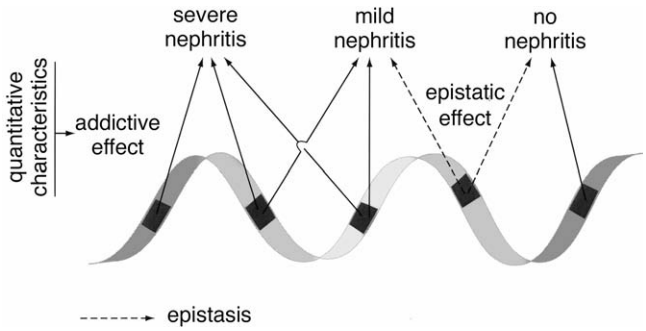

FIGURE 1 Interplay of additive and epistatic effects of genes participating in the development of lupus nephritis. The algebraic sum of these would yield the result, e.g., mild nephritis.

Figure 2 presents a scheme of potential genes that may participate in the development and/or the clinical and serologic picture of SLE. We also show how they may interplay with the other factors within the first troika as well as with the other two troikas. There are specific or general autoimmune disease-susceptibility genes, genes of disease severity or acceleration, and disease-modifying genes. There may be participation of genes for immune responses, complement components, immunoglobulin structure, T-cell receptor alleles, FcGRII, MHC, cytokine promoters, regulation of apoptosis and lymphoproliferation, and germline genes that encode for natural autoantibodies. There are also genes

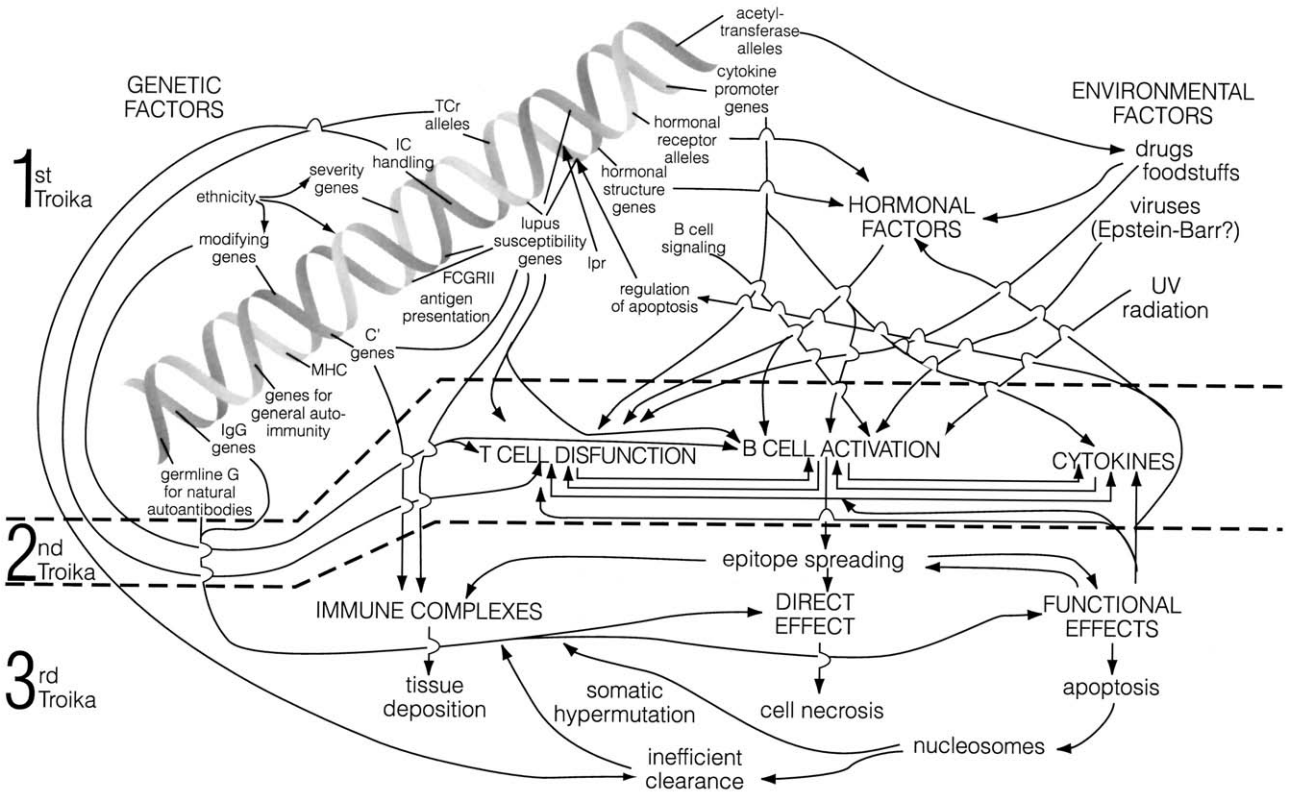

FIGURE 2 A tale of three troikas: Overview of the interplay of various factors at the etiologic (first troika) level. Etiopathogenic (second troika) and pathogenic (third troika) levels.

that regulate hormonal structure and hormone receptor alleles, as well as genes that participate in pharmacogenetics such as acetyltransferase alleles. Some of these genes exert their influence through the second and third horses of the first troika or extend their influence to the other two troikas.

In the field of lupus, human genetics is advancing and in the near future it is hoped that we will witness an explosion of findings that will result in new therapies that will improve the life of hundreds of thousands lupus patients. Identification of the genetic variants involved in disease susceptibility or expression should lead to better understanding of the mechanisms behind the other components of the troikas.

Hormonal Factors in SLE

That lupus occurs predominantly in females might relate to hormonal factors. Again, studies in lupus-prone mice have helped us define their role. Multiple experiments in castrated and noncastrated NZB/NZW mice have shown a disease-accelerating effect of estrogens that also causes H-2 related antibody production [60]. These effects of estrogens have also been encountered in MRL-*lp*-*lpr* and even in Balb/c mice immunized with the 16/6 pathogenic idiotype of anti-DNA antibodies [60–63]. Similar studies using testosterone instead of estrogens have shown a protective effect instead of a deleterious effect [64]. These contrary effects of the two groups of hormones could relate to their respective interactions with the immune system. In general, estrogens tend to have an activating effect on the immune system whereas testosterone has more of a quieting role. However, independent of the effect of hormones, the immune system of females is, in general, more powerful. In most species, thymuses of females are larger at birth. Another hormone that may have a role in the pathogenesis of SLE is prolactin, which can be found elevated in both males with SLE [65–66].

Prolactin participates in immune functions and there are receptors for prolactin on human lymphocytes and monocytes [67, 68]. Nonlupus patients with hyperprolactinemia tend to have lupus autoantibodies and may have a decreased production of, and response to, interleukin 2 (IL-2) that can be corrected with bromocriptine treatment that decreases prolactin levels [69]. It has been found that peripheral blood mononuclear cells from patients with SLE preferentially secrete a bioactive 60-kDa species of prolactin both in resting and in stimulated states [70]. This could point to an autocrine

loop of prolactin participating in the immune dysregulation of SLE. In support of this is the finding that prolactin may enhance the *in vitro* production of IgG by peripheral blood mononuclear cells from SLE patients as compared to those of normal controls [71]. Interestingly, mononuclear cells derived from patients who had hyperprolactinemia were the ones that produced more IgG. Whether the IgG thus formed consisted primarily of autoantibodies was not determined [71].

Although female patients with SLE may have normal estradiol levels, they have been shown to have increased 16α hydroxylation of estrone with a potent estrogenic activity [72–74]. Conversely, they tend to have low testosterone levels [75]. Males with lupus may have increased plasma 16α hydroxyestrone and decreased testosterone [76–78], and patients with Klinefelter's syndrome who have significantly increased 16-hydroxylation of estrone may be more prone to develop SLE [79]. This could also point to a role of genes on the X chromosome. As mentioned previously, hormonal factors could also be genetically influenced either at the level of hormonal structure or of hormonal receptor alleles. Some of these interactions between genetic and hormonal factors are also shown in Fig. 2.

Environmental Factors in SLE

That environmental factors play a role in the etiopathogenesis of SLE seems beyond dispute. Ultraviolet light, for instance, can clearly provoke the initiation or activation of the disease. A number of drugs, as well as some foodstuffs (e.g., alfalfa sprouts), have also been shown to cause lupus-like syndromes, and their lupus-inducing potential may be influenced by their pharmacogenetics. Individuals with a slow drug acetylator phenotype are more prone to have drug-induced lupus upon exposure to drugs that are a substrate for hepatic acetyl transferase [80]. That patients with spontaneously occurring SLE may also be predominantly slow acetylators has been controversial probably due to ethnic factors [81]. The potential role of viruses in the etiopathogenesis of SLE has long been suspected. A study of lupus patients of less than 20 years of age found a remarkable increased prevalence of Epstein–Barr virus infection as compared to matched controls [82]. These findings raise several possibilities, particularly that of triggering of the disease in individuals with the proper genetic background. The finding of increased EB virus infection could be significant in view of the well-known B-cell activation/immortalization properties of this virus on B cells. It should be kept in mind that in different ethnic groups, different geographies, or both, other viruses could be involved [83].

That normal individuals may have the genetic predisposition to develop SLE should an adequate triggering environmental factor come along, was amply discussed when dealing with genetic factors. Thus normal mice may contribute genes that increase the severity of lupus in their offspring. That an environmental factor may elicit a full-blown picture of SLE is exemplified by the pristane model of murine lupus where a single intraperitoneal injection of this compound into BALB/c mice can cause the disease with a corresponding cohort of autoantibodies [84]. Interestingly, the first autoantibodies to appear following an intraperitoneal pristane injection of mice are germline gene-encoded low-affinity IgM natural autoantibodies. This would also indicate the potential pathogenic importance of natural autoantibodies, whether subjected to mutations or not. Interactions of environmental factors with hormonal (e.g., estrogen administration) and genetic ones are also depicted in Fig. 2. From here we move to the second troika, which travels inside immune regulation territory.

THE SECOND TROIKA: ETIOPATHOGENESIS

The genetic, hormonal, and environmental factors that constitute the three horses of the first troika exert their influence on the three elements of the second troika. To pull this troika, we choose as its horses T-cell dysfunction, B-cell activation, and abnormal cytokine production, which are hallmarks of immune dysregulation present in SLE. Obviously all three are closely interrelated and it has been difficult to determine which, if any one, comes first. The end result, however, of T-cell dysfunction and abnormal cytokine production is the activation of B cells that produce pathogenic autoantibodies. These will pull our third troika. At the level of immune dysregulation of SLE there may be other participants. These include dendritic cells whose homeostasis is altered in murine lupus [85] and NK cells whose function is disrupted in human SLE [86], can regulate antibody production, and, through transforming growth factor-β (TGF-β), downregulate T-cell activity [87]. In turn, TGF-β has a role in the generation of $CD4^+CD25^+$ suppressor T cells that prevent $CD8^+$ T cells from proliferating in response to alloantigens and from becoming cytotoxic effector cells [88]. It should be recalled that a disturbed suppressor cell function was one of the first abnormalities of immune regulation encountered in SLE [89] and has reacquired attention for their potential role in autoimmunity [90].

T-Cell Dysfunction

That a T-cell dysfunction occurs in SLE has been amply demonstrated. In general, circulating blood

mononuclear cells from SLE patients show a decreased Th1 and an increased Th2 profile. T cells operating at the level of actively inflamed organs in SLE may belong to the Th1 and Th0 subsets [91], but in normal skin of lupus patients there is an accumulation of γδT cells that seems to correlate with disease activity [92]. In analogy to what has been described in the mouse, in human SLE there is a general decrease of cytokines produced by T cells to regulate other T cells. These include IL-2, TNF, IL-12, and interferon-γ [93]. In contrast, cytokines produced by Th2 cells are mostly B-cell growth, differentiation, and stimulatory factors (e.g., IL-4, IL-5, IL-6, IL-10). T-cell functions themselves are also affected, including the response to T-cell mitogens, decreased suppression of T cells on B cells, decreased contrasuppression, and decreased response in autologous mixed lymphocyte reactions [94]. The algebraic sum of these regulatory disturbances would tend to facilitate autoantibody production. Activation of T lymphocytes requires antigen-mediated signaling through the T-cell receptor as well as costimulatory signals transmitted through B7-1 and/or B7-2 with CD28. These costimulatory signals regulate autoantibody production in a murine lupus model as well as its ultimate renal pathology [95]. Impaired signaling in SLE T cells may, at least partly, be due to deficient protein kinase A phosphotransferase activity [96].

Polyclonal B-Cell Activation

Patients with SLE have hypergammaglobulinemia and characteristically produce a large number of autoantibodies. Whether these reflect passively the polyclonal B-cell activation itself, are antigen driven, or are the result of a somatic hypermutation of germline gene-encoded natural autoantibodies is difficult to tell at this time. The fate of autoreactive B cells within a monoclonal B-cell repertoire may be different from that in a polyclonal one [97]. If we return to the mice models, we find that anti-dsDNA B cells in nonautoimmune mice exit from the bone marrow to populate the spleen where they locate at the T–B interface of the splenic follicle where they have an increased *in vivo* turnover rate [98]. As opposed to anti-dsDNA B cells that locate in the spleen, those that produce natural autoantibodies to bromelain-treated erythrocytes, which may cause hemolytic anemia in NZB mice, locate in the peritonaeum [99]. It is thus possible that the various autoantibodies, including germline gene-encoded ones, emerge, escape deletion, or are subject to enhancement in SLE by different mechanisms. Also, as discussed in the first troika, genetic factors influence the appearance of particular autoantibodies in SLE.

Contrary to the way they had been considered in the past, B cells are not just the passive recipients of signals leading them to differentiate into antibody-producing plasma cells. Data on the autocrine production of cytokines by B cells that act as signals to themselves and to T lymphocytes, a recently described role in promoting the spontaneous activation of T cells [100], as well as the expression by them of lymphotoxin a/b, which is essential for the differentiation of follicular dendritic cells [101], indicate that B cells may have more active participation in the immune dysregulation of SLE than previously thought [102]. Whether this role is primary or results from the effects of T cells, monocytes, dendritic, or NK cells is yet unknown. A potential role for a B lymphocyte stimulator member of the TNF superfamily in triggering self-antigen-driven early B-cell activation in SLE has also been proposed [103]. It seems to be, however, that there are profound abnormalities in homeostasis in various B-cell compartments in SLE. Interestingly, B cells in each of these may respond differently to immunosuppressive therapy [104].

Cytokines

When we described the decreased production of, and response to, IL-2 in SLE [105], we thought this to be a primary event in the etiopathogenesis of SLE. We soon found that the production of, and response to, IL-1 is also defective [106]. It was found, however, that the production of IL-2 by lupus T cells would recover if these were allowed to rest in culture medium [107]. This suggested that decreased IL-2 production was the result of either exhaustion or secondary to the effect of other factors, including other cytokines and/or increased expression of increased of phosphorylated cAMP-responsive element modulator that binds to the –180 site of the IL-2 promoter [108]. The complexity of this became apparent when we and others found an increased production by T cells of B-cell-stimulating and differentiation factors in SLE patients [109, 110]. An important part of the riddle may have been solved when it was found that IL-10 both inhibits the production of IL-1 and IL-2 and enhances the production of Th2 cytokines (Fig. 3) and that monocytes and B cells from patients with SLE have an increased spontaneous production of IL-10 [111]. The role of IL-10 in B lymphocyte hyperactivity and autoantibody production of SLE was then tested both *in vitro* and *in vivo* and compared to those induced by IL-6, another cytokine suspected to play a role in these abnormalities [112]. The spontaneous *in vitro* production of immunoglobulins was increased modestly by recombinant (rIL)-6 but strongly by rIL-10 [112]. In severe combined immunodeficiency (SCID) mice injected with human SLE blood mononuclear cells, injection of the anti-IL-6 monoclonal antibody did not affect the serum concentration

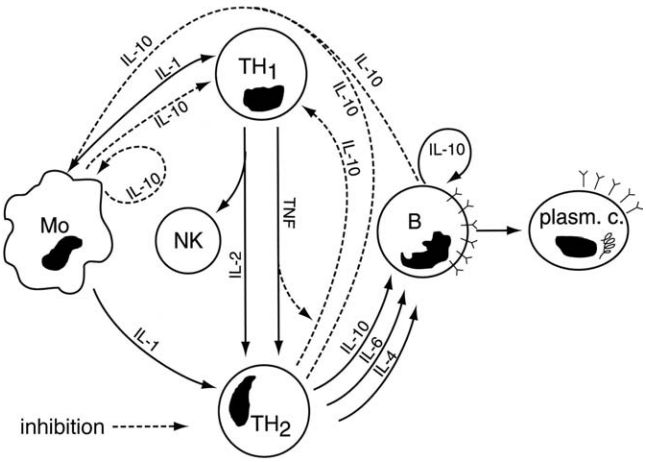

FIGURE 3 Cytokine networks in SLE, spontaneous production of IL-10 by monocytes, and B cells in SLE result in inhibition of IL-1 and IL-2 production with B-cell activation and autoantibody production.

of IgG or of anti-dsDNA IgG, whereas that of anti-IL-10 abrogated the production of human IgG anti-dsDNA without greatly decreasing the production of total human IgG. It would therefore seem that the production of anti-dsDNA by SLE B lymphocytes is largely IL-10 dependent and that the increased production of IL-10 by SLE monocytes and B cells is critical at the level of the second troika (etiopathogenesis). As a result of these observations, a pilot trial of the anti-IL-10 monoclonal antibody was carried out in six SLE patients whose disease required persistent corticosteroid treatment lest it be activated. The patients thus treated had remarkable responses to this form of treatment, supporting the notion of an important role of IL-10 in the immune dysregulation of SLE [113]. It was, however, found that monocytes and B cells from the healthy relatives of SLE patients also constitutively produce large amounts of IL-10 [114]. Interestingly, this increased production of IL-10 in lupus relatives was independent of age, sex, and of whether the relationship to the lupus patients was of first or second degree. This would pose two questions: if IL-10 is so important in the etiopathogenesis of SLE, how is it that lupus relatives who have high levels do not become ill? If we return to the first troika we find that a possible explanation could lie in the genetic makeup of patients as opposed to that of their relatives. These could have inherited the increased production of IL-10 but not the resulting effect on autoantibody production. In this regard it is of interest that the production of anti-ssDNA by mononuclear cells from SLE relatives in the SCID mice model is not affected by monoclonal anti-IL-10 (L. Llorente *et al.*, unpublished observations). The second and related question pertains to whether the IL-10 gene plays a role in the susceptibility to develop SLE. This gene has been located to chromosome q31–32 (the genome data base, www.gdb.org). Three studies have analyzed a microsatellite found in the promoter region of the IL-10 locus with controversial results. In one study there was association of polymorphisms in this locus [115], whereas in another study, associations with some alleles were only found when patients were subgrouped as per anti-Ro positivity or renal involvement [116].

In a third much larger study, no significant difference was found in the frequency of microsatellite alleles in the promoter region of IL-10 in 330 Mexican SLE patients compared to 368 controls of the same ethnic background [117]. Because ethnicity could explain the differences with the other two studies done in the United Kingdom, parametric linkage analyses were done in 22 northern European (14 Swedish and 8 Icelandic) and 13 Mexican multiplex families and again no linkage was revealed between the IL-10 gene promoter and SLE [117]. It seems, therefore, that as attractive as it might be, the hypothesis that the IL-10 gene promoter is implicated in SLE and explains the increased production of IL-10 in both patients and their relatives, the answer may lie elsewhere. One possibility could be that of associated altered production of a related cytokine. Increased serum levels of IL-13 and IL-15 have also been found in patients with SLE [94, 117].

Under the influences of the three elements of the first troika, the dysfunction of T cells, the activation of B cells, and the production of cytokines interact among themselves and lead to the production of pathogenic autoantibodies.

THE THIRD TROIKA: PATHOGENESIS

As a result of the immune dysregulation of the second troika and under the direct or indirect influence of the genetic, hormonal, and environmental factors described in the first Troika, a great variety of autoantibodies appear in the serum of patients with SLE. The nature of each of these autoantibodies may be reflecting the role of elements from these two Troikas (e.g., antihistones in drug-induced lupus, anticardiolipin antibodies by genes of the MHC, natural autoantibodies encoded by germline genes such as antibodies to phosphatidylcholine, or lack of arrest of autoreactive anti-dsDNA B cells in the spleen). Potential spreading of the immune reaction with a specific peptide segment of a molecule to other epitopes may also help explain the diversification of the immune response and the vast

array of autoantibodies. These, in turn, may have a pathogenic role. Their nature and variety, their immunochemical characteristics [118], and their potential to elicit anti-idiotypes will determine the resulting clinical manifestations or lupus subsets [119]. In turn, these characteristics, particularly their specificity and binding kinetics, may implicate different stimuli for their production [120]. There are too many variables to allow any one clinician to see two identical lupus patients. The third troika considers three mechanisms of potential damage done by autoantibodies: immune complex-mediated damage, a direct damaging effect, and functional effects of the autoantibodies that may either take place at this pathogenic level or revert to influence the second troika or even perhaps the first one.

Immune Complex-Mediated Damage

Lupus has long been considered as an immune complex-mediated disease (type III hypersensitivity of Coombs' and Gell classification) [121], but this is only one of the mechanisms whereby autoantibodies participate in the pathogenesis of the disease with a deposit of preformed circulating immune complexes at the site of damage. This is a rather passive or chance situation that will have no other specificity than that provided by the quantitative and qualitative (e.g., antigen excess) characteristics of complexes as it occurs in serum sickness. Higher specificity of their location is attained when the autoantibody seeks an antigen deposited in an organ (e.g., DNA attached to basement membranes of the skin or glomeruli) in an Arthus type of reaction. Either or both of these situations may participate in lupus nephritis, vasculitis, interstitial cystitis, pulmonary hemorrhage, neuronitis, and central nervous system involvement through immune complex deposition in the choroid plexus. The presence of a pathogenic idiotype in an autoantibody such as anti-dsDNA (e.g., the 16/6 idiotype) [122] may be another participating factor in this type of immune-mediated damage.

In vivo clearance of immune complexes may be influenced by Fcγ receptor polymorphisms that may be skewed toward genotypes yielding longer half-lives of IgG-coated erythrocytes [123]. This exemplifies the ample connections among the three troikas.

Direct Damaging Effects by Autoantibodies

Hemolytic anemia, thrombocytopenia, neutropenia, and perhaps some aspects of the lymphopenia of SLE are more likely due to a direct lytic effect by autoantibodies and/or facilitation of removal of these cells by the phagocytic system (type II hypersensitivity of Gell and Coombs' classification) [121]. There are two general types of autoantibody systems in lupus that may lead to this: autoantibodies directed to specific antigens on the cell surface and autoantibodies directed to more ubiquitous antigens, such as phospholipids and/or their protein cofactors [124]. Recognition of platelets by autoantibodies detected by conventional anticardiolipin assays requires platelet activation or aggregation, which causes the translocation of anionic phospholipids to the outer leaflet of the platelet wall. These anionic phospholipids are subsequently bound by proteins with a high affinity for anionic compounds, such as β2-glycoprotein-I (β2GPI). Upon binding to the anionic phospholipid now available on the surface of the platelet, β2GPI seems to suffer a conformation change that may expose cryptic epitopes in this protein. These are, in turn, recognized by autoantibodies putatively directed to cardiolipin but actually reactive with the protein at this epitopic site [124]. It is also possible that reactivity of β2GPI with the anionic phospholipid or even with an oxygenated plate causes it to be bound by antibodies with lower affinity that would otherwise not recognize the native molecule [125]. Other protein cofactors that have been implicated in the binding of these autoantibodies include prothrombin, thrombin, kininogen or kininogen-binding protein, annexin V, and perhaps protein C [124].

The occurrence of hemolytic anemia, both in SLE and as a variant of the primary antiphospholipid syndrome [126], as well as the terminal event in NZB mice, involves a different mechanism. Here a natural autoantibody to PTC recognizes this zwitterionic phospholipid on the erythrocyte surface when a glycoprotein that would impede it is removed either by the effect of proteolytic enzymes (e.g., bromelain) or upon aging of erythrocytes [127]. Because this antibody is normally present in all mammals tested so far, it is possible that for it to become pathogenic, either a subtle mutation or the participation of another autoantibody (e.g., Coombs' antibody) is required.

Neutropenia in SLE patients has also been found to associate with antibodies to phospholipids and/or its protein confactors [128]. The possible mechanism and specific autoantibody that may cause this have not been determined. Although the association has been found with anticardiolipin antibodies as detected in conventional enzyme-linked immunosorbent assays (ELISA), there may be ample cross-reactivity of these antibodies with those directed primarily to other phospholipids, including zwitterionic ones [129].

Functional Effects of Autoantibodies

In addition to the potential to cause cell or tissue damage, serum autoantibodies present in patients with

SLE can cause functional alterations that manifest themselves in the clinical spectrum of lupus patients or go back to the other troikas to influence immune regulation or even hormonal factors of the first troika (Fig. 2). Thus, antiprolactin antibodies have been found in patients with SLE having hyperprolactinemia [130] (Fig. 3).

The aforementioned antibodies to phospholipids or their protein cofactors can participate in phospholipid-dependent coagulation, natural anticoagulation processes, or both. As a result of this, an acquired (phenotypic) defect of protein C activation may occur in these patients that could lead to increased thrombogenesis [131]. In addition, because β2GPI may itself be a natural anticoagulant, antibodies to this protein could also favor thromboses.

Another mechanism whereby autoantibodies may cause functional disturbances is by their penetration into live cells. This mechanism was described in 1978 [132], but despite having being studied extensively by our group, it has been until only recently recognized as a potentially important phenomenon from both the standpoint of immunobiology and of immunopathology [133]. In our initial studies we were able to determine that the penetration of antibodies to RNP could cause immunoregulatory disturbances [134]. We also found that anti-RNP and anti-DNA antibodies could cause cell cycle arrest at different levels [135, 136] and that both could cause protracted cell death. It was later found that cell death caused by antibody penetration is due to apoptosis [137, 138]. Increased apoptosis in SLE could lead to an increased availability of nucleosomes, which because of inherent phagocytic disturbances may not be removed promptly and thus be capable of stimulating the antigen-driven production of anti-DNA/nucleosome antibodies. The LE cell phenomenon itself is an example of these mechanisms: causation of apoptosis by the penetration of the anti-DNA antibody and phagocytosis of the apoptotic body by a polymorphonuclear leukocyte [139]. Antibodies to ribosomal P proteins can also penetrate into live hepatocytes and cause cellular dysfunction [140]. This could explain the association of antiribosomal protein P antibodies and hepatic disease in SLE patients [141]. It is possible that the heart block caused by anti-Ro and/or anti-La antibodies to the offspring of pregnant lupus patients results from this same mechanism because antibodies penetrate best into immature cells [142]. A role for calreticulin as a surface receptor allowing the penetration of autoantibodies has been postulated [143], and increased expression of this protein has been found to be associated with congenital heart block [144].

SUMMARY

Our previous division of the etiopathogenesis of SLE into three consecutive levels continues to be pertinent, as is their respective subdivision making use of the troika analogy to emphasize how each of these are pulled concomitantly by at least three factors riding together. At the etiology level, genetic, hormonal, and environmental factors participate concertedly. In turn, genes involved in SLE may be multiple, behaving in an additive fashion, some acting as lupus susceptibility genes proper and others as disease-modifying genes. Some may have an epistatic role modulating the effect of other genes. As a result of the interplay of genetic, hormonal, and environmental factors, a level is reached where T-cell dysfunction, B-cell activation, and imbalance of cytokines cause a complex immune dysregulation. A result of this is the production of a vast array of autoantibodies that will be the main determinants of the clinicopathologic manifestations of SLE. At this pathogenic level autoantibodies may cause damage by forming immune complexes, by producing cell lysis, or by causing functional disturbances. These include, among others, an imbalance of coagulation–anticoagulation systems with resulting thrombophilia and penetration of autoantibodies into live cells, a process that may cause immune regulation disturbances, cellular dysfunction of specific cells, or apoptosis. A potential treatment of SLE is currently being sought at these various levels of disturbance.

MHC CLASS II AND NON-MHC GENES IN THE PATHOGENESIS OF SYSTEMIC LUPUS ERYTHEMATOSUS

John D. Reveille
George S. Bruce Jr.

INTRODUCTION

The actual cause of systemic lupus erythematosus (SLE) is unknown. No environmental agent, whether chemical, infectious, or otherwise, has been implicated. However, the importance of genetic influences is being increasingly recognized. After numerous reports of familial aggregation in this disease, the first genetic factors to be identified as important in the pathogenesis of SLE were those of the major histocompatibility complex (MHC) on chromosome 6 in the early 1970s. Until recently, most of the studies of markers in SLE have focused on this region.

It is most widely accepted, however, that MHC genes constitute only a part of the genetic susceptibility to SLE. The past few years have seen a great deal of effort in defining other genes outside the MHC, and the results from such searches have already pinpointed other chromosomal regions, where numerous genes reside whose products are critical in the immune response.

In the previous edition of this book [1], this author stated: "by the time the next edition of this book is published, the genetic contribution to SLE probably will be almost completely defined." Despite the huge number of studies (with over 150 new investigations included in this chapter since the last edition in early 1998), the past 4 years have, unfortunately, fallen short of that prediction. One of the best explanations is the clinical heterogeneity of SLE, which requires such large numbers of patients and families to attain the necessary statistical power that few studies have approached this.

This chapter reviews the genetic basis for SLE, the familial aggregation in SLE (in way of historical perspective and in establishing the genetic basis of this disease), the current status of genome-wide scans in families of SLE patients (including defining the terminology relevant to genetic studies), organization of the MHC, whose numerous genes have been studied extensively in their relation to SLE, the association of MHC genes and susceptibility to SLE, the autoantibody subsets of SLE and their MHC class II associations, and finally the status of the ongoing search for non-MHC genes in SLE susceptibility.

FAMILIAL AGGREGATION IN SYSTEMIC LUPUS ERYTHEMATOSUS

The classic method to show a genetic basis for any disorder is to demonstrate that it occurs more commonly in family members than would be expected by its frequency in the general population. The major *caveat* in this rationale is that environmentally triggered diseases would also be more likely to occur at the same location, such as in a single household. Therefore,

proving familial aggregation *per se* does not establish that a disease is transmitted genetically. Instead, where familial aggregation is established, showing that nonconsanguinous household contacts (such as spouses) are not as likely to develop the disease in question, that affected family members are more likely to develop the disorder around the same age and not at the same time chronologically, and, finally, in twin studies, that monozygotic (identical) twins are more likely to concordant for the disease than dizygotic (fraternal) twins indicates nature instead of nurture.

Family Studies

Familial Aggregation in SLE

Reports of familial aggregation in SLE date from as early as 1903, when Sequera [2] reported its occurrence in two sisters. Since then, there have been numerous other reports (reviewed in Reveille [1]). Siegel *et al*. [3] were the first to examine the prevalence of SLE in relatives of SLE patients, finding no evidence of significant familial clustering. Estes and Christian [4] reported seven (10%) of their cohort of 150 North American SLE patients to have first-degree relatives similarly affected. Buchman *et al*. [5] reported, from a cohort of 340 patients with SLE, that 41 (12%) had affected relatives of whom 5 had multiply affected family members. Hochberg [6] carried out a case–control study of 77 SLE patients and 77 matched controls, and found significant familial aggregation, with eight of the patients (10%) vs one of the controls (1%) having a similarly affected first-degree relative. Lawrence *et al*. [7] examined first-degree relatives and spouses of 36 patients with SLE and 37 with discoid LE, finding definite SLE in 3.9% of SLE probands and in 0.3% of controls, but not at all in spouses of SLE patients. Koskenmies *et al*. [8] reported a cross-sectional nation-wide clinical study of familial systemic lupus erythematosus in Finland and identified a prevalence of familial SLE of 4–5%. No differences were found in the clinical presentation of SLE between familial and sporadic cases. More recently, Michel *et al*. [9] reported a frequency of SLE in first-degree relatives in 8% of 137 French-Caucasian SLE probands.

Relationships between Affected Family Members

Virtually every kind of familial relationship between relatives with SLE has been reported (reviewed in Reveille [1]). As would be expected from the propensity of SLE to occur in women, the overwhelming majority of familial cases involved sister:sister or mother:daughter pairs. While this might raise the possibility of X-linked transmission, Lahita *et al*. [10] presented four kindreds in whom there were father–son pairs affected with SLE, suggesting that in these families genetic transmission may have been similar to that in the BXSB mouse, where there is a disease-linked gene on the Y chromosome, with resultant male–male transmission.

Concordance for SLE Features and Other Autoimmune Diseases in Family Members of SLE Patients

Arnett *et al*. [11] examined eight families multiplex for SLE and reviewed previously reported familial cases and found that an impressive concordance for disease features was found in identical twin and parent : offspring pairs and not for sib pairs (suggesting more of a genetic than an environmental contribution). However, studies of the *timing* of disease onset between family members with SLE have suggested that environmental factors may also be at work in triggering disease. In the same study of Arnett *et al*. [11], the average difference in *time* at disease onset in nontwin sibling pairs was only 3 years, whereas the average difference between *ages* at onset was 9 years. Kaplan [12] also found a shorter interval between the times of onset compared with the ages at SLE onset in the affected siblings, underscoring the importance of nongenetic factors.

The higher frequency of other autoimmune diseases in family members of SLE patients has also been long observed [13, 14–16], particularly autoimmune thyroid disease [13, 14], inflammatory arthritis [especially rheumatoid arthritis (RA)] [1, 17, 18], and even scleroderma [16–19]. Larsen [15] found that thyroid disease was four times more frequent in family members of SLE patients who themselves also had thyroid disease than in relatives of SLE patients who did not have this complication. Dubois *et al*. [17] found 5.5% of his cohort of 520 SLE patients had a family member with RA. However, Siegel *et al*. [3] could not document an increased frequency of RA in 155 relatives of 66 SLE patients. Flores *et al*. [20] described eight families where one family member had scleroderma and the other SLE. What was particularly noteworthy about this latter report was that even though five of the six pairs studied for HLA antigens shared haplotypes, seven of the eight pairs did not live in the same household at the time disease developed, suggesting a genetic predisposition. Arnett *et al*. [21] reported 19 extended multiplex SLE families, finding 13% of the relatives to have other immune-mediated disorders and 26% to express autoantibodies [including antinuclear antibodies (ANA), anti-ss DNA, and/or biologic false-positive tests for syphilis (BFP-STS)]. Considering the presence of other autoimmune disease or these autoantibodies as an

TABLE 1 Serologic Abnormalities in Family Members of SLE Patients[a]

Antibody	Technique	Patients	Relatives	Controls
Antinuclear antibodies (ANA)	IIF on tissue substrate	72–100%	4–50%	4–14%
ANA	IIF on Hep-2 cells	75–100%	17–33%	19%
Anti-ssDNA	Modified Farr	70%	23%	n.a.[b]
Anti-ssDNA	ELISA	40%	20%	0%
Anti-dsDNA	Farr	74%	5%	0%
Anti-dsDNA	*Crithidia lucilae*	14–56%	1%	0%
Anti-Ro (SS-A)	Immunodiffusion	25%	1%	0%
Anti-Ro (SS-A)	ELISA	60–80%	28%	6%
Anti-RNP	Immunodiffusion	8–40%	0%	0%
Anti-Sm	Immunodiffusion	5–12%	1%	0%
Anti-Sm	ELISA	n.a.[b]	12%	2%

[a] modified from a review of previous studies by Miles and Isenberg [36].
[b] Not available.

autoimmune "trait," formal genetic analysis of these kindreds suggested the presence of an autosomal-dominant non-MHC-linked "autoimmune gene" that is epistatic to other "secondary" genes (such as HLA class II) in influencing the tendency to develop autoimmunity [22]. This consideration has been largely replaced by more sophisticated genome-wide scans covered later in this chapter.

Other Immunologic Abnormalities in Family Members of SLE Patients (Table 1)

Antinuclear Antibodies

Since the initial reports of antinuclear antibodies in family members of SLE patients in 1960–1961 using tissue substrates [9, 23–34], the increased frequency of a positive ANA has been well documented [1] with frequencies ranging from 4% [3, 28] to 50% [34]. In most studies, the presence of ANA did not correlate with clinical abnormalities in the non-SLE family members; however, in a study by Sato *et al*. [35] of 120 first-degree relatives of 25 SLE patients, the presence of ANA in non-SLE family members (as determined by a *Hep2* assay) was associated with a higher frequency of arthralgias and Raynaud's phenomenon. These and most of the following data on serologic abnormalities in relatives of SLE patients have been reviewed [36].

Antiextractable Nuclear Antigen Antibodies (ENA) and Anticardiolipin Antibodies (aCL)

In contrast to antinuclear antibodies, anti-Ro, La, Sm, and RNP autoantibodies occur uncommonly in healthy family members of SLE patients. Their frequency varies as to the technique utilized. Studies examining these autoantibodies using less sensitive immunodiffusion technique found them to occur rarely in healthy relatives [13, 35]. The use of more sensitive ELISAs in determining ENA autoantibodies has increased the frequency of anti-Ro antibodies in healthy relatives to 29% and of anti-Sm to 13% [37]. The clinical significance of this, however, is unclear. More recently, Van der Linden *et al*. [38] tested plasma from 50 patients with SLE, 154 unaffected first-degree family members, and 330 healthy controls for the presence of autoantibodies (by ELISA). Seventy-four percent of patients, 32% of first-degree family members, and 1.5% of healthy controls had antibodies against any nuclear antigen. Most frequent autoantibodies in the patients were antihistone and anti-Ro (SS-A), whereas in family members these were anti-RNP-C and anti-Topo-I/Scl. The presence and specificity of autoantibodies in family members were independent of the presence or absence of that autoantibody in the probands with SLE.

Radway-Bright *et al*. [39] reported an increased frequency of IgG antiphospholipid antibodies in healthy first-degree relatives of SLE patients with antiphospholipid antibody syndrome relative to both nonconsanguinous household contacts and unrelated controls.

Antipolynucleotide Antibodies and Lymphocytotoxic Antibodies

DeHoratius *et al*. [40, 41] examined North American SLE patients, their family members, and nonconsanguinous household contacts for the presence of anti-DNA and RNA and lymphocytotoxic autoantibodies. Anti-DNA and RNA autoantibodies were found in the SLE patients and their relatives, but not in household contacts. However, lymphocytotoxic antibodies were

found in all, including close nonconsanguinous household contacts, leading to the conclusion that both genetic and environmental influences were at work. Cleland *et al*. [42] examined 103 members of four multiplex Canadian SLE kindreds. Over 50% of SLE family members and nonconsanguinous household contacts had positive ANA as compared to 5% of controls, further suggesting environmental agents. Lymphocytotoxic antibodies, however, were not increased in non-SLE family members or controls. Folomeeva *et al*. [43] confirmed the increased frequency of antipolynucleotide antibodies in 15 Russian SLE probands and 41 of their relatives, finding an increased frequency compared to control families. However, nonconsanguinous household contacts were not examined. Eroglu and Kohler [44] examined 26 North American families and found antilymphocytotoxic antibodies in 83% of SLE patients, 50% of family members, and only 11% of nonconsanguinous household members. Malave *et al*. [45] examined 50 Venezuelan SLE patients and 109 of their relatives, finding an increased frequency of antilymphocytotoxic antibodies in consanguineous relatives and in unrelated spouses compared to controls. Hazelton [46], as well as LePage *et al*. [47], however, could not confirm an increase in antilymphocyte or lymphocytotoxic antibodies in British studies of SLE families.

Antisingle-stranded DNA antibodies commonly occur in family members of lupus patients, having been in 20–30% [13, 31, 47, 51], whereas anti-dsDNA antibodies are rare. Studies employing the less specific Farr or ELISA assays report frequencies of anti-dsDNA antibodies up to 23%, respectively [34, 47, 48]. However, using the more specific *Crithidia lucillae* assay, the frequency approaches zero [13, 31, 49].

Abnormalities in T- and B-Cell Function and IL-10 Production

Miller and Schwartz [50] documented abnormalities in suppressor T-cell function in 11 of 15 SLE patients and in 26% of their female relatives, which did not correlate with the presence of antilymphocytotoxic antibodies. Mendlovic *et al*. [51] examined proliferative T-cell responses to an anti-DNA idiotypic DNA antibody in 38 Israeli SLE patients and 18 of their first-degree relatives, finding a lower response in both patients and family members. Haug *et al*. [33] found the healthy relatives of SLE patients to have a decrease in the synthesis of poly(ADP-ribose), a nucleic acid polymer involved in several cell functions, and suggested that abnormalities in the function of the poly(ADP-ribose) polymerase may be a predisposing factor to SLE. Isenberg *et al*. [31] examined 44 SLE patients and 147 healthy first-degree relatives for the presence of anti-DNA antibody idiotypes, finding elevated levels in 40% of patients and 24% of relatives, suggesting a higher frequency of certain disease-relevant immunoglobulin genes to be present in SLE families. Tomana *et al*. [52] examined 30 patients with SLE and 58 members of an additional five families with multiple members with SLE and other autoimmune diseases, finding abnormal galactosylation of IgG in 60% of the patients and family members. The importance of this finding has been underscored by the discovery that a mutation of the gene encoding α-mannosidase II, which regulates protein glycosylation, results in a systemic autoimmune disease in mice resembling SLE [53].

van der Linden *et al*. [54] determined IL-10 production after endotoxin stimulation in 163 first-degree relatives of patients with systemic lupus, 50 first-degree relatives of patients with chronic cutaneous lupus, and 133 control persons. IL-10 production was higher in the families of patients with systemic lupus than in the control families. Similarly, Grondal *et al*. [55] studied IL-10 as well as levels of IgG and ANA in SLE patients and their first-degree relatives and spouses in Icelandic SLE multicase families. The SLE patients had a significantly higher number of IL-10-producing cells compared with both first-degree relatives and healthy controls, although first-degree relatives also had a significantly higher number of IL-10-producing cells compared with healthy controls. Conversely, this was also true for the spouses of SLE patients, who had a higher number of IL-10-producing cells compared with matched healthy controls, which suggests both genetic and environmental factors influencing the development of immunologic abnormalities in family members of patients with SLE.

Twin Studies

Block *et al*. [56, 57] reported the first series of nine North American twin pairs, with a concordance rate of 67%. Reichlin *et al*. [58] subsequently analyzed eight of these twin pairs and found serologic concordance for autoantibodies (anti-Ro, La, Sm, and RNP determined by ELISA) in both concordant and discordant monozygotic twin pairs. Deapen *et al*. [59], however, found a lower rate of concordance (24%) in a large North American cohort of 100 identical twins. One concern that has been raised about series of twins is a bias from clinical selection, where families with multiple cases of a given disease would be more likely to be ascertained than families with single cases [7]. Jarvinen *et al*. [60] examined nine sets of identical twins and 10 sets of dizygotic twins in Finland, where every citizen is assigned a code and complete disease ascertainment is thus possible, and found only a 11% concordance rate for SLE in

the identical and none concordant in the dizygotic twins. One of the most intriguing findings came from the study of Grennan *et al*. [61] where one of four sets of Australian monozygotic twins and none of six sets of dizygotic twins were concordant for SLE. A further analysis of HLA haplotypes in the families of 38 SLE patients found none of 18 HLA identical, same-sex siblings to have definite SLE, suggesting that most of the genetic predisposition to SLE is attributable to genes outside the HLA region.

Genetic Studies in Familial SLE

Basic Genetic Terms

One of the most daunting tasks facing the nongeneticist is understanding the difficult and often changing terminology used in genetic studies. An HLA *specificity* refers to the HLA protein as expressed on the cell surface, which is detected most commonly by serologic typing. HLA specificities are thus designated by terms such as HLA-DR1 or DR4. An *epitope* is literally defined as an antigenic determinant on a complex antigenic molecule. A *locus* is a site on a chromosome occupied by a specific gene. An HLA *allele* refers to one of potentially many forms of the HLA gene itself. Because this term refers to differences in the DNA sequence of the gene, different alleles (or forms) of an HLA gene are usually detected by examination of the DNA sequence, which is now possible by a variety of techniques. *Linkage disequilibrium* refers to alleles of two genes that are physically spaced close together on the same chromosome that tend to be passed from generation to generation *en bloc* and thus occur together more frequently than would be expected from the chance frequencies of the individual genes. A *haplotype* is a set of genes, usually linked, which are passed *en bloc* from generation to generation (the presence of haplotypes is usually established by conducting family studies, wherein the inheritance pattern and linkage can be determined). Centimorgan (cM) is a measure of genetic distance between two loci; 1 cM is the distance between two loci that will recombine with a frequency of exactly 1%. *Linkage analysis* examines the phenomenon of linkage whereby loci that are are close to one another on the same chromosome tend to be transmitted together more frequently than chance, such as a disease or disease trait and a genetic marker. *Linkage analysis* tests whether affected relatives inherited a region identical by descent more often than expected under random Mendelian segregation. A quantitation of the support for linkage (versus absence of linkage) is provided by the *lod score*, which is the common logarithm (to the base 10) of the likelihood ratio. Although linkage analysis can be carried out in large families with multiple affected members, the easiest and most effective method is by *affected sib pair analysis*, whereby an affected sib pair may share 0, 1, or 2 alleles identical by descent (IBD) with probabilities of 0.25, 0.5, or 0.25, respectively, at any marker locus if by chance alone. If the ratios differ significantly from this, then linkage between the two marker alleles or traits in the siblings exists.

Genome-Wide Scans in Familial SLE

Genome-wide scans in familial SLE have been underway since the mid-1990s in at least five different locations [62, 64–75]: two in California [63, 64], one in Minneapolis [65–68], one in Oklahoma City [68–72], which is the only site to focus on African-American kindreds, and one in Uppsala [73–75], which not only includes families from Sweden, but also from Iceland and Mexico City) (Figs. 1 and 2). The first report was from Tsao *et al*. [62] in Los Angeles, who analyzed seven microsatellite markers from human chromosome 1q31–1q42 in 43 families with at last two siblings affected with SLE and found five markers located at 1q42–1q42 to show linkage. This region is syntenic with the murine chromosomal region containing the gene *SLE1* [63].

This was followed by Gaffney *et al*. [65] in Minneapolis, who reported the results of a genome-wide scan in 105 sib pair families, finding the strongest evidence for linkage in the HLA region (lod score 3.9) and at three additional regions—16p11–21(lod score 3.64); 14q21–23 (lod score 2.81), and 20p12 (lod score 2.62). Subsequent to this, this group reported the results of a second scan on an additional 82 families, finding evidence of linkage at 7p22 (lod score 2.87), 7q21 (lod score 2.3), 10p13 (lod score 2.24), and 7q36 (lod score 2.15). A combined analysis of both scans 6p11–p21 and 16q13 met criteria for linkage (LOD scores 4.19 and 3.85, respectively). In addition to this, four intervals had weaker evidence for linkage, including 2p15, 7q36, 1q42 [67] and 4p16–15.2 [68].

At the same time, Moser *et al*. [69] reported the results of a scan on 94 extended multiplex kindreds, finding evidence of linkage at 1q41, 1q23 [70], and 11q14–23 in 40 African-American kindreds and 14q11, 4p15 [68], 11q25, 2q32, 19q13, 6q26–27, and 12p12–11 in 40 Caucasian families. Combining both races, 1q23, 13q32, 20q13, and 1q31 were identified. Subsequent to this observation, Gray-McGuire *et al*. [68] presented data on an additional 32 pedigrees from this group, which, when combined with the original families studied, provided stronger evidence of linkage to 4p16 (lod score 3.84), with additional evidence for epistasis at 5p15. Nath *et al*. [71] and Rao *et al*. [72] analyzed 101

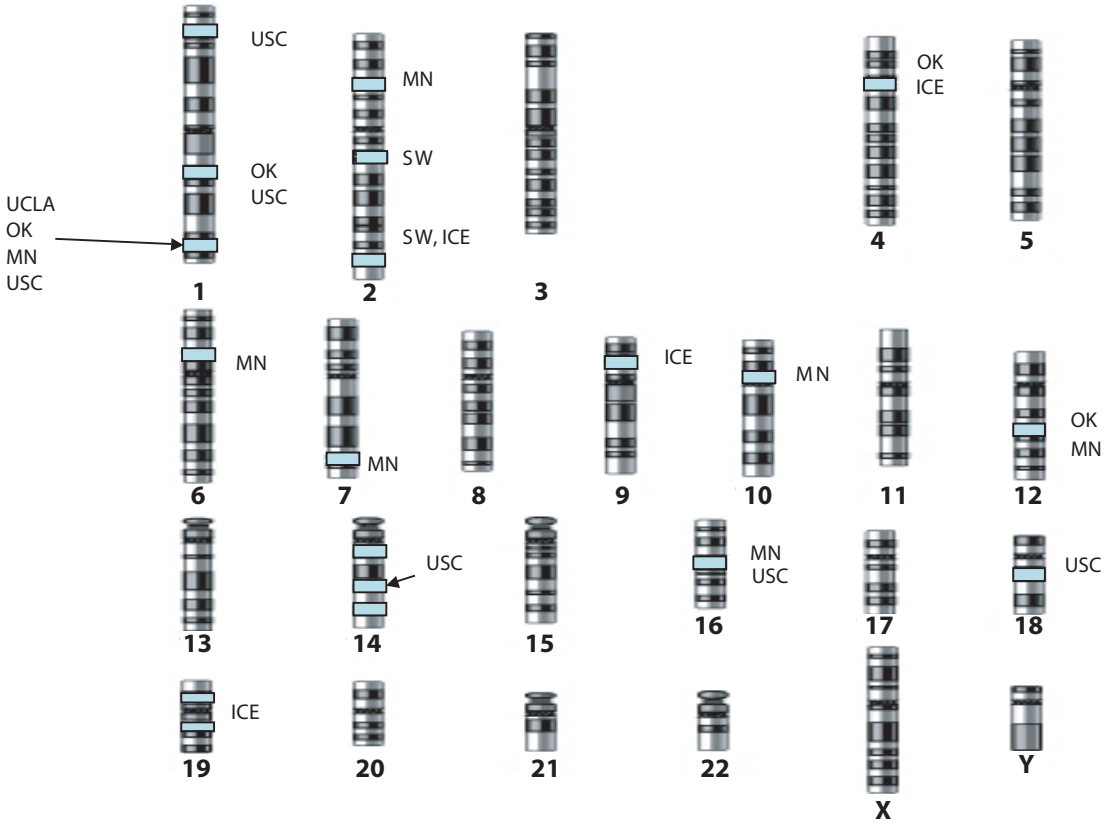

FIGURE 1 Locations of SLE susceptibility regions identified on genome-wide scans. Included are regions seen in the scan from the University of Southern California (USC) [64], Oklahoma Medical Research Foundation (OK) [68–72], the University of Minnesota (MN) [65–68], the University of California, Los Angeles (UCLA) [62], and Uppsala University, including families from Sweden (SW), Iceland (ICE), and Mexico City (MEX) [73–75].

SLE-affected sib pairs with respect to dermatologic, renal, immunologic, hematologic, neurologic, cardiopulmonary, and arthritic characteristics. Significant linkage with vitiligo was identified at 17p13. In addition to this, significant linkage for an individual trait was on chromosome 2 at 228 cM (immunologic; $P = 0.00048$), and the most significant linkage to an individual principal component was on chromosome 4 at 208 cM ($P = 0.00007$). The largest multivariate linkage was on chromosome 7 at 69 cM ($P = 0.0001$). Of the individual organ systems, dermatologic involvement had the largest effect ($P = 0.0083$) at this peak at 7p13 on chromosome 7. Further analyses revealed that malar rash, a subtype of dermatologic involvement, was linked significantly ($P = 0.00458$) to this location.

Shai *et al.* [64] examined 80 SLE families from southern California with two or more affected relatives, finding evidence of linkage at 1p21, 1q24, 1q44, 14q23, 16q13, 18q21, and 20p13.

Johanneson *et al.* [73], Lindquist *et al.* [74], and Magnusson *et al.* [75] reported genome-wide scans performed in multicase extended families from three different population groups: Sweden (11 families containing 54 individuals, including 28 SLE patients), Iceland (8 families composed of 147 individuals, including 16 SLE patients, with a high degree of homogeneity), and a recently admixed population of Mexican Mestizos, with 14 families containing 32 patients with SLE. A number of chromosomal regions showed maximum lod scores indicating possible linkage to SLE in both Icelandic and Swedish families. In the Icelandic families, five regions showed lod scores greater than 2.0, three of which (4p15–13, 9p22, and 19q13) are homologous to the murine regions containing the lmb2, sle2, and sle3 loci, respectively. The fourth region is located on 19p13 and the fifth on 2q37. Only two regions showed lod scores above 2.0 in the Swedish families: on chromosome 2q11 and 2q37. Thirteen Mexican families were analyzed separately and found not to have linkage to this region (Table 2).

From these at times confusing and confounding results the following chromosomal regions appear to

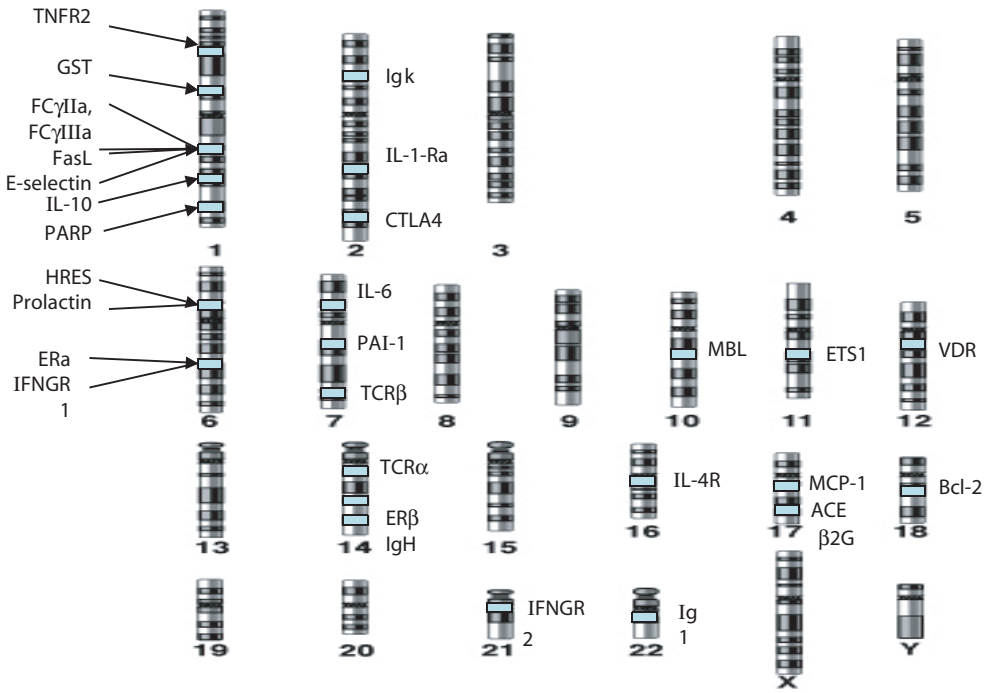

FIGURE 2 Locations of genes implicated in susceptibility to SLE. Included are only genes implicated in at least one study, whether predisposing to SLE or a clinical subset thereof.

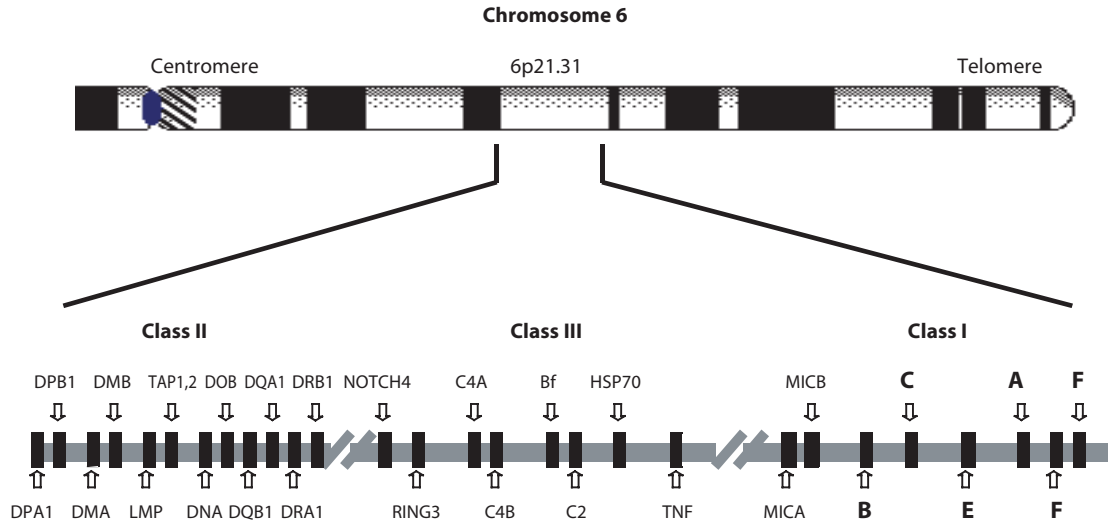

FIGURE 3 Schematic of the major histocompatibility complex. The 3.6 Mb MHC contains over 220 genes and is divided into three classes. Only genes with known (or presumed) immunological function are shown.

have been confirmed by more tham one group: (1) chromosome 6p11–21, near the MHC; (2) chromosome 1q42 and (3) chromosome 4p15, whose disease relevant genes have yet to be identified. It is hoped that with more families collected, pooling of data, and stratification for clinical subsets of SLE may provide more clues by the publication of the next edition of this book.

STUDIES OF CANDIDATE GENES IN SLE

Genes of the Major Histocompatibility Complex

Organization of the MHC (Fig. 3)

HLA-DP Alleles

The last and most centromeric lying of the "classical" class II loci to be described, this region is organized much like DQ, with two α and two β chain genes, only one of each being functional. HLA-DPA1 exhibits limited polymorphism, while over 86 alleles now have been identified for HLA-DPB1.

HLA-DM

While the newest discovered of the functional loci within the MHC class II region [76], HLA-DM has nonetheless been shown to have a unique and important function in the immune system, acting as both a chaperone and an editor in the loading of the peptides onto the HLA-class II heterodimer in the cytosol. It exerts its effect mainly in the acidic lysosomal or late endosomal compartments, but also (about 10% of total) can be found at the cell surface. HLA-DM heterodimers, however, cannot bind peptides on its own [77]. Genes encoding DMA and DMB lie between HLA-DQ and the TAP/LMP gene complex. DMA alleles are defined by variants at three nucleotide positions involving codons 140, 155, and 184 of exon 3 and seven DMB alleles by variants at two nucleotide positions involving codons 144 and 179 of exon 3 [78–80].

TAP-1 and -2 Genes

These genes together encode a heterodimeric protein that transports peptides from the cytosol into the lumen of the endoplasmic reticulum. Newly synthesized HLA class I molecules (MHC peptide plus β_2-microglobulin) are associated with the TAP heterodimer before binding to endogenous peptides. Once the latter occurs, class I molecules disassociate from the TAP molecule and move to the cell surface for presentation of the bound peptide to the appropriate T-cell receptor [81–84].

LMP 2 and 7 Genes

These genes encode proteosomes that degrade endogenous products (plus viral and tumor proteins) to generate peptide fragments that bind to MHC class I molecules [85].

HLA-DO

HLA-DO is a nonpolymorphic MHC class II-like heterodimer composed of the products of the genes DNA and DOB, which lie beween the TAP/LMP complex and the HLADQ complex. The HLA-DO

heterodimer appears to function in B cells and modulates the function of DM. In fact, DO is stably complexed with DM during intracellular transport and in endosomal/lysosomal compartments [77, 86]. Like DM, it does not bind peptides on its own.

HLA-DQ Alleles

This region is composed of two DQA and two DQB genes, only one of each encoding a functional product. The DQA1 locus has over 9 known alleles, whereas DQB1 has over 17. HLA-DQA2 and DQB2 genes are not known to be functional.

HLA-DR Alleles

This region is composed of one nonpolymorphic DRA gene whose product combines with the product of numerous DRB genes to form HLA-DR heterodimers. Most of the polymorphism of classic HLA-DR molecules is derived from the DRB1 gene, where over 150 polymorphisms are now recognized. The presence and number of other DRB loci vary on different HLA-DR haplotypes, e.g., DRB3, found on DR3, DR5 (DR11, 12), and DR6 (DR13, DR14) haplotypes, encodes, in conjunction with DRA, the DR52 molecule. The HLA-DRB4 gene is found on HLA-DR4, DR7, and DR9 haplotypes and, in conjunction with DRA, encodes HLA-DR53 specificity. HLA-DRB5 is found on DR2 haplotypes and with DRA encodes what is now recognized serologically as HLA-DR51.

MHC Class III Region

Here lie the early components of the classical and alternate complement cascade (C4, which has undergone a gene duplication resulting in C4A and C4B, C2 and properdin factor B), as well as heat shock 70 gene complexes and tumor necrosis factor (TNF) complexes. In addition to these genes are newly discovered genes RING3 and Notch 4, which lie between C4 and HLA-DRA. RING3 a is nuclear-localized, serine-threonine kinase, and Notch 4 a receptor that controls differentiation or proliferation in various cells. Also found in the MHC class III region are other genes which either do not have a known immunologic function (21-hydroxylase B) or whose function is not well understood [RAGE, RD, and the B-associated transcript (BAT) complex]. This region and its relevance to SLE are better covered in Chapter 5.

MHC Class I Region

Located most telomeric in the MHC and spanning two megabases of DNA [87], the MHC class I region contains HLA-A, B, and C genes (class Ia), a number of other class I-like genes, HLA-E, F, and G (class Ib), and MIC genes. MIC genes include MIC A and B, which are located between HLA-B and the TNF complex [87]. MIC proteins are considered to be markers of stress in the epithelia and act as ligands for cells expressing a common activatory natural killer cell receptor NKG2D. HLA-E is widely expressed on different tissues but displays limited allelic polymorphism. It presents hydrophobic peptides from the leader sequences of other class I molecules. HLA-E:peptide complexes constitute the only known ligands for CD94/NKG2 receptors on natural killer (NK) and T cells [88]. HLA-G is expressed in high amounts on trophoblastic cells and is thought to function in inducing maternal–fetal tolerance. The function of HLA-F, considered to be the progenitor of all MHC class I genes, is unknown and has a restricted pattern of expression in tonsil, spleen, and thymus. Also found are a number of pseudogenes (such as HLA-H, J, K, and L). There is little to support a significant role of this region in SLE, and it is not discussed further.

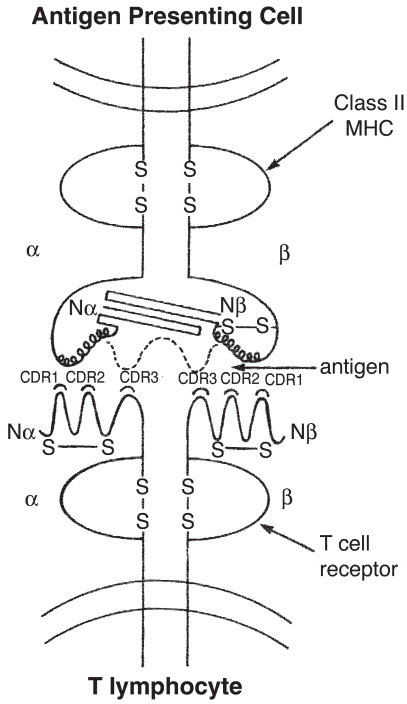

FIGURE 4 HLA class II heterodimer: antigen: T-cell α:β receptor complex (the trimolecular complex).

HLA Class II Molecules: Structure and Function (Fig. 4)

Unlike HLA class I molecules, which are expressed on the surface of all nucleated cells, HLA class II molecules have a more limited distribution, being present in varying amounts on the surface of antigen-presenting

cells such as macrophages, dendritic cells, and B cells (although other cells can be induced to express HLA class II molecules by interferon-γ). HLA class II molecules, which include HLA-DR, DQ, and DP, function in presenting to the α:β T-cell receptors on CD4-positive lymphocytes peptides, which are derived from proteins that have been internalized from outside the cell (exogenous antigens) and degraded within lysosomes to peptide fragments.

The HLA class II molecule is a glycosylated heterodimer composed of an α chain of 32 kDa in size and a β chain of 29 kDa. Each of these two polypeptides folds into four domains. The α1 and β1 domains project outermost from the cell surface and form the peptide-binding groove. These domains also form the contact point for interaction with the T-cell receptor, and it is in these domains that most of the polymorphism of the HLA class II molecule is found. This polymorphism is, for the most part, grouped into three "diversity" or "hypervariable" regions along the approximately 90 amino acid span of the domain, encompassing amino acids 9 to 13 (the first "diversity" region), 25 to 38 (the second), and 57 to 86 (the third). The next domains (α2 and β2) project more proximally outside the cell surface (membrane proximal domains). These are more conserved in amino acid sequence and share sequence homology with immunoglobulin and TCR membrane-proximal domains. They also contain the point of binding to the CD4 receptor, which in turn increases the affinity of interaction between the T cell and MHC class II:peptide complex and facilitates T-cell activation. Both α and β polypeptides also contain more highly conserved transmembrane and intracytoplasmic domains, which serve to anchor the HLA class II heterodimer into the cell surface. The HLA-DR molecule has now been crystallized and its fine molecule structure defined. Studies of the antigen-binding cleft of the HLA class II heterodimer show important differences from HLA class I molecules. Both types of MHC molecules are bordered by α helical loops, and the floor of the cleft consists of a series of β-pleated sheets. However, the class I molecule has rigid size requirements for what it binds, permitting peptides of only 9 to 10 amino acids in length. The class II cleft is less constrained, allowing peptides of 13–25 amino acids in length. This cleft, in turn, is composed of up to nine "pockets," into which specific amino acids of the peptide in the cleft protrude and are, to a greater or lesser extent, noncovalently bound. Deepest and most critical is the first pocket, P1, which anchors the peptide fragment and which has the most stringent binding requirements. The other pockets are shallower and more permissive in their binding. However, is noteworthy that these pockets are composed of amino acids that differ among different DR molecules, hence the amino acid polymorphism of HLA class II molecules critically affects which amino acids residues can be bound in the peptide-binding groove and hence which peptide fragments can be presented to the T-cell receptor.

Soon after MHC class II polypeptides are synthesized in and inserted into the endoplasmic reticulum of the cell, they come into association with another peptide, the invariant chain (I_i), which promotes the proper folding and assembly of the MHC class II heterodimer and protects the peptide-binding groove from premature occupancy by endogenous peptides. In addition, I_i is responsible for the delivery of the HLA class II α:β:I_i complex through the *trans*-Golgi network to the acidic endosomal–lysomal compartment, where it encounters peptide fragments of internalized exogenous proteins or internalized self-antigens. At that point I_i undergoes proteolytic cleavage, leaving only a peptide in the HLA class II peptide-binding groove called CLIP. Unless the CLIP peptide is removed, MHC class II peptide binding cannot occur. Removal of CLIP is facilitated by HLA-DM, which transiently binds to the HLA class II molecule in the endosomal–lysomal compartment, removes the CLIP peptide, and further acts as a peptide editor, selecting for high-stability MHC class II–peptide complexes, which are sorted to the cell surface for effective antigen presentation.

MHC Class II Genes and Susceptibility to SLE

Differences in the Frequencies of HLA-DR and DQ Genes in Different Ethnic Groups

Whereas certain HLA-DRB1 alleles occur in all populations (*DRB1*0701*, *DRB1*1301*, *DRB1*1302*), there are important differences in the frequencies of HLA class II alleles in different ethnic groups. Not only do frequencies of HLA class II alleles differ, but also the HLA-DQ alleles to which they are linked. For example, *HLA-DRB1*0405* is linked to *HLA-DQB1*0302* in Caucasians, whereas in Chinese and Japanese, linkage disequilibrium for *DRB1*0405* instead is found with the *HLA-DQB1*0401*. The *HLA-DRB1*1602*, *DQB1*0301* haplotype is well described in Native Americans, whereas in Africans the haplotype is more characteristically *HLA-DRB1*1602*, *DQB1*0502*. The different linkage disequilibrium seen in different ethnic groups gives one justification for examining disease associations thus in order to better evaluate the relative contributions of HLA-DR and DQ alleles to disease pathogenesis (Tables 3 and 4).

TABLE 3 Selected HLA-DRB1-DQA1-DQB1 Haplotypes in Different Ethnic Groups

HLA-DR specificity	DRB1 allele	DQ specificity	DQA1 allele	DQB1 allele	Ethnic group

[a] From data in Reveille [1].

HLA-DR and DQ Genes and SLE Predisposition (Table 5)

The earliest attempts at defining HLA associations with SLE were with class I antigens, where either weak correlations with HLA-B8 were seen [89–91] or no associations were seen at all [92]. Over 25 years have passed since an association of HLA-DR2 and DR3 with SLE has been recognized, initially in Caucasians in the United States [93, 94]. HLA-DR3 has been associated with SLE in nearly every other Caucasian population group studied, including those from the United Kingdom [95, 96], Australia [97], Spain [98], Italy [99], Scandinavia [100–102], Switzerland [103, 104], Austria [105], Germany [106], and Iceland [107], as well as from other studies from the United States [108, 109]. The only exceptions come from studies of southern and eastern Europe, where Slavic genetic admixture predominates and significant associations of HLA-DR2 and DR3 were not seen [110, 111]. In a multicenter study from Europe, composed of 534 patients [112], HLA-DR3 (*DRB1*0301*) emerged as the only significant association with SLE *per se*.

However, the association of HLA-DR2 with SLE has remained consistent in other Caucasian groups [93, 113, 114] (where a more specific association with lupus nephritis was seen in one group [115]) as well as in Orientals [140–143]. With the advent of DNA typing, where numerous HLA-DR2 alleles are recognized, the DR2-allele *DRB1*1501* (linked to *HLA-DQA1*0102* and *DQB1*0602*) has been shown to constitute this association in Caucasians [96, 106]. Tsuchiya *et al.* [116] recruited 91 Caucasian SLE family samples recruited in southern California and analyzed them for the association with HLA-DRB1, TNF promoter positions at –1031, –863, –857, and –308, and TNFR2-

[a] Not tested.

196M/R polymorphisms. Significant transmission was observed for *HLA-DRB1*1501*, but not for *HLA-DRB1*0301* nor for the TNF haplotype that codes for –308A.

The HLA-DR2/*DRB1*1501* association has also been seen in Oriental groups, including Japanese [117–119], Chinese [120–126] and Koreans [127, 128]. This *HLA-DRB1*1501* association in Orientals is particularly noteworthy, as the most frequent HLA-DR2 allele in these groups is *DRB1*1502*, which is linked to different HLA-DQ alleles (*DQA1*0103*, *DQB1*0601*) [119]. Zhang *et al.* [126] reported an increased frequency of DR2 and DR3 alleles in northern Chinese Han SLE patients. A study of SLE patients from northern India described an association with HLA-DR4 [129], despite a nonsignificant increase in HLA-DR3 alleles.

Initial studies in African-Americans using serologic or restriction fragment length polymorphisms (RFLP) typing yielded either weak associations with HLA-DR2 and DR3 [130, 131] or no associations at all [132–134]. With the utilizing of oligotyping, the association of HLA-DR2 with SLE in African-Americans appears to reside with *HLA-DRB1*1503*, a uniquely African DR2 allele that differs from *DRB1*1501* by a single amino acid substitution at position 30 of the DRB1 outermost domain [108, 135, 136] and is also linked to *HLA-DQA1*0102* and *DQB1*0602*.

No immunogenetic studies have been conducted in Native Americans with SLE. However, Hispanics, especially those from Mexico and Central America, are composed of varying degrees of European and Native American ancestry. Reveille *et al*. [137] examined 52 Mexican-Americans, finding a similar, although weaker, association with HLA-DR3 (*DRB1*0301*) that has been described in other Caucasian groups. A similar observation was made in a group of patients from Mexico City [138]. However, another study of Mexican Mestizos residing in Texas has suggested a stronger association with HLA-DR8 (*DRB1*0802*) [139].

Some studies have focused on additional contributions to SLE pathogenesis of the *other* set of HLA class II alleles that an individual possesses. Reinharz *et al*. [104] reported the combination of HLA-DR2 (*DRB1*1501*) and DR3 (*DRB1*0301*), whose presence has been reported by others to produce the highest risk for anti-Ro autoantibodies (see later) [140–142] to occur rarely in SLE patients. Skarsvag *et al*. [101] found patients who were homozygous for MHC class II genes to have a higher likelihood of developing SLE, with *HLA-DRB1*0301*, *DQA1*0501*, *DQB1*0201* homozygosity having the highest risk, followed by non-*DRB1*0301*, *DQA1*0501*, *DQB1*0201* homozygotes. However, in another European study of 356 SLE patients by Hartung *et al*. [105], homozygous and heterozygous combinations of HLA class II antigens appeared with frequencies expected from observed gene frequencies. Among Japanese SLE patients, a combination of HLA-DR2 and DR4 has been reported as providing the highest risk for SLE [119].

HLA DR and DQ Genes and Autoantibody Subsets of SLE (Table 6)

SLE is both a clinically and a serologically heterogeneous disorder, such that many of the MHC associations are better explained when considering autoantibody subsets. Just as in the consideration of the HLA studies themselves, analyzing associations with autoantibody subsets should take into consideration the techniques

TABLE 6 Non-MHC Genes Implicated in Predisposition to SLE

Gene	Function	Location	Group
TNFR2	Cell surface receptor for TNF	1p36.3	EA
Glutathione-*S*-transferase	Protects against oxidative stress	1q12	C
FcγRIIa	Preferentially binds Fc portion of IgG2	1q22	C, AA, EA, H
FcγRIIIa	Preferentially binds Fc portion of IgG1 and IgG3	1q22	C, EA
FAS ligand	Mediates apoptosis	1q24	H, C, EA
E-Selectin	Leukocyte–endothelium interactions	1q23–25	C
T-cell receptor ζ chain	Anchor site for TCR on CD3	1q23–24	C
IL-10	Multifunctional cytokine, promotes apoptosis	1q31–32	C, H, EA
PARP	Involved in DNA repair and apoptosis	1q42	C, H, AA
HRES-1	Endogenous retroviral sequence	1q42	C
Igκ	Immunoglobulin light chain	2p12,	C
IL-1-Ra	Endogenous anti-inflammatory agent	2q12	C
CTLA-4	Maintains peripheral T-cell tolerance	2q33	C, EA
Prolactin	Influences T-cell function	6p22.2	C
IFNGR2	Interferon-γ receptor 2	6q23–24	EA
ERa	Estrogen receptor α	6q25.1	EA
IL-6	Multifunctional Th2 cytokine	7p21	C
PAI-1	Plasminogen activator inhibitor-1	7q21.3	EA
TCRβ	T-cell receptor β chain gene	7q35	C
Mannose-binding protein	Activates complement independent of antibody	10q11.2	C, A
ETS1	Transcription factor activation	11q23	C, AA
VDR	Vitamin D receptor	12q12–14	EA
TCRα	T-cell receptor α chain gene	14q11–12	C
ERb	Estrogen receptor β	14q23–24	EA
IgH	Immunoglobulin heavy chain gene	14q32.33	C, AA, EA
CYP1A1	Activate drugs to reactive metabolites	15q22	C
IL-4-R	B-cell activation, Th2 response	16p12.1	EA
MCP-1	Recruitment of monocytes to sites of injury/infection	17q11.2	C
β2-Glycoprotein	Required cofactor for the production of aPL	17q23	C
ACE	Angiotensin-converting enzyme gene	17q23	EA, C, AA
Bcl-2	Prolongs survival of lymphocyte	18q22	C, H
IFNGR1	Interferon-γ receptor 1	21q22.1	EA
Igλ	Immunoglobulin λ light chain gene	22q11.2	C

utilized in the autoantibody determinations, which differ significantly in the sensitivity and specificity. For example, in most of the "classical" studies, autoantibody determinations were carried out by immunodiffusion. By the mid-1980s, many studies began utilizing ELISAs, which improved the sensitivity of autoantibody detection 10- to 100-fold. Subsequently, immunoblot analyses allowed the detection of immune responses against constituents of the autoantigen.

Anti-dsDNA The anti-dsDNA response, which is associated with disease activity in SLE, particularly with glomerulonephritis, has been associated with both HLA-DR2 (*DRB1*1501*) [113, 143] and DR3 (*DRB1*0301*) [144] and their respective linked HLA-DQ alleles (*DQA1*0102*, *DQB1*0602* and *DQA1*0501*, *DQB1*0201*) [106, 145]. Azizah *et al*. [122] found an association of *DQA1*0301* with antibodies to dsDNA in Malaysian Chinese.

Anti-Ro and La Anti-Ro and La, associated with sicca symptoms, photosensitive skin rashes, vasculitis, and later onset disease, were initially associated in Caucasians with HLA-DR2 and DR3 [113, 134, 146].

Subsequent studies, also using serologic typing, implicated HLA-DQ molecules, specifically the broad specificities DQ1 and DQ2. In fact, the presence of both these alleles concomitantly gave the highest risk for and antibody levels of the anti-Ro and La responses [140, 141, 147], although more recent studies have implicated their respective linked DQ alleles, particularly those DQA1 alleles encoding a glutamine at position 34 and DQB1 alleles encoding a leucine at position 26 [148, 149]. The development of ELISA to anti-Ro and La allowed quantitation of the actual levels of the autoantibodies [150]. With the introduction of immunoblotting and the recognition of the 60- and 52-kDa isoforms of anti-Ro, it was found that both isoforms were most highly associated with *HLA-DRB1*0301* and its respective linked DQ alleles, *DQA1*0501* and *DQB1*0201* [151, 152], as well as with the linked gene *C4A*Q0* gene deletion [145]. Studies from two different European centers have implicated the HLA-B8-*C4A*Q0-DRB1*0301-DQA1*0501-DQB1*0201* haplotype in susceptibility to the anti-Ro/La autoantibody response in Caucasians [153, 154]. In addition, Logar *et al*. [155] examined 65 anti-La-negative Slovenian SLE patients and found the antibody response to anti-Ro without anti-La to be associated with *HLA-DQB1*0202*, a DQ2 allele closely related to *DQB1*0201* that is found on DR7-bearing haplotypes. Azizah *et al*. [122] found an association of DQA1*0102 with anti-Ro/La antibodies in Malaysian Chinese with anti-Ro, and in Japanese, the only association reported has been with the HLA class II haplotype *DRB1*08032/DQA1*0103/DQB1*0601* and *DRB1*08032* allele [156].

Anti-RNP and Sm Anti-U1-RNP has been associated with Raynaud's phenomenon and myositis [113]. The presence of high titers of anti-U1-RNP was initially linked to a disorder characterized by Raynaud's phenomenon, myositis, sclerodactyly, and lung disease designated "mixed connective tissue disease" [157]. Subsequent studies, however, have revealed that many of these patients evolved clinical patterns more compatible with SLE or systemic sclerosis [158]. These autoantibodies are particularly enriched in African-Americans [159]. Initial associations in both Japanese and Caucasians were with HLA-DR4 and DQw3 (the serologic group comprising *HLA-DQB1*0301*, **0302*, and **0303*) [101, 107, 160]. Subsequent studies using oligotyping and DNA sequencing have implicated both HLA-DRB1 and DQB1 alleles, specifically shared epitopes between HLA-DR2 and DR4 [161] and *HLA-DQB1*0302*, linked to HLA-DR4, as well as other specific DQB1 alleles sharing specific epitopes with *DQB1*0302* in both Caucasians [162] and Japanese [163].

Anticardiolipin Antibodies (aCL)/Lupus Anticoagulant These autoantibody systems have their clinical relevance in their association with venous and arterial thrombosis, recurrent fetal loss, livedo reticularis, and valvular heart disease and occur in up to 40% of SLE patients [164]. Savi *et al*. [165] reported an association with HLA-DR7 in northern Italians with SLE. McNeil *et al*. [166], in a study of Australian Caucasians, could not confirm this finding, instead showing an increased frequency of HLA-DR4 and an HLA-DR antigen whose gene is linked to HLA-DR4, DR7 and DR9 alleles, DR53 (whose gene is designated *HLA-DRB4*0101*). Hartung *et al*. [167], in a multicenter study of 412 German SLE patients, confirmed the HLA-DR4 and the DR53 (*DRB4*0101)* association, here with IgM aCL. Galeazzi *et al*. [112] studied 577 European SLE patients and showed positive associations with *HLA-DRB1*04*, *DRB1*0402*, *DRB1*0403*, *DRB1*07*, *DRB3*0301*, *DQA1*0201*, *DQA1*0301*, and *DQB1*0302* and negative associations with *DQA1*0501* and *DRB3*0202*. None of these studies, however, utilized DNA typing, and HLA-DQ alleles, other than the broad serologic specificities HLA-DQ1–3, were not examined. Arnett *et al*. [168] examined 20 patients with the lupus anticoagulant (of whom only nine met criteria for SLE, the other having 1°APS or other CTD) and reported an association with *HLA-DQB1*0301* (DQ7). Panzer *et al*. [169] examined 27 patients with the lupus anticoagulant and found instead an association with *HLA-DQB1*06* (DQ6). Both of these authors [168, 169] postulated that the actual association with the lupus anticoagulant was with the TRAELDT sequence in the third diversity region of the HLA-DQB1-outermost domain, which is shared by both alleles. Goldstein *et al*. [170] confirmed this in 91 Canadian SLE patients, of whom 19 had either IgG aCL or a positive lupus anticoagulant, and 16 with 1°APS, as well as confirming earlier serologic associations with HLA-DR53 (*DRB4*0101*) and HLA-DR7. Granados *et al*. [171] further confirmed the association of IgG and IgM aCL with HLA-DR7 in 80 Mexican SLE patients and found this association to persist when clinical symptoms of the aPL syndrome were examined regardless of the presence of aCL. Arnett *et al*. [172] examined 262 patients with primary antiphospholipid antibody syndrome (APS), SLE, or another connective tissue disease and found the *HLA-DQB1*0302* (DQ8) allele, typically carried on HLA-DR4 haplotypes, to be associated with anti-β2GPI when compared with both anti-β2GPI-negative SLE patients and ethnically matched normal controls, especially in Mexican-Americans and, to a lesser extent, in whites. Galeazzi *et al*. [173] studied 577 European SLE patients for IgG and IgM anti-β2GPI and found a positive association with *DRB1*0402*,

*DRB1*0403*, *DQB1*0302*, and *DRB1*0402* (RR = 4.6). Hashimoto *et al*. [174] studied 145 Japanese patients with SLE and found a significant association with *DRB1*0901* as compared to those without β2GPI-dependent aCL (41.4% vs 15.5%, $P < 0.005$, RR = 3.8), although the corrected *P* value was not significant. In two families multiplex for SLE and clinical/serologic manifestations of the aPL syndrome, affected family members shared an HLA-DR4, DQ3 (DQ7) haplotype [175, 176].

Antiribosomal P This autoantibody system, which occurs specifically in patients with SLE, is associated with neuropsychiatric disease, particularly with psychosis and/or depression [177–179], as well as with lupus hepatitis and renal disease [180, 181]. Arnett *et al*. [182] determined the frequency of anti-ribosomal P autoantibodies in a large multiethnic cohort of 394 SLE patients, finding a frequency of 13–20%. The HLA-DR2, DQ6-bearing haplotypes, specifically those bearing HLA-DQB1*0602, were seen most frequently in all ethnic groups.

Other Autoantibodies HRES-1 is a human T lymphotrophic virus (HTLV)-related human endogenous retrovirus, which encodes a 28-kDa nuclear autoantigen that is capable of eliciting cross-reactive antibodies with retroviral gag proteins. Perl *et al*. [183] and Magistrelli *et al*. [184] examined 153 patients with CTD, including 96 with SLE, and found that 52% of the latter had antibodies to HRES-1, especially those with anti-U1 RNP autoantibodies and those who were negative for anti-Ro and La. A significant association was seen with specific HLA-DQB1 alleles, especially *DQB1*0402*. Autoantibodies to the epidermolysis bullosa acquisita antigen (EBA) occur in SLE patients with bullous LE lesions. Gammon *et al*. [185] found them to be closely associated with HLA-DR2 alleles. Galeazzi *et al*. [186] studied antiganglioside antibodies (aGM1) in 448 European SLE patients in eight centers from six European countries. Associations were seen with various neuropsychiatric manifestations or SLE, and aGM1-IgG were associated with *HLA-DQB1*0404*, whereas aGM1-IgM were associated with *HLA-DQB1*0605*. No associations were found between aGM1 and anti-dsDNA, aCL, anti-β2GP1, or ANCA.

HLA-DPB1 Alleles in SLE

Few studies have addressed a possible role for HLA-DP alleles in the pathogenesis of SLE. Those that have found only associations with autoantibody subsets have been largely weak and inconsistent. Galeazzi *et al*. [187] examined 17 HLA-DPB1 alleles in 42 Caucasian SLE patients and found *HLA-DPB1*0301* and **1401*, which only differ in sequence by one amino acid, to be increased in frequency compared to controls, especially in those SLE patients with anti-Sm and RNP and anti-cardiolipin autoantibodies. Using the same technology, Reveille *et al*. [188] studied 68 Caucasian SLE patients, finding only a weak correlation of HLA-DPB1 alleles sharing the ILEE sequence around positions 65–70 with the presence of the lupus anticoagulant. Hsu *et al*. [189] examined 21 Caucasian connective tissue disease patients (including those with SLE, MCTD and systemic sclerosis) with anti-U1-70-kDa RNP autoantibodies and 27 without and found a weak association with *HLA-DPB1*0401*, the most common DPB1 allele in most populations. Thus it is unlikely that the HLA-DP locus is a significant factor in the pathogenesis of SLE.

Other MHC Class II Genes and SLE

Given the role of HLA-DM alleles in MHC class II:peptide loading, it would not be surprising to find an association with MHC class II-associated diseases. To date, two independent studies in Chinese and Japanese SLE patients have shown no convincing associations of HLA-DM alleles [190, 191].

Frequencies of the MHC class I transporter genes *TAP1* and *TAP2* have been studied in Caucasians and Japanese SLE patients. Savage *et al*. [121] examined 51 Chinese SLE patients and 103 controls, finding no association.

Extended Haplotypes and SLE Susceptibility

The subject of MHC class III genes and susceptibility to SLE is covered in Chapter 5. However, the HLA-A1, B8, C4A*Q0, DR3 haplotype explains the HLA-DR3 association in nearly every Caucasian population studied [106, 107, 193–196]. The sole exception is in Spain, where the predisposition to SLE, especially to renal involvement therein, has been associated with the HLA-B18, DR3 haplotype. The association of TNF genes with SLE, covered in Chapter 5, has been suggested to be independent of HLA-DR3 [195]. It is entirely possible that genes present on a given haplotype may actually function as an interrelated cassette of complementarily functioning genes, i.e., HLA-DM, DO, DQA1, DQB1, DRB1, DRA1, C4, C2, TNF, and so on, though this possibility has not been proven and needs further work.

HLA Genes and Outcome in SLE

Since the earliest HLA studies in SLE, it has been suggested that HLA genes affect the clinical presentation and prognosis of SLE. Rigby *et al*. [197] studied HLA class I antigens in 44 Australian Caucasian SLE patients classified as mild or severe on the basis of renal

biopsy changes and the degree of proteinuria, finding that the presence of HLA-A1 and B8 (associated with DR3) was associated with more severe disease and HLA-A2 and B7 with milder disease. Bell *et al*. [198] could not confirm this, however, in a study of 62 Canadian Caucasian SLE patients, finding only an association of HLA-B8 and DR3 with later-onset disease and female sex. Hochberg *et al*. [134] confirmed this association with later-onset disease in Caucasians. In a retrospective outcome study of 94 Caucasians with SLE, Gulko *et al*. [199] found HLA-DQ7 (*DQB1*0301*) to be independently associated with a higher likelihood of death. More recently, Alarcon *et al*. [200] in a prospective outcome study of 229 SLE patients of approximately equal proportions of Hispanics, African-Americans, and Caucasians, found that the *absence* of HLA-DR3 (*DRB1*0301*) was associated with greater disease activity. In another study of damage from SLE, 72 Hispanics, 104 African-Americans, and 82 Caucasians were included [201]. Greater damage was independently associated with different HLA-DRB1 and DQB1 genes (i.e., *DRB1*0301*, *DQB1*0201*, *DRB1*08*).

Non-MHC Genes in Predisposition to SLE (Table 4, Fig. 3)

Genes Located on Chromosome 1

Although not arranged as compactly as the MHC on chromosome 6p, genes on chromosome 1, the largest chromosome in the human genome, contain a number of immunologically relevant genes whose importance to the pathogenesis of SLE is only now being realized (Fig. 2).

TNF Receptor II (TNFR2)

A number of studies reported associations of HLA-DRB1, TNF-α promoter and TNF receptor II (TNFR2, TNFRSF1B) polymorphisms with systemic lupus erythematosus; however, the results have often been inconsistent. Komata *et al*. [202] genotyped 81 Japanese SLE patients and 207 healthy controls for exon 6 polymorphisms of the TNFR2 gene and found 37% of the SLE patients to have the 196R allele compared to 18.8% of the controls ($P = 0.001$). Lakahasi *et al*. [203], TDT, 91 Caucasian SLE family samples recruited in southern California for the association with HLA-DRB1, TNF promoter positions at –1031, –863, –857 and –308, and TNFR2-196M/R polymorphisms. No transmission distortion was observed for TNFR2 alleles.

Morita *et al*. [204] analyzed all 10 exons of the TNFR2 gene in 105 Japanese SLE patients and 99 controls and found an increased frequency for the 196R allele (20.5% vs 12.6%, $P = 0.03$). This finding has not been confirmed in other ethnic groups. Al-Ansari *et al*. [205] typed 128 Spanish and 74 United Kingdom Caucasoid SLE patients and found no differences, as did Sullivan *et al*. [206] in North American Caucasoid SLE patients, Lee *et al*. [207] in 139 Korean SLE patients and 137 healthy control subjects, and Takahasi *et al*. [203] in another cohort of 143 Japanese SLE patients.

BCMA (TNFRSF17), along with TACI, has been demonstrated to be a receptor for BLyS (TNFSF13B). Studies have indicated a substantial role of the BLyS signaling pathway for systemic lupus erythematosus. Kawasaki *et al*. [208] examined polymorphisms of human BCMA in Japanese SLE patients, finding only a nonsignificant increase in the frequency of the BCMA.03 allele ($P = 0.089$).

Glutathione-S-Transferase (GSTM1) Null Alleles

Data suggest a role for members of the glutathione-*S*-transferase supergene family in protection against oxidative stress. Ollier *et al*. [209] examined 90 British Caucasian patients for GSTM1 null homozygosity and found all patients with anti-Ro antibodies (without anti-La) were GSTM1 null, suggesting that the dysfunction of these genes may contribute either to the anti-Ro autoantibody response or to photosensitivity, with which anti-Ro is strongly associated. This could not be confirmed in another larger study by Tew *et al*. [210], who examined a prospectively followed cohort of Caucasian, African-American, and Mexican-American SLE patients, finding no association with SLE *per se*, anti-Ro autoantibodies, or clinical features.

The Fc γ Gene (FcγR) Family

FcγR receptors mediate the elimination of immune complexes and infectious agents by phagocytosis [211]. Abnormal handling of immune complexes is widely considered to be an important factor in the pathogenesis of SLE and has long been postulated that inefficient FcγR binding of immune complexes is pathogenic in SLE patients [212]. Three main classes of FcγR receptors have been defined in humans—FcγRI (CD64), FcγRII (CD32), and FcγRIII (CD16)—each containing multiple distinct genes and alternative splicing variants. Their genes have been mapped to chromosome 1q23. FcγRIIa has two codominantly expressed alleles, R131 and H131, which differ by two nucleotides, resulting in amino acid differences at positions 27 and 131, which differ substantially in their ability to bind IgG2 and IgG3, suggesting that they have significant functional differences. In fact, FcγRIIa-H131 is the only human FcγR that recognizes IgG2 efficiently. Salmon *et al*. [212] examined 103 African-American SLE patients with nephritis and 100 controls and demonstrated a skewed distribution of FcγRIIA alleles (although the same was

not seen in Caucasians examined) with only 12% of SLE patients versus 27% of controls being homozygous for FcγRIIa-H131 alleles. Moreover, patients with SLE who were homozygous for R131 alleles were at greater risk for invasive pneumococcal infections [213]. Duits *et al*. [214] examined 95 Caucasians and found the negative association with H131 homozygosity to cross ethnic boundaries. Botto *et al*. [215] found no association with SLE *per se*, although a correlation with nephritis persisted.

Manger *et al*. [216] examined 108 Caucasian SLE patients and 187 Caucasian controls, finding no significant skewing of the FcγRIIa polymorphism was observed in the SLE cohort. In patients with the genotype IIa-R/R131, significantly higher frequencies of proteinuria, hemolytic anemia, antinuclear RNP antibodies, and hypocomplementemia were found. The only clinical symptom observed more frequently in patients homozygous for IIa-H/H131 was livedo. Patients with the IIa-R/R131 genotype were significantly younger at disease onset and had an earlier incidence of arthritis, sicca syndrome, nephritis, lymphadenitis, hematologic abnormalities, immunologic abnormalities, lupus anticoagulant, cryoglobulinemia, and hypocomplementemia.

Norsworthy *et al*. [217] studied 195 Caucasian lupus patients for anti-C1q(CLR) antibodies and FcγRIIA genotypes. Fifty-six patients were anti-C1q antibody positive, and Ig subclass analysis indicated a predominance of IgG2 anti-C1q antibodies. Analysis of the SLE population as a whole revealed no significant difference in the allele frequencies of R131 and H131 compared with controls. There was, however, a significantly increased frequency of the R131 allele both in the anti-C1q-positive subgroup of patients and in the 71 patients with nephritis compared with controls.

Michel *et al*. [218] examined FcγRIIa genotypes in 80 French Canadian SLE patients and 183 controls and found that the proportion of SLE patients with the R/R131 genotype was significantly greater than controls (35% vs 18%, $P < 0.02$), although no association with nephritis was seen.

Dijstelbloem *et al*. [219] examined polymorphisms of FcγRIIa and -IIIa in 230 Caucasian patients with SLE and 154 controls. A strong trend toward skewing of FcγRIIa was found, with an enrichment of the homozygous FcγRIIa-R/R131 genotype in patients compared with controls. No correlation between this genotype and the development of lupus nephritis was seen.

Zuniga *et al*. [220] studied 67 Hispanic SLE patients and 53 disease-free control subjects. Patients were followed longitudinally for 3 years. In the nephritis group ($n = 46$), as well as the entire SLE cohort, there was a predominance of genotypes with low-binding alleles (FcγRIIa-R131 and FcγRIIIa-F176) at both loci. The frequency of individuals homozygous for high-binding alleles at either locus decreased as the burden of disease increased. There was no linkage disequilibrium between FcγRIIA and FcγRIIIA in Hispanics; however, in SLE patients, there was a clear overrepresentation of the FcγRIIa-R131:FcγRIIIa-F176 haplotype and a decrease in the frequency of the high-binding haplotype.

Song *et al*. [221] examined 73 Korean SLE patients and found an abnormal distribution of FcγRIIa alleles when compared with 64 controls: 11.0% of the SLE patients were homozygous for FcγRIIa-H131 compared with 34.4% of the controls. The allelic frequency of FcγRIIa-H131 was significantly lower in SLE patients than in controls, and it was also significantly lower in lupus patients with nephritis compared with the normal population, but was not significantly lower in lupus patients without nephritis. Clinically, the level of proteinuria was significantly higher in lupus nephritis patients who had R/R131 than in those who had H/H131 or R/H131.

Yun *et al*. [222] examined FcγRlla and FcγRIIIa polymorphisms and their association with clinical manifestations in 300 Korean lupus patients and 197 Korean disease-free controls. There was significant skewing in distribution of the three FcγRIIa genotypes between the SLE and the controls, but not in FcγRIIIa genotypes. The FcγRIIa-R allele was a significant predictor of lupus nephritis, as compared with SLE patients without nephritis, but proliferative nephritis (WHO classes III and IV) was less common in patients with FcγRlla-R/R131 and in FcγRIIa-R allele.

Yap *et al*. [223] investigated the polymorphism for FcγRIIA in 175 Chinese and 50 Malays SLE patients, as well as 108 and 50 ethnically matched healthy controls for the respective groups and found no significant differences between the two groups.

Sato *et al*. [224] studied the distribution of the FcγRIIa polymorphism in 90 Japanese patients with SLE, as well as the association between FcγRIIa polymorphism and the disease activity of SLE and the histopathological findings of lupus nephritis. The allelic frequency of H131 in patients with SLE was significantly lower than that of normal controls. No significant association was observed between FcγRIIa polymorphism and the clinical parameters for the activity of SLE. There was no association between FcγRIIa polymorphism and the histological findings in lupus nephritis.

Hatta *et al*. [225] determined FcγRIIA-131H/R, FcγRIIIA-176F/V, and FcγRIIIB-NA1/2 genotypes in 81 Japanese patients with SLE and 217 healthy individuals. Unlike in other populations, a significant difference was not observed in the frequencies of FcγRIIA and FcγRI-

IIA genotypes between patients with SLE and healthy individuals. However, a significant difference was detected in the frequencies of FcγRIIIB genotypes between SLE and healthy individuals. Among the patients with SLE, individuals with NA2/2 were significantly more likely to have lupus nephritis. Significant linkage disequilibrium was detected between FcγRIIIA and IIIB, but not between IIA and IIIA or between IIA and IIIB.

Seligman *et al*. [226] compared the frequency of low-affinity alleles of two FcγR polymorphisms (FcγRIIA and FcγRIIIA) among 235 patients with SLE and proven nephritis (nephritis patients) and among 352 SLE patients with no evidence of renal disease (non-nephritis control subjects). The ethnic distribution of patients in the study was 49% Caucasian, 20% Hispanic, 17% Asian/Pacific Islander, 12% African-American, and 2% from other ethnic groups. All patients were genotyped for the FcγRIIA-131R/H and FcγRIIIA-158V/F polymorphisms. Univariate and multivariate analyses demonstrated a striking association between the low-affinity FcγRIIIA-158F allele and the FF genotype and the risk of nephritis among Caucasians, but not among non-Caucasians. This association was even stronger among Caucasians with severe nephritis. In contrast, inheritance of the low-affinity FcγRIIA-131R allele (and RR genotype) was not associated with an increased risk of lupus nephritis among any of the ethnic groups examined. Smyth *et al*. [227], however, when examining 123 Caucasian SLE patients (81 from the United Kingdom and 42 from Greece), found no association with FcγRIIa alleles, nor did Villarreal *et al*. [228], who examined 125 Catalan SLE patients.

More recently, Karassa *et al*. [229] conducted a meta-analysis of 17 studies involving R/H 131 genotyping of 1404 patients with lupus nephritis and 1709 SLE patients without nephritis and found a dose–response relation between the R131 allele and risk for SLE, but no clear effect on susceptibility to nephritis.

FcγRIIB is unique in its ability to transmit inhibitory signals, and animal studies have demonstrated a role for FcγRIIB deficiency in the development of autoimmunity. Kyogoku *et al*. [230] screened for polymorphisms of the human FCγRIIB gene in 193 Japanese patients with SLE and 303 healthy individuals. A single nucleotide polymorphism in FCGR2B (c.695T > C), coding for a nonsynonymous substitution, Ile232Thr (I232T), within the transmembrane domain was increased significantly in SLE patients compared with healthy individuals.

FcγRIIIa is expressed on natural killer cells. Wu *et al*. [231] examined 200 "ethnically diverse" SLE patients and found an increase in homozygosity for a phenylalanine at position 176, especially in those with nephritis. Koene *et al*. [232] genotyped 70 Caucasian SLE patients for all known FcγR polymorphisms, finding the frequency of the FcγRIIIA-158F to be associated with SLE. Salmon *et al*. [233] examined 148 Korean SLE patients, including 79 with nephritis, and found an association with homozygosity for the FcγRIIIa allele-F176 compared with those without nephritis or with 97 controls. Similarly, Kyogoku *et al*. [230] found a significant association in 193 Japanese SLE patients of a FcγRIIIA-176F allele compared to 303 controls. However, Yap *et al*. [234] examined 183 Chinese and 55 Malays SLE patients, as well as 100 Chinese and 50 Malays healthy controls, and found no differences in the gene frequencies for FcγRIIIB-NA1 and FcγRIIIB-NA2.

These data suggest that Fcγ genes constitute the best candidate for a non-MHC gene in the pathogenesis of SLE. Clearly, this area will provide a fruitful area of investigation in the near future as the single nucleotide polymorphisms that best impact on the susceptibility to and outcome of SLE are better defined.

FAS *Ligand and* FAS

The APO1 (*fas*) antigen (48 kDa), defined by the mouse monoclonal antibody anti-APO1, is expressed on the cell surface of various normal and malignant cells, including activated human T and B lymphocytes and a variety of malignant human lymphoid cell lines. APO1 cDNA shows significant sequence similarity to members of the tumor necrosis factor/nerve growth factor receptor superfamily and is in fact the same as the *fas* antigen. Binding of the anti-APO1 antibody to the APO1 antigen induces apoptosis. Mutations in the human analogue of the *fas* gene have been associated with a lymphoproliferative disorder resembling those seen in the *lpr* mouse [235, 236]. The contribution of defective *fas* gene function to predisposition to SLE is controversial, as defects in activation-induced cell death or alterations in *fas* gene expression have not been documented in patients with SLE [237, 238].

Lee *et al*. [239] evaluated whether the polymorphism of *fas* promoter –670 is associated with susceptibility to SLE and clinical features thereof. The genotype distribution of the *fas* promoter –670 did not differ between patients with SLE and control subjects, nor were there any significant differences in age at onset, anti-dsDNA titer, C3, C4 level, renal involvement, number of ACR criteria met, disease activity, or damage. However, a significant association with the anti-RNP antibody was seen. Huang *et al*. [240, 241] could confirm neither an association with the –670 polymorphism nor another promoter polymorphism at position –1377 in 86 Australian Caucasian SLE patients, although homozygosity for the *MvaI*2* allele at the –670 promoter polymorphism was weakly associated with photosensitivity and oral ulcers. Horiuchi *et al*. [242] investigated the fre-

quency of a novel polymorphism at nucleotide 297 which was linked to another *fas* polymorphism at position 416 in 82 Japanese SLE patients and 132 ethnically matched controls, finding an increased frequency of a 297C/416G allele. Because this was a silent polymorphism at the amino acid level, if it is relevant to SLE at all it reflects linkage to another more disease-relevant but unidentified polymorphism. Finally, Cascino *et al*. [243] could find no differences of *fas* gene polymorphisms between patients and controls.

The *fas* ligand is a member of the T-cell receptor superfamily whose gene has been mapped to chromosome 1q23. Wu *et al*. [244] examined 75 SLE patients for mutations in the *fas* ligand gene and found one patient with a heterozygous mutation (an 84-bp deletion) whose expression resulted in decreased *fas* ligand activity, decreased activation-induced cell death, and increased T-cell activation after activation. However, Mehrian *et al*. [245] found a significant association of SLE with a *fas* ligand intragenic marker. Thus, whether either the *fas* gene or *fas* ligand mutations contribute significantly to the pathogenesis of SLE in most patients is controversial and needs further study. Kojima *et al*. [246] investigated the possible association of a *fas* ligand (FasL) gene mutation(s) or polymorphism(s) with SLE in 143 SLE patients, and by SSCP analysis did not identify any mutations or polymorphisms in the FasL mRNA transcripts or in any of the four exons or areas of the introns adjacent to the exons.

E-Selectin

E-selectin is expressed on cytokine-stimulated endothelial cells and plays an important role in leukocyte–endothelium interactions and inflammatory cell recruitment. The best-characterized polymorphism in the E-selectin molecule is A561C, which codes for Ser128Arg. El-Magadmi *et al*. [247] studied the prevalence of the A561C E-selectin gene polymorphism in Caucasian patients with SLE and controls from three different ethnic populations: the United Kingdom (113 and 148), Spain (145 and 179), and Turkey (93 and 96), respectively. The C allele occurred more frequently in United Kingdom and Spanish patients, but not in Turkish patients.

C-Reactive Protein (CRP)

Elevation of baseline CRP is associated with an increased risk of cardiac disease. This increase might reflect low-grade inflammation, but differences in CRP serum levels may also have a genetic component. To test this possibility, Szalai *et al*. [248] investigated whether a polymorphic GT repeat in the intron of the CRP gene contributes to variation in baseline CRP. The polymorphism was associated with differences in baseline CRP both in normal individuals and in patients with the inflammatory disease systemic lupus erythematosus, namely donors carrying two GT(16) alleles, two GT(21) alleles, or GT(16/21) heterozygotes had twofold lower serum CRP than those with other genotypes. The frequency of GT(16) and GT(21) was twofold higher in Caucasians than in African-Americans, but there was no difference in allele distribution between patients and controls. It is not yet known how this genetic polymorphism mediates its effect on CRP expression, and it probably is not a systemic lupus erythematosus susceptibility factor, although an impact on disease severity has not been evaluated.

T-Cell Receptor ζ (CD3-ζ)

Signaling molecules from the T-cell receptor ζ/Fc ε receptor γ (TCRζ/FcRγ) family play a critical role in the function of Fcγ receptors and the TCR and are located on human chromosome 1q22–23, where lupus susceptibility genes are located. Nambiar *et al*. [249] sequenced TCR ζ chain cDNA from 48 SLE patients, 18 disease controls, and 21 healthy volunteers and found several widely distributed missense mutations and silent polymorphisms in the coding region of the TCR ζ chain, which were more frequent in SLE patients than in patients with other rheumatic diseases or healthy controls ($P < 0.0001$). Several of the missense mutations were located in the three immunoreceptor tyrosine activation motifs or the GTP-binding domain, which could lead to functional alterations in the TCR ζ chain. A splice variant of the TCR ζ chain with a codon CAG (glutamine) insertion between exons IV and V was found in half of the SLE and control samples. Two larger spliced isoforms of the TCR ζ chain, with an insertion of 145 bases and 93 bases between exons I and II, were found only in SLE T cells.

Wu *et al*. [250], however, found no unique mutations or differences in the frequencies of splice isoforms of TCR ζ in Caucasian, African-American, Hispanic, Chinese, or Japanese SLE patients living in North America.

Complement Receptor 1 (CR1)

CR1, the receptor for complement fragments C3b and C4b, is a membrane glycoprotein important not only for the control of complement activation, but also (as expressed on erythrocytes) for the efficient removal of circulating immune complexes. Three types of polymorphisms are known to exist for CR1: one is recognized as the Knops blood group. A second determines the quantitative expression of CR1 on erythrocytes, where a *Hind*III RFLP has been found to correlate with high and low expression of erythrocyte CR1 [251, 252]. Early data suggested that a low erythrocyte copy

number might be a genetic risk factor for SLE [253, 254]. However, other studies have shown this to be an acquired defect in SLE patients [255–260]. Satoh *et al*. [261] examined the frequency of the *Hind*III RFLP in Japanese, Kumar *et al*. [262] in Indian, and Tebib *et al*. [263] in Mexican SLE patients and found no difference in frequency between patients and controls. This further suggested the low CR1 levels to be an acquired phenomenon.

A third type of polymorphism exists in the CR1 molecular structure. Four codominantly inherited allelic size variants have been identified, with molecular masses of 160 kDa (CR1-C), 190 kDa (CR1-A), 220 kDa (CRC-B), and 250 kDa (CR1-D). These size variants evolved through duplication or deletion of a highly homologous unit. Van Dyne *et al*. [264] found an increased frequency of CR1-C in Caucasians with SLE. This observation seemed relevant because Wong and Farrell [265] proposed that CR1-C might be less efficient in removing immune complexes because of having only one C3b-binding site. However, Cornillet *et al*. [266] found instead an association with CR1-B. Moulds *et al*. [267] examined structural polymorphisms of CR1 in 219 SLE patients of approximately equivalent proportions of Hispanics, African-Americans, and Caucasians and found no differences from healthy controls. Thus it is unlikely that CR1 size polymorphisms contribute to susceptibility to SLE. Thus to date there is no suggestion that polymorphisms of the gene encoding CR1 contribute to the pathogenesis of SLE.

Interleukin-10 (IL-10) and IL-10 Receptor (IL-10R)

IL-10 is an important multifunctional cytokine, which has been found to be important in a variety of rheumatic and neoplastic diseases. Relative to autoimmunity, IL-10 reduces MHC class II expression on macrophages [268], antagonizes human T-cell clonal expansion [269], and inhibits the development of antigen-specific cytotoxic T cells [270]. Il-10 also, under certain conditions, can inhibit apoptosis in human T cells [271]. Most relevant to autoimmunity, IL-10 can serve as a potent activator of B cells [272] and, in patients with rheumatoid arthritis and SLE, promotes the secretion of rheumatoid factor [273] and other autoantibodies [274]. The gene for IL-10 has been mapped to chromosome 1q31–q32, near the genes for CR1 and CR2 [275]. Eskdale *et al*. [276] studied 56 Scottish SLE patients for the frequency of two novel dinucleotide repeats in the IL-10 promoter region (IL10.G and IL10.R) and suggested an association with IL10.G alleles, which correlated even better with the presence of renal disease and specific autoantibody production. More recently, Mehrian *et al*. [245] found a synergistic effect between IL-10 and bcl-2 polymorphisms in susceptibility to SLE in Mexican-Americans.

D'Alfonso *et al*. [277] determined whether seven candidate genes, including tumor necrosis factor receptor II, bcl-2, CTLA-4, interleukin-10, CD19, Fcγ receptor type IIA (CD32), and the IL-1 receptor antagonist, may contribute to susceptibility to SLE in Italians: A significant increase was found in SLE patients in the frequency of the 140-bp allele of the IL10.G microsatellite located in the promoter region of the IL-10 gene. Conversely, no significant association was detected for the remaining six candidate genes, even when the patients were stratified according to the presence of different clinical and immunologic features according to the presence of the associated HLA-DR or IL-10 alleles.

Ou *et al*. [278] studied 100 SLE patients and 103 healthy controls for IL-10PR by polymerase chain reaction and electrophoretic analysis and found no difference in the distribution of IL-10PR alleles, genotypes, and SBA as compared to healthy controls. Forty-nine patients with nephritis also showed no difference in IL-10PR alleles, genotypes, and SBA, as compared to 51 SLE patients without nephritis, although a strong association between IL-10PR and severe progression of lupus nephritis was seen.

Rood *et al*. [279] identified an IL-10 promoter haplotype that was found more frequently in 42 SLE patients with neuropsychiatric involvement compared with 50 patients without this complication, although no association was seen with SLE *per se*.

Mok *et al*. [280] studied the association of interleukin-10 promoter polymorphisms in 88 Southern Chinese patients with SLE and 83 ethnically matched controls and found no significant difference in the allele or haplotype frequencies However, when clinical features were examined, the *A allele at the –597 position and the *T allele at the –824 position were significantly associated with lupus nephritis, and the haplotype –1087*A/–824*T/–597*A was also associated with renal involvement.

Alarcon-Riquelme *et al*. [281] found no significant difference in the frequencies of the IL-10 promoter microsatellite alleles of 330 Mexican patients with SLE compared to 368 controls from the same population, and two-point linkage analyses carried out using 13 Mexican, 13 Swedish, and 8 Icelandic families with two or more cases with SLE found no linkage between IL-10 and SLE. Similarly, Van der Linden *et al*. [54] determined IL-10 genotypes in 163 first-degree relatives of patients with systemic lupus, 50 first-degree relatives of patients with chronic cutaneous lupus, and 133 control persons. The frequency of –1082/–819/–592 haplotypes GCC, ACC, and ATA was similar among patients and compared with the controls. Likewise, Crawley *et al*.

[282], could find no association of IL-10 genotypes with SLE, renal disease, or autoantibodies.

This suggests that the impact of IL-10 genes on susceptibility to SLE *per se* is weak, if present at all, although an impact on disease severity may be operative.

The IL-10 receptor maps to chromosome 11q23.3. Nakashima *et al*. [283] examined IL-10R genotypes in 109 Japanese SLE patients and 102 controls and found no differences in genotype frequencies.

Poly(ADP-ribose) Polymerase

Tsao *et al*. [284] and Delrieu *et al*. [285] used a multiallelic, transmission disequilibrium test (TDT) and found a skewing of transmission of alleles of poly(ADP-ribose) polymerase, which encodes a zinc finger DNA-binding protein that is involved in DNA repair and apoptosis, to affected offspring in 124 families ($P = 0.00008$) and a lack of transmission to unaffected offspring. Unfortunately, these finding could not be confirmed in a study of 171 French Caucasians and 193 ethnically matched healthy controls [286] in a larger study of three cohorts from Minnesota, Oklahoma City, and San Francisco [287], or in another study from Germany [288].

HRES-1

HRES-1 is a single-copy human T-cell lymphotrophic virus type I (HTLV-I)-related endogenous retroviral sequence (ERS), which is transcriptionally active and contains open reading frames (ORFs) [184]. It is thought to have entered the genome of Old World primates. *HRES-1* encodes a 28,000 MW nuclear protein, which is expressed in a tissue- and cell type-specific manner. Its function is unknown. Magistrelli *et al*. [184] examined the frequency of alleles of a polymorphic *Hind*III site at position 653 of the long terminal repeat region in 60 Caucasian SLE patients and 100 controls and found that homozygosity for a 5.5-kb RFLP was 3.2-fold lower in frequency in patients compared to controls. The significance of this finding is unclear, especially as it relates to susceptibility to SLE, and needs further study.

Genes Implicated in Susceptibility to SLE on Other Chromosomes

Immunoglobulin Heavy and Light Chain Genes

Studies of immunoglobulin heavy chain genes (located on chromosome 14q32) and gene products (Gm protein allotypes) have yielded conflicting results. Earlier studies suggested a possible disease association in American and Australian Caucasian SLE patients [289, 290]. Fedrick *et al*. [291] examined 61 African-Americans and showed an association with the Gm phenotype 1,17;5,6,13. Nakao *et al*. [292] also found a Gm association in Japanese SLE patients. Hoffman *et al*. [293] examined 78 North American Caucasians with SLE, MCTD, and scleroderma and found an association with an immunoglobulin κ light chain phenotype Km [1] (encoded on chromosome 2). Genth *et al*. [294] found an association with the Gm (1,3:5,21) phenotype and the U1-RNP autoantibody response. Stenszky *et al*. [295] found no Gm association among 90 Hungarian SLE patients, although homozygosity for Gm and HLA-B8 predicted those at the highest risk for developing renal disease. Kumar *et al*. [296] found no disease association with a *Bst*EII immunoglobulin constant region RFLP in North American or Mexican SLE patients. Hartung *et al*. [297, 298] examined immunoglobulin heavy chain (Gm) and κ light chain (Km) allotypes in 323 central European SLE patients and found no association with SLE *per se*, autoantibodies, or clinical manifestations of the disease. Blasini *et al*. [299] examined constant region λ polymorphisms in 78 Venezuelan SLE patients and could likewise demonstrate no association.

It is difficult to exclude a contribution of immunoglobulin genes to the pathogenesis of SLE based on these data, however. The Gm and Km allotypes correspond to regions of the heavy and light chains of limited polymorphism, and RFLP studies give little information about the rich polymorphism that resides at the immunoglobulin genes. Just as for T-cell receptor genes, immunoglobulin genes undergo extensive rearrangement, and the role of these immune response genes in the pathogenesis of SLE remains to be determined. Queiroz *et al*. [300] examined 56 Brazilian SLE patients and 103 controls for *EcoRI* RFLP of the Ig λ V8 gene and found no occurrence of a 6.0-kb *Eco*RI RLFP in the patients compared to 10% in controls.

However, it has been hypothesized that deletions of certain Ig variable region genes may predispose to autoimmunity [301]. Olee *et al*. [301] and Huang *et al*. [302] found that approximately 20–25% of patients with RA or SLE have deletions of RFLP associated with certain autoreactive V genes, although these associations were felt to be "weak" [302].

Interleukin-1 Receptor Antagonist (IL-1-RA) Gene

IL-1RA is a powerful endogenous anti-inflammatory agent whose protein is 22–25 kDa in size and which competes with IL-1α and IL-1β for the occupancy of cell surface receptors, inhibiting the action of IL-1. The gene for IL-1RA lies on the long arm of chromosome 2, in the same gene complex as IL-1α and IL-1β [303].

Blakemore *et al*. [304] found a weak association of a five allelic variable length polymorphism in intron two of the IL-1RN gene (*IL1RN*2*) in 81 English SLE patients. This allele was particularly associated with photosensitivity and discoid rashes, leading to the conclusion that IL-1RA alleles were probably more important in the clinical expression of SLE than in actual predisposition. Tjernstrom *et al*. [305] investigated 81 patients from a defined area in southern Sweden and 10 consecutive Caucasian families with multiple cases of SLE. As control group, 189 healthy blood donors was used and an increased frequency of *IL1RN*2* was found in both the epidemiological cohort and the multicase families. Although alone *IL1RN*2* and MHC class II (*DRB1*0301*, *DQB1*0201*) separately increased the SLE risk moderately, the occurrence of these alleles together increased the risk for SLE sevenfold. An association between *IL1RN*1* and arthritis was also seen.

Cytotoxic T Lymphocyte Antigen 4 (CTLA-4)

Cytotoxic T lymphocyte associated antigen 4 (CTLA-4), a structural homologue of CD28, has been reported to be an important negative regulator of autoimmune diseases. The negatively signaling molecule CTLA-4 is involved in establishing and maintaining peripheral T-cell tolerance, which controls T-cell activation and reactivity. Its attenuating action helps to prevent an inappropriate initiation of T-cell responses to self-antigens and to terminate ongoing T-cell responses. CTLA-4 genotypes have been implicated in various autoimmune diseases (Hashimoto thyroiditis, Graves' disease, IDDM). Pullman *et al*. [306] tested if there was an association between CTLA-4 and SLE in 102 SLE patients and in 76 healthy controls and found that the distribution of CTLA-4 exon 1 genotypes in the SLE group was significantly different from that in the controls. The frequency of the G allele was significantly higher in SLE patients than in controls. These data were further confirmed by Ahmed *et al*. [307] in 113 Japanese SLE patients and 200 controls from the northern Kyushu area of Japan, where SLE patients had a higher frequency of the CTLA-4 49G allele and of the CTLA-4 (AT)n microsatellite repeat polymorphism.

These data have not been confirmed in other groups. Heward *et al*. [308] genotyped 126 SLE patients and 363 controls from the United Kingdom and found no differences in either allele or genotype frequencies. Matsushita *et al*. [309] screened 71 Japanese SLE patients and 150 controls and found no association with CTLA-4 polymorphisms, nor with polymorphisms of human CD28, CD80, and CD86 genes [310]. Liu *et al*. [311] examined CTLA-4 gene polymorphisms in the promoter and exon 1 in 81 Chinese SLE patients and 81 normal controls and found no statistically significant differences. Lee *et al*. [312] examined 80 Korean SLE patients and 86 healthy control subjects and no disease correlation was found between CTLA-4 exon 1 (+49) and promoter (–318) polymorphisms.

IL-4 Promoter and Receptor Polymorphisms

Interleukin-4 (IL-4) is a cytokine produced by T cells that regulates proliferation and differentiation of a variety of cells. It plays a major role in inducing activation and differentiation of B cells as well as in stimulating the Th2 response. The –590C/T polymorphism of the IL-4 gene is associated with increased IL-4 promoter activity. The interleukin-4 receptor is composed of two subunits: a 140-kDa α subunit, which binds interleukin-4 and transduces its growth-promoting and transcription-activating functions, and a γc subunit, common to several cytokine receptors, which amplifies signaling of the interleukin-4 receptor α. Polymorphisms at codons 50 and 551 of the IL-4R α chain affect IL-4R function; an isoleucine residue at position 50 enhances receptor responsiveness to IL-4 compared to a valine in this position. Similarly, an *arginine* at codon 551 impairs binding of a negative regulatory molecule, which leads to increased receptor activity relative to the alternative glutamine allele. Kanemitsu *et al*. [313] genotyped these polymorphisms in 50 Japanese SLE patients and 100 controls. SLE patients had a higher frequency of an isoleucine allele at codon 50 and an arginine allele at codon 551 in IL-4R than controls, although no differences were seen with the position –590 alleles of the IL-4 promoter.

Prolactin

Hyperprolactinemia is associated with systemic lupus erythematosus, but the mechanism is unknown. Prolactin is expressed in T lymphocytes and is under the control of an alternative promoter region. Altered local prolactin production by immune cells may contribute to disease progression by affecting T-cell function. Stevens *et al*. [314] characterized a G/T single nucleotide polymorphism (SNP) at position –1149 of this promoter and found a functionally significant polymorphism that altered prolactin promoter activity and mRNA levels in the lymphocytes.

Estrogen Receptor: α and β

The estrogen receptor (ESR) is a ligand-activated transcription factor composed of several domains important for hormone binding, DNA binding, and activation of transcription. Two isoforms of the human ESR, ESR-α and ESR-β, occur, each with distinct tissue and cell patterns of expression. Kassi *et al*. [315] analyzed the coding sequence of ERα and ERβ in 10 Greek SLE patients and 12 controls, finding splicing variants

and deletions in exons 2, 5, and 7 to occur in equivalent frequency in both groups. Chang *et al*. [316] and Liu *et al*. [317] examined *Pvu*II and *Xba*I RFLP of the ER gene (type not specified) in 245 biopsy-proven lupus nephritis patients (187 females, 58 males) and 172 normal controls (71 females, 101 males). Male SLE patients had an increased frequency of the PpXx genotype compared to male controls, although no difference was found in females. Also, skin rash and arthritis were seen more frequently in those with the PpXx genotype.

Interferon-γ Receptor 1 and 2

Interferon-γ has an important role in activating macrophages in host defenses. At least two steps are involved in the action of interferon-γ; the binding of IFN-γ to its receptor coded by chromosome 6 and the coupling of this binding event through a factor coded by chromosome 21 to trigger biologic action. The IFN-γ receptor is a complex consisting of IFN-γR1 and IFN-γR2. Tanaka *et al*. [318] found an increased frequency of a genetic polymorphism in the IFN-γ receptor 1 (IFNGRI) gene that causes an amino acid polymorphism (*Val14Met*) located at the COOH terminal of the signal peptide of IFNGRI in 110 Japanese SLE patients and 110 controls. In a subsequent study from this group, Nakashima *et al*. [319] found an amino acid polymorphism (*Gln64Arg*) within IFN-γR2 and discovered that the greatest risk of the development of SLE was detected in individuals who had the combination of IFNGR1 *Met14/Val14* genotype and IFNGR2 Gln64/Gln64 genotype.

Lee *et al*. [320] analyzed the gene frequency of eight different alleles in 99 controls and 136 patients with SLE. There were no statistically significant differences in allele frequencies between patients and controls, although allele 1 was associated with gastrointestinal lupus and allele 6 was associated with disease severity. Allele 2 appeared to be protective for arthritis. This suggests that genetic variation in interferon-γ expression might influence the disease course.

Interleukin 6

Linker-Israeli *et al*. [321] examined IL-6 genes in 57 SLE patients and 36 controls, finding allelic, higher molecular weight *Xba*I bands in 9/57 compared with one of 36 controls, suggesting that this variability may be related to the abnormal IL-6 expression seen by his group and others. This group further evaluated the association of alleles of regions having regulatory potential in the IL-6 gene with SLE in 146 Caucasian and African-American SLE patients and 139 controls, finding that the AT-rich minisatellite allele distribution pattern was significantly different in SLE as compared to controls [322]. In either race, short allele sizes (< or = 792 bp) were seen exclusively in SLE patients, whereas the 828-bp allele was overrepresented in controls. In contrast, there was no preferential association of SLE with G/C alleles in the 5′ region of the IL-6 gene. Furthermore, these results suggest that the 3′ minisatellite alleles have biological significance: (1) B lymphoblastoid cells of patients having one or two SLE-associated alleles secreted IL-6 in three- to four-fold higher levels than nonallelic cells; (2) higher percentages (approximately four-fold) of IL-6 positive monocytes were observed in individuals having SLE-associated IL-6 alleles; and (3) in lupus patients having SLE-associated minisatellite alleles, IL-6 mRNA stability was enhanced significantly.

However, Schotte *et al*. [323], examining 211 German SLE patients, found no difference in the frequency of the IL-6 –174G/C promoter polymorphism between patients and controls (where the G allele is associated with higher IL-6 expression), although there was a weak association with discoid skin lesions and antihistone antibodies. This attractive locus clearly needs further confirmation.

Plasminogen Activator Inhibitor-1 (PAI-1)

PAI1 cDNA encodes a protein containing 402 amino acids with a predicted nonglycosylated molecular mass of 45 kDa. The plasminogen activator inhibitor shows structural similarities to angiotensinogen, α_1-antitrypsin, and antithrombin III. Plasminogen activator inhibitor-2 is less similar to PAI1 than it is to the other proteins of this group. There are at least three immunologically distinct plasminogen activator inhibitors (PAIs): placental PAI, protease nexin, and endothelial cell-derived PAI. The last is also distinctive for its β mobility in agarose zone electrophoresis and its inhibition of both tissue-type PA and urokinase-type PA. Wang *et al*. [324] examined the frequency of a single base pair insertion/deletion polymorphism of the PAI-1 gene (4G/5G) in 118 southern Chinese patients with SLE and 103 controls that has been shown to alter PAI-1 gene expression. Although no differences were seen between patients and controls, lupus nephritis patients who had the 4G/4G polymorphism had significantly heavier proteinuria, higher activity indices, and a higher frequency of extensive necrotizing lesions on renal biopsy compared to patients with 4G/5G and 5G/5G, suggesting an impact of PAI-1 on the course of SLE.

T-Cell Receptor Genes

The α:β T-cell receptor molecule, expressed on $CD4^+$ and $CD8^+$ lymphocytes and to which both HLA class I and class II molecules present their processed peptides,

is a heterodimer whose respective α and β polypeptides are encoded on different chromosomes. The TCRα gene complex spans over 1000 kb and has been mapped to chromosome 14q11–12. The TCRβ complex spans 600 kb at chromosome 7q35. A number of studies have examined the frequencies of TCR in SLE patients and their families. Neither Wong *et al*. [325] nor Dunckley *et al*. [326], using RFLP analysis and Southern blotting, found no linkage of TCRα, -β, or -γ genes in five multiplex Caucasian families. Tebib *et al*. [327], working with the same group, subsequently described an association of a 1.3- and 3.0-kb *Pst*I TCRα constant region RFLP band pair in Caucasians with SLE, although the same was not seen in nine Mexican multiplex SLE families examined concomitantly or in another North American study of 41 unrelated SLE patients and 14 multiplex SLE families [327]. Frank *et al*. [328] described an association of a 9.8-kb *Bgl*II and a 1.75-kb *Kpn*I TCRβ RFLP with the anti-Ro autoantibody response in 76 SLE patients of mixed ethnicity.

There are technical problems of these studies of TCR polymorphism in that the RFLP analyses performed are usually done on genomic DNA. Much of the antigenic and MHC specificity results from the DNA rearrangement that the constant, diversity, joining genes and variable region genes, which exist at different segments on the chromosome, undergo. Any one of over 80 known Vβ genes can combine with one of two Dβ, one of 12 Jβ, and one of two Cβ segments. Similarly, any of over 100 Vα segments can combine with one of 50 Jα and the one Cα gene, which is not considered by RFLP studies of genomic DNA, and further studies are necessary to rule in or out a significant contribution of TCR genes to the pathogenesis of SLE.

Mannose-Binding Protein (MBP) Genes

Mannose binding protein is an acute-phase serum protein whose polypeptide chains form trimers that associate to give a structure analogous to that of C1q, thus being able to activate the classical and alternative complement component pathways independent of antibody [329]. MBP deficiency results in an opsonic defect that causes recurrent infections in children. The best-characterized hereditary defect in MBP is a point mutation at nucleotide 230 of exon 1, causing the substitution of aspartic acid for glycine [330]. This results in a significant reduction of serum MBL. Homozygosity for this mutation is considered the most common inherited immunodeficiency, and the gene frequency of this allele is 17% in the Caucasian British population [331]. Given the associations of complement deficiencies with SLE, it would be reasonable that MBP deficiency might contribute to predisposition to SLE. Davies *et al*. [332] examined 102 Caucasians with SLE from northwestern England, finding the allele in 41% (compared to 30% of controls), leading to the conclusion that this MBP allele might represent a "minor" risk factor for SLE. Further studies in 50 Caucasians from Spain [333] found an even higher frequency (52%), although the frequency of individuals homozygous for this mutation was not increased. This led to the conclusion that this "dysfunctional" MBP allele might affect the susceptibility to SLE in an additive manner with C4 null alleles [333]. Sullivan *et al*. [334] confirmed this association in 92 African-American SLE patients, finding two MBP structural polymorphisms associated with low serum levels of MBP to be increased in frequency and a MBP promoter haplotype associated with high serum MBP levels to be negatively associated with SLE.

Ip *et al*. [335] studied serum MBL levels and codon 54 mutations in 112 Chinese patients with SLE and 110 healthy controls and found a significant difference in the distribution of the two pairs of promoter polymorphisms, H/L and Y/X, between SLE patients and controls.

Garred *et al*. [336] determined MBL alleles and serum concentrations in 91 Danish patients with SLE and in 250 controls. Homozygotes for MBL had an increased risk of acquiring serious infections compared with patients who were heterozygous or homozygous for the normal. In a subsequent study, Garred *et al*. [337] conducted a meta-analysis of eight previously published studies, suggesting that the presence of MBL variant alleles confers a 1.6 times overall increased risk for SLE . Moreover, in 99 Danish SLE patients, MBL variant allele carriers had higher disease activity (SLEDAI index) in a 2-year follow-up period and had an increased risk of acquiring complicating infections in general and respiratory infections in particular.

Tsutsumi *et al*. [338] analyzed the MBL gene polymorphisms of Japanese SLE patients and controls and found that patients studied had a significantly higher frequency of having a homozygous codon 54 mutation compared to controls. In particular, patients with SLE or Sjogren's syndrome showed higher probabilities of being homozygous for this mutation. Among subjects with the same genotype, SLE patients tended to have higher serum MBL concentration than controls. Analysis of the promoter region suggested that SLE patients heterozygous for the codon 54 mutation have a higher probability of having a low producing haplotype for the gene without the codon 54 mutation.

Horiuchi *et al*. [339] examined the frequency of the polymorphism at codon 54 (substitution from Gly to Asp; G54D) in 105 healthy Japanese individuals and 95

SLE patients, as well as two polymorphisms at positions of –550 and –221 in the promoter region, and found no associations.

Acetylation Phenotype and Cytochrome P450 Oxidase Genes

It has long been recognized that patients with drug-induced LE were genetically low acetylators of aromatic amine and hydrazine compounds [340]. However, extensive acetylation phenotyping of SLE patients has failed to show this as a contributing factor to SLE [341, 342]. In several cases, however, xenobiotics (i.e., drugs and occupational agents) were identified as etiologic agents, and associations with certain polymorphic alleles of xenobiotic-metabolizing enzymes have been reported. Cytochrome P4501A1 (*CYP1A1*) and *N*-acetyltransferase 2 (NAT-2) are xenobiotic-metabolizing enzymes of phase 1 and phase 2 metabolism, respectively. *CYP1A1* may activate drugs and other chemicals to reactive metabolites. NAT-2 is the most important enzyme in the acetylation of aromatic amines, and thus may be responsible for the detoxification of many of these compounds. Two polymorphisms of the human *CYP1A1* gene, a point mutation in the 3′ flanking region of the gene (Msp1) and a mutation in exon 7 leading to an isoleucine–valine–exchange in the heme-binding region of the enzyme, have been described and may lead to higher basal and inducible enzyme activity. With respect to NAT-2, several alleles that combine for the two phenotype "fast" and "slow" acetylators have been described. Von Schmiedeberg *et al*. [343] analyzed the gene frequencies of the *CYP1A1* polymorphisms and the phenotypes of NAT-2 in 68 and 88 German SLE patients, respectively, compared to 184 controls and found a significant increase in the mutant Val allele when compared to controls. Regarding the NAT-2 phenotype, 80.2% of patients with SLE were slow acetylators compared to 55% slow acetylators in the healthy German population. This supported the notion that nonacetylated xenobiotics in slow acetylators may accumulate and are subsequently metabolized by other enzymes into reactive intermediates. Thus, an enhanced formation of reactive metabolites could alter self-proteins presented to the immune system, thus stimulating autoreactive T cells, which induce autoimmunity.

Sullivan *et al*. [344] found no association of the polymorphic *CYP17* allele with SLE, nor did Kortunay *et al*. [345] find any differences in the *CYP2C19* (an enzyme important in the metabolism of a number of drugs, including mephenytoin, diazepam, and omeprazole) genotypes between 37 Turkish SLE patients and 161 healthy controls.

ETS1

ETS1 encodes a set of nuclear phosphoproteins ranging in size from 42 to 52 kDa, which are transcription factors that activate transcription by interaction with purine-rich sequences present in the promoter/enhancer region of the T-cell antigen receptor, α subunit (TCRA) gene. Given the identification of chromosome 11q23 containing a potential susceptibility locus for SLE in a genome-wide scan [65], Sullivan *et al*. [346] examined 119 SLE patients and 130 controls for polymorphisms of the ES1 gene. None of the seven alleles examined were seen more frequently in patients vs controls, although marginal associations were seen of specific alleles and discoid LE and vasculitis. These findings need confirmation in a larger series of patients.

Vitamin D Receptor (VDR)

Previous studies have shown that polymorphisms of the vitamin D receptor can not only influence bone density, but also, indirectly, IL-2 gene transcription. Ozaki *et al*. [347] examined 58 Japanese SLE patients and 87 controls for VDR genotypes, finding the BB genotype to occur in 15.5% of patients compared to 5.7% of controls. Furthermore, the BB genotype was seen more frequently in patients with nephritic syndrome (61.5% vs 35.7). Given the relatively small number of patients studied and the smaller proportion that had the BB genotype, this finding needs to be confirmed in a larger cohort.

DNase I

Deoxyribonucleases are important enzymes involved in the clearance of DNA from apoptotic cells, and low serum deoxyribonuclease activity has been documented in human SLE patients [348]. Yasumoto *et al*. [349] reported that 2 of 20 Japanese SLE patients (and 0/100 controls) possessed a heterozygous *AWG* mutation in exon 2 of *DNASE1*, resulting in a premature stop codon. Although these patients had very low serum deoxyribonuclease activity, the authors also found that compared to normal controls, serum deoxyribonuclease activity was also low in SLE patients who did not carry any *DNASE1* mutations. In contrast, Tew *et al*. [350] sequenced a cohort of 18 North American SLE patients with lupus nephritis and known low serum deoxyribonuclease activity and found no mutations in *DNASE1*. Furthermore, transcript levels of *DNASE1* were not significantly different between SLE patients compared to age-, sex-, and race-matched controls. This and the fact that the majority of SLE patients (whose *DNASE1* was sequenced) did not possess mutations in *DNASE1*, yet have a low serum deoxyribonuclease phenotype, imply factors other than germ line mutations

may be more important in influencing serum deoxyribonuclease activity in SLE patients.

Monocyte Chemoattractant Protein-1 (MCP-1) Promoter

Monocyte chemotactic protein-1, a member of the small inducible gene (SIG) family, plays a role in the recruitment of monocytes to sites of injury and infection and is regulated by NF-κB. Aguilar *et al*. [351] examined a biallelic G/A polymorphism at position –2518 of the MCP-1 gene in 276 Spanish SLE patients and 194 controls and found no correlation with SLE *per se* or with nephritis. However, patients with cutaneous vasculitis were more likely to have the genotype A/G than other genotypes. This gene may represent a disease modifier in SLE, although it is premature to consider it a candidate gene in SLE susceptibility.

Angiotensin-Converting Enzyme Gene Polymorphisms

ACE takes part in the renin–angiotensin and kallikrein–kininogen systems by creating angiotensin II and inactivating bradykinin. ACE gene insertion/deletion polymorphism is associated with the level of circulating enzymes—subjects with the DD genotype have higher levels of circulating ACE than subjects with the II genotype and show an increased tendency toward impaired vascular function and structure. Patients with systemic lupus erythematosus suffer from differentially expressed vascular pathology.

Sato *et al*. [352] investigated the correlation between insertion (I)/deletion (D) polymorphism of the ACE gene and the disease activity in 93 newly diagnosed SLE patients. Individuals with II genotype showed a significant increase in SLE activity. Patients with the ACE II genotype showed a higher serum level of anti-dsDNA antibodies than those with the DD genotype. Moreover, patients with the II genotype also showed lower levels of serum CH50 than those with the DD genotype. Patients with the II or DI genotype had a significantly higher SLEDAI score than those with the DD genotype.

Tassiullas *et al*. [353] investigated the potential role of ACE polymorphisms in 216 SLE patients (121 Caucasians, 78 African-Americans, and 17 others) and 200 normal controls; 134 patients had evidence of renal disease. The frequency of genotype DD was increased in African-American normal controls compared to Caucasians and in African-American normal controls vs African-American lupus patients. Trend analysis of the genotype distribution across the three African-American groups (renal, nonrenal, controls) revealed a trend of an increased frequency of I and an decreased frequency of D as the likelihood of renal disease increases ($P = 0.008$). No association between any ACE genotype with parameters of renal disease and/or response to therapy was identified. African-American patients with lupus have a lower frequency of DD genotype as compared to African-American normal controls.

Conversely, Pullman *et al*. [354] determined ACE polymorphisms in 101 SLE patients and found that the frequency of the D allele was higher in the SLE group than in controls. Moreover, an association between the DD genotype and visceral damage was also observed. Prkacin *et al*. [355] found that the DD genotype was more common in 18 patients with systemic lupus erythematosus compared to 21 controls and that patients with the II genotype had a lower proteinuria and creatinine level and a shorter time to disease remission than those with the DD genotype.

Finally, in a study of 56 Israeli SLE patients and 48 controls, Molad *et al*. [356] found a similar distribution of the ACE genotype D/D, D/I, and I/I in the lupus group and controls and also failed to find any significant association among the ACE genotype and disease manifestations, SLEDAI, renal function, or cardiovascular and cerebrovascular morbidity. Likewise Kaufman *et al*. [357], analyzing 158 pedigrees (56 African-American, 90 European American, and 12 from other ethnic groups), was unable to detect significant linkage or genetic association between the ACE gene and SLE.

These contradictory data suggest that if this gene has any relevance to SLE, it appears to be marginal.

β2-glycoprotein

Apolipoprotein H (apoH, protein; APOH, gene) is a required cofactor for the production of antiphospholipid antibodies (APA). Kamboh *et al*. [358] examined 222 Caucasian women with SLE for four APOH polymorphisms (codons 88, 247, 306, and 316) and for plasma apoH concentrations by ELISA. Although none of the four APOH polymorphisms were significantly associated with variation in risk for SLE, the codons 306 and 316 polymorphisms showed significant, gene dosage effects on plasma apoH concentrations. No significant association was observed between anti-apoH status and APOH polymorphisms or plasma apoH levels; however, plasma apoH concentrations were significantly higher in patients positive for APA than in patients negative for APA. The frequency of the mutant allele (Ser316) was significantly lower in the APA-positive group than the APA-negative group, indicating that the Ser316 mutation is protective against the production of phospholipid–apoH-dependent APA.

Gushiken *et al*. [359] determined the frequency of mutations in the phospholipid-binding domain of β2-glycoprotein I (β2GPI) in 95 patients with SLE. In patients with SLE, 4 of 6 patients with exon 8 mutations

had thrombosis compared with 22 of 82 patients without the mutation; 5.6% were heterozygous for the mutation at exon 7 (codon 306) and 7.7% were heterozygous for the mutation at exon 8 (codon 316). No homozygous subjects were found for either mutation. No significant correlation between these mutations and the presence of aPL, LAC, or anti-β2GPI antibodies was found.

Bcl-2

The *bcl-2* protooncogene encodes a 24-kDa protein that is localized in the inner membrane of mitochondria, which promotes prolonged lymphocyte survival, by the prevention of apoptosis. Graninger [360] studied 24 Caucasian SLE patients, finding an increased concentration of *bcl-2* mRNA in 19 of the patients. The degree of overexpression of *bcl-2* was found to correlate with disease activity both here and in another study by Miret *et al*. [361], who observed increased levels of bcl-2 in SLE patients with active disease in relation to those with inactive SLE and controls. There was also a significant correlation between bcl-2 levels and SLEDAI values. Mehrian *et al*. [245] described an association of a *bcl-2* intragenic marker with SLE in 162 Mexican-American SLE patients and suggested synergism between the IL-10 locus and *bcl-2* genes in heightening disease susceptibility.

Johansson *et al*. [362] examined 378 Mexican SLE patients (n = 378) and 112 Swedish simplex families using a microsatellite marker and two single nucleotide polymorphisms located within the gene and were unable to detect association between *bcl-2* and SLE in either population. Clearly this gene, if indeed it has any relevance to SLE, needs to be confirmed in another cohort of patients.

CONCLUSION

Although family and twin studies clearly have established the importance of genetic factors in SLE, and studies of HLA class II and III genes since the mid 1970s have underscored their consistent associations with disease in nearly all ethnic groups, the contribution of non-MHC genes to SLE predisposition, clinical and autoantibody subsets, and course and prognosis are only being determined presently. Studies defining associations with non-MHC genes and linkage studies of multiplex families from several centers have raised as many new questions as they have answered. Inadequate power from small sample sizes and family collections, stemming undoubtedly from the clinical heterogeneity posed by SLE in no small part, has caused this. However, as the family collections continue, data are pooled and reanalyzed, and clinical subsets of SLE further considered, definitive candidate genes should emerge byond perhaps those three that have withstood time and reconfirmation in different groups of patients: the MHC, the FCγ genes, and whatever disease-relevant gene found in the region on chromosome ′q41–42. This will result in better insights into the immunologic perturbations that set the stage for SLE, which will in turn allow novel approaches to therapy. Similarly, as the contribution of genetics to prognosis in SLE is better understood, those at highest risk for a worse outcome can be targeted earlier with aggressive which may result in improvement in the quality and length of life of those affected.

5

GENETIC SUSCEPTIBILITY AND CLASS III COMPLEMENT GENES

John P. Atkinson
Peter M. Schneider

INTRODUCTION

The great interest in this genetic region of chromosome 6 in humans relates to the now several decades old observation that individuals with complete deficiency of C4 or C2 come to medical attention with the clinical syndrome of systemic lupus erythematosus (SLE). Thus, these two proteins along with their friends (C1q, C1r, C1s) in the early part of the classical pathway are the only known single protein deficiency states that commonly (~90% in case of C1q and C4 deficiency) develop SLE. The problem that has been so elusive to solve is how these deficiency states in turn lead to SLE. One focus in this chapter will be on this question. After providing background data on the structure and function of the class III genes and their protein products, we will first review the older data relative to the long-appreciated role of the complement system in immune complex (IC) handling and then move into the more recent results on the role of the complement system in the immune response and in the processing of cellular debris. The new tools of this field, namely knockout mice, have been particularly helpful in more elegantly and firmly establishing an important role for the complement system in innate and adaptive immunity as well as in preventing autoimmunity.

The class III, or complement (C), region of the human major histocompatibility complex (MHC) is located between class I (B, C, A) and class II (DP, DQ, DR) regions on the short arm of chromosome 6 (Fig. 1). Complement genes in this 130-kb cluster include C4A, C4B, factor B, and C2. C4A and C4B are duplicated (>99% homologous) genes. The C2 and factor B genes encode serine proteases, which are approximately 30% homologous, indicating a more ancient duplication. C4 and C2 are required for the classical (CP) and lectin (LP) pathways, whereas factor B is necessary for alternative pathway (AP) activation (Fig. 2). Upon CP activation by IC, C4 is cleaved by the C1s subcomponent of the first component of complement (C1). For the LP, mannan (or mannose)-associated serine proteases (MASPs), which are homologous to C4r and C1s, cleave C4. The larger proteolytic fragment of C4, C4b, has the transient capacity to attach covalently to the target antigen (Ag) and to the activating antibody (Ab) (Fig. 3). Bound C4b has two roles: an opsonic one in which it is a ligand for complement receptors and an enzymatic one in which it serves as the noncatalytic domain of the CP C3 and C5 convertases. C2 and factor B are serine protease precursors and play identical roles in their respective activation pathways. After proteolytic cleavage by C1s or MASPs, C2a combines with C4b to form the classical pathway C3 convertase. Factor B birds to C3b and then it is cleaved by factor D, forming the alternative pathway C3 convertase. C2a and factor Bb are the catalytic (serine protease) domains of both C3 and C5 convertases.

As noted, attention was drawn to this gene cluster because of its location within the MHC and because inherited deficiencies of C2 (C2def) and C4 (C4def) were associated with SLE (see Chapter 6). A deficiency of any one of the early components of the classical

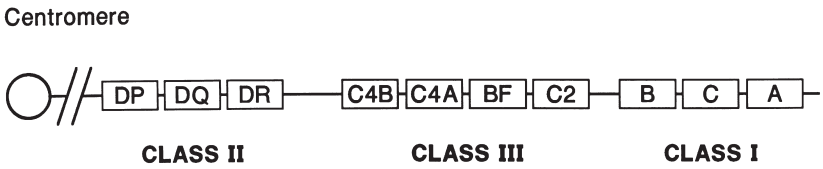

FIGURE 1 The human major histocompatibility complex on the short arm of chromosome 6. The class III or complement gene cluster, which covers a distance of 130 kb, includes complement activation components C4 (two highly homologous genes termed C4A and C4B), factor B (also noted as BF), and C2. From Liszewski *et al*. [152], with permission.

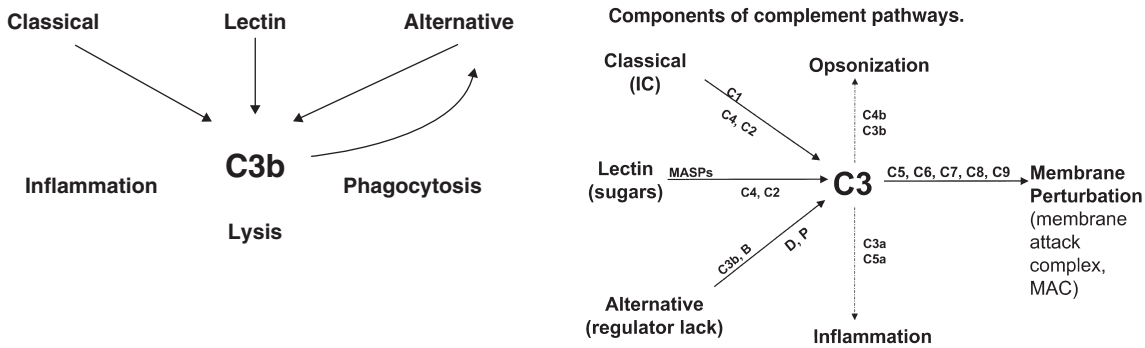

FIGURE 2 The three pathways of complement activation. Deposition of clusters of C3b on a target is the primary goal. The alternative pathway also serves as a feedback loop such that C3b deposition can be amplified.

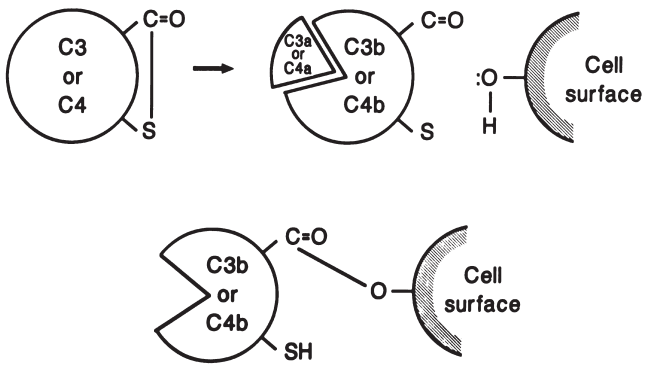

FIGURE 3 The thioester bond of C3 and C4. Activation of the thioester bond in C4 and C3 occurs in association with their proteolytic cleavage and liberation of the C4a and C3a fragments. Condensation with a hydroxyl group (formation of an ester linkage) is shown. Amino groups on the target surface can also be bound (formation of an amide linkage). From Hughes-Jones [153], with permission.

pathway is the only single protein deficiency state currently known that causes SLE in humans. Initially, this striking disease association was attributed by many observers to the class I or class II markers inherited with the C deficiency. While there may be an independent contribution to disease susceptibility from genetic markers that are in linkage disequilibrium, such as HLA class II genes, C deficiency itself is key, as summarized below.

1. C4def and C2def are inherited on distinct genetic (MHC) backgrounds. Moreover, C4def is inherited on different MHC backgrounds in, for example, Asians compared to Caucasians and yet the SLE association still holds. Therefore, it is not the company it keeps (i.e., other MHC-linked genes) that produce the disease association but the C deficiency itself.
2. C1qdef and C1r/C1sdef also predispose to SLE [1, 2]. The associations of SLE with C1q (>90% deficient individuals have SLE) and C1r/C1s deficiency are even a little stronger than that for C4def and SLE [3]. These subunits of C1 are, of course, immediately upstream of C4 and C2 in the classical pathway, strongly implying that it is activation of the cascade itself that is critical. Further and in support of the first point, the structural genes for these C1 subunits are at separate genetic loci, outside the MHC [1–7].
3. A partial deficiency of C4, especially of C4A, predisposes an individual to SLE in some populations [3, 5–7]. In the Caucasian SLE population, C4Adef is observed about two-thirds of the time on the DR3-B8 haplotype while the remaining one-third are associated

with a *diverse* array of haplotypes. Moreover, in Asian populations, C4Adef appears to be a risk factor for SLE as well, yet the DR3-B8 haplotype is unknown. Thus, a problem in interpretation related to linkage disequilibrium (in other words, which genes are the disease-promoting ones) has been further resolved by studies in ethnically diverse populations [5–7].

4. The major biologic function of these early components of the classical C pathway, C1, C4, and C2, and the pivotal C3 component *is to bind to antigens and thereby facilitate antigen processing (the immune response) and immune complex (IC) formation and handling* [8–14]. SLE is the prototypic spontaneously occurring human disease in which many of the clinical manifestations are mediated by the deposition of the IC in undesirable locations (e.g., kidney). Consequently, on the one hand, patients have an illness, SLE, in which the IC is mediating much of the tissue damage and, on the other hand, they possess an inherited deficiency of proteins, one of whose functions is to process IC.

5. Acquired C4 and/or C2def, particularly in the setting of hereditary angioedema, have been reported in association with SLE, again suggesting that it is the protein deficiency per se that is the critical factor (see Chapter 6).

Taken together, these data establish deficiency of an early component of the CP as a predisposition to the development of SLE. Next, we will provide some caveats to this statement and deal with several apparent discrepancies.

1. Since the major function of the early components of the CP is to activate C3 so its fragments can deposit on IC, the expectation is that C3 deficiency would be an even greater predisposing deficiency state for SLE. However, most patients (numbers are small, however) with C3 deficiency present with recurrent pyogenic infections and occasionally glomerulonephritis but certainly not with the SLE-like picture as one sees with C1q, C4, or C2 deficiency. Several explanations are possible. One is that C4b (a structural and functional homolog of C3b) is sufficient such that autoimmunity is largely avoided. Along this line of reasoning, Michael Carroll and colleagues have proposed a theory that C4b binding to immunocompetent autoreactive bone marrow B cells inhibit their activation (a negative feedback to prevent autoimmunity) [15]. While this is an attractive hypothesis [3], there is as yet no clear idea as to how this takes place and C1q-deficient mice did not demonstrate a defect in B-cell tolerance [16].

2. Another theory, championed by Mark Walport and colleagues, is the so-called "garbage hypothesis" [3, 17]. It centers on a role for the CP in the clearance of cell debris, including apoptotic cells. If intracellular debris is not cleaned up efficiently (analogous to IC containing foreign antigens), then modifications could occur to DNA/protein, RNA/protein, and other cellular constituents such that they now become immunogenic. With this argument, one, however, would also expect C3 deficiency to be a cause of SLE. Perhaps C1q and C4b binding to the "garbage" are sufficient to prevent autoimmunity.

3. Two other issues that remain problematic are the striking female predominance and the antibody specificity for nuclear material. The "garbage hypothesis" does provide a potential explanation for the antibody specificity question (see later) [3, 17] whereas the gender issue continues to defy a plausible explanation.

4. A point also emphasized by the Walport and Botto group is that C1qdef has a higher frequency of SLE (90%) than C4def (80 to 90%) or C2def (10 to 30%) [3, 18]. This hierarchical relationship suggests that the binding of C1q to apoptotic material is most critical in preventing SLE. These data also imply an interaction with C1q receptors, a field that is in flux as to the identification and function of such proteins. Also, C1r/C1s def (8/14 cases described to date have SLE) [3, 17] and SLE in C4def and C2def take place in the setting of "normal C1q."

5. Therefore, a more plausible hypothesis would seem to be that CP activation through at least C4 is the most critical issue in preventing SLE. The initial approach therefore that many of us took to unravel how the C deficiency led to SLE was to analyze the genetics, structure, and function of C4 and C2 and the receptors and regulators that interact with these two components. The more recent approach has been to utilize gene targeting (knockouts) of C1q, C4, or C2 in the mouse. Both types of studies have contributed much to our understanding of complement activation and its association with SLE. We will first summarize the earlier studies and then the mouse model systems.

FOURTH COMPONENT OF COMPLEMENT (C4)

Structure

C4 is an abundant (15 to 45 mg/dl) 200,000-Da, three-chain, disulfide-linked, plasma glycoprotein (Fig. 4) [19–21]. It is synthesized by the liver as a single chain precursor (pro-C4), which undergoes proteolytic cleavages at two sites to give rise to the three chain protein: α, 95,000; β, 70,000; and γ, 35,000. The secreted protein possesses three N-linked complex sugar residues on the α chain and one N-linked high mannose type on the β chain [22]. The COOH terminus of the α chain

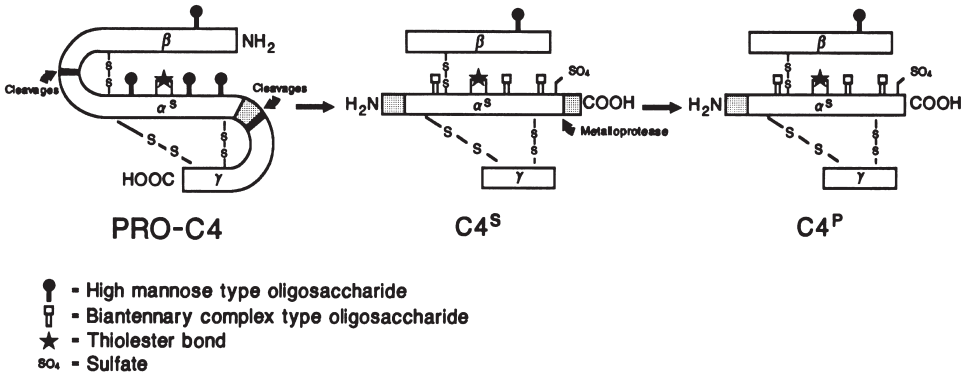

FIGURE 4 Schematic diagram of the structural features of human C4. Pro-C4 is the intracellular, single chain precursor of C4. Following a series of posttranslational modifications that include sulfation, glycosylation, and proteolytic cleavage, a three chain protein is secreted ($C4^s$). The major form of C4 in plasma, however, is $C4^p$. This form differs from $C4^s$ by removal of a 22 amino acid peptide from the carboxyl terminus of the α chain. The shaded area at the NH_2 terminus of the α chain represents the C4a fragment. Modified from Chan and Atkinson [22], with permission.

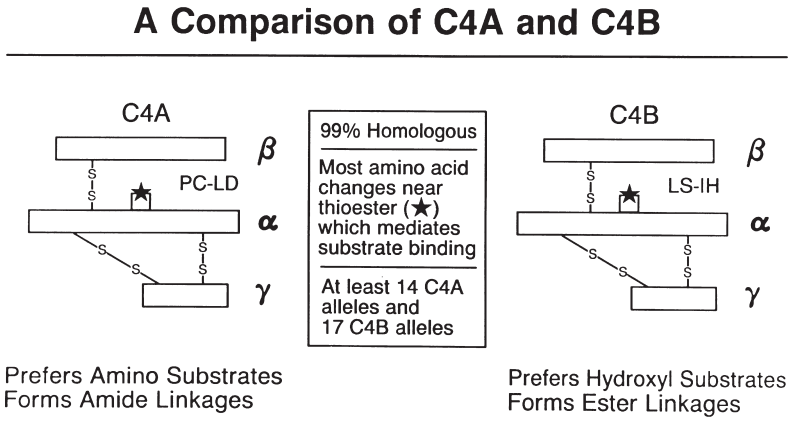

FIGURE 5 Although highly homologous, C4A and C4B differ in their binding specificities for substrates. From Liszewski and Atkinson [154], with permission.

undergoes two remarkable posttranslational modifications. The first is sulfation of two or three tyrosine residues [23], a modification that increases severalfold the efficiency of its cleavage by C1s [24]. The second modification, following secretion into plasma, involves removal of a 22 amino acid peptide from the carboxyl terminus [25, 26]. This cleavage exposes a highly charged, acidic stretch of amino acids, including the sulfation site, that likely is a recognition motif for C1s and MASPs. Thus, truncation and sulfation are designed to improve the efficiency of C4 cleavage by C1s and presumably by the MASPs as well.

Function

C4 is the first component of the classical C pathway to become directly bound to antigen in IC (C1 is bound through C1q to the Fc of Ab). Upon cleavage of the amino terminus of the α chain to liberate C4a by C1s or MASPs, C4b undergoes a molecular rearrangement. In so doing, a thioester bond in the central portion of the α chain is broken (Figs. 2 and 5). This thioester is formed over a four amino acid peptide between a γ-carboxyl group of glutamic acid and a sulfhydryl of cysteine [27, 28]. A reactive carbonyl species is formed that is capable of interacting with a hydroxyl group to form an ester linkage or with an amino group to form an amide bond. The result, in either case, is the covalent attachment of multiple, clustered C4bs to the target.

As outlined earlier, C4b serves two roles in the classical C pathway. First, C4b is a ligand (opsonic role) for complement receptor type one (CR1; CD35; C3b/C4b or immune adherence receptor) of peripheral blood cells (erythrocytes/B lymphocytes/monocytes/granulocytes) and B lymphocytes and follicular-dendritic cells in immune organs [29–31]. Second, C4b

is the noncatalytic domain of the classical pathway C3 and C5 convertases (enzymatic role) (Fig. 2). C4b, bound covalently to the target antigen, captures the C2a cleavage fragment of C2. This bimolecular enzyme complex, C4bC2a, is the classical pathway C3 convertase. C2a is a serine protease with very limited substrate specificity; i.e., it cleaves C3 but only if C2a is associated with C4b. If a C3b becomes bound covalently to an acceptor site on C4b, the enzyme complex changes its specificity from C3 to C5 (C4b2a3b is the classical pathway C5 convertase). Thus, the serine protease domain of C2 cleaves two proteins, C3 and C5.

C4A and C4B

Plasma C4 is composed of two distinct but highly homologous (>99%) isotypes, C4A and C4B (Fig. 5). C4A and C4B are each composed of 1725 amino acids [19, 32, 33]. Eight amino acid differences in positions near the thioester are responsible for the electrophoretic (fast vs slow), serologic (Chido and Rodgers blood group antigens), and hemolytic (C4B is several-fold more active than C4A in a whole complement assay) differences [34, 35]. In addition to their isotypic variations, C4A and C4B each demonstrate additional polymorphisms, defined initially by electrophoresis, giving rise to at least 14 C4A and 17 C4B alleles [36, 37]. Those alleles that have been sequenced result from single amino acid differences in the region containing the thioester (also known as the C4d fragment) [38], but additional amino acid exchanges may also exist outside this region, as demonstrated by the hemolytically inactive C4A6 allele [39].

The C4A gene is 22.3 kb long and lies about 10 kb from a similarly sized C4B gene (C4B long). A smaller 16-kb C4B gene (C4B short), lacking a 6.3-kb intron near the 5′ end of the gene, occurs in approximately one-third of Caucasians and in a higher frequency of African-Americans [5, 19]. This gene size variation is due to an ancient insertion of a complete endogenous retrovirus with strong homology to the HERV-K family [40, 41]. As this retroviral insertion is not present on all MHC haplotypes, it may have functional implications related to disease associations of certain MHC haplotypes. It has been shown that the insertion may regulate the expression of exogenous retroviral sequences, indicating the possibility of protecting the host by antisense inhibition [42].

Deletions and duplications of C4 and the nearby 21-hydroxylase genes are common [4, 5, 19, 33, 38, 43–50]. The most intensively analyzed deletion in this region occurs on the DR3-B8 haplotype (Fig. 6) and results in a loss of most of the C4A and all of its closely linked cytochrome P450 21-hydroxylase steroidogenesis pseudogene (CYP21A). Duplications and deletions in this area occur, probably as a result of unequal crossing over, which is promoted by the high homology of C4A and C4B and other members of the associated gene cluster (Tables 1 and 2). A *de novo* C4B-CYP21B gene deletion has been investigated, providing clear evidence for unequal crossing over as the basic mechanism for modular variation [49]. On a substantial number of haplotypes there are various combinations of one, two, or

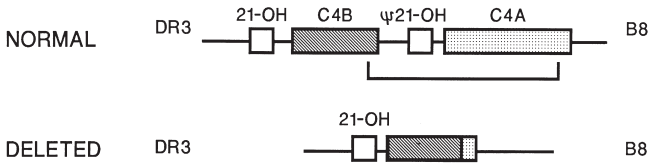

FIGURE 6 On the DR3-B8-extended haplotype, a deficiency of C4A is caused by a 30-kb deletion. (Top) What *should* be present; however, the DR3-B8 haplotype is always associated with this deletion. Most of the gene for C4A and a portion of C4B are deleted along with an intervening pseudogene, 21-hydroxylase A (ψ21-OH). Approximate limits of the deletion are indicated, although the precise end points remain to be determined. From Kemp *et al*. [77], with permission.

Total	28.1	53.0	1.6

[a] In addition to showing HLA-B and -DR results, the haplotypes listed include the complement alleles of factor B, C2, C4A, and C4B in that arbitrary order. Thus, the abbreviation SC01 (= complotype) stands for the S allele of factor B, the C allele of C2, an absence of C4A (= Q0), and the C4B allele 1. The HLA-A allele associated most frequently with each haplotype is shown in parentheses. Modified from Kruskall *et al*. [155].

three C4A and C4B genes [46, 47, 50, 51]. C4A and C4B null alleles also result from intact but noncoding C4A or C4B, as has been shown for the HLA-B60-linked C4A null allele. This is caused by a 2-bp insertion in exon 29 leading to a frame shift mutation and a premature stop codon in exon 30 [52]. In addition to this more commonly observed deficient allele, a few cases with other mutations have been described as well [53–55]. Gene conversion, a change in a C4B allele to that of a C4A allele, probably has occurred in several noncoding C4B null alleles, providing another explanation for C4A null genes [45]. Of the extended HLA haplotypes bearing the C4 null gene (Table 2), the DR3-B8 haplotype, carrying the C4A deletion, is most common in Caucasians.

A molecular genetic and immunochemical analysis of C4A and C4B genes/proteins was carried out in 150 normal Caucasians [50]. Results indicate substantial variation in this locus with approximately two-thirds of the population carrying C4A and C4B genes on both chromosomes. This means that approximately one-third of the population have a partial deficiency of C4A or C4B (about 15% of each). A homozygous deficiency of C4A or C4B was found in 1/150 and 2/150 individuals, respectively. The interested reader should review the paper from the Yu laboratory, which contains a wealth of genetic information relative to the C4A/C4B locus and describes the methods required to rigorously assess C4def [50].

A completely C4def individual (C4def, double homozygote) possesses null alleles at all four loci (two C4A and two C4B) and therefore produces no C4 (Table 3). This is a rare situation with approximately 30 individuals reported in the literature (80 to 90%) with SLE [3, 18, 56, 57]. More commonly, individuals are homozygous for null alleles at *either* the C4A *or* the C4B locus, often with reduced serum C4 levels. Heterozygous C4A- or C4Bdef individuals have one null allele at either of the two loci, with serum C4 levels usually in the lower end of the normal range. Other combinations, such as homozygous C4Adef and heterozygous C4Bdef, have been described [18, 56].

C4A binds more avidly to amino groups than does C4B (Fig. 5) [58, 59]. As a result, C4A is more efficient at handling certain types of immune complexes [9, 10, 12–14, 60]. In contrast, C4B binds more efficiently to hydroxyl groups. Its greater hemolytic activity in the total complement (CH_{50} or THC) assay relates to the fact that sheep erythrocyte, the target antigen in this lysis assay, is a hydroxyl-rich substrate. Differences in affinities of C4A and C4B for substrates result from amino acid changes in the vicinity of the thioester bond [19, 33, 35, 61, 62]. This arrangement likely provides a survival advantage, allowing for a wider range of substrates to be bound efficiently by C4. There is also a variation in the ability of C4A and C4B to serve as a ligand for the C3b/C4b receptor [63], which provides a second explanation for differences in IC processing between C4A and C4B-coated antigens.

Serum C4 Concentration

The total C4 concentration results from expression of the protein product of two C4A genes and two C4B genes. Individuals deficient in one or more genes are common and although they do have reduced total C4

TABLE 3 Classification of C4 Deficiency

Genetic background	Phenotype		Serum C4[a]	THC[b]
Normal	C4A C4A	C4B C4B	Normal	Normal
Complete deficiency	C4A-Q0[c] C4A-Q0	C4B-Q0 C4B-Q0	None	Very low (0 to <10)
Partial deficiency				
C4A homozygous	C4A-Q0 C4A-Q0	C4B C4B	Variable, but usually low	Normal
C4B homozygous	C4A C4A	C4B-Q0 C4B-Q0	Variable, but usually low	Normal or slightly low
Heterozygous C4A or C4B deficiency				
C4A heterozygous	C4A-Q0 C4A	C4B C4B	Normal	Normal
C4B heterozygous	C4A C4A	C4B-Q0 C4B	Normal	Normal
Mixed C4A and C4B deficiency	C4AQ0 C4A	C4B-Q0 C4B	Variable, but usually low	Normal or slightly low

[a] Serum C4 levels, as determined by antigenic or functional assays.
[b] Total hemolytic complement refers to the standard whole complement assay that measures the ability of serum to lyse sensitized sheep erythrocytes. This assay requires the nine components of the classical pathway to be present to obtain a normal titer. Also termed CH_{50} assay.
[c] A null allele (i.e., quantity zero or no detectable protein).

levels, the concentration is usually still in the "normal" range. One group has provided data to suggest that the remaining genes are upregulated when one or more C4 null genes are present [64–66]. Also, C4, an acute-phase protein, may increase 1.5- to 3-fold during an inflammatory response [67]. In normal individuals and in SLE patients, there does not appear to be preferential activation (utilization) of one C4 type versus another [66]. This result is in keeping with the evidence that C1s cleaves C4A and C4B with equal efficiency [58, 59]. Thus, in an individual with two C4B genes and one C4A gene, two out of every three molecules of C4 activated would be derived from C4B. However, this does not necessarily mean that two out of every three C4 fragments bound to the IC will be derived from C4B in view of their different ability to react with substrates.

C2 AND FACTOR B

The C2 and factor B (BF) genes are only 421 base pairs apart and reside about 30 kb from the C4A locus (Fig. 1). The C2 and factor B genes encode for mature proteins of 734 and 939 amino acids, respectively [19, 68]. Factor B and C2 consist of three distinct domains: the serine protease, the von Willebrand type A and three of complement control protein repeating motifs (Fig. 7). In structure and function, C2 and factor B are homologous. Two common polymorphic protein variants of C2, as well as a null allele (C2Q0), have been described. Most individuals (>95%) are homozygous for the common (C2C) variant [69]. A restriction fragment length polymorphism (RFLP) subdivides this C2C allele [19]. There are two common factor B alleles, F and S, with gene frequencies of 0.27 and 0.71, respectively,

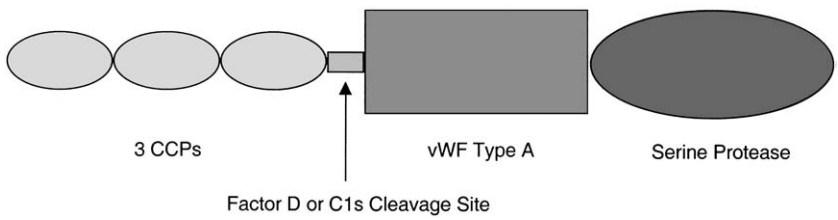

FIGURE 7 Domain structure of factor B and C2. CCP, complement control protein repeat (~60 amino acids each with two disulfide bonds); VWF type A; von Willibrand factor repeat domain.

two less common alleles, F1 and S07, and 14 rare variants [69]. However, there is no association between factor B deficiency and SLE. A patient with homozygous factor BF deficiency has not yet been observed, as this deficiency would most likely result in a severe impairment of the innate immune defense.

Clinical aspects of the association between C4 and C2def and SLE are reviewed in **Chapter 6**. The points to keep in mind for the discussion to follow are that C4def and C2def are inherited on distinct MHC haplotypes and they are part of an activation cascade. Animals and humans lacking an early component of the classical C pathway, up to and including C3, have a markedly abnormal (reduced) clearance of antibody-coated erythrocytes [70], which is representative of a general problem with the handling of IC or apoptotic cells or any other process requiring CP activation.

PARTIAL C4 DEFICIENCY AND SUSCEPTIBILITY TO SYSTEMIC LUPUS ERYTHEMATOSUS

In view of the association between complete complement deficiency and SLE, investigators naturally assessed this relationship in partial C deficiency. In the early 1980s, two groups, one in England [71] and one in Australia [72–74], first reported an association between partial C4 deficiency and susceptibility to SLE. This observation has been confirmed and extended (Table 4) [3, 18, 57].

Although total C4 deficiency is rare, one of every eight or nine Caucasian SLE patients has a partial deficiency in which C4A is lacking (Table 4). This produces a relative risk for SLE of more than eightfold for the C4A-deficient state [7, 71–90]. Fifty to 70% of these C4A-deficient individuals are on the DR3-B8 haplotype [46, 47, 77, 91]. This is the most common, extended haplotype in Caucasians (Table 2), possessing an approximately 30-kb deletion that encompasses both the C4A and the 3′ adjacent CYP21A genes [46, 47] (Fig. 6).

There is clear evidence for a significant increase of the C4A*Q0 allele in SLE patients. However, the association of homozygous C4Adef is not stronger than that for heterozygous deficiency among the patient population, indicating that a threshold might exist for the availability of functionally active C4A in serum to prevent autoimmunity. Also, a technical difficulty in some of the studies relates to evaluating the C4 phenotypes in SLE patients without studying their relatives. In cases where the C4 null allele cannot be confirmed by RFLP studies at the DNA level due to the absence of gene deletions (e.g., in Asian patients), heterozygous C4 deficiency is only reliably detected in family studies by following the segregation of null alleles [1, 3]. Table 4 presents data for several races on the gene frequency of C4A and C4B null alleles, as well as significant associations with HLA class II alleles of DR and DQ loci. There is an association of C4A deficiency with SLE in all Caucasoid populations studied, except for the French and Spanish populations, who exhibit an association with C4B deficiency. C4AQ0 allele frequencies are 0.25 to 0.41 in patients vs 0.10 to 0.23 in controls. As already mentioned, the C4AQ0 allele is linked to the common DR3-B8 haplotype. The DR3 allele is also significantly increased in patients with SLE, although in some studies, the C4A null allele was not increased when the DR3-positive individuals were subtracted from the patient group [82, 92]. In contrast, a survey among 188 American patients to detect nonexpressed C4A null alleles not linked to DR3 by screening for the 2-bp insertion in the C4A gene [52] found that this mutant C4AQ0 allele was significantly increased in particular among SLE patients of Caucasoid origin [93]. The C4B null association in the French and Spanish studies [94, 95] might reflect a different MHC association, as the haplotype HLA-A30, B18, DR3, DQ2, C2C, BF1, C4A3BQ0 is significantly increased only in SLE and insulin-dependent diabetes patients of southern European ancestry. Thus, the strong linkage disequilibrium of C4 null alleles with extended MHC haplotypes makes it difficult to ascertain the genetic contribution of the individual loci within these haplotypes to disease susceptibility in the Caucasoid population.

To help resolve this issue, association studies have also been carried out in other ethnic groups with a different MHC background, particularly in African and Asian populations. In African-Americans, the C4A null allele is also increased in patients with frequencies between 0.15 and 0.2 vs 0.04 and 0.08 in controls. As African-Americans have been influenced by genetic admixture from Caucasoids, data from native African populations would be highly desirable, but are not available yet except for HLA-DR. However, these admixture effects can be excluded for Asians. Except for one study, Chinese [81, 88, 96], Korean [97], and Japanese [79, 98] SLE patients also exhibit a significant increase of C4A null alleles. C4A alleles in Asians are not due to the common deletion of the C4A-CYP21A gene pair observed in Caucasoids [97, 98]. Also, the observed HLA-DR2 association in Chinese and Korean SLE patients appears to be independent from the presence of C4 null alleles. These data further imply that it is the C4A protein deficiency itself that predisposes an individual to SLE.

Although the association of complete and partial C deficiency and SLE is accepted by most investigators, there are dissenting opinions. For example, relative to

complete Cdef, most C2def individuals do not have SLE or a related rheumatic syndrome (Table 5). Also, the frequency of SLE in C2def family members or probands with SLE is less than 30%, suggesting a possible ascertainment bias, as individuals with SLE have their C values determined more often than healthy persons or patients with other autoimmune diseases. While the frequency of C2def in SLE could be somewhat inflated [3], the association with C1q, C1r, C1s, or C4 deficiency cannot be accounted for by such an explanation. In a population survey, Japanese investigators examined complement activity in over 150,000 individuals [99, 100]. Total deficiency of early components was not observed, indicating that an ascertainment bias cannot explain the association [1, 3, 10]. Also, C2def may not be as severe a defect because there is a means to bypass this component in the cascade [43, 101]. Another explanation is that IC fixation by activated C4b alone leads to binding to CR1, which may be sufficient to solubilize and process some immune complexes.

TABLE 5 C2 Deficiency and SLE

C2 deficiency in SLE					C2 deficiency in Normals

[a] Not available.

The C4A deficiency association with SLE has not held up in all populations. As pointed out previously, in French and Spanish Caucasians, in southern Chinese, and, most notably, in Mexican Mestizos (see Table 4), the frequency of C4A deficiency in SLE patients was not significantly greater than in the control population. Furthermore, it has also be taken into consideration that 40 to 50% of all SLE patients do not carry a C4 null gene. Therefore, a more complex situation with several independent risk alleles has to be considered (Table 4). In German Caucasoid patients, the MHC class II allele DR2 was increased significantly [90], and DR2 was also identified as a risk factor in another group of Caucasoid patients [102], in South Africa Blacks [103], in Chinese [81, 103], and in Koreans [97]. Finally, the closely linked HLA-DQA and -DQB loci appear to exhibit significant associations in Caucasoids (DQA1*0501, which is in linkage disequilibrium with the DR3-B8 haplotype [95, 104, 105] and in Africans DQB1*0602 [103]). Thus, it can be concluded that in addition to C4 deficiency, class II genes represent independent pathogenetic risk factors, most likely related to modulation of the immune response.

ACQUIRED C4 AND/OR C2 DEFICIENCY AND SUSCEPTIBILITY TO SYSTEMIC LUPUS ERYTHEMATOSUS

Inherited or acquired deficiency of the C1 inhibitor (angioedema syndrome associated with C1 inhibitor deficiency) is associated with an increased frequency of autoimmunity, especially SLE [106] (see Chapter 6). With a deficiency of the C1 inhibitor, C1 cleaves, in an unchecked fashion, its natural substrates, C4 and C2, causing a marked reduction in their serum levels. In some patients with C1 inhibitor deficiency, C4 and C2 concentrations are chronically so reduced that it simulates a C4/C2def state. A similar situation exists with autoantibodies that stabilize C3 convertases (nephritic factors). Such individuals may have chronically low levels and usually present with either lupus (if the classical pathway convertase is stabilized) or glomerulonephritis (if the alternative pathway convertase is stabilized) [10]. Evidence has also shown that the mechanism whereby hydralazine and isoniazid induce SLE may be mediated through inhibition of C4 function [107]. The concentrations of hydralazine and isoniazid (but not procainamide) that inhibited the activity of C4 by 50% were in the range of those obtained during therapy. Perhaps related to this observation was the finding of an increased frequency of C4A null alleles in hydralazine-induced SLE patients [107].

PARTIAL C2 DEFICIENCY AND SUSCEPTIBILITY TO SLE

Homozygous C2 deficiency is associated with SLE **(see Chapter 6)**. Moreover, the clinical picture may be suggestive of the deficient state. These patients tend to have an early childhood onset of a milder disease process with prominent photosensitive dermatologic manifestations, speckled anti nuclear antibodies [which on further testing demonstrate that the antibody specificity is for the Ro (SSA) antigen], and a family history of SLE. Although an informative subset, complete C2D accounts for less than 1% of all SLE patients. Heterozygous C2 deficiency may be slightly increased in lupus patients compared with controls (Table 5), although a recent comprehensive review concluded that there is probably no association [3]. Heterozygous C2D occurs in 1 to 2% of Caucasians, usually on part or all of the A10 (A25)-B18-DR2 haplotype [108].

IMMUNE COMPLEX PROCESSING AND THE COMPLEMENT SYSTEM

The primary goal of the humoral immune response is to bind (recognition function) and process (effector function) foreign antigens. Immune complex formation with C activation is a beneficial and essential part of this process [8–12, 14, 109–113]. A new concept in this arena is that this scheme may also be important for the handling of host cellular debris [3, 17, 18, 114–116].

C4b and C3b deposit on the IC and thereby maintain the solubility of the IC [11]. The interaction of Ag with Ab may produce aggregates of increasing size in a network of cross-linked complexes. As the size of the IC increases, so does the possibility of precipitation and cryoglobulin activity. C3 serves a critical role in IC formation by limiting their size thereby preventing precipitation. This "maintenance of IC solubility" requires the intercalation of C3b into the IC. A precipitated IC, especially in the vascular bed of organs such as the kidney, induces a local inflammatory reaction (glomerulonephritis, vasculitis). A deficiency of one or more CP components, up to and including C3, predisposes to inappropriate formation and deposition of the IC. Sera from patients deficient in C1q, C1r/C1s, C4, C2, or C3 do not efficiently solubilize preformed IC or inhibit the precipitation of the IC [3, 8–12, 14, 109, 111–113, 117]. Also, particularly with certain types of antigens, C4A is more efficient in preventing IC precipitation than C4B [118, 119]. A corollary here is that the processing of cellular debris, including apoptotic cells, may be a special case of this IC processing [3, 114]. Increasing evidence points to the CP playing a role in the safe disposal of damaged, degenerative, effete, and apoptotic cells.

C4b and C3b are ligands for C receptors [29–31]. This interaction provides a means to ingest the IC that form in tissue at sites of inflammation and to bind, transport, and transfer IC that enter or form in the circulation [110]. In tissue, such IC are ingested by dendritic and mononuclear cells and granulocytes, and the former, especially with migration to a regional lymph node, initiate the immune responses through their antigen-processing activities. In the vascular system, IC become bound to cells (Fig. 8), primarily erythrocytes (a phenomenon known as *immune adherence*), and are then transported to the liver and spleen. In the liver, the IC is transferred to Kupfer cells and the antigen is destroyed. In the spleen, the IC is transferred to follicular-dendritic cells and mononuclear phagocytes for processing. The erythrocyte returns to the circulation, deficient in some of its C3b receptors, but also ready to "shuttle" additional IC. This mechanism probably evolved to facilitate the clearance of IC that arise in the normal course of a humoral immune response to infectious organisms. Analysis of the steps in the pathway indicates that "pathologic" IC may arise from (1) excessive IC formation that overwhelms clearance pathways, (2) inefficient CP activation because of deficient antibody response, e.g., a weak IgG or an IgA response (rather than IgG), (3) C1, C4, C2, or C3 deficiency, or (4) C receptor anomalies. Again, this same set of problems would play out if the CP was involved in the clearance of cellular debris [3, 17, 115, 116, 120, 121].

TARGETED GENE KNOCKOUTS

Pertinent to the preceding discussion, C1q, C4, factor B, and C2/factor B-deficient mice have been produced in the mouse [3, 122, 123]. The major lessons learned from these knockouts have been as follows.

1. On most genetic backgrounds, C1q or C4def mice do not develop spontaneous autoimmunity (namely autoantibodies and a SLE phenotype). When SLE did develop spontaneously, it was on a background of low-level autoimmunity. The message is that the genetic background is extremely important and that C1q or C4d *alone* is unable to cause autoimmunity in most strains of mice (in contrast to the outbred human population).
2. In lupus mouse models, C4def or C1qdef substantially enhanced the phenotype. Disease onset was generally earlier and ANA titers were higher with a greater frequency of DNA antibodies. There was also more pronounced GN.
3. Factor B and C2/factor B knockouts did not develop spontaneous autoimmunity (on any genetic background tested). The effect of these combined deficiencies on lupus mouse models was mixed. In several cases, there was no disease amelioration [3, 123], whereas in another there was lessening in the glomerulonephritis and vasculitis (end organ damage) [124].
4. C3def mouse did not develop spontaneous lupus and it had little or no effect on the lupus mouse models. This is a surprising result, as the dogma would be that C3 activation would mediate some of the tissue damage.

In the following section, more details are given relative to these deficient mice.

C4

High titers of ANA developed spontaneously in C4 KO mice [15, 125] on an autoimmune permissive background. Further, in the Chen study [125], by 10 months of age all female and most male mice had a high-titer ANA and IC deposition in the glomerulus. In these two studies C4 KO mice were also crossed with complement

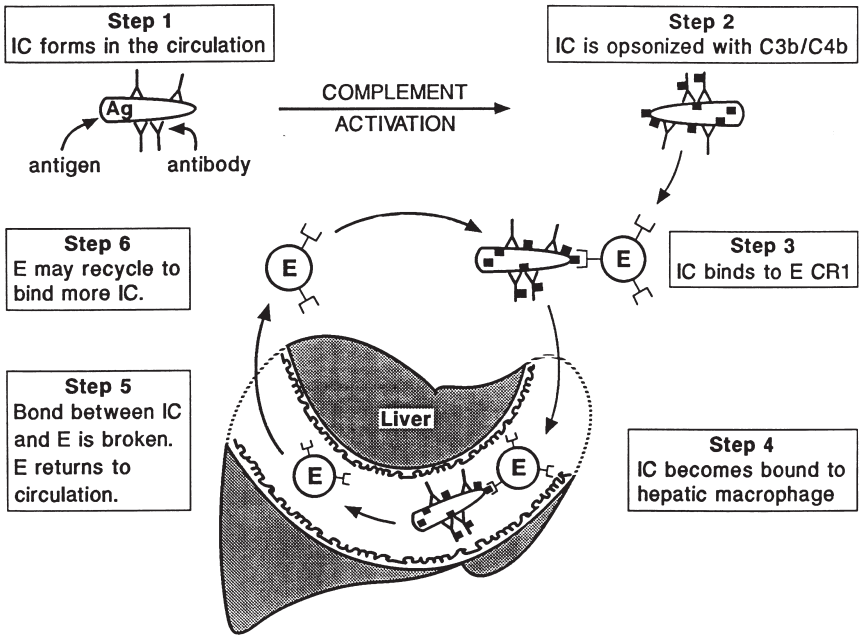

FIGURE 8 Erythrocyte processing of immune complexes (IC) or the "EPIC phenomenon." This diagram delineates a pathway for processing immune complexes (IC). Complement-coated IC adhere to the erythrocyte (E) C3b/C4b receptor, also termed *complement receptor type 1* (CR1). This binding of IC through C3b and its receptor to erythrocytes in most primates and to platelets in most nonprimates is known as the *immune adherence phenomenon*. The erythrocyte transports, like a shuttle or ferry, the IC to the liver and spleen. In the liver IC are transferred to macrophages and destroyed. In the spleen IC are transferred to B lymphocytes, macrophages, and follicular-dendritic cells for antigen processing, leading to a humoral immune response. The erythrocyte returns to circulation, possibly stripped of some of its receptors. This model was initially defined in baboons by Hebert and colleagues, but the essential elements of the scheme have now been described in humans, other primates, guinea pigs, and rabbits. Several different antigen–antibody systems, including tetanus–antitetanus, DNA–anti-DNA, and BSA–anti-BSA, have been analyzed. Adapted from Hebert and Cosio, [110], with permission.

receptor 1 and 2 KO mice, and these mice had a disease phenotype like C4 KO alone. The authors concluded that C4 deficiency causes lupus-like autoimmunity through a mechanism independent of CR1/CR2. In other words, C4b did not need to bind to these complement receptors to mediate its protective effect against the development of SLE. The investigators favor a direct regulatory effect on autoreactive B cells. Two other points were made in these studies that are worth noting. In Prodeus experiments, CR1/CR2 deficiency markedly worsened the disease phenotype (like C4def), whereas C3def had no effect (by itself or in conjunction with C4def).

On another genetic background, C4 KO mice did not spontaneously develop a SLE phenotype [15, 126]. However, if the C4def was bred into a strain that develops SLE, a more *severe* SLE like-illness developed [126]. The authors of this report also believe that this may be related to defects in the central tolerance of B cells. Of note, in all of these C4-deficient animals, C1q levels are normal and therefore its presence does not prevent the autoimmune phenotype from evolving.

In lupus-prone mice, animals null for both C3 and C4 were studied [126]. Interestingly, the disease process was similar in C4def and the combined C3/C4-deficient animals. Thus, severe SLE developed in the absence of C3. These data have two straightforward implications. One is that C3 activation is not required to cause SLE in the mouse, and the second is that C4 contributes much more to SLE susceptibility than C3. It should be remembered that the complement system is involved in susceptibility to as well as in mediating tissue damage

in SLE. Further, human and mouse SLE may have distinct causes and pathogenesis. Nevertheless, in both human and mouse, C4 (and C1q) provides an important protective role against the development of SLE.

Factor B/C2

A combined factor B and C2 [127] or a factor B alone [128] targeted gene deletion mouse did not develop spontaneous autoimmunity. Of interest, factor B/C2-deficient mice crossed into C1qdef did not prevent SLE from developing [129]. Because these animals cannot activate C3, these data again show that C3 is not required for the development of lupus phenotype. In a different model system, factor B deficiency was crossed into lupus-prone mice. The disease phenotype was milder [124]. Because autoantibody levels were similar, these results suggest that factor B plays a role primarily on the effector side of the equation, presumably via alternative pathway amplification of complement activation.

C1q

C1q, of course, is not part of complement gene cluster on chromosome 6 but it is also part of the pathway (as is C4 and C2) required for CP activation. About 50% of mice on a mixed genetic but autoimmune-prone background developed high titers of ANA [16, 130, 131]. By 8 months of age, 25% of the mice had glomerulonephritis with immune deposits. The authors also demonstrated larger numbers of apoptotic bodies in diseased glomeruli. Their hypothesis is that increased numbers of apoptotic cells are present because of a C-dependent clearance defect for processing autoantigens. It is difficult to accept, however, that C1qdef is the whole story in view of data with C4def mice (in the setting of normal C1q). Perhaps it is hierarchy, as pointed out in another publication [16] by these authors, in which C1q > C4 >>> C2 in leading to SLE. To buttress this argument, they point out that C1q could have two roles. One is to serve as a ligand for C1q receptors on phagocytes and the other being to activate the CP, thereby providing additional ligands for the disposal of apoptotic cells.

In a more recent study of C1qdef, the effect of the genetic background on disease expression was further employed [130]. In two strains, the autoimmune phenotype was not altered (worsened or improved), but in a third strain the disease process accelerated with the production of more autoantibodies and a more severe and earlier onset of glomerulonephritis.

FURTHER SPECULATION ON THE ASSOCIATION BETWEEN SYSTEMIC LUPUS ERYTHEMATOSUS AND COMPLEMENT DEFICIENCY

As discussed earlier, C is activated by IgG or IgM, and C activation through C3 is required to efficiently eliminate many infectious agents. This cannot be accomplished readily in a C-deficient host and therefore would potentially predispose such an individual to more prolonged exposure to infectious or damaged self-materials.

One problem thus faced by a C-deficient host is defective clearance of foreign antigens or damaged self constituents. As discussed in the preceding section, the lack of C3b deposition on an IC leads to impaired antigen localization such as to follicular areas of the spleen. This appears to be the critical factor in the poor antibody response of such individuals [132–134]. For example, if C4A, C2, or C3def guinea pigs or humans are immunized intravenously with ØXC174, a relatively low-titer IgM response is produced. Moreover, a secondary IgG response is not made, even with repetitive intravenous immunizations. A failure to localize the antigen to the follicular area of the spleen probably accounts for the defective immune response. The primary and secondary immune response can be rescued in C4def guinea pigs by adding purified human C4A but not C4B or an adjuvant with the primary immunization [62]. This presumed failure of antigen presentation is explained more simply by C4A being required for efficient opsonization of this antigen. A plausible scenario then for deficient antibody production in C deficiency is defective antigen localization. CR1 (the C3b/C4b receptor) and CR2 (C3d receptor) are expressed by B lymphocytes and follicular-dendritic cells. On both cell types they facilitate the localization of C-coated IC to B cells and enhance B-cell activation [30, 31, 135]. In these model systems, immunization with increased amounts of antigen lead to a normal immune response.

In a C-deficient host there are several avenues to a vasculitic state. Perhaps the simplest is the failure to efficiently eliminate an infectious material. Prolonged antigenemia could result (with or without significant tissue damage to the organ, which harbors the infection). Chronic antigenemia is the setting for impaired IC formation, such as at Ab-Ag equivalence or slight Ag excess. In experimental serum sickness models, such IC are prone to deposit in glomeruli and other tissues. Clinical examples of this type of problem are chronic serum hepatitis B and C infections [136]. Although we do not understand the reason for the poor antibody response

and failure to eliminate the virus, the consequences are clear: chronic antigenemia, IC formation, and IC deposition in undesirable sites, resulting in glomerulonephritis or a more generalized vasculitic syndrome.

Hepatitis B and C are surely not the only such infections of humans that produce this type of a syndrome. More likely, hepatitis is the one that we recognize because of its means of transmission and because of sensitive serologic and biochemical markers for these infections. Complement deficiency would contribute to and potentiate other defects in the immune response. In this context, it is interesting to note that C4A deficiency also appears to play a major role in nonresponders to HBsAg vaccination. It has been demonstrated that this nonresponse is significantly associated with C4A null alleles independent from the presence of the DRB1*0301 allele [137, 138]. This line of reasoning also suggests that some forms of SLE actually represent immune deficiency syndromes. Lupus associated with C deficiency or hypogammaglobulinemia are two examples.

In a C-deficient host, even normal amounts of IC (such as those that form because of passive absorption of bacterial antigens from epithelial surfaces) or in association with infections or associated with physiologic tissue turnover and cell death would have a greater likelihood of being processed inappropriately. The prevention of IC precipitation in vascular structures, their adherence to erythrocytes or leukocytes, and their transport to and deposition in the liver and spleen would all likely be impaired. Thus, if such individuals develop a condition leading to chronic antigenemia, they would be at greater risk for mishandling IC than a normal host. Lachmann and Walport [10] have noted that autoantibodies arise transiently in association with infections such as infectious mononucleosis and following tissue necrosis such as in myocardial or pulmonary infarctions. They suggest that a deficiency of effector mechanisms, especially immune complex processing, induces pathogenic inflammatory reactions at extrahepatic sites. A vicious cycle then ensues as intracellular antigens are exposed and become autoantigens, possibly modified by the inflammatory response with cell injury or death; i.e., the normal decay of an immune response does not occur.

DETECTION OF COMPLEMENT DEFICIENCY

A complete deficiency of a C-activating component is usually first suggested by the finding of a very low or zero whole complement (THC or CH_{50}) titer [139, 140]. This assay requires C1–C8 to be present to give a measurable titer and C9 to give a normal titer. Partial component deficiency is more difficult to ascertain. For example, a 50% reduction of C4 or C1 or most other components is not reflected by a 50% reduction in a THC. Usually, in this case the THC is within the normal range. The possibility of a partial C4 deficiency is often first suggested by a lower than expected antigenic level of C4 in a patient with SLE or a related vasculitic/autoimmune syndrome. A typical clinical example is a lupus patient with a persistently low C4 but who is in clinical remission and has a normal C3. The clinical question then becomes whether this represents an inherited partial C4A or C4B deficiency or "subclinical" complement activation by IC. Separation of these two possibilities can be difficult but a semiquantitative assessment by electrophoretic separation of C4A and C4B can be helpful [37, 141–145]. Several commercial laboratories now test for the presence of and quantitate the concentration of C4A and C4B. HLA typing may also be useful, as two-thirds of C4A-deficient alleles in the Caucasian population are on the DR3B8 haplotype.

Several experimental issues, however, may complicate these determinations of partial C4 deficiency, and improved means for detecting such deficiencies are needed. Monoclonal antibodies specific for C4A or C4B are available [46, 147], and several reports describe capture assays to measure the antigenic levels of C4A and C4B [64–66, 146]. Finally, molecular probes or polymerase chain reaction-based assays provide a means to assess RFLP variants and detect patterns specific for deletions such as the DR3-B8 haplotype (by standard Southern blotting or pulsed field gel electrophoresis) [19, 47, 69, 148–150]. If possible, genetic typing at the protein and/or DNA level of the patient and his relatives in family studies allows reliable assignment of C4 null alleles [69, 151]. To summarize, at present, the detection of complete complement deficiency states or homozygous C4A or C4B deficiency can be accomplished easily and such data are of utility to the clinician in caring for lupus patients. Partial C4A or C4B or C2 deficiency is more complicated to assess and is currently of no clinical utility.

COMPLEMENT DEFICIENCY AND SYSTEMIC LUPUS ERYTHEMATOSUS

György Ábel
Vincent Agnello

The exact etiology of systemic lupus erythematosus (SLE) is not known. Evidence from human and animal studies suggests that multiple factors, including genetic, endocrine, and environmental components, are involved. Hereditary complement deficiency, especially deficiency of an early complement component of the classical pathway, is a genetic factor associated with SLE and SLE-like disease in humans and most recently in mouse models with "knockout" of these components. In addition to hereditary deficiencies of complement, acquired deficiencies of the early components that persist over long periods of time may be similarly associated with SLE and SLE-like disease. The clinical observation that both genetic and acquired deficiencies of the early components are associated with SLE first suggested that deficiencies of the early complement components lead to SLE and SLE-like disease in some patients and that these components had distinct biologic activities that were part of the host's defense to this disease [1, 2]. Since those initial observations, clinical data accumulated on patients with early complement component deficiencies (reviewed in this chapter), the delineation of the genetics of the early complement components, and complement component "knockout" mice models (reviewed in Chapter 5) have proved evidence supporting this hypothesis.

This chapter reviews the association of hereditary and acquired complement deficiency states with SLE and SLE-like disease. The emphasis is on clinical manifestations in patients with these deficiencies, the differences in many patients from classic SLE, and the implication of these differences for current hypotheses on the specific role of the early complement components in SLE. The chapter begins with a description of the complement system. Next, the biological activities and the associations of deficiencies of the complement system with disease are described to provide the context for this review on the early components. The genetics of complement components and the clinical manifestations of genetic and acquired complement deficiencies are then reviewed with the exception of the genetics of the C4 component of complement are reviewed in the previous chapter (Chapter 5). The chapter concludes with a speculative discussion of the role of complement deficiency in SLE, including recent studies and hypotheses on the role of early complement components in apoptosis.

THE COMPLEMENT SYSTEM

The complement system consists of numerous proteins: plasma proteins that are inactive enzyme precursors, plasma or cell-bound regulators proteins, and cell membrane glycoproteins, which serve as specific receptors for complement protein cleavage fragments (Tables 1–3). Twelve proteins are present in plasma as inactive precursors, which can be activated by a complex series

of highly specific biochemical reactions. Seven of the components (C1r, C1s, C2, C3, C5, B, and D) have proteolytic activity when activated. Activation for C2, C3, C4, and C5 involves limited proteolytic cleavage and results in the generation of biologically active peptide fragments. Eight additional plasma and cell-bound proteins have been identified that regulate the activation and degradation of all complement proteins and cleavage fragments.

TABLE 1 Proteins of the Complement System

	Molecular weight	Serum concentration (μg/ml)
Classical pathway		
C1q	460,000	65
C1r	83,000	50
C1s	88,000	40
C4	206,000	640
C2	117,000	25
C3	180,000	1,600
Alternate pathway		
C3	180,000	1,600
Factor B	93,000	200
Factor D	24,000	1
Lectin-binding pathway		
MBL	32,000 (subunit)	1
MASP-1	100,000	7
MASP-2	75,000	??
Membrane-attack pathway		
C5	180,000	80
C6	128,000	75
C7	121,000	55
C8	154,000	55
C9	79,000	60

Classical Pathway Activation

Activation of the complement system is initiated in three different ways (Fig. 1). There is a marked difference in the mode of activation for the three different pathways. Antibody–antigen complexes initiate activation of the classical pathway, whereas alternative pathway activation occurs in the absence of antibody. The classical activation pathway involves proteins C1q, C1r, C1s, C2, C4, and C3. The C1 component consists of three subunits: C1q, C1r, and C1s. The C1q molecule consists of six units of polypeptide chains, A, B, and C in triple helices that form a bouquet-like structure with six globular "flowers" at the carboxyl-terminus end, and a stalk that has a collagen-like composition at the amino-terminal end. The six globular structures each contain a combining site that are receptors for a specific sequence found on the Fc portion of IgG1, IgG2, IgG3, and IgM. The collagen portion can bind a variety of polyanionic substances, including DNA [3, 4] that provides a potential nonimmune activation pathway. Immunoglobulins, when complexed to an antigen, will bind C1q and cause activation of the molecule. Activated C1q generates enzymatic activity in C1r, which cleaves C1s and generates the first major enzyme in the complement system, C1 esterase (C1). C1 esterase then cleaves C4 and C2, whose major cleavage products form a bimolecular complex, C4b2a, which has C3 convertase enzymatic activity. The C3 convertase cleaves C3 and generates a small fragment, C3a, and a larger fragment, C3b. Attachment of C3b to the C4b2a complex forms the C4b2a3b complex, which exhibits C5 convertase activity. The generation C5 convertase leads to activation of the membrane attack complex.

TABLE 2 Complement Regulatory Proteins in Serum

Protein	Abbreviation	Molecular weight	Serum concentration (μg/ml)	Regulatory action
C1 esterase inhibitor	C1-INH	90,000	180	Binds to activated C1r, C1s, inactivates C1qrs esterase
C4 binding protein	C4bp	560,000	250	Enhances decay of C4b2a and cleavage of C4 by I
Factor I	I	88,000	34	Inactivates C4b and C3b
Factor H	H	150,000	500	Enhances decay of C3bBb and cleavage of C3b by I
Anaphylatoxin inactivator		310,000	35	Inactivates C3a, C4a, and C5a
S protein (vitronectin)	S	83,000	300	Binds to and inhibits the C5b-7 complex
SP40, 40 (clusterin) (apolipoprotein J)	Apo J	80,000	75	Binds to C5b-6 and prevents conversion to C5b-7
Properdin	P	220,000	20	Enhances stability of C3 and C5 convertases

TABLE 3 Cell Membrane Recognition and Regulatory Proteins

Protein	Molecular mass (kDa)	Cell type[a]	Complement protein bound	Protein function
CR1 (CD35)	160, 190, 220, or 250	PMNs, RBCs, T and B lymphocytes, eosinophils, monocytes, macrophages, dendritic cells, glomerular podocytes	C3b, C4b, iC3b, C1q	Control of C3 breakdown, immune complex binding
CR2 (CD21)	145	B lymphocytes, NK cells, follicular dendritic cells	C3d, C3dg, iC3b, C3b, C3c	Regulation of B cells, EBV receptor
CR3 (CD11b/CD18)	165, 95 dimer	PMNs, monocytes, macrophages,	iC3b	Mediates phagocytosis, NK cells, cytotoxic T cells enhances antibody synthesis
CR4 (CD11c/CD18)	150, 95	PMNs, monocytes, macrophages, NK cells, cytotoxic T cells	C3d, g	Unknown
MCP (CD46)	45в70	Lymphocytes, PMNs, monocytes, platelets, endothelial cells, epithelial cells, fibroblasts	C3b, C4b	Control of C3 cleavage
DAF (CD55)	70	Lymphocytes, PMNs, monocytes, platelets, endothelial cells, epithelial cells, RBCs, fibroblasts	C4b2a, C3bBb	Decay of C3 and C5 convertases
MIRL (CD59)	19	RBCs, renal cells, all WBCs, endothelial cells, fibroblasts	C5b-8	Prevents formation of MAC complex
HRF	65	RBCs	C8, C9	Prevents insertion of MAC into cell membranes
C3a/4a receptor	?	PMNs, mast cells, macrophages	C3a, C4a	Binding anaphlatoxins
C5aR (CD88)	50	PMNs, eosinophils, monocytes, macrophages, mast cells, platelets, vascular endothelial cells	C5a	Binding anaphylatoxin
gC1q (globular)	33	PMNs, B cells, monocytes, macrophages	C1q heads	Mediates phagocytosis
C1qRp (collagen) of adhesion molecules	126	Myeloid cells, monocytes, macrophages, vascular endothelium	C1q tails	Mediates phagocytosis, upregulation
cC1qR complex	60	Wide cell distribution, WBCs, platelets, fibroblasts, smooth muscle, vascular endothelium	C1q tails, MBL, SP-A, SP-B (collectins)	Mediates phagocytosis, immune binding
C3e R	?	PMNs	C3e	Release of PMNs from bone marrow
Factor H receptor	?	PMNs, B cells, macrophages	H	?
Factor Ba receptor	?	PMNs, B cells, macrophages	Ba	?

[a] NK, natural killer; WBC, white blood cells.

Alternate Pathway Activation

Activation via the alternate pathway involves factors B, D, and C3, but the specific molecular interactions are not as clearly understood as for the classical pathway. No specific recognition sites analogous to the antibody–C1q interaction have been identified for the alternate pathway. It is known that activation occurs on the surface of certain fungi, bacteria, lymphoblastoid cells, and virus-infected mammalian cells, which have repetitive polysaccharide or lipopolysaccharide structures and lack sialic acid. Alternate pathway activation is mediated by C3, which contains a thioester bond that may hydrolyze spontaneously and form covalent bonds with certain types of chemical compounds. This may lead to the conversion of C3 to a C3b-like molecule, which interacts with B and magnesium. This C3B complex is then cleaved by B and is then assembled

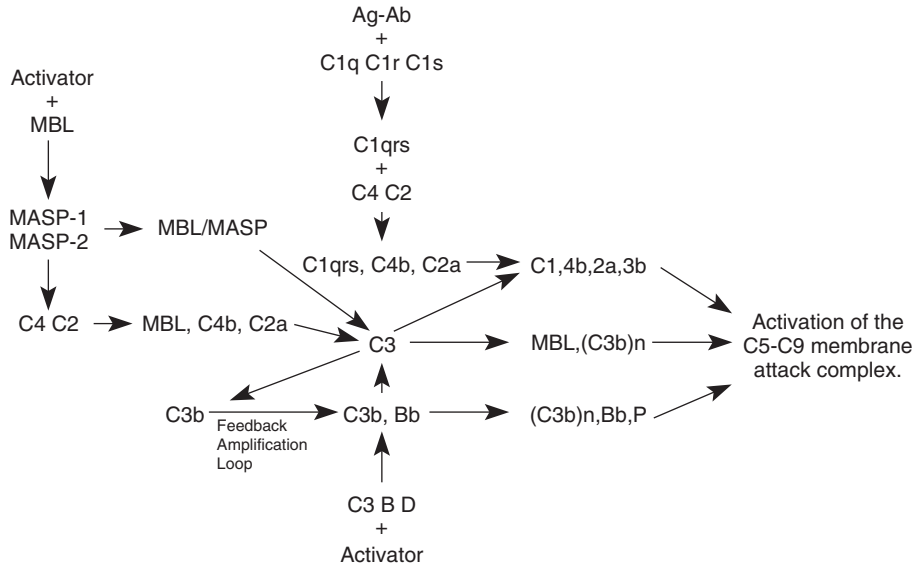

FIGURE 1 Simplified scheme of the pathways for complement activation. Table 1 lists the symbols used for each complement component. Activation fragments are designated by lowercase letters.

into larger complexes containing multiple molecules (C3bBb)n, and the C3 convertase molecule is generated. The C3 convertase molecule then cleaves additional C3 molecules, which also bind B and ultimately generates the C5 convertase that leads to the activation of the membrane attack complex.

The activation pathways utilize different complement components but are similar in that both pathways generate C3 convertase and C5 convertase enzymes. The C3 convertases generated are C4b2a and C3bBb. These are structurally similar complexes in that the C2 and factor B proteins have very similar amino acid sequence and are encoded by two genes closely linked on chromosome 6 thought to have arisen by gene duplication. The C5 convertases C4b2a3b and (C3bBb) are also very similar in that both contain activated C3b molecules. The cleavage of C5 by esterases generated by either pathway initiates the activation of the remaining complement proteins C5–9 and the assembly of the membrane attack complex.

Mannan-Binding Lectin Activation Pathway

A third pathway of complement activation was first reported by Ikeda *et al.* [5] where mannan-binding lectin (MBL) was demonstrated to activate the classical pathway. MBL is a protein with a complex structure composed of both a collagenous region and a lectin-binding domain. MBL has a "bouquet-like" structure with some structural similarity and multiple binding domains similar to C1q and IgM. MBL binds to a wide variety of sugars, including *N*-acetylglucosamine, mannose, *N*-acetylmannosamine, fucose, maltose, glucose, galactose, and *N*-acetylgalactosamine. This lectin-binding activity is weak with single sugars but the functional avidity becomes very strong with repeating sugar structures such as those found on a variety of bacterial cell surfaces, yeasts, and viruses, including human immunodeficiency virus (HIV)-1, HIV-2, and influenza A. In plasma, MBL is associated with a second protein, mannose-associated serine protease (MASP), which has a similar structure and function to C1r and C1s. A second protease, MASP2, which has structural homology to MASP, C1r, and C1s, may also be associated with the MBL/MASP molecule [6]. When the MBL/MASP is activated by binding to multiple sugar molecules, the serine protease is capable of cleaving both C4 and C2, thereby activating the complement pathway in a manner analogous to that of the C1qrs complex. In addition, the MBL/MASP complex can also cleave C3 directly and activate the complement pathway in this method [7]. This MBL/MASP activation is downregulated by α_2-macroglobulin in a manner analogous to the C1 esterase inhibitor (C1-INH) control mechanism [8, 9]. *In vitro* MBL can also associate with the activated C1r–C1s complex and cause C4 and C2 activation.

Membrane Attack Complex Activation

The membrane attack complex utilizes complement components C5, 6, 7, 8, and 9. Initially, cleavage of C5 by C5 convertase produces a small fragment C5a and a larger fragment C5b. The latter forms a stable trimolecular complex with C6 and C7. The complex has the

ability to bind to biological membranes. C7, C8, and C9 are then adsorbed to the complex. After initiation by the enzymatic cleavage of C5, the self-assembly of the membrane attack complex occurs without further enzymatic activity. The complex, when fully assembled, forms a cylindrical structure that extends through the entire lipid bilayer. Electron microscopy has been used to demonstrate that the structure has a circular shape with a central hole. Assembly of the attack complex disrupts the cell membrane and results in cell lysis. Leakage of the cell membrane occurs with C8 binding and is accelerated with the addition of C9.

Regulation and Control of Complement Activation and Cell Lysis

A large number of proteins have been identified that influence the initial activation, amplification, cell membrane deposition, and biological effects of the complement components (Table 2). Nine plasma proteins influence the activation, assembly, and stability of complement esterase enzymes in the fluid phase, whereas four transmembrane proteins influence the activity and stability of C3b and the deposition and stability of the membrane attack complex on cell membranes. The plasma proteins that influence the classical and alternate pathway activation steps are (1) C1-INH, which binds to both activated C1r and C1s and causes disassembly of the activated C1qrs complex; (2) C4BP, which causes decay of the C4b2a complex and increases the C4b cleavage by factor I; (3) H, which causes decay of the C3bBb complex and increases the C3b cleavage by factor I; (4) I, which degrades C4b and C3b; (5) S protein, which binds to C5b–7 and prevents binding of the complex to cell membranes; (6) decay accelerating factor (DAF), which causes decay of the C3 and C5 convertases; (7) serum apolipoprotein SP40, 40 (clusterin) binds to C5b–6 and prevents binding of C7, and also binds to the soluble SC5b–9 complex in solution; and (8) properdin, which binds to C3 and C5 convertases of the alternate pathway and stabilizes them. The first eight proteins all exert negative effects on the activation and amplification of the complement system, whereas properdin significantly, positively amplifies alternative pathway activation. Two other proteins that have factor H-like activity have been identified in plasma: factor H-like protein 1 (FHL-1) and factor H-related 1 β-protein [10]. Both of these proteins have cofactor activity to enhance the factor I-mediated cleavage of C3b.

Six transmembrane glycoproteins, H, CR1, MCP (membrane cofactor protein), DAF, MIRL (membrane inhibitor of reactive lysis), and HRF (homologous restriction factor) have been identified and characterized that influence complement protein functions (Table 3). CR1, MCP, decay accelerating factor (DAF), and H all affect the binding and stability of C3b complexes to the cell membrane. H, DAF, and CR1 cause disruption of the C3bBb complex, the activity described as DAF. Factor H, MCP, and CR1 all cause degradation of C3b into fragments iC3b and C3f. CR1 and I then cause further degradation of iC3b into C3c and C3dg. These activities take place at the cell membrane, but secreted and transmembrane forms of factor H and DAF have been identified that may exert inhibitory effects in the plasma phase as well as at the cell membrane. Because DAF and MCP are found on many cell types, they are thought to be involved in protection of a variety of cells from cell lysis. HRF and MIRL inhibit the binding of the membrane attack complex (MAC) into the cell membrane, HRF binds to C9 and C9, and MIRL binds to C5b–9 to prevent polymerization of C9.

Seven additional transmembrane glycoproteins have been identified that bind complement components and mediate a variety of biological functions: CR2, CR3, CR4, C3aR, C5aR, cC1qR, gC1qR, and mannose-binding lectin receptor (MBLR) (Table 3). CR2 (CD21) found on B cells binds iC3b, C3d, g, and C3d-containing immune complexes. Immune complex binding to B cells has been shown to augment B-cell responses and increase the efficiency of antigen processing by B cells [11]. Coligation of the antigen receptor and CR2 on the B-cell membrane is also important in the immune response to T-dependent antigens, which is mediated by the CD21 ligand CD23 [12]. CR2 is also the B-cell membrane receptor for the Epstein–Barr virus (EBV). CR3 (CD11b/CD18) and CR4 (CD11c/CD18) both bind iC3b and immune complexes containing iC3b. Binding of the complexes causes cell activation and a variety of biological responses. Glycoprotein inositol (GPI)-linked proteins including CD14, CD16b, and CD87 are associated both physically and functionally with CR3. In a number of studies reviewed [13], studies have shown that glycoprotein inositol (GPI)-linked proteins utilize CR3 to signal across membranes. Studies have indicated that the CR3 surface protein may be a major binding site for *Borrelia burgdorferi* (Lyme spirochete) and *Mycobacterium tuberculosis* and thus play a major role in the binding of the organisms to phagocytes in the absence of immunoglobulin or complement components [14, 15]. C3aR and C5aR bind the anaphylatoxin complement fragments and mediate the biological activities of blood vessel dilation, smooth muscle contraction, and chemotaxis. There are at least three receptors that bind C1q: cC1qR, which binds to the collagen portion of the C1q molecule; gC1qR, which binds to the globular heads portion of the C1q molecule; and CR1, which binds C1q in addition to C3b. cC1qR has also been reported to bind mannan-binding lectin and

conglutinin. A second MBL-binding receptor (MBLR) has also been described that has sequence homology with calreticulin.

BIOLOGICAL ACTIVITIES OF THE COMPLEMENT SYSTEM

Cytolysis appears to be a main function of the complement system that requires a complete sequence of activation of most of the soluble complement components. In addition to cytolysis, a variety of other biological activities are mediated by proteins of the complement system. The major activities associated with various complement components are shown in Table 4. For activation of the membrane attack system, all components of the classical or alternative pathway are required. The cytolytic process is more efficient in the classical pathway. The actual lysis of the membrane is a function of C8 and C9 molecules binding to the cell membrane and C9 molecules polymerizing into a circular complex.

Opsonization of particles is a second major biological function of the complement system. Opsonization is mediated by the C1q, MBL, and the C3b split products of C3 generated during complement activation. Opsonic activity can be generated either by antibody–antigen complexes or in the absence of specific antibody by alternative pathway activation or MBL binding and complement activation [16]. Alternate pathway-activated opsonization and MBL-mediated opsonization are critical host defense systems for unimmunized individuals.

TABLE 4 Major Biological Activities of Complement Components

Activity	Component
Enhancement of phagocytosis	C3b, MBL
Viral neutralization	C1C4b
Viral lysis initiation	C1q
Clearance of apoptotic debris	C1q, C4b
Enhancement of yeast phagocytosis	C5b, MBL
Solubilization of immune complexes	C3, B, D, P, H, I
Clearance of immune complexes	C3b, CR1
Mediators of inflammation	
Chemotactic factor	C3a, C5a, C5b67
Anaphylatoxin	C3a, C5a
Enhanced vascular permeability	C2 fragment (C2 kinin)
Marrow leukocyte release	C3e
Cell lysis	C8, C9
Modulation of immune response	C4b, C3b, C3d, CR2

A second major function of complement is the clearance of soluble immune complexes [17]. This activity is mediated by receptors for the activated complement components that are found in a variety of cell types. The majority of immune complex clearance is usually done via binding to the CR1 receptor present on red blood cells (RBCs). RBCs transport the complexes to the spleen where they are removed by macrophages and other cells of the reticuloendothelial system.

A major biological activity of the alternative pathway, which has been demonstrated *in vitro*, is that six components of the alternative pathway alone are capable of solubilizing insoluble immune complexes. This may represent a major physiologic mechanism for processing immune complexes and hence a host defense system to immune complex disease.

Other defense mechanisms may be mediated by the early components of the complement system. *In vitro* studies demonstrated that C1 and C4b are sufficient for the neutralization of certain viruses coated with nonneutralizing antibodies. Other studies have demonstrated a direct role for complement in the lysin of virally infected cells. In several studies, C1q bound directly to oncornaviruses in the absence of antibody. Although antigen–antibody complexes are the major mode of activating the classical pathway, evidence shows that C1 can be activated by diverse other substances in the complete absence of antibody [18, 19]. These substances include a wide variety of proteins, lipids, carbohydrates, and polyionic molecules.

Additional biological activities are mediated by other cleavage products of complement components. Patients with hereditary angioneurotic edema produce a peptide, C2 kinin, which enhances vascular permeability. The C2 peptide is generated by the cleavage of C2. C3a has both chemotaxic activity and anaphylatoxic activity. A breakdown product of C3b, C3e, appears to induce leukocyte release from the marrow. C5a has a relatively weak anaphylatoxic activity but a potent chemotaxic activity. C5b has been shown to enhance the phagocytosis of yeast. The complex C5b, 6, 7 has also been shown to have chemotaxic activity. Some complement fragments are also involved in modulation of the immune response by their specific receptors on lymphocytes.

The biological activities of the complement components are regulated and mediated by plasma and membrane-bound complement receptors. The anaphylatoxin inactivator (carboxypeptidase B) exerts a negative effect on C3a, C4a, and C5a, enzymatically cleaving a terminal arginine residue and inactivating the anaphylatoxin activity. At least 16 different transmembrane proteins have been identified that have specificity for activated complement fragments (Table 3). These recep-

tors bind complement components and then play a role in activation of the cells and mediating the biological roles of those cells in phagocytosis (CR1, CR3, CR4), B-cell function (CR2), anaphylatoxic responses (C3aR and C5aR), and lymphocyte migration (C3e). The biological functions mediated by CR4 and the receptors for C1q, C3aR, and C5aR have not yet been well characterized.

GENETICS OF COMPLEMENT COMPONENTS

Genes encoding proteins of the complement system are clustered on at least three different chromosomes (see also Chapters 4 and 5). The genes for C2, factor B, and two genes for C4, C4A and C4B, are located on the short arm of chromosome 6 in the major histocompatibility (HLA) complex [20–22] (see Fig. 2). In this chromosomal area are genes that control three different host defense systems: self-recognition (HLA-A, B, C), immune response (HLA-Dr, Dp, Dq), and complement (C2, C4A, C4B, B). Factor B and C2 genes are closely linked on the chromosome and are separated from each other by only 421 bases. They are about 30 kb from the C4A locus, which is separated from the C4B locus by 10 kb. As seen with the HLA class I and class II genes, the complement genes in the HLA complex show a high degree of polymorphism. This polymorphism is present at both protein and DNA levels. Because these four genes are closely linked, they are usually inherited as a single group and the polymorphisms defined by complotypes.

For patients with hereditary C2 deficiency, a single 28-bp mutation that results in a pseudogene incapable of producing C2 protein is present in essentially all Caucasian cases. The majority of patients have the complotype S042 and the HLA B18, DR2 phenotype [23]. In studies in Sweden [24], the prevalence of the 28-bp deletion was found to be 5.8% of SLE patients; 5 of 86 patients were heterozygous. In Brazilian studies [25], the prevalance was 6.6% in SLE patients and 2.2% for blood donors. In this study, patients with heterozygous C2 had an earlier disease onset, a higher prevalance of oral ulcerations, and a lower prevalance of anti-dsDNA antibodies compared to patients with normal C2 levels. In North American studies [26], the 28-bp deletion gene frequency was 0.0246 for SLE patients and 0.0070 for normal controls. The 28-bp deletion was not seen in 127 Black SLE patients or 194 Black controls.

For factor B, four allelic forms have been identified (S, F, F1, and S1) with gene frequencies of 0.71, 0.27, 0.01, and 0.01, respectively. Additional polymorphisms can also be demonstrated for factor B by restriction fragment length polymorphism (RFLP) [27]. Complotypes missing the factor B gene have not yet been described [28].

Polymorphism of C4 is very complex. There are two genes, C4A and C4B, that encode C4 proteins and are highly homologous at both protein and DNA sequence levels. For a review of the genetics of C4, see Chapter 5.

Polymorphism has also been demonstrated for the other complement proteins—C3, C6, C7, and C8 [28]—but is much more limited than that which exists for genes within the HLA complex. Polymorphism has not been identified at the protein level for C1q, C1r, C1s, C5, or C9. The C6, C7, C8, and C9 proteins are all structurally similar to each other; C6 and C7 are single polypeptides, and C8 and C9 are dimers containing α and β chains. The genes for C6, C7, and the α and β chain genes of C8 are located on chromosome 1; C6 and C7 genes are very closely linked. An increased incidence of deficiencies of C6 and C8 has been identified in Blacks and deficiencies of C7 and C9 in Japanese. Two types of C8 deficiencies have been identified: type I, in which there are low levels of the β chain but normal levels of the α chain (which is functionally normal), and type II, in which there are dysfunctional α subunits and low levels of β chains in the plasma [29]. The majority of C8 deficiencies are type I.

There are two polymorphic forms of C3: S and F. The C3F form has weakly been associated with glomerulonephritis. Studies comparing the S and F forms have demonstrated that the S form was slightly more efficient in hemolytic assays than the F form [30]. No differences were detected in the ability of the S and F forms to interact with factors H, 1, and CR1. The C3 protein has significant homology to both C4 and C5 proteins. The C3 gene is located on chromosome 19. C3 deficiencies

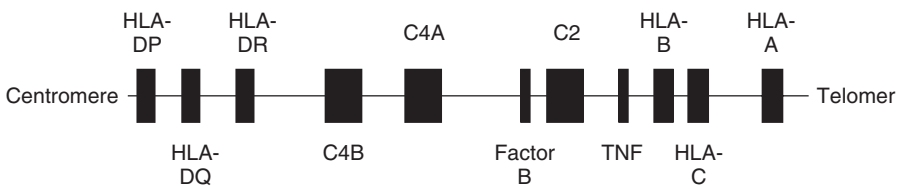

FIGURE 2 Simplified representation of the HLA gene complex of chromosome 6.

are very rare; in the single case analyzed at the DNA level, a stop codon was present within exon 18, leading to premature termination of the MRNA, and no C3 protein product was produced.

The C1 molecule is composed of one C1q, two C1r, and two C1s molecules. C1r and C1s are highly homologous proteins, each containing two short consensus repeats (SCRs; see later). The molecules contain low-density lipoprotein (LDL) receptor type B sequences and serine protease portions. The genes for C1r and C1s are closely linked within 50 kb and and are found on chromosome 12. The genetics of C1q have been reviewed previously [31]. Three different genes within 24 kb on chromosome 1 encode the A, B, and C, and chains of C1q. In contrast to other complement component genes, there is no polymorphism of the C1q genes. Single base mutations in one of the three genes are thought to be responsible for the C1q deficiency phenotype. Two types of C1q deficiencies have been identified. In type I, no C1q protein is assembled because premature chain termination takes place. In type II C1q deficiency, the quantity of C1 is normal but the molecule is nonfunctional. C1q molecules that cannot polymerize into the high molecular weight complex are formed and result in excess low molecular weight C1q in the plasma. Only individuals homozygous for the defective C1q genes have the C1q deficiency phenotype; heterozygous individuals have normal C1q and CH_{50} levels.

The MBL gene has four exons and encodes a peptide chain of 32 kDa. Three of these peptide chains associated together to form a basic subunit that has an N-terminal "neck" region, a collagenous triple helix "arm," and a C-terminal "flower" that is the lectin-binding site. MBL can exist as dimers, trimers, tetramers, pentamers, and hexamers of this basic subunit bound together by disulfide bonds in the "neck" region. The three-dimensional structure of the MBL molecule is very analogous to the C1q structure. In the human plasma, the majority of MBL is dimer, trimer, or tetramer in structure. The MBL gene contains four exons and is located on the long arm of chromosome 10 in a gene cluster that also contains the genes for SP-A and SP-D and a pseudogene SP-A. The DNA sequence has features typical for other acute-phase proteins in the 5N region, including a heat shock consensus element, three glucocorticoid responsive elements, and a sequence with similarity to that of serum amyloid A protein. The gene encodes protein with homology to a family of other proteins of the collectin family that includes pulmonary surfactant proteins SP-A and SP-D and conglutinin. Three different point mutations that cause immunodeficiency and significantly decreased MBL plasma levels have been identified [32, 33]. The mutations are in exon 1 at codons 52, 54, or 57 and cause amino acid substitutions that influence the protein function. The changes at 54 and 57 disrupt the structure of the collagen-like region and result in aberrant subunit structures that cannot form multimers. In addition, the codon 54 change results in the inability of the MASP protein to bind to the MBL protein and results in a lack of function of the complex [34]. The codon 54 and 57 mutations show dominant inheritance, and heterozygous individuals have MBL less than 10% of normal plasma levels. The change at position 52 introduces an additional cysteine residue and may result in extra disulfide bond formation. Patients heterozygous for the codon 52 mutation have MBL levels at 50% of normal plasma levels. Patients homozygous for any of the three mutations have undetectable levels of serum MBL. MBL deficiency is common with the actual frequency of the mutation dependent on the racial makeup of the population [35]. About 20% of the Caucasian population have at least one mutant allele, either codon 52 or 54 alleles. Studies on British and Danish Caucasian populations have shown gene frequencies of about 0.16 for the codon 54 allele and 0.06 for the codon 52 allele. The frequency in Caucasian populations of individuals with homozygous codon 52 is about 0.2%, homozygous codon 54 individuals about 2.0%, and heterozygous codon 52/54 alleles about 0.6%. The codon 57 allele is found in high frequency in African populations. In a study done in the West Africa country of Gambia, the gene frequency in native Africans for codon 57 mutations was 0.29, for codon 52 was 0.02, and for codon 54 was 0.003. Gambians who were racially Caucasians (British) and Hong Kong Chinese had codon 54 gene frequencies of 0.17 and 0.11 but did not have any 57 mutations present. Levels of MBL in the serum are also influenced by genetic elements in the promoter region of the MBL gene. Three haplotypes of protein expression, HY (high), LY (intermediate), and LX (low) phenotypes corresponding to the serum MBL levels, have also been identified [36]. These phenotypes are a result of two variants in the promoter region of the molecule that are in linkage disequilibrium located at codons –221 (X or Y) and –550 (H or L). The HY haplotype has a gene frequency of 0.38 in Caucasians and 0.11 in Africans, the the LY haplotype is found at 0.38 in Caucasians and 0.65 in Africans, and the LX haplotype is found at 0.24 in Caucasians and 0.24 in Africans.

The MASP gene has been mapped to the long arm of chromosome 3 and contains six exons. The encoded protein has a molecular mass of 100 kDa and contains an epidermal growth factor-like domain, two SCR repeats, and a serine protease domain similar in structure to that of C1r and C1s. In addition, the MASP molecule has a histidine loop structure present in many

serine proteases such as trypsin and chymotrypsin [37]. It is this histidine structure that enables the molecule to have specificity for C3 cleavage.

GENETICS OF COMPLEMENT REGULATORY MOLECULES

C1-INH is a protein of the serpin family of protease inhibitors. There are two known allelic variants of C1-INH. Two types of deficiencies have been characterized: type I, in which normal molecules are produced but in levels only 5–30% of normal, and type II, in which the protein is present in normal levels but is nonfunctional. RFLP analysis of DNA from deficient patients has shown wide genetic variability at the DNA level.

Factor I is a 88-kDa plasma glycoprotein composed of two chains, a light chain (38 kDa) and a heavy chain (50 kDa) containing LDL receptor domains, a CD5 domain, and sequence unique to factor I, and a segment with sequence homology with C6 and C7 proteins. The gene for factor I is located on chromosome 4 and spans 63 kb with 13 exons. Polymorphism of factor I has been identified in Japanese individuals [38] and hereditary deficiency of factor I has been reported for 23 individuals from 19 families [39]. Factor I DNA mutations have been studied for two families [40]. In the first family, a missense mutation led to the substitution of histidine by leucine in a semiconserved area near the enzyme active site. In the second, one allele had the same mutation as the patient in the first family (although there was no evidence that they were related) and the other allele had a splice site point mutation that led to deletion of the fifth exon from the mRNA transcript. Both affected individuals had no detectable circulating factor I protein.

The four transmembrane glycoproteins, factor H, CR1, MCP, and DAF, are highly homologous molecules with similar structures. Genes encoding these molecules are closely linked on chromosome 4 in the regulators of complement activation (RCA) gene cluster [41]. Analysis of genes and amino acid sequences have identified common domain-like structures with SCRs of about 60–70 amino acids; factor H contains 20 SCRs; CR1, 33 SCRs; and DAF, 4 SCRs [42]. Similar SCRs are also found in C4BP (56 SCRs); CR2, C2, and factor B (3 SCRs); and factor I (1 SCR). These highly homologous repeated sequences may be involved in the binding of C3. Because the transmembrane proteins have many SCRs, it is possible that a large number of C3 molecules interact with a single membrane protein. Factor H is transcribed into two messages, which are 4.3 and 1.8 kb. These are transcribed into a 155-kDa transmembrane protein with 20 SCR domains and a 45-kDa protein with 7 SCRs. All identified patients with factor H deficiency have been shown to have point mutations in either SCR 9 or SCR 16 domains, which modify cysteine residues and are predicted to profoundly influence the three-dimensional structure of the 155-kDa protein [43]. Two additional factor H-like proteins, FHL-1 and FHR-1-β, have similar structures to the smaller factor H protein and each has seven repetitive SCR segments. Structures of the four NH-terminal SCRs are critical for the function of the FHL-1 and factor H molecules [10].

Four allelic forms of CR1 (CD35) have been identified: A, B, C, and D [44]. The A (or F) allotype is found with a gene frequency of 0.87 in Caucasians, 0.74 in Blacks, and 0.98 in Asians. The B (or S) allotype is found with a gene frequency of 0.12 in Caucasians, 0.22 in Blacks, and 0.02 in Asians. The C allele is only found in Blacks at a frequency of 0.04 and the D allele in Caucasians at a frequency of 0.01. CR1 molecules produced by the four different alleles are different sizes: the A protein is 190 kDa, the B protein is 220 kDa, the C protein is 160 kDa, and the D protein is 250 kDa. When the gene structure for the A, B, and C alleles was determined, significant differences in the genes for the alleles were found [45, 46]. The A gene contained 39 exons that encoded four long homologous repeats (LHRs) each of which encodes seven SCR repeated sequences. The B gene contained an additional eight exons and a fifth LHR. The C gene was truncated and only contained three LHR segments. Because each of the SCR repeated sequences binds to C3 and C4 molecules, the allelic forms could bind different quantities of complement fragments. The two most common alleles can be easily distinguished from each other at a DNA level by a *Hin*dIII restriction polymorphism detected by RFLP analysis with a CR1.1 probe [47]. The A gene produces a 7.4-kb fragment, whereas the B gene produces a 6.9-kb fragment.

The binding site for the CR1 molecule is located in residues 727–768 on the C3 molecule. This area is also involved in the binding of C3 to factor H and factor B and involves at least two areas on the C3 molecule [48]. The allelic forms of C3, C3S and C3F, bind with equal affinity to the CR1 receptor [49]. The CR1 receptor also binds the C4 molecule. Studies with C4A and C4B show that erythrocyte-bound CR1 as well as recombinant soluble CR1 (sCR1) bind with a significantly higher affinity to C4A than to C4B [50, 51]. It was also demonstrated that CRP bound to soluble ligands can also bind to the RBC CR1 [52]. This suggests that CR1 may mediate a biological function of C-reactive protein (CRP).

The C4-binding protein (C4BP) is composed of multiple α chains (70 kDa) associated with a single β chain (45 kDa). C4BP is present in a variety of isoforms in

plasma, each of which has a different number of α chains present in the molecule. The relative level of each of the isoforms is determined by genetic factors that localize in the RCA gene cluster [53]. Two genes, C4BPA and C4BPB, have been identified. The β chain contains three SCRs and contains a binding site for the anticoagulant protein S in the SCR-1 region [54]. Enzyme assays have been developed to measure the serum levels of C4BP and the protein S–C4BP complex. Levels of both of these proteins have been shown to be increased in patients with membranous nephropathy, decreased in liver cirrhosis patients, and unchanged in patients with IgA nephropathy [55]. SLE patients have not yet been studied.

Receptors for the C3a and C5a molecules have been identified and cloned [56–58]. The C5a (CD88) and C3a receptors have similar structures, both are within the G-protein superfamily of similar receptors that include receptors for IL-8, Mip-1/Rantes, thrombin, formyl peptide, and platelet-activating factor. Each of these receptors has seven hydrophobic domains that span the cell membrane and have a serpentine topology. The C5a receptor structure is complex and contains at least two separate C5a-binding sites. Only one site needs to be activated to cause intracellular signaling [59]. The C3a receptor has 37% homology to the C5a receptor but differs from it by the presence of a large extracellular loop with greater than 160 amino acids that is between transmembrane domains 4 and 5. Expression of mRNA for C3a and C5a has been found in tissues throughout the body and in the central nervous system (CNS). At least two monoclonal antibodies have been studied that react with the C5a receptor and inhibit the biological effects of C5a, which may in the future be useful to control anaphylactic responses *in vivo* [60, 61].

The C1q receptor (collectin) has been identified as a single protein chain of 60 kDa. At an amino acid level it has homology to calreticulin, a component of the SS-A antigen, an *Onchocerca* antigen, and a murine melanoma antigen. The receptor is found on leukocytes, platelets, and endothelium where it binds to C1q, mannan-binding protein (MBP), lung surfactant protein A (SP-A), and conglutinin [62]. The protein has three domains, N, C, and central P, and recombinant studies have demonstrated that the C1q-binding site spans the N and P domains [63] and binds to the collagen stalk portion of the C1q molecule. The consequence of C1q binding to its receptor varies with the cell location, binding to monocytes enhances phagocytosis, whereas binding to granulocytes, eosinophils, endothelial cells, or smooth muscle cells generates toxic oxygen molecules. These consequences may aid in the destruction of foreign pathogens but may also damage host tissues [64]. C1qR has also been shown to prevent the association of C1q with C1r and C1s and functions to control complement activity [65]. A second C1q-binding protein receptor, gC1qR, has been identified that binds to the globular heads portion of C1q. The second protein receptor is present on vascular endothelium, platelets, neutrophils, and eosinophils and binds vitronectin in addition to C1q [66]. C1q may also bind to CR1 on leukocytes and RBCs [67].

DEFICIENCIES OF THE COMPLEMENT SYSTEM AND DISEASE

Complete hereditary deficiencies have been described for many of the complement system proteins and regulatory molecules, and a variety of disease manifestations have been associated with these deficiencies (Table 5). The diseases can be grouped into two major types: rheumatologic and infectious. The rheumatologic diseases associated most frequently with complement deficiencies are SLE and SLE-like disease, and the infectious diseases are bacterial diseases, especially life-threatening infections caused by neisserial organisms. However, individuals who are completely deficient for a complement component can be free of disease so the development of disease is undoubtedly multifactorial.

Susceptibility to Infection

The important role the complement components play in hostdefenses is demonstrated by the striking association between complement deficiencies and susceptibility to infection. Deficiencies that result in significant decreases in C3 (deficiencies in C3 or factor I), the alternate pathway proteins (factor D or properdin), or in the membrane attack complex (deficiencies in C5, C6, C7, C8, or C9) are strongly associated with infections with *Neisseria* or other pyogenic bacteria. In one study of patients with *Neisseric* meningitis, 11 of the 104 patients studied were found to be completely deficient for at least one complement component [68]. In a second study of 30 patients with meningococcemia or meningitis seen in one hospital over 20 years, 3 patients (10%) had complement deficiencies. One of the 3 patients had congenital C7 deficiency and the other 2 patients had SLE. The prevalence of complement deficiency in the meningococcal disease was 100 times greater than the prevalence in the normal population [69].

The role that complement proteins and receptors play in HIV infection has been studied extensively over the last few years. The complement system functions to limit viral spreading through the infected host by activating immune cells and mediating the lysis of viral

TABLE 5 Clinical Findings in Complete[a] Hereditary Deficiency of Complement Components[b]

Deficient component	Number of reported cases	Percent with infections	Rheumatologic clinical findings
C1q	42	24	MPGN, SLE, DLE, skin rash, SLE-like disease
C1r-C1s	14	22	SLE, SLE-like, glomerulonephritis
C4	25	16	SLE, SLE-like, DLE, Henoch–Schönlein and anaphylactoid purpura, cryoglobulinemia
C2	109	10	SLE, subacute cutaneous LE, glomerulonephritis, anaphylactoid purpura, vasculitis, dermatomyositis arthritis, arthralgias, rheumatic fever, cold urticar, inflammatory bowel disease, Hodgkin's disease, idiopathic atrophodermia, common variable immunodeficiency
C3	24	60	glomerulonephritis, SLE-like
C5	27	70	SLE
C6	77	84	DLE, SLE-like, Sjögren's syndrome, arthritis
C7	73	65	SLE, CREST syndrome, pyelonephritis, hematuria
C8	73	65	SLE, hepatosplenomegaly, sickle cell and thalassemia hemoglobinopathies
C9	18	8	SLE
C1 INH[a]	Hundreds, 25	Rare	Angioedema (hundreds); SLE, DLE, SLE-like (25 patients)
H	13	80	SLE, vasculitis
D	3	74	None
P	70	74	SLE, vasculitis
C4bp	3	None	Angioedema
I	23	100	SLE, vasculitis
MBL	Many	60	SLE?
CR3	<20	100	None
DAF	Many	None	Paroxysmal nocturnal hemoglobinuria

[a] Homozygous deficiencies, except for heteroxygous C1 INH.
[b] Data from Vyse *et al.* [39], Pickering *et al.* [91], and Whaley and Schweble [113].

particles and infected host cells. However, the HIV virus utilizes complement receptors to invade various cell types more efficiently and to activate viral replication in latently infected cells. These studies with HIV, which have been reviewed [70], demonstrate that complement proteins and regulatory proteins can play either a beneficial or a detrimental function in host defense against viruses.

Heterozygous and homozygous deficiency of MBL has been shown to be associated with several types of immunodeficiencies. A primary immunodeficiency characterized by defective yeast opsonization was described 20 years before the molecular defect that was identified as the codon 54 mutation in the MBL [71, 72]. Many studies have now been published, including two large studies of 229 and 345 children with unknown primary immunodeficiencies [73, 74], which have demonstrated significant associations for both homozygous and heterozygous MBL mutations with an increased risk of infection. In the largest study, of the 17 homozygous MBL-deficient patients identified, 13 presented with severe infections, including septicemia, cellulitis and boils, severe tonsillitis, and otitis media. Homozygous MBL mutations have also been reported to be a factor in susceptibility to *Mycobacterium tuberculosis* and *avium*, *Trypanosoma cruzi*, *Klebsiella*, *Cryptococcus neoformans*, other fungal infections, hepatitis B virus, and influenza A.

In several published studies, MBL deficiency has been seen in increased frequency in HIV-infected men. In one study from Copenhagen [75], 96 HIV-infected men were compared to 123 healthy Danish adults and 36 Danish homosexual HIV-uninfected men. The incidence of homozygous MBL mutations was 8% in the HIV-infected men and 0% in the control groups. Infected HIV men with the most rapid progression of their disease had the lowest levels of MBL in the serum. Interpretation of these studies is controversial and work is needed to further characterize the possible role of MBL deficiency in HIV disease.

Patients deficient in CR3, the cell membrane receptor for C3, have increased susceptibility to infectious

agents. In initial reported studies, about 20 patients suffering from severe recurrent infections caused by phagocyte dysfunction were identified that lacked the β chain of the CR3 molecule [76, 77]. These patients are missing CR3 molecules as well as the LFA-1 and CR4 membrane molecules, which share the same types of β chains. Granulocytes from these patients are defective in the ability to opsonize and adhere to foreign organisms and cell membrane. Lymphocyte function is also impaired in these individuals.

Complement receptors may also play a significant regulatory role in the activation or suppression of PMN responses to a variety of infectious agents. It has been found [77, 78] that iC3b-containing immune complexes that bind to CR3 caused PMN activation and a respiratory burst in peripheral blood PMNs. This demonstrated a possible significant role for complement fragments in PMN activation during an infection. In addition, a suppressive role for CR1 was also demonstrated because the PMN respiratory burst was enhanced significantly by the monoclonal antibody blockade of CR1 sites specific for C3b. The authors hypothesized that CR1 present on PMNs and RBCs in whole blood promote the degradation of immune complex-bound iC3b to C3dg. This biological function would prevent binding of the complement-containing complexes to the CR3 and downregulate the PMN activation by immune complexes.

Autoimmune Manifestations of Complement Deficiencies

SLE and other rheumatic diseases have been associated for the most part with deficiencies of the early components, but there are documented rheumatic disease cases associated with virtually all complement deficiencies described. A summary of identified deficiencies and associated rheumatologic diseases found in published case reports is given in Table 5. Hereditary complement deficiencies with a complete lack of a complement protein are seen in the population at low frequencies with the exception of C1-INH, C4A, or C4B deficiencies, which are seen more frequently. Screening studies done on serum from blood donors in Osaka, Japan, found an approximate frequency of 0.003% for C5, C6, C7, and C8 deficiencies [79]. In contrast, C4A and C4B deficiencies are seen much more frequently (see Chapter 5). Complement deficiencies have also been reported that are not hereditary deficiencies but rather are acquired conditions associated with the presence of anticomplement protein autoantibodies. The most frequently occurring form of acquired complement deficiency is a result of C1-INH deficiency.

TABLE 6 Homozygous C2 Deficiency: 52 Kindred Studies

Clinical findings	All cases	Nonindex cases
Normal	23	20

Atypical Cutaneous Lupus Erythematosus: A Hallmark of Deficiencies of Early Complement Components

SLE associated with homozygous deficiency of the early components of complement was the first of the associations of early complement deficiency with lupus disease to be reported [80]. A striking finding present in the first index case and subsequently confirmed was that some of the lupus disease in these patients, called *atypical cutaneous lupus erythematosus* for lack of a better term, differs from classic lupus in the following four ways: (1) increased incidence of discoid skin lesions, (2) an absence of renal disease, (3) low or absent titers of ANA and antibodies to native DNA, and (4) infrequent findings of immunoglobulin and complement in the skin lesions (see section on C2 deficiency and Table 6). These features were also found in some patients with complete deficiencies of C1q, C1r–C1s, and C4 that were reported later.

Hereditary C1q Deficiency

The last early complement component homozygous deficiency associated with SLE-like disease to be reported was C1q and in effect provided evidence for the hypothesis that all the early components, C1 through C4, were involved in host defenses to the development of SLE. Of the 42 patients reported, 39 (93%)

had a clinical syndrome similar to SLE [81–91]. Skin rash, predominantly with photosensitivity, occurred in 37 patients with negative lupus band tests in 3 of 9 cases reported. Glomerulonephritis was present in 16 patients with the membranoproliferative type present in 5 of the 8 cases characterized. Antinuclear antibodies were present in 24 of 35 patients tested but only 5 of 25 patients had antibodies to double-stranded DNA. Although patients with complete C1q deficiency had some features of lupus disease, the diagnostic criteria for SLE were usually not met in most cases. The female to male ratio was 1.3:1 in the C1q-deficient group compared to a ratio of 15:1 in classic SLE (see Chapter 7). Hereditary deficiencies of C1q can be subdivided into two major groups: those with normal levels of C1q and those with depressed levels of C1q protein in the blood. Only individuals with homozygous deficiency are affected (as described earlier in the genetics section).

Hereditary C1r–C1s Deficiency

There have been 14 patients with C1r–C1s patients reported in the literature [91–95]. C1r and C1s deficiencies usually occur together in affected individuals, perhaps because the C1r and C1s genes are located very close to each other on chromosome 12 where simultaneous deletions of both closely linked genes may occur. Some patients have been reported to have a complete absence of both C1r and C1s, whereas others have complete absence of one of the molecules and significantly decreased levels of the other. Eight of the 14 (57%) had lupus disease; all had skin rash, DLE was diagnosed in 2 and SLE in 2. Five of 8 had glomerulonephritis; only 1 was characterized and had mesangioproliferative glomerulonephritis. The female to male ratio was 1.7:1. ANA was negative or weakly positive in 3 of 8, and DNA antibodies were negative in 3 of 5 patients studied. LE band tests were not reported.

Hereditary C4 Deficiency

C4-deficient patients of two types have been characterized: complete C4 deficiency, in which both the C4A and C4B protein products are absent, and partial C4 deficiencies, in which C4 levels are decreased and one or more of the genes for either C4A or C4B genes are missing. Complete C4 deficiency is rare; among 25 reported patients, 21 (84%) had SLE or SLE-like disease [22, 96–103]. Seventeen patients had skin rash, predominately with photosensitivity; lupus band tests were negative in four of the five cases studied. Nine patients had mainly mild glomerulonephritis; the mesangial type was present in all seven cases characterized. ANA was negative or weakly positive in 10 of 20 patients tested. DNA antibody tests were negative in 9 of 11 patients tested. Anti-SS-A(RO) was positive in 6 of 8 patients tested. The female to male ratio of affected patients was 2:1. There were 2 asymptomatic patients and single case reports of Henoch–Schönlein purpura [104] and cryoglobulinemia [105] associated with complete C4 deficiency.

Partial deficiencies may exist in individuals who are missing one, two, or three of the C4 genes (see Chapter 5 for gene frequencies and risk factors for SLE-like disease for the C4 isotypes). Absence of both C4A genes is associated with an increased susceptibility to SLE. The clinical manifestation associated with homozygous C4A deficiency has been reported in several studies. In a study from Sweden [106], homozygous C4A deficiency was found in 13 of 80 SLE patients (16%). C4A-deficient patients had an increased incidence of photosensitivity but other clinical features were similar to the non-C4A-deficient patients. No differences were seen in the percentage of anti-dsDNA, Sm, RNP, SS-A, SS-B, rheumatoid factors, or cardiolipin antibodies for these patients. In a North American study [107] that included Caucasians and Blacks, patients with homozygous C4A deficiency had less proteinuria, lower levels of anti-dsDNA, Sm, SS-A, and cardiolipin antibodies and higher C3 levels. The C4A gene deletion was found in 23.4% of 121 patients with SLE and was associated with subacute cutaneous lupus erythematosus and Sjögren's syndrome.

One large family of 35 individuals from three generations in Iceland with C4A null alleles has been reported [108]. HLA typing and C4 allele typing were done by agarose–immunofixation techniques. Five of the family members had four or more criteria for SLE and an additional five members had clinical or laboratory evidence of SLE but did not fulfill four American College of Rheumatology (ACR) criteria. No other autoimmune diseases were seen in the family. The C4A null allele was highly associated with SLE in this family in that 9 of the 10 members with symptoms were C4A deficient. Interestingly, five different C4A null haplotypes were involved, including three that originated from nonconsanguineous spouses.

Absence of both C4B genes is associated with an increased risk of IgA nephropathy and glomerulonephritis [109]. Absence of at least one C4B gene, which leads to low levels of plasma C4, has been associated with dermatological diseases, specifically discoid lupus erythematosus, angioedema, and urticaria [110]. C4 deficiencies have also been shown to be associated with anti-SS-A antibodies and with anticardiolipin antibodies in Blacks [111, 112].

Hereditary C2 Deficiency

C2 deficiency is the most common homozygous complement component deficiency. The prevalence of either of C4 null genes is higher but the prevalence of complete C4 deficiency, inheritance of both null genes, is not (see Chapter 5). Larger numbers of patients with C1 INH deficiency than homozygous C2 patients have been reported because the inheritance of CI INH deficiency is autosomal dominant (Table 5). Homozygous C2 deficiency has an approximate prevalence of 1:20,000 in the western European Caucasian population. Over 100 patients with homozygous C2 deficiency have been reported [113]. C2 deficiency was the first complement deficiency reported to be associated with SLE. This disease association has been confirmed as shown in a study of the first 52 kindred reported with homozygous C2 deficiency (Table 6) [114]. Twenty-eight patients (34%) had lupus disease with a female to male ratio of 8:1. Eighteen patients (22%) were diagnosed as SLE but only 14 fulfilled ARA criteria for the diagnosis of SLE. The atypical aspects of the lupus disease present in the original index case [80] were also confirmed; 10 patients, a third of the patients, had atypical cutaneous LE. Idiopathic glomerulonephritis was present in 9 patients and recurrent infection in 8 patients; 7 of the 9 patients with glomerulonephritis were males. The 8 patients with recurrent infections were all young children. Frequent infections have also been noted as secondary diagnosis in several of the other childhood cases of homozygous C2 deficiency. The prevalence of lupus disease in this study most likely is inflated due to a patient selection bias, as the studies were mainly performed in SLE clinics. Among the nonindex cases (Table 6), a less biased population, only 1 of 29 (3.4%) C2 homozygotes had lupus disease; interestingly, the patient had atypical cutaneous LE. Hence, while the true prevalence of lupus disease among homozygous C2-deficient patients is not known, it is most likely considerably less than 34% and much lower than the very high prevalence of lupus disease associated with C1q, C1r–C1s, and C4 complete deficiencies.

Comparison of homozygous C2-deficient patients with SLE and atypical cutaneous LE (Table 7) illustrates the four differences noted earlier: an increased incidence of discoid skin lesions, absence of renal disease, low or absent titers of ANA and antibodies to native DNA, and infrequent findings of immunoglobulin and complement in the skin lesions. Glomerular lesions in patients with SLE varied in histological type and included membranoproliferative, mesangial, membranous, and focal sclerosis. Clinically and serologically, these cases resemble two subgroups of classic SLE: the ANA-negative SLE with photosensitivity group and the cutaneous lesions and subcutaneous lupus erythematosus (SCLE) group [115, 116]. The rash in atypical cutaneous lupus erythematosus patients (Fig. 3) bears striking resemblance to the rash in the antinuclear antibody (ANA)-negative group and to that in SCLE. The skin lesions have been described as nonscarring, papillosquamous, or annular polycyclic, with a characteristic distribution (i.e., the lesions spare the knuckles, inner aspects of the arm, axilla, lateral part of the trunk, and are rarely seen below the waist). Because the skin lesions differ from those in discoid lupus erythematosus in their clinical appearance and immunohistology, the diagnosis of the discoid type in some of these complement-deficient cases was inaccurate. The two subgroups of SLE and the complement-deficient patients with atypical cutaneous LE all share a high incidence of positivity for the anti-Ro (SSA) antibody [112, 115, 117].

TABLE 7 Homozygous C2-Deficient Patients: Comparison of SLE with Atypical Cutaneous Lupus Erythematosus

	SLE		Atypical cutaneous LE	
	Number studied	Number positive	Number studied	Number positive
Discoid LE lesion	17	4	10	10
Renal disease	17	5	10	0
ANA	17	17	10	2
dsDNA antibody	12	6	8	0
Ig, C′ in skin lesion	4	3	8	0

Whether there is an association of lupus disease with heterozygous C2 deficiency similar to that seen with heterozygous C4 deficiency (Chapter 5) is controversial [91, 118, 119]. There appears to be a slight increase in the prevalence of heterozygous C2 deficiency among SLE patients compared to controls (see Chapter 5). Moreover, in the study on 52 kindred with C2 deficiency cited earlier, the prevalence of lupus disease among nonindex heterozygous C2 deficiency cases was 0.6% compared to a prevalence of 3.4% among nonindex homozygous cases, suggesting that there may be an association of lupus disease with heterozygous deficiency that is six times less than that with homozygous C2 deficiency.

The effect of homozygous C2 deficiency on the clearance of immune complexes has been studied [120]. A patient with C2 deficiency was injected with hepatitis B surface antigen–anti-HbsAg immune complexes labeled with ^{123}I. The patient's uptake of complexes in the liver, spleen, and clearance of the complexes from

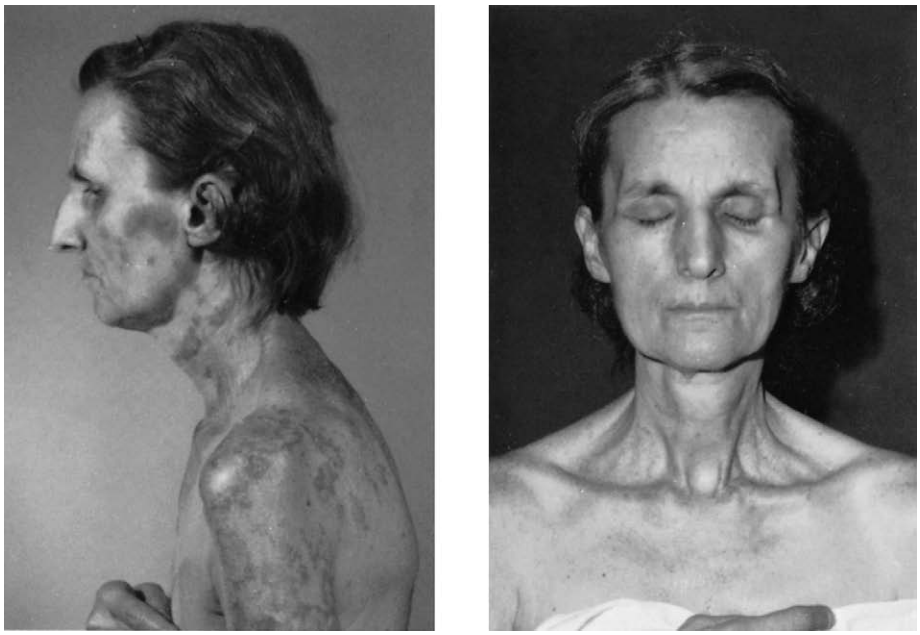

FIGURE 3 Homozygous C2-deficient patient. (*Left*) Characteristic rash. Note the annular polycyclic pattern. (*Right*) Patient after therapy. Rash cleared slowly but completely with topical steroids. There was no residual scarring.

the circulation was studied before and after fresh-frozen plasma treatment. When her C2 and CH50 levels were zero, the complexes were taken up rapidly by the liver and cleared from the circulation. No binding of the complexes was seen in the spleen or on RBCs via CR1. After treatment with FFP, which normalized her complement levels, the complexes cleared from the circulation more slowly, and 20% of the complexes were found in the spleen. These studies suggest that uptake of immune complexes by the spleen is complement dependent and that abnormal processing of immune complexes by complement-deficient patients may take place.

Hereditary C3, C5, C6, C7, and C8 Deficiencies

The major disease association with homozygous deficiencies of components C3 through C8 is infection (Table 5); few cases of SLE and SLE-like disease are associated with deficiencies of these components. The relative infrequency of these associations may indicate that no causal relationship exists, although such a relationship cannot yet be excluded because of the small numbers of cases of each deficiency studied.

Of 24 reported cases of homozygous C3 deficiency, three patients had SLE-like disease and seven had glomerulonephritis, proteinuria, or IgA nephropathy [39]. The SLE-like disease patients had rash and arthralgias or arthralgias and photosensitivity [121, 122]. All three had negative serologic assays for ANA, LE cells, and rheumatoid factor assays.

More typical SLE occurs among individuals with C5–C8 deficiencies. One case of homozygous C5 deficiency with SLE has been reported [123]. There were no unusual features of SLE in this case. The lupus erythematosus, ANA, and dsDNA antibody tests were positive. The prominent skin lesions were typical of lupus. There were deposits of immunoglobulin and complement along the dermal–epidermal junction. There are three cases of homozygous C6 deficiency with SLE or SLE-like disease [124–126]. One case had typical SLE, and one case had SLE-like disease with polyarthritis, pleurisy, and Raynaud's phenomenon. The lupus erythematosus and dsDNA tests were negative, the ANA was weakly positive, and an ssDNA test was positive. The third case had discoid lupus and Sjögren's syndrome with negative serologic test studies. Two cases of C7 deficiency have been reported with classical seropositive SLE [127]. Two cases of C8 deficiencies have been reported: one had classic seropositive SLE and the other had clinical criteria for SLE with negative serologic tests for ANA and lupus erythematosus cells and a positive rheumatoid factor [128, 129].

Hereditary C9 Deficiency

Initially, C9 deficiency was thought to be rare and not associated with disease. A further study of C9

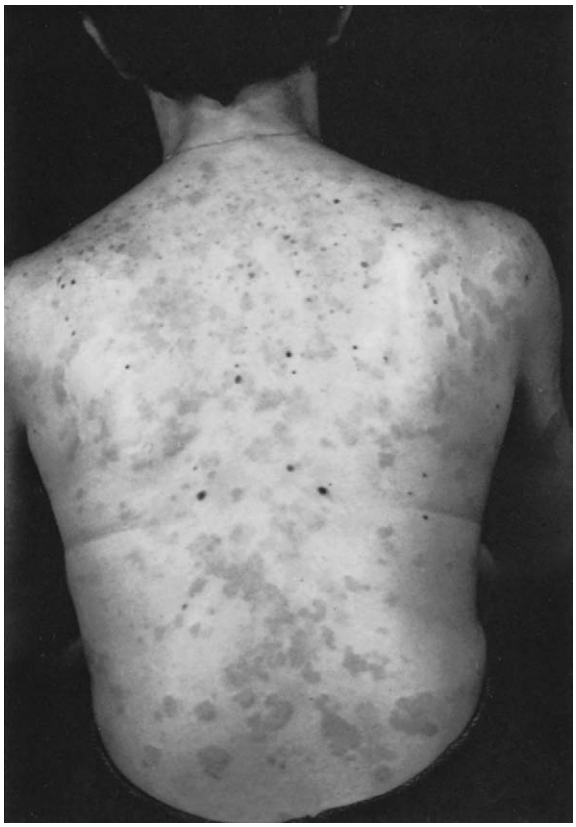

FIGURE 4 Patient with typical rash of hypocomplementemic urticarial vasculitis syndrome.

deficiencies, especially in ethnic Japanese, has demonstrated that the incidence of C9 deficiency in Japan is about 0.086%, much higher than in initial studies of other populations. Three cases of SLE have been reported in association with C9 deficiencies in Japan. The first reported patient had sicca syndrome accompanied by severe Raynaud's phenomenon [130]. Serologic tests for ANA and dsDNA were positive, as were assays for RNP, Sm, and SS-A (Ro) antibodies and immune complexes. The other two patients [131, 132] had low CH50 and absent C9 protein and function. One of the patients had recurrent urinary tract infections, pleuritis, pericarditis, proteinuria, and facial edema with a positive ANA of 1:640 and a dsDNA antibody of 28 U/ml. This patient had two other sisters with homozygous C9 deficiency with hypergammaglobulinemia and low titered ANAs (1:80). Their father was heterozygous for C9 deficiency with a positive ANA of 1:640. Four other C9-deficient patients with disease have been reported: one had sicca syndrome and the remaining three had rheumatoid arthritis. Cases of C9 deficiency associated with neisserial meningitis have also been identified.

Hereditary MBL Deficiencies

MBL protein deficiencies, which are a result of the gene mutations of the MBL gene, have been studied in SLE. Serum levels of MBL were measured in a study with 58 SLE, 92 HIV, 30 chronic liver disease, 20 rheumatoid arthritis, and 161 healthy controls [133]. Severely decreased levels of serum MBL protein were found in 12% of SLE patients, 4% of HIV patients, 3% of liver disease patients, no RA patients, and 4% of healthy controls. In one study [134], 102 Caucasian SLE patients were compared to 136 healthy controls to determine their MBL genotypes. The mutant adenine at nucleotide 230 (the codon 54 allele) was found in 41% of patients and 30% of controls, with the frequency of homozygosity for the SLE group of 10% compared to 7% for the control group. This study showed an increase but not a statistically significant frequency of MBL mutation in the SLE patient group. In addition, when DQA*0501/Dr3/C4A*Q0 gene studies were also done, the association with SLE for the presence of the C4 null allele and MBP genes was stronger than association of the C4 null allele alone. Three additional studies have been done with other racial populations. In a study of Chinese individuals in Hong Kong [135], 111 SLE patients and 123 healthy controls, 33% of patients (37) and 23% of controls (28) were positive for the codon 54 mutation. Two of the SLE patients were homozygous for the codon 54 mutation. Mean levels of MBL in the serum were about 10% of normal levels for the codon 54+ patients and controls, whereas MBL levels for SLE patients without the mutation were about 50% of the normal levels. A second study of a Black cohort with SLE and matched normal controls was done to determine the gene frequency and relative risk of the codon 54, codon 57, –550, –221, HY, LY, and HX gene frequencies [136].

Codon 54 mutations were found with a frequency of 0.163 in the SLE group and 0.087 in the control group; codon 57 mutations had a frequency of 0.125 in the SLE group and 0.047 in the control group. For the promoter mutations, mutations in the –550, –221, and the LX haplotype were found in increased frequency in the SLE group, whereas the HY haplotype was found in increased frequency in the controls. The LY haplotype was found in equal frequency in both groups. Homozygous LX/LX haplotypes were found in 11% of the SLE group but only in 2.6% of the controls. Overall, the prevalence of any of the MBL genetic deficiencies in the SLE population was 46% compared to 23% of the control group. This study also identified an additional promoter haplotype, HX, present in 3 of their SLE patients. In a third study of 50 SLE patients and 49

controls in Spain [137], codon 54 mutations were found in 52% of SLE patients and 31% of controls; codon 57 mutations were found in 6% of patients and 4% of controls. Homozygosy for codon 54 was found for two SLE patients and one control. C4A and B genes were also determined for this group of patients. The C4B allele was at increased frequency in the SLE group (37% versus 12%), and there was a stronger association for SLE with the C4A null allele and the MBL mutant alleles than for either mutation alone. In summary, several studies have now documented an increased frequency of MBL mutations that result in nonfunctional MBL proteins in SLE patients in a variety of racial groups. This association of MBL gene mutation with an increased risk for disease appears to demonstrate a gene dosage effect associated with C4A null alleles. Additional studies are necessary to further elucidate the mechanism of this increased risk for the development of SLE.

Combined Hereditary Complement Deficiencies

A combined heterozygous C4 and C2 deficiency has been reported for 15 individuals from six families [138]. About 30% of the people had SLE or another autoimmune disease. The C2 deficiencies were all due to the 28-bp deletion in the C2 gene, whereas eight of the C4 deficiencies were all due to heterozygous C4A null alleles and five were due to C4B null alleles (the other two C4 deficiencies could not be identified as null alleles). From the frequencies of C2, C4A, and C4B deletions, the expected combined C2 and C4 deletion frequency of the population is 0.001.

A family with four children has been identified in which three of the children are homozygous deficient for factor H and two of the three children are heterozygous deficient for C2. One of the two children with both C2 and factor H deficiency had classic SLE with nephritis. Two patients have been identified with combined homozygous C7 and C4B deficiency; one of the patients was normal and one had SLE [139]. The patient with SLE had a sister who was asymptomatic but was also homozygous C7 deficient. Additional patients have been identified with combined properdin and C2 deficiency, and DAF and C9 deficiency, but rheumatic disease was not reported for any of them.

Acquired Deficiencies of Complement

Two forms of acquired complement deficiency states with prolonged persistent complement depression have been associated with SLE-like disease similar to that seen in hereditary complement diseases. These syndromes are early complement component depression associated with chronic hypocomplementemic cutaneous vasculitis and C3 deficiency with mesangiocapillary glomerulonephritis or SLE.

TABLE 8 Forty-Seven Patients with Hypocomplementemic Urticarial Vasculitis Syndrome

Clinical and laboratory findings	Number studied	Number positive	Percent positive
Rash	46	46	100
Depression of C1–C3	47	46	98
Anti-C1q antibodies (C1q precipitins)	20	27	74
Arthralgias or nondeforming arthritis	34	23	68
Angioedema	46	26	56
Renal disease	42	12	29
Obstructive lung disease	42	10	24
Antinuclear antibodies (>1:20)	46	9	20

Hypocomplement Urticarial Vasculitis Syndrome

Hypocomplementemic cutaneous vasculitis is an acquired form of deficiency that leads to chronic decreases in complement components C1, C2, C4, and C3. The syndrome is now called hypocomplementemic urticarial vasculitis syndrome (HUVS) but in the past was identified as SLE-related syndrome, hypocomplementemic cutaneous vasculitis, chronic hypocomplementemic cutaneous vasculitis, or hypocomplementemic vasculitis urticaria syndrome. Patients with this syndrome have several distinct clinical features similar to those of SLE but do not fulfill SLE diagnostic criteria [140–159]. The typical patient is a young female with chronic rash, angioedema, and arthralgias. Table 8 contains a summary of the clinical and serologic studies of 47 patients (37 females, 6 males, 4 sex not reported) with SLE-related syndrome. Two patients developed pseudotumor cerebri [146, 155]. The rash, which is the most characteristic and prominent feature of the syndrome, was initially called erythema multiforme like because of the presence of classic target lesions [140]. More recently it has been called urticaria like but is very atypical urticaria because of the absence of itching and the persistent nature of the rash. Histologically, the skin lesions form a perivasculitis to a true leukocytoclastic vasculitis. The presence of

immunoglobulins and complement in the lesions also varies, but in most cases they are absent. Renal disease, when present, is usually mild to moderate, and obstructive lung disease, which may be severe, occurs in some patients. Studies done on isolated glomeruli basement membranes demonstrated a high level of antibody to C1q in the glomerular tissues [160]. When pulmonary function was measured in 17 patients, 11 of them had dyspnea and severe airflow obstruction [161]. Six of these patients died of respiratory failure.

The major serologic finding in the majority of patients is the presence of low molecular weight C1q precipitins, which have been demonstrated in most cases to be antibody to the C1q molecule [162]. These antibodies can be demonstrated in this syndrome as well as in SLE, findings that are consistent with the original description of the low molecular weight C1q precipitin that was reported to be present not only in the first case of HUVS, but in SLE patients as well [114]. The majority of patients can be distinguished from those with SLE serologically because the majority of patients with the syndrome have negative ANA tests, negative assays for lupus erythematosus cells, and negative assays for dsDNA. A small number of patients identified were found to have low titered antibodies to the Sm antigen. When patients with SLE were tested for anti-C1q antibodies by enzyme-linked immunosorbent assay (ELISA), 33.6% of 113 patients were positive [163]. Plasma titers of anti-C1q antibodies were inversely correlated with CH50 activity. Eighty-five percent of patients with severe complement consumption had positive results for anti-C1q antibodies. Only 14% of patients with no evidence of complement consumption had positive results for anti-C1q antibodies.

The most striking serologic feature of patients with the syndrome is the marked depression of serum complement. The pattern of complement depression resembles that in SLE except that there is severe depression of C1q and associated marked depression of C2 and C4 levels. Depression of C3 tends to be moderate, and all terminal components are present at normal levels. Normal C1 esterase inhibitor levels differentiate the syndrome from the hereditary and acquired forms of angioedema.

The antibodies present in patient serums have been shown to react with a variety of epitopes on the C1q molecule. By Western blot, antibodies can be detected that react with the B and C chains in patients with HUVS. Serum from HUVS also react with the CN-CN and AN-BN dimers of the collagenous C1q fragments. Patient serums from SLE patients were negative by Western blot and thus the antibodies must be directed toward conformational epitopes of bound C1q [164].

Patients with HUVS are similar to patients with hereditary complement deficiency and SLE in that the skin rash is prominent and the ANA test is negative. However, the rash in patients with HUVS does not resemble discoid or atypical cutaneous lesions. None of the inherited forms of deficiency of C1q have similar rashes and all are negative for antibodies to C1q. Hence, the relationship of this acquired complement deficiency to SLE appears to differ in major ways from the association of hereditary complement deficiencies and SLE.

Acquired C3 Deficiency and Systemic Lupus Erythematosus

A portion of patients with chronic mesangiocapillary glomerulonephritis will have associated depressed serum levels of C3. In a study of 21 patients with partial lipodystrophy, 17 were found to have low C3 with normal C4 and C2 concentrations [165]. Seven had chronic mesangiocapillary glomerulonephritis. Patients with depressed C3 levels have been shown to have a protein in their sera capable of cleaving C3 in normal serum. This protein has been termed *C3 nephritic factor* (C3Nef) and has been shown to be an autoantibody that stabilizes the C3 convertase of the alternative pathway.

A 34-year-old Caucasian woman with partial lipodystrophy since age 5 years has been reported with classic SLE [166]. The patient had pleuritis, polyarthritis, and a photosensitive rash on her arms. Lupus erythematosus cells, ANA, native DNA antibody, and rheumatoid factor tests were positive. C3 was markedly depressed, with normal levels of C1q, C2, and C4. C3Nef was demonstrated in the serum. A renal biopsy showed focal mesangial sclerosis without any electron-dense deposits on electron microscopy. This patient's lupus is classic SLE and bears little resemblance to the lupus-like syndrome seen in three of the homozygous C3-deficient cases except that all had skin rashes and three had photosensitivity. The significance of any of these observations remains to be determined.

Deficiencies of Regulatory Molecules

C1 Inhibitor Deficiency and Systemic Lupus Erythematosus

Genetic and acquired forms of C1-INH are associated with the syndrome of hereditary angioneurotic edema, which consists of recurrent bouts of noninflammatory swelling involving the subcutaneous tissues, intestinal walls, airways, and lungs. Twice as many males as females are affected. Two major types of the genetic

deficiency exist. In approximately 85% of patients, functional and antigenic assays show a low serum concentration of the inhibitor. In the variant form, which comprises approximately 15% of the cases, there is a normal or elevated concentration of a functionally inactive inhibitor. Two types of acquired deficiency have been identified: type I, which is associated with B-cell lymphoproliferative disease, and type II, which is characterized by the production of autoanti-C1-INH antibodies. A summary of the information from 22 patients has been published [167]. The autoantibodies are directed at epitopes at or near the reactive center of the molecule and prevent the inactivation of target proteases by the C1-INH. The levels of free antibody in the serum do not correlate with C4 levels, C1-INH functional assays, or clinical symptoms.

The clinical syndrome is very similar for the genetic and acquired forms of the disease. The severity of the clinical syndrome does not correlate directly with C1 inhibitor quantitative serum concentrations. Some affected individuals with a clear depression of C1 esterase inhibitor do not have clinical manifestations of disease. During attacks, patients usually develop detectable levels of free C1 esterase, which cannot be found in the circulation of normal individuals. C4 and C2, the substrates of C1 esterase, are chronically depressed in most patients. The chronic depression of C4 and C2 in these patients may be similar to levels seen in hereditary deficiency disorders.

A number of patients with hereditary deficiencies of C1 esterase and lupus disease have been reported [110, 168–186] (Table 9). Of 25 affected patients, 6 had SLE, 9 had discoid lupus erythematosus, and 10 had SLE-like disease. Three of the latter patients appeared to have atypical cutaneous LE; there were insufficient data on the remainder for assessment. Three of the 5 lupus bands tested were negative as found in the atypical cutaneous LE lesions. The female to male ratio was 7:1. As with the hereditary C2 deficiency and the C4 deficiency, the lupus disease is characterized by a high incidence of skin rash, which often has been diagnosed as discoid lupus erythematosus; some of these patients may have atypical cutaneous lupus erythematosus. Most skin biopsies of the lesions showed no immunoglobulin or complement deposits. In 7 of 19 and 5 of 11 patients the ANA and 5 DNA antibody tests were negative,

TABLE 9 Twenty-Five Patients with Hereditary Angioedema and Lupus

Number of cases	Sex	Clinical findings	ANA	Skin biopsy, immunofluorescent studies	Ref.

[a] Possible atypical cutaneous LE.

respectively. Membranoproliferative glomerulonephritis was present in 4 of the 6 patients with SLE.

There are two published investigations of twins with hereditary C1 esterase deficiency. Identical male twins who both exhibited classic symptoms of hereditary angioedema and marked depression of C4 had discoid lupus that appeared through both clinical and immunologic studies to be typical discoid lupus erythematosus [178]. In the second set of twins, identical girls with a complete absence of C1 esterase inhibitor, one remains normal while the other, since age 6 years, has manifested classic symptoms of hereditary angioedema [179]. At age 14 years she developed classic SLE with a positive anti-dsDNA antibody and profuse proliferative glomerulonephritis. C4 levels in the affected twin were 4% of normal, whereas the twin without clinical hereditary angioedema or SLE had C4 levels that were chronically in the range of 10–15% of normal. The findings suggest that chronic low C4 is not sufficient to predispose to lupus disease in patients with C1 esterase deficiency disease; very low levels may be required. This may be analogous to the greater association of lupus disease with homozygous C4 deficiency than with the heterozygous states. Indirect evidence for a relationship between C4 levels and lupus skin lesions has come from treatment of two patients with danazol [186, 187]. Danazol, an impeded androgen, has been shown to increase C1 inhibitor levels and to control clinical symptoms in hereditary angioedema. In both patients, danazol therapy resulted in complete remission of the skin rash and elimination of photosensitivity accompanied by increases in the C1 esterase inhibitor and C4 levels. Discontinuation of danazol in both cases resulted in recurrence of the skin rash.

TABLE 10 Clinical Findings among Nonindex Cases from Kindred Studies of Homozygous and Heterozygous C2-Deficient Patients

Asthma and eczema	1
Total	318

Factor I Deficiency

Twenty-three patients have been identified with homozygous factor I deficiency. Recurrent infections and meningitis infections with *S. pneumoniae*, *N. meningitidis*, *H. influenzae,* and otitis media were reported in 21 of the patients [188, 189]. One patient was asymptomatic and one patient had a fatal systemic vasculitis following penicillin therapy. Levels of plasma and RBC associated factor I were both decreased significantly in these patients. The absence of factor I was also shown to lead to significant increases in RBC-bound C3c and C3d antigens on patient red cells. In addition, there was continual formation of the alternate pathway convertase (C3bBb), which led to consumption of factor B and C3 in the serum and to the increased formation of C3b fragments. All leukocytes from these patients are also covered with C3b fragments. When peripheral blood cells from two patients with factor I deficiency were studied, CR1 levels were significantly lower and CR2 levels were somewhat reduced on B cells; CR1 levels on monocytes and granulocytes were normal or slightly elevated.

Factor H Deficiency

Fifteen individuals from seven families have been identified with homozygous factor H deficiency [190]. The disease is inherited as an autosomal-recessive trait and results in the uncontrolled cleavage of C3. This C3 cleavage depletes the factor B and properdin components of the alternative pathway and depletes C5. Patients with factor H deficiency have been associated with recurrent bacterial infections, including meningococcal meningitis, glomerulonephritis, SLE, and subacute cutaneous lupus erythematosus. In 21 relatives encompassing three generations for one reported patient, 10 had low factor H levels, which indicated probable heterozygous deficiencies in these relatives. Decreased factor H serum levels, C3 serum levels, C3 functional activity, factor B levels, and properdin levels were all strongly associated for these heterozygous relatives.

CR1 Deficiency

A quantitative deficiency of the number of CR1 molecules on white cells and red cells from SLE patients

has been reported in many studies. Because of the possibility that the level of expression on cell membranes is related to the CR1 genotype, studies have been done to determine the frequency of CR1 alleles in SLE patients. In a group of 63 French SLE patients and 158 normal controls, a significantly higher frequency of the S (B) allele was found in patients (51%) than for controls (26%) [191]. However, many other studies that have utilized the *Hin*dIII polymorphism detection method have not shown any association between SLE and the B allelle [44, 45, 192–194]. Studies have also shown that the CR1-C allele, smallest of the CR1 alleles, was not shown to be at increased frequency in SLE patients in either Black or Caucasian populations [195]. The quantitative number of CR1 receptors on lymphocytes, granulocytes, macrophages, and RBCs has been found to be decreased in patients with a wide variety of autoimmune diseases, including SLE, rheumatoid arthritis, hydralazine-induced lupus, discoid lupus erythematosus, primary phospholipid syndrome, essential mixed cryoglobulinemia, primary biliary cirrhosis, ulcerative colitis, and on cells in the MRL/lpr mouse SLE model. The decrease in receptor numbers has been correlated with disease activity and can be reversed on red cells by the production of new red cells stimulated by erythropoietin in some patients.

CR3 Deficiency

A single reported case of the association between SLE and CR3 deficiency has been reported [196]. The patient had classic SLE and an immune vasculitis. The patient had normal levels of CR3 on cell membranes but the molecule was nonfunctional. The CR3 was unable to interact with the C3bi ligand.

DAF Deficiency and Clinical Disease

Two types of deficiencies in the DAF (CD55) regulatory membrane molecule have been characterized. The acquired anemia condition of paroxysmal nocturnal hemoglobinuria (PNH) has been shown to be due to a lack of DAF and HRF20 (CD59) on red cell membranes of affected patients. A number of studies have demonstrated that the molecular defect in PHN is a clonal mutation that results in a defective PIG-A gene located on the X chromosome that encodes a glycosyltransferase. The deficiency of the enzyme leads to the inability of the cells to link a number of glycoproteins to the membrane via their usual glycosylphosphatidylinositol (GPI)-linked anchors. Expression on the red cell and white cells of over 20 glycoproteins is deficient. The lack of CD55 and CD59 on the red cell membrane results in an increased sensitivity to complement-mediated red cell lysis because of the increased uptake of C3b and increased levels of C5–9 complexes on the cell. This is due to a lack of the regulatory functions of CD55, which disassembles the C3 convertase, and the CD59, which restricts the binding of C8 and C9 and prevents assembly of the membrane attack complex. Inherited forms of CD55 and CD59 deficiency have also been identified. Three individuals have been identified who are deficient in the Cromer red cell blood group antigens (Inab phenotype) found on DAF molecules [197]. The red cells were lacking DAF molecules. No episodes of *in vivo* hemolysis were reported for the patients, but the red cells were extremely sensitive to *in vitro* lysis. In contrast, the few patients with inherited CD59 deficiency have all been associated with hemolytic episodes. PNH associated with rheumatic disease has not been reported, but PNH- and GPI-linked deficiencies have been demonstrated in aplastic anemia, hypercoagulable states, and increased susceptibility to bacterial infections.

SPECULATION ON THE ROLE OF EARLY COMPLEMENT COMPONENT DEFICIENCY IN SYSTEMIC LUPUS ERYTHEMATOSUS

There is now considerable evidence from studies on patients with hereditary deficiencies of individual complement components that complement has specific roles in host defense, independent of other systems. Specific roles have most clearly been defined for deficiencies of C3 and C5–8 that are associated with diseases caused by bacterial agents. In these instances the component is directly involved in a physiologic mechanism that eliminates the disease agent (i.e., opsonization and bacterial lysis). A hypothesis, proposed in the 1970s, on specific roles for early complement components in host defense was that these components protect against lupus diseases. Evidence reviewed in Chapter 5 and in this one has confirmed that the early complement proteins, C1 through C2, are directly involved in the host defense against lupus disease. It appears from the review of the prevalence of lupus disease with other complement components that these host defenses are related to biological activities of C1, C4, and C2 and are not dependent on activation of C3 or the rest of the complement cascade. Early reservation that the association of early complement component deficiency genes with lupus disease may not be a casual relationship, but rather a result of linkage to some other genes in the HLA complex involved in the pathogenesis has been dispelled as reviewed in Chapter 5. Other HLA genes, in particular the D/DR genes, may be involved in lupus

disease as described in Chapter 4 but independently of the complement genes.

Complete hereditary deficiency of a complement component, nature's "knockout" experiments, can provide insights to the biological function of individual components that cannot be gleaned from patients with complement activation where multiple components may be decreased or from *in vitro* studies. Much of the lupus disease associated with early complement component deficiencies lack hallmarks of classic SLE: female predominance, antibodies to dsDNA, or glomerulonephritis. The atypical cutaneous LE that lacks these features of classic SLE suggests that host defense mechanisms mediated by these components occur in the skin. For C1 and C4, these mechanisms appear to be independent of female hormones. Hence, the notion that early complement component deficiencies cause SLE is most likely incorrect. It appears more likely that these deficiencies cause specific aspects of lupus disease. Consistent with this assessment is the observation that atypical cutaneous LE constitutes 36% of the lupus disease in homozygous C2-deficient individuals but that the apparent equivalent form of disease in the general populations of patients with lupus disease, subacute lupus erythematosus, affects only 9% of lupus patients. This hypothesis is similar to that proposed for murine SLE [198], i.e., multiple genetic factors predispose to lupus disease, whereas some genes or absence or certain genes, as well as certain infectious agents, accelerate or enhance disease. The early complement component deficiency genes may be one of the accelerator or disease-enhancing groups of genes. In some deficient individuals, especially in females bearing other lupogenic genes, the result is classic SLE.

Several other clinical observations are relevant in considering hypotheses on the role of early complement component in the etiology of lupus disease. There is a greater prevalence of the disease in complete genetic deficiencies compared with partial ones. Similar disease associations occur in acquired deficiencies of early components as in the genetic deficiencies of these components, suggesting that the greater the deficiency of the complement protein the greater the susceptibility to disease. Initial observations that the prevalence of lupus disease with complete deficiency of C2 was lower than those of complete deficiency of C1 or C4 and a marked female predominance among affected patients with C2 but not C4 of C1 [114] have been confirmed.

At the time when the original hypothesis was formulated, the leading hypothesis on the etiology of SLE was that the disease was initiated by some yet unidentified viral agent. Hence, it was postulated that the early complement components were involved in specific host defenses to the putative viral agent. This hypothesis has not been totally excluded, but no viral etiologic agent has been identified in human SLE after 25 years of searching. A new major hypothesis on the etiology of SLE is that aberrant apoptosis leads to a breach of self-tolerance and autoimmunity. New evidence on the role of early complement components in the clearance of apoptotic cells has led to a new interesting hypothesis on how complement is involved in host defenses to lupus disease. The most widely accepted hypothesis (discussed in Chapter 5) is that these components are essential for the clearance of immune complexes and because SLE disease is mediated by immune complexes, deficiencies of these components lead to disease. This hypothesis appears untenable for two reasons: (1) the existence of other complement pathways for clearing immune complexes that bypass the early components and (2) the absence of evidence for increased immune complex disease in early component complement-deficient patients.

Complement has been implicated in the apoptosis processes involved in tolerance [199] except a preliminary report that C4 participates in negative selection of autoreactive cells in mouse model studies [200]. However, complement is involved in the clearance of apoptotic cell, and another mechanism for breaking tolerance may be the generation of autoantigen resulting from a defective clearance of apoptotic cells.

The aforementioned findings have led to the hypothesis by the Walport and Ahearn groups that C1q deficiency may predispose to autoimmune disease, that abrogation of tolerance leading to autoimmunity in SLE may be initiated in the skin lesions, and that the hierarchy of early complement component efficacy in the clearance of apoptotic cells mimics the hierarchy of prevalences of lupus disease among humans with deficiencies of these components. In the terminal phases of apoptosis the plasma membrane undergoes blebbing that results in cell surface expression of a variety of self-antigens involved in autoantibody formation in lupus disease, Ro (SS-A), La (SS-B), nucleosomes, and ribosomes [201]. It has been demonstrated *in vitro* that C1q binds independently of immunoglobulin directly to cell surface blebs on keratinocytes undergoing apoptosis following UV irradiation or viral infection [202]. In addition, a C1q knockout mouse model was shown to develop a lupus-like disease characterized by antinuclear antibodies and glomerulonephritis with increased numbers of glomerular apoptotic cells [203]. Further studies comparing the clearance of apoptotic cell in C1q and C4 knockout mice and glomerularnephritis in C1q and C2 knockout mice demonstrated a hierarchy in clearance with a greater deficit in C1q- than C4-deficient mice [204] and glomerulonephritis with an

excess of glomerular apoptotic bodies in C1q-deficient, but not C2-deficient mice [205], respectively.

The hypotheses are appealing because they are consistent with some of the clinical findings in the hereditary C1q deficiency, i.e., UV induced lesion lacking immunoglobulins and the most severe glomerulonephritis among patients with early complement component deficiencies. The lowest prevalence and least severe glomerulonephritis occur in C2-deficient patient; the prevalence in C4-deficient patients was similar to that among C1q-deficient patients but all were the milder mesangial lesions. Hence, the mouse C1q knockout mouse mimics the nature's C1q knockout experiment. However, there are several contrary observations. The characteristic skin lesion occurs in C4- and C2-deficient patients where C1q levels are normal. C1q alone is insufficient to cause lupus disease, as illustrated by normal individuals with C1q deficiency and the requirement for an autoimmune background in mice that develop lupus disease with deletion of the C1q gene. The development of lupus disease predominantly in females, in patients with prolonged depression of C4 and C2, and with normal levels of C1q in patients with C1INH deficiency also indicates that deficiency of C4 and C2 without a deficiency of C1q, along with female hormones, can produce susceptibility to lupus disease.

Thus far, studies have not been performed in human lupus to confirm the observations made on the role of apoptosis and C1q deficiency in mouse lupus models. It should also be empasized that the etiology of SLE is unknown so that any hypothesis on the role of early complement components is purely speculative. However, studies of patients with lupus disease and complement deficiencies have led to clues to possible etiologies and have provided a new understanding of the specific roles that complement components can play in host defense systems, as illustrated by studies on the role for C1q in the clearance of apoptotic cells.

GENDER AND AGE IN LUPUS

Robert G. Lahita

LATE-ONSET SYSTEMIC LUPUS ERYTHEMATOSUS

Introduction

The clinical onset of systemic lupus erythematosus (SLE) and its clinical course are affected by age. The relationship between age and the morbidity and mortality of SLE is unknown, but evidence shows that older age in women may be good. A discussion of SLE in the neonatal and the prepubertal child can be found in Chapters 17 and 18, respectively. This chapter limits the discussion of the "older" patient, to people over age 50.

The ratio of males to females is 1:8 in the older patient instead of 1:15 [1, 2]. Patients with drug-induced lupus are distinctly older and are usually male [3] because commonly used drugs such as procainamide and hydralazine are widely used for conditions in people over age 50 years. There are more male patients taking drugs such as procainamide. The topic of drug-induced SLE is covered in Chapters 44 and 45.

SLE has no predilection for males who are older, but relative to younger male patients (<50 years), the number of men with SLE increases with age. About 25% of the males in one study were over age 50 years [4]. Most investigators report that the ratios of females to males with SLE after age 50 decrease from 10–15:1 to 8:1. The older male presentation of SLE was atypical [5] in one study. In the largest series of SLE patients studied who were 50 years of age or older, 79% were women [6]. Reasons for an increase of older males with SLE may relate to a variety of factors and are given as sexual senescence, environmental agents, and possibly an increase of prolactin [7].

Clinical Presentation of the Aged Patient with SLE

In almost all studies of aged people with SLE, the majority met four or more of the American College of Rheumatology (ACR) criteria for SLE. In another study, 81% of older patients met four or more criteria, whereas 19% met three or less [8]. Because of late age of onset, the initial diagnosis of SLE was incorrect in 55% of patients. This is not surprising as physicians are reluctant to diagnose SLE and because this age group presents with atypical signs and symptoms. Therefore, the diagnosis of older age SLE can be delayed for up to 2 years. While there is no question that age may modify the clinical presentation of the disease, it is imperative that physicians learn to include SLE as part of any differential diagnosis in patients of older age presenting with myalgia, arthralgia, unexplained weight loss, fatigue, and low-grade fever.

The presentation of SLE in the older patient (aged 50–80 years) is different. The older SLE patient presents clinically more like a patient with drug-induced SLE than one with idiopathic disease [9]. These older patients have a low to absent incidence of renal disease and primarily pleuropericardial and musculoskeletal symptoms [10]. Older patients rarely have low complement levels and native DNA antibodies, whereas anti-single-stranded (ss) DNA antibodies are common [2]. Serositis, interstitial pulmonary disease, anti-La anti-

TABLE 1 Clinical and Laboratory Features in 13 Late-Onset Patients with SLE Compared to a Meta-Analysis of Other Series[a,b]

	13 patients, present study (OR)	170 patients (pooled OR)
Clinical		
Fever	0.51	0.21 ↓
Butterfly rash	0.23 ↓	
Discoid rash	0.86	
Photosensitivity	0.83 ↓	1.10
Mouth ulcer	0.85	0.74
Alopecia	0.21 ↓	0.47 ↓
Raynaud's syndrome	0.38	0.48 ↓
Arthritis	0.41	
Pleural	7.32 ↑	
Pericarditis	3.51	
Serositis	5.32 ↑	1.63 ↑
Lung involvement	7.33	3.48 ↑
Cardiac involvement	0.87	
Nephritis	1.71	0.79
CNS involvement	0.71	0.52 ↓
Myositis	1.84	0.68
Lymphadenopathy	0.54	0.39 ↓
Laboratory		
Leukopenia	0.87	0.67
Thrombocytopenia	1.17	
Anti-daDNA	0.56	0.76
Anti-Ro antibody	0.66	
Anti-La antibody	3.44	4.24 ↑
Hypocomplementemia	1.18	0.54 ↓

[b] ↑/↓: increase/decrease incidence of feature compared to patients with early-onset disease.

bodies, and Sjogren's syndrome symptoms (secondary sicca) are commonly associated with the disease of the older age group [1] as revealed by meta analysis. Alopecia, Raynaud's, phenomenon, fever, lymphadenopathy, hypocomplementemia, and neuropsychiatric disease are not common in this age group. As in all aspects of medicine, generalizations cannot be made because some older patients have native DNA antibody and severe clinical signs of renal disease [11, 12].

In a retrospective study of 102 patients with late-onset SLE, there was loss of the female preponderance, a more insidious onset of presentation, less skin manifestations, and more serositis. Table 1 shows 13 patients from a study compared to a meta-analysis of other studies. No differences in renal, neuropsychiatric, cardiac, pulmonary, or liver involvement were found when the older group was compared to the new [13].

Race

In most studies cited, Caucasians are the predominant ethnic group with late-onset SLE [14]. In one study [2], 59% of the younger SLE group were Black patients, whereas only 20% in the older age group (>50 years) were Black. In still another study, 87% of the patients in the older group were Caucasian and about 6.5% were Black [8]. Reasons for this unusual racial predilection for older age SLE patients need further investigation but may be related to a greater severity of the disease in Blacks. In fact, data from the National Institutes of Health suggest that the over all mortality of lupus in the young black female is five times greater than that found in Caucasians. It is clear that age and race influence both morbidity and mortality. A major study [15, 16] of survival in SLE in which follow-up was 75.6 months revealed that race and socioeconomic status had significant effects on survival. No diminished lupus-related mortality with age was documented but morbidity in women decreases with age. The authors suggested that race distribution between young and old patients with SLE might confound the results.

Course and Therapy in the Older Patient

Older SLE patients had a mean age of onset of disease of 59.5 years in one study (range 50–81 years). In that study the mean age at diagnosis was 62.4 years (range 52–83 years). Moreover, these patients can be maintained on lower doses of corticosteroid, and conservative therapy is usually the rule. Only 42% of these patients required high-dose corticosteroid (>25 mg/day × I month), whereas 23% could be maintained on 1–25 mg per day, and 35% never needed steroids [8]. Patients with late-onset disease require less medication and lower doses of immunosuppressive agents [17].

Survival in the older age group is good; the 5-year survival rate was 92.3 ± 5.3%, and 83.1 ± 10% survived 9 years at follow-up. One conclusion might be that older patients rarely die of their disease or the complications of therapy when they are treated conservatively. However, at least one study suggests that major causes of death in the older age groups are related to therapy [18]. Unlike younger patients, where the major mortality is atherosclerosis, infections and perforated peptic ulcers remain the most common cause of death in older patients [6, 19, 20].

Comments on the Elderly SLE Patient

There are many factors that hypothetically could predispose the older patient to SLE, including [8] liver and thyroid disease or exposure to certain exogenous

agents, such as hormones. None of these theories is proven at this time.

A popular leitmotiv about why the immune system becomes hyperactive at a time when a human ages is that there is a decline of immune surveillance. The appearance of autoantibodies in older people without disease has always suggested that tolerance might decline with age. Readers are referred to Chapter 1 on autoimmunity, Chapter 3 on etiology, and Chapter 2 on antigenic tolerance and are asked to draw their own conclusions regarding the possible pathogenetic mechanisms that are operable.

GENDER AND SLE

Sex steroids play an important role in the maturation of organ systems that affect animals throughout life [21] and are therefore important to the health of most vertebrates. Even though the most obvious effects occur at puberty in the development of secondary sexual characteristics, hormones affect major developmental changes even before parturition. Diverse biologic functions including behavior, intelligence, sexual preference, physical stature, and the immune system, are likely targets for these hormones. The effects of sex steroids on the immune system are profound and long lasting because they control the maturation of various cell systems and may influence susceptibility to disease through the modulation of immune cell populations throughout the life of the animal. This might happen through alteration of cytokine levels, control of cell populations through processes such as apoptosis, or alteration of very basic molecular mechanisms. Lupus is one disease that is very affected by hormones, as the skew toward females is significant for SLE.

Murine Models of Autoimmunity and the Sex Hormones

Although this book contains an entire chapter about murine models of lupus (Chapter 8), it is appropriate to briefly mention the background for the study of gender effects on experimental SLE. Several strains of mice are used as models of autoimmune disease [22]. The disease in some murine models predominates in females of the species, examples are the *New Zealand white/black (NZW/NZB)Fl hybrid* and the *MRL lpr* strains in which females die before males [23, 24]. In one specific strain of mice the disease favors males, the *BXSB* (derived from the *C57BI/6* and satin beige mouse), and this strain is unusual in that the males die of early SLE-like disease [25] . Unlike the female predisposed strains of mice, disease manifestations in the *BXSB* mouse are not mediated hormonally because neither administration of sex steroids nor gonadal extirpation improves or changes the disease manifestations. One strain of mice bred because the mouse develops polyarteritis nodosa, called the *Palmerston North* (PN) mouse [26, 27], also develops an SLE-like illness that favors females. Gender is not solely responsible for the disease lupus in these inbred strains, as all mice succumb to lupus, male and female; however, sex hormones affect both the severity and the onset of the illness in both sexes of any species.

NZB/NZW Strains

The effects of gonadal hormones were first noted to play a regulatory role with regard to SLE in the New Zealand (NZB/NZW) mouse. The F1 descendants of the parental strains were important to lupus because inbreeding resulted in accelerated disease and development of disease manifestations such as autoimmune hemolytic anemia [23, 24] and diffuse proliferative glomerulonephritis. Circulating DNA-containing immune complexes and a variety of autoantibodies like those to native DNA and ssDNA [28–30] also accompanied the clinical disease as in the human. Before the discovery of the NZB/W strain, the manifestations of autoimmune disease were unknown in any animal species except humans. The gender difference is not amazingly large in the parent strains as a high percentage of the NZB females develop severe proliferative glomerulonephritis and die by 15 months of age, whereas the mortality for males is 17 months. When NZB mice are mated with NZW mice, the offspring (F1 hybrids) begin to develop kidney disease at 9 months, and again the most severe lesions are found in females [24]. To again emphasize gender, renal lesions are more common to the female (NZB x NZW)F1 in the cross of an NZB female and NZW male. In the F1 hybrids, 90% of the females develop dsDNA antibodies at age 8.5 months and more than 50% of the females die as a result of renal disease [31].

An explanation of various immune functions in these lupus mice has not revealed much. Thymic functions in these mice, particularly T-cell-mediated responses, have been studied and are blunted [32]. After age 22 weeks, the phytohemagglutinin responsiveness of circulating lymphocytes is lost, and this loss of function is more pronounced in females [33, 34]. This finding, one that is distinctly and skewed toward the female, might be the result of the development of anti-T-cell antibodies [35].

Cellular changes found in the NZB/NZW mouse are covered elsewhere in detail (Chapter 8). These observations are found more commonly in females of the F1 generation, which have an apparent B-cell abnormality

that is present from birth that results in the overproduction of IgM [36]. Athymic NZB mice are known to have hyperactive B cells (consistent with polyclonal B-cell activation) [37]. Aberrant B-cell dysfunction in NZB mice is reflected by their resistance to the induction and maintenance of tolerance [38]. This last characteristic is part of the "female character" of most of the murine SLE strains. Sex hormones also influence the response of the NZB strain to thymus-dependent antigens, as high-dose testosterone therapy decreases and orchidectomy increases plaque-forming colonies (PFC) in NZB males if the mice are irradiated sublethally after treatment with sex hormones [39].

Sex steroids also adversely affect the course of disease in F1 female hybrids of the NZB/NZW cross. As the mice age, the illness becomes more profound, but prepubertal castration of the NZB female mouse does not decrease the death rate. Early estrogen therapy accelerates the disease in females, whereas ovariectomy or testosterone therapy prolongs the life of the mouse. In males of this strain, castration causes early death and estrogen produces a mortality rate that is similar to that of females [40, 41]. Overall, testosterone therapy of female mice prolongs life and decreases overall morbidity [42–45].

It is possible that sex steroids modulate the generation of antigen-specific suppressor cells and that true sex differences in the responses to T- and B-cell mitogens exist in this strain. Androgens increase suppressor cell activity in NZB/NZW mice [46, 47] and it may do this by increasing levels of interleukin 2. Androgens also suppress the development of the thymocytotoxic antibody [48–50].

It is not rewarding to study sex hormone receptors on the lymphocytes of these mice because there are no differences. The thymus, a target of sex steroids, is of great physiologic significance, but estrogen and testosterone receptors are not located on mouse peripheral blood lymphocytes [51]. However, estrogen-induced receptor binding is observed in thymic tissues from male NZB/NZW mice, and estrogens may act entirely on the thymus gland [52]. The role of sex steroids in the pathogenesis of lupus-like disease in the inbred mouse is based on simple observations that alteration of sex steroid levels or gonadectomy affects the progression of disease. Importantly, the mouse will succumb to lupus whether male or female, but the sex steroids regulate disease activity.

MRL Strain

The MRL (Ipr/lpr or n/n) strain of mice has a lupus-like disease that is closer serologically to the human disease for various reasons. This mouse produces a greater variety of antibodies to antigens such as DNA, RNP, SM, and rheumatoid factor [53]. Because of the rheumatoid factor, this strain is a useful model for the study of rheumatoid arthritis [54]. These mice are also models of Sjogren's disease because of serologic characteristics and the development of signs such as lymphadenopathy. The mice are homozygous for the lymphoproliferative gene lpr and a large number have profound lymphadenopathy. The congenic n/n or +/+ strain lacks the lpr gene [55].

Sex differences in these MRL mice are less marked than in the NZB/NZW strain. No lymphadenopathy is found in +/+ mice, although necrotizing arteritis and glomerulonephritis are common and about 50% of the +/+ mice die with neoplasms. Again the female gender predominates, consequently, the mean ages for death are 17 months for females and 22 months for males [56].

Hormone therapy of these mice using high doses of the androgens testosterone and 5β-dihydrotestosterone delayed the occurrence of both lymphadenopathy and autoantibody production [57, 58]. Increased prolactin levels accelerate autoimmune diseases in NZB/W F1 mice.

BXSB Strain

BXSB mice are unique in that spontaneous autoimmune disease is more common in the males. This is distinctly different from the female predilection in most murine lupus strains. The males have a mean life span of 5 months, and the female life span averages 15 months. Examinations of cell populations of this strain have shown that both B- and T-cell functions are normal [25]. The accelerated autoimmune disease in these mice is linked to the Y chromosome, and prepubertal castration will not alter the course of the disease. The transfer of bone marrow cells from diseased males to nondiseased males leads to the development of the autoimmune disease [59, 60].

General Remarks about Murine Lupus and Sex Steroids

All of the evidence cited earlier indicates that sex hormones play a major role in the modulation of autoimmune diseases of some lupus mouse strains. There are certainly many other aspects to consider in the morbidity of murine SLE, and the major one is genetics and possibly the presence of a transmissible agent. It is also apparent that sex steroids have an adverse effect on the disease as in the human.

The disease manifestations wax and wane in a fashion commensurate with fluctuating steroid levels,

which vary with the estrus cycle in females. Fundamental questions, such as the susceptibility to SLE and the "window," if any, during which sex steroids exert their most profound influence, are the subjects of current investigation.

Sex Chromosomal Effects

Chromosomal effects are important because at least one murine strain, the BXSB, depends on the Y chromosome for the character of its immune responses. There are many other examples. Immune responses to DNA are linked to the presence of the X chromosome in the NZB/NZW mouse. NZB or NZW males mated to BXSB females result in female offspring that die of SLE nephritis at an early age. This suggests a role for the recessive X chromosome in the male parent [61].

Steroid Effects

Some research on the effects of androgens on immune function suggest that they act on immune tolerance [62]. Mice that develop autoimmune diseases have defective tolerance to a variety of antigens, and androgen levels could be at the heart of the problem. Graft-vs-host disease can induce a SLE-like syndrome in some mouse strains, and tolerance probably has a major position in the schema of autoimmunity [63]. Because androgens modulate the T-cell phenotype in transition from marrow to the thymus [46, 47], the target of androgen action is likely to be the thymocyte. Using 20α-hydroxysteroid dehydrogenase as a T-cell marker, investigators noted a decrease in thymocytes and a rise in T suppressor cells after androgen administration [64]. The hypothesis that androgens act in this manner is attractive because androgens afford a method of altering the absolute numbers of T cells.

Gonadotropin Effects

There is great interest in the effects of prolactin on immune function in mice and humans [65]. There are diverse effects of hyperprolactinemia in both male and female mice, and multiple studies show that prolactin stimulates the appearance of murine disease. Early studies found that the male NZW/NZB mouse autoimmune disease was accelerated and mortality was worsened by prolactin [66, 67]. Murine lupus, as noted earlier, is similar to that found in the human in that prolactin has a role to play in the exacerbation and possibly the initiation of lupus in the human (see later). Estrogens stimulate prolactin and may be the overriding mechanism. Bromocriptine inhibits the development of murine lupus [68]. Murine studies even demonstrate that estrogen itself might depend on the stimulation of prolactin for activity [69].

Sex Steroids and Human SLE

In human SLE there is little consistency of disease manifestation from patient to patient even within the same family. A patient or sibling from one family may present with autoimmune hemolytic anemia, whereas another will present with encephalopathy. Moreover, siblings from the same family who are of different gender might be equally affected.

Therefore, while gender plays a major role in the expression of SLE, it is not likely to be part of the etiology but rather an expression modifier. The vast majority of patients who present with SLE after puberty are females. Present evidence suggests that estrogens or those steroids that are exceptionally feminizing exacerbate SLE [70]. Among such compounds are synthetic estrogens, such as birth control agents [71, 72]. There are data to suggest that previous estrogen use is a predisposing factor for lupus and data to show that it is not.

The times in a woman's life that are important to SLE activity are the menstrual period [73, 74] and pregnancy, both before and after parturition. These periods may worsen the activity of SLE and depend on the levels of gonadal steroids. Because of the large numbers of women with lupus, the X chromosome could play a role [61]. A major concern regarding women with SLE is the fact that they are 50 times more likely to have a myocardial infarction than men (35 to 44 age groups). In those who had a cardiovascular event, an older age at diagnosis, longer disease duration, more steroid use, postmenopausal status, and high cholesterol levels were all associated with this increase in SLE cardiac disease [75].

Patients with Klinefelter's syndrome (XXY) are described who have clinical SLE and disordered estrogen metabolism [76]. Study of such males provoked the initial series of experiments designed to look at the patterns of estrogen and androgen metabolism in SLE. These studies revealed that patients with SLE have altered sex steroid metabolism. Because sex steroids regulate immune function, there can only be differences between the way the immune systems of males and females respond to sex steroids and gonadotropins. The only gonadotropin shown to have a major effect on the SLE of mice and humans at this time is prolactin.

Estrogens

Females are likely to have more aberrations of the immune system than males. Male and female patients with SLE have normal levels of estrogen; however, the

overall metabolism of such compounds favors more feminizing compounds such as estriol and 16β-OH estrone [70]. Specifically, the pattern of hydroxylation of estrone (Fig. 1) favors the 16-hydroxylated compounds over the cathechol estrogens [77]. Patients of both sexes have increased levels of 16α-hydroxyestrone (Table 2), whereas only SLE females and Klinefelter (XXY) males had elevated levels of estriol [78]. The compound 16α-hydroxyestrone and its elevation in SLE patients could have some special significance, as later studies demonstrated that this hormone had unique qualities [79].

One estrogen, 16α-hydroxyestrone, is feminizing, highly uterotropic, and modestly bound to cytosol receptors and testosterone–estradiol-binding globulin in contradistinction to compounds such as 17β-estradiol [80]. A radioimmunoassay, however, failed to show

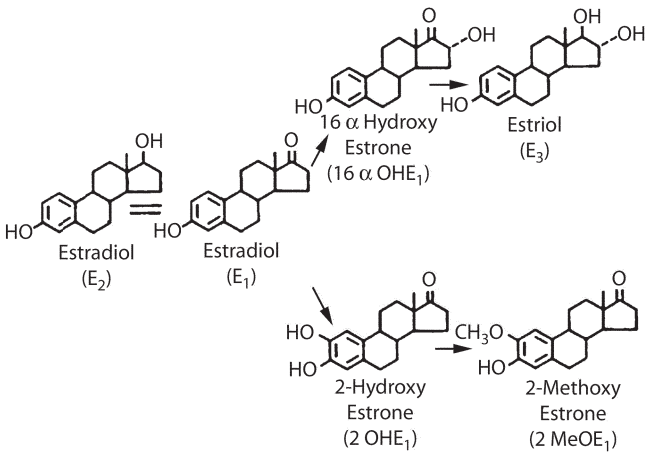

FIGURE 1 The metabolism of estradiol. Estradiol is converted to estrone that can go in one of two directions: toward the 16-feminizing metabolites or the catechol estrogens that are the 2-hydroxylated metabolites. In patients with lupus the preferential direction of estrone metabolism is in the 16-hydroxylated direction.

uniformly elevated levels of 16α-hydroxyestrone in active SLE patients [81]. This suggested either that a conjugated form of this steroid was active or that there were many metabolites of importance from this proposed scheme. Enzymatic systems in certain animals might favor the formation of such compounds, although nothing is known about lupus mice with regard to this metabolism. Clinical studies on the steroid 16α-hydroxyestrone showed that it had interesting properties *in vivo* that might explain its possible role in disease, including covalent binding of this steroid to erythrocytes and lymphocytes via a Heyn's rearrangement *in vivo* and the possibility that such covalent binding might occur at the level of the estrogen receptor or the T-cell receptor and result in an alteration of immune function [82, 83]. Studies of family members of SLE patients indicated that elevated hydroxylation of estradiol was commonly observed in nonaffected first-degree relatives as well as patients [84].

Enhanced binding of l6α-hydroxyestrone to various cell proteins was found in normal women ingesting oral contraceptives. Of particular interest, specific antiestrogen–protein adduct immunoglobulins were isolated from normal and SLE patients ingesting oral contraceptives, which means that these adducts are common. This finding suggested a common pathway to adduct formation in all women who ingest large amounts of estradiol or for one reason or another have an endogenous source of high estrogen level [79]. Males with SLE were also reported who had hormone protein adduct-specific IgG in their sera.

Androgens

There have been several studies of androgen levels in plasma of men and women with SLE and of androgen metabolism in men and women with SLE [70]. Some investigators have said that the reasons for SLE in the male are the result of too little androgen and too

TABLE 2 Rate of Hydroxylation in SLE

		Rate	
	Number studied	2-Hydroxylation[a]	16-Hydroxylation[a]
Males			
Normal	13	21.3 (±8.7) (7.4–34.2)	7.5 (±2.1) (3.2–11.1)
SLE	6	21.9 (±13.4) (8.6–35.0)	12.3 (±2.7) (8.8–16.8)[b]
Females			
Normal	14	40.4 (±5.9) (17.7–54.7)	9.5 (±2.2) (5.9–14.1)[b]
	15	25.6 (±17.4) (6.0–67.1)	15.7 (±5.0) (9.0–30.0)

much estrogen [85, 86]. These studies are exceptions, however, as most studies indicate that young men with SLE are hormonally normal and that estrogen:androgen ratios might be minimally elevated (if at all). Furthermore, data from studies of males with SLE do not help explain the large numbers of females who predominate with the disease. Studies of androgen metabolism in SLE females indicate that a difference in the overall metabolism of androgens can be found (Fig. 2). The oxidation of testosterone at C17 in SLE females is increased in comparison with males, who have both normal oxidation of testosterone and normal plasma levels of androgenic steroids [87]. Several studies of females with active SLE who never took corticosteroids had decreased plasma levels of androgen [88–90]. This observation was also found in Klinefelter patients, as well as in women with lupus. Low plasma androgens in women with SLE form the basis for androgen replacement therapy in this disease. Clinical studies involving the use of DHEA as a therapy for lupus result from this observation.

Gonadotropins

Prolactin is an immunomodulatory pituitary hormone and could be considered a cytokine itself. In the human, prolactin elevations have been observed in SLE juveniles and correlated with both disease activity and central nervous system (CNS) manifestations [91]. This finding is supported by *in vitro* work showing IgG and IgM induced anti-DNA antibodies by both normal and SLE lymphocytes in the presence of high levels of prolactin. Lectins did not produce this effect [92]. One study correlates elevated prolactin levels with elevated cortisol levels [93, 94].

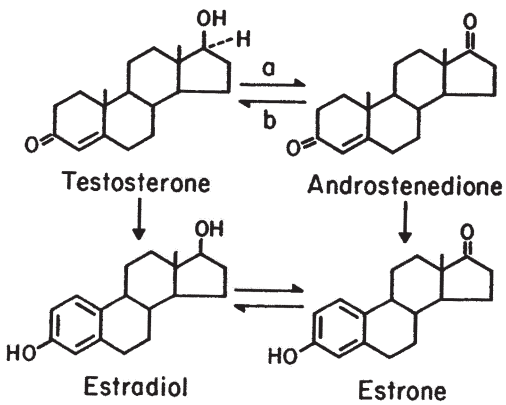

FIGURE 2 The oxidation of testosterone. Testosterone has several possible fates in the human. Testosterone can be converted to the weak androgen androstenedione that can then become estrone or testosterone can be aromatized to estradiol directly. In lupus patients the oxidation of testosterone at C17 (reaction a) is increased in women with lupus and not in men.

Women who are pregnant have higher serum prolactin levels if they have SLE [95]. Moreover, some investigators have associated the decline in serum testosterone during pregnancy in SLE patients to hyperprolactinemia. Perhaps, however, the most significant descriptions of hyperprolactinemia have been in men with SLE [96]. These descriptions of hyperprolactinemia are of particular interest as hyperprolactinemia is treated readily with bromocriptine. Studies using bromocriptine to treat SLE are routine in some clinics around the world.

Many studies refute the significance of prolactin in human SLE [97–99]. In a detailed study of a Chinese cohort of patients with SLE, Mok *et al*. [100] found no correlation of clinical activity with levels of prolactin in 72 lupus patients. A look at autoantibodies in patients with lupus found no association of prolactin levels with specific lupus autoantibodies [101]. One particular study suggests that prolactin is complexed with IgG but remains biologically active in the lupus patient [102, 103]. This binding of prolactin (a specific 23-kD a nonglycosylated form) to IgG is not covalent. Delayed clearance of this complex due to its high molecular weight is the proposed reason for the activity of the prolactin in most patients with lupus.

Many investigators associate prolactin with disease activity [104]. In one study, 61.9% of patients with hyperprolactinemia had active disease. The SLEDAI correlated with the levels of prolactin in these patients as well when prolactin levels were measured by both tests of immunoradioactivity and biological activity. Another series noted an association of hyperprolactinemia in the serum and urine of patients with severe renal disease [105]. The statistical power of most of these prolactin studies could explain the lack of consistency among research laboratories. One study suggests that the published results are contradictory due to the statistical power of the studies. In fact, the authors reviewed five studies and found that two of the studies did not have the statistical power to conclude an association with lupus activity and prolactin levels, whereas the other three studies did suggest an association [106]. High prolactin levels are found in 20–30% of patients with SLE in some clinics [107]. In addition to the suggestion that prolactin is itself a cytokine that provokes the synthesis of immunoglobulins by lymphocytes [108], German investigators found that using lymphocytes from SLE patients and measuring clinical activity with the European activity measure (ECLAM) that SLE patients have lymphocytes that are sensitive to levels of prolactin and are likely to be activated by physiological concentrations [109]. These data are supported by the

findings that T lymphocytes from SLE patients secrete more prolactin than controls, suggesting a difference in the regulation of genes responsible for control of this cytokine. In fact, single nucleotide polymorphisms in the upstream promoter regions of both pituitary and non-pituitary prolactin secretion exist. Such polymorphisms that are specific can affect prolactin transcription and possibly disease association in a cohort of lupus patients. This was the case in a study where patients had an increased frequency of the prolactin-1149G allele when compared to control subjects [110]. Whether prolactin is a cytokine or is itself increased by cytokines common in certain active lupus patients remains the subject of major investigation.

Finally, prolactin levels of mothers who were pregnant or breast-feeding and had lupus were studied as reproductive risk factors for the development of disease [111]. Surprisingly, breast-feeding was associated with a decreasing risk of developing SLE. In addition, the numbers of pregnancies or live births with lupus activity showed no relationship to levels of prolactin. These authors found no association of elevated prolactin levels with an increased risk of lupus.

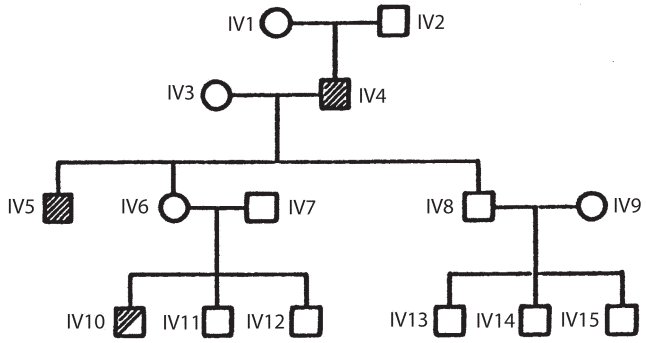

FIGURE 3 This pedigree shows one of three families where lupus occurs in males of each family. No females have acquired lupus in any of these families, whereas three generations of males are affected.

Males with SLE

The age of onset of the disease is distributed more evenly in males, as one-fourth are diagnosed after age 50 years [112]. Hormonal metabolic study data suggest that an increase in feminizing 16-hydroxylated estrogenic metabolites is found in SLE males, although no phenotypic evidence of hyperestrogenism is found [77, 84, 113–115]. The BXSB mouse develops SLE-like disease in a nonhormone-dependent fashion. The presence of the Y chromosome is most important in this strain. A group of human male relatives has been described who resemble the mouse strain BXSB in that "male-predominant" families exist in which SLE occurs in men in preference to females (Fig. 3) [116]. In one interesting study of males with lupus, females that have a male relative with lupus were more likely to have renal disease [117].

Males with SLE are in some series reported to be clinically different [118–120]. While several male studies show no clinical difference in severity of disease between women and men, others have suggested that males have a more severe form of the disease [121]. For example, increased pleuropericardial disease and peripheral neuropathy are said to be more common in males. Men were found to have more discoid lupus erythematosus and papular nodular mucinosis [122]. In a Spanish series of 261 SLE patients, 11.5% were males and they had less arthritis, more serositis, and a greater propensity for discoid rashes. A database on males from Malta also found more cardiorespiratory problems in males [123], and a Taiwan study suggested that males have a significantly lower FcγR distribution on monocytes and neutrophils and high prolactin levels that might have a role in the pathogenesis of lupus in this sex [124]. All of these data are collected from small numbers of men and such things as statistical bias might be significant.

Sex hormone profiles indicate that men with lupus have significantly higher levels of gonadotrophins like follicle-stimulating hormone (FSH) or leutinizing hormone (LH) than controls. A small percentage of patients (14%) in one study had low testosterone and elevated LH levels [125]. Patients with low androgens had more CNS disease and serositis when compared to controls. Finally, the prolactin to testosterone levels correlated with the SLEDAI scores in these men.

Studies of Russian male lupus patients are perhaps the most insightful [126, 127]. Investigators described elevated LH and FSH in SLE males; a lower trochanteric index (1.89 vs 2.00 for normal men), which is indicative of a lack of androgen effect on bone growth; severe aortic insufficiency and sacroileitis (12% of all men); and overall a greater incidence of severe vascular diseases, such as Raynaud's phenomenon and digital vasculitis [128].

Russian investigators found more severe disease in men, with 63% dying from end stage renal disease. Table 3 illustrates the vascular manifestations of male patients with SLE. Table 4 shows the frequencies of various clinical manifestations in both male and female patients. Note that the only significant increases in Russian males with SLE are the incidences of nephritis, Raynaud's phenomenon, and malar rash.

Finally, the Russian study also included male SLE patients with profound impotence. The causes of such impotence in young SLE males remain unknown

(Table 5). Elderly males who present with SLE are also found to have low androgen levels and are hypogonadal [12]. Such males might respond to androgen therapy.

Males with Klinefelter's Syndrome

Patients with Klinefelter's syndrome can also have a variety of rheumatic diseases such as SLE and scleroderma [129–134]. Such males commonly have gynecomastia, infertility, a female fat phenotype, and the usual sequelae of hypogonadism. These Klinefelter males have met ARA criteria for SLE both serologically and clinically (Fig. 4). The incidence of SLE or any other autoimmune disease is not increased in patients with

TABLE 5 Results of Studies of Impotence in Systemic Lupus Erythematosus[a]

1. Thirty-six percent of males with SLE have sexual disturbances
2. Impotence develops before SLE onset
3. Decreased libido and satisfactory effect of androgen therapy suggest an imbalance of sex hormone levels
4. Impotent patients with SLE have a twofold decrease in testosterone levels

[a] These are male SLE patients with mild and moderate disease activity who did not receive cytotoxic or corticosteroid drugs.

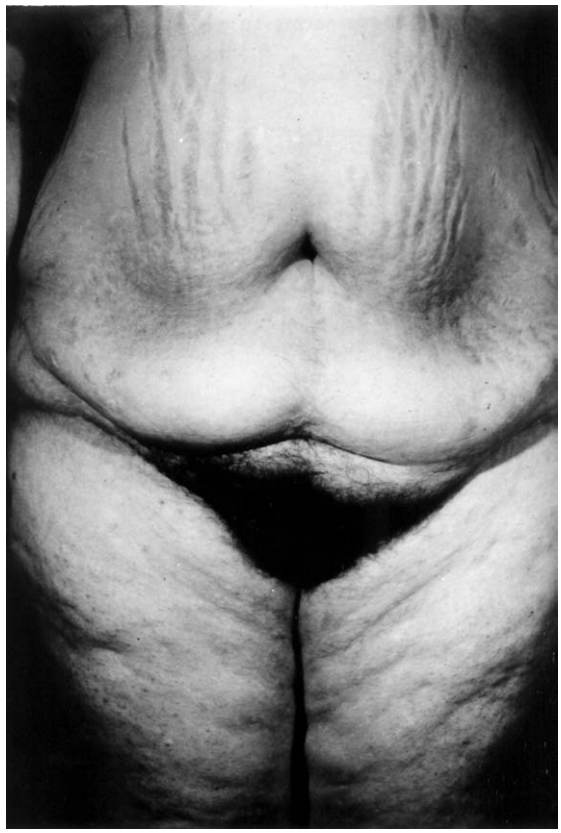

FIGURE 4 This is the midsection of a Klinefelter male with SLE. Note the ambiguous genitalia and the female distribution of fat.

Klinefelter's syndrome, even though this is frequently stated. Patients with SLE and Klinefelter syndrome together have the estrogen and androgen metabolism of females with SLE [76], but low levels of both sex steroid classes. This is the reason that the Klinefelter syndrome is a hypergonadotrophin state. When SLE does occur in young Klinefelter males, it can be treated with the synthetic androgens usually given to such males. Androgens such as methyltestosterone as a tablet, androgen patch,

or gel can alleviate the symptoms of the disease in Klinefelter males but do not alter the amount or type of autoantibody. The male with Klinefelter's syndrome and SLE oxidizes testosterone in an exaggerated fashion like females with SLE. This increased oxidation is not found in the SLE male with a normal XY karyotype. The hypergonadotropic state of men with Klinefelter's syndrome and SLE has not been investigated adequately at this time and may have some role in the etiopathogenesis of the disease.

Hyperestrogenism

Hyperestrogenic conditions are associated with antoantibodies in both normal males and females. In the human female, periods of hormonal change such as pregnancy and normal menses are associated with changes in immune function. These changes are also observed in mice. Clinical syndromes such as insulin-resistant diabetes mellitus, hirsutism, and cystic ovaries are found in patients with autoantibodies [52, 135]. Polycystic ovary disease may be considered autoimmune, and autoantibodies could result from the unopposed actions of plasma estrogen [136]. More recently, autoantibodies have been described in patients with endometriosis, and patients have been referred as those with a lupus-like illness [137, 138]. This may be of particular interest, as the uterus and the ovaries of humans and animals are a source of cytokines [139].

Estrogens and Lupus

Data from mice and humans have shown that unopposed estrogens exacerbate SLE. Data from human studies, however, are largely *in vitro* or are derived from anecdotal studies of patients on oral contraceptives. Most studies involving oral contraceptives and SLE or hormone replacement therapy in postmenopausal women with SLE suggest that the disease worsens with these agents. However, these studies are inconclusive and difficult because of the variability of the human illness, the designate end points of therapy, the steroids chosen, and the lack of a double-blinded study. Data strongly suggest that the use of hormone replacement therapy (HRT) predisposes women to the development of SLE [140]. Results of the contraceptive/hormone replacement trial, a double-blinded control study to look at oral contraceptive use and HRT in lupus women, are in progress and data should be available shortly. Current epidemiological studies do not support the idea that female hormones increase the risk of developing SLE [111, 141]. Sex steroids have been considered for use in inflammatory diseases such as gout and osteoarthritis because estrogens suppress neutrophil function [142], which is why [143] gout is uncommon in the premenopausal female [144]. The overall gender-related mechanisms for the selectivity of one sex for a disease over another continues to evade explanation and there is debate about this from some quarters [145]. Estrogens may be effective in the treatment of rheumatoid arthritis, and several clinical studies have argued both for [146, 147] and against their use [148]. The mechanism of suppression of inflammation in cases of rheumatoid arthritis may give some significant insight into the pathogenesis of this common disease and is based on two observations: (1) patients improve when pregnant and (2) oral contraceptives may have a protective effect. Menopause is an interesting time for most lupus patients. For many years, patients who reached menopause were known by most clinicians to improve. These conclusions were without data until recently when menopause has been conclusively associated with a remission of illness [149]. Most authors conclude that a "modest" decrease of activity occurs in those women reaching menopause [150].

Androgens and Lupus

Therapy of SLE with anabolic steroids such as Danazol or cyproterone acetate is not effective therapy for either murine or human SLE [151–154]. However, the use of hormones such as Danazol in idiopathic thrombocytopenic purpura increases platelet numbers and coagulation factors such as factor VIII. This suggests a role for certain patients with SLE [155, 156]. Other androgens under study, such as 19-nortestosterone, have also had limited use in the treatment of SLE in women. Doses used were 100 mg/ml per week intramuscularly. While the overall condition of female patients improved and patients admitted increased energy, loss of joint pains, and resolution of svstemic abnormalities such as skin rashes or anemia (Fig. 5), no significant change of serologies was noted. Anti-DNA and ANA titers remained elevated. Most curious in this treatment group was an overall worsening of lupus symptoms in male patients [157]. These findings in males on 19-nortestosterone correlated with lowered endogenous testosterone levels and elevated estradiol levels.

Another steroid, cyproterone acetate, a potent antigonadotrophic agent [158], resulted in resolution of some systemic abnormalities such as oral ulcers after 50 mg daily for a mean of 63 months. As with other androgens, no improvement in serologic features was observed.

Another approach to the treatment of lupus involves the use of gonadotropic hormone-releasing hormone agonists. These agents are used effectively to treat endometriosis and prostate carcinoma. Data about their

FIGURE 5 (**A**) A young woman prior to the institution of 19-nortestosterone therapy. (**B**) The same woman 2 years later after intramuscular injection of 100 mg/week of 19-nortestosterone.

use in SLE are inconclusive because of the small numbers studied [159, 160].

One androgen, studied extensively in women, is dehyroepiandrosterone (DHEA) [161, 162]. This drug at doses of 200 mg per day in tablet form results in clinical improvement as measured by standard indices and is steroid sparing, i.e., the total dose of prednisone might be lowered with its use. This drug suppresses cytokine levels such as IL-4, -5, and -6 and increases IL-2 during treatment. Natural killer cell activity also increases with this agent [163–165]. This drug is discussed in more detail in Chapter 48.

Sex Hormones, Behavior, and Autoimmune Diseases

Sex steroids are important to the development of various organs, and a major one is the brain. Attention has been directed to cerebral development, cerebral dominance, and the incidence of autoimmune disease [166, 167]. Some studies say that patients with antoimmune disease are predominantly left handed, indicating dominance of the right cerebral hemisphere. This variation is reported in patients with SLE [168–170] and other diseases of the immune system. Neuronal migration is under the influence of steroids such as testosterone, and new data suggest that SLE mice have aberrant neuronal migration patterns consistent with those observed in humans with learning disabilities such as dyslexia. Handedness in patients with SLE is more directed to the left than in the normal population. The finding of increased learning disabilities such as developmental dyslexia in patients with SLE, their unaffected male offspring, and unaffected male siblings has been confirmed by several groups and is a subject of considerable interest.

Sex Hormones and Immune Function

Androgens

Androgens have many effects on immune function. They are immunosuppressive because of *in vitro* observations in normal lymphocytes and because of their

effects on the disease manifestations of inbred autoimmune mice [171]. Testosterone suppresses anti-DNA antibody production in peripheral blood mononuclear cells from patients with SLE [122]. This occurs through the downregulation of IL-6 and the inhibition of B-cell activity. Graft rejection in rodents is delayed by the injection of testosterone. Resistance to certain viral infections is reduced, whereas in some cases resistance to certain infections is enhanced when androgens are given at certain doses [172, 173]. A consistent effect of androgens in animals is the immunosuppression of chickens through the retardation of the function and development of the *bursa of fabricius* [174–176]. Androgens also have an effect on the pluripotential stem cells of the bone marrow: namely the accelerated proliferation and differentiation of such stem cells into compartments of cells that number among them lymphoid elements. The important effects of androgens on immune maturation are reflected by the discovery of receptors for estrogen and dihydrotestosterone, a 5α reduced metabolite of testosterone in the thymus [177–179]. Androgen receptors are found on lymphocytes, but data are inconsistent. Androgens inhibit B- and T-cell maturation, reduce B-cell synthesis of immunoglobulins, and suppress the phytohemagglutinin-induced blast transformation of lymphocytes. Androgens are implicated as modifiers of regulatory genes that influence the function of structural genes [180]. For example, guinea pig mammary epithelial Ia antigens are increased in number through the effects of estrogens and prolactin and are decreased by testosterone [181]. The wide range of effects that this steroid displays might be due to variable androgen sensitivity of certain cell groups or the *in vivo* conversion of androgens to estrogens through well-recognized pathways.

Estrogens

Female mice make more antibody to foreign antigens than males, and this difference is reported for a variety of antigens [182]. Depending on the dose, estrogens have been both immunosuppressors and immunostimulants. The steroid 17β-estradiol prolongs first and second set skin grafts in mice after X irradiation and inhibits corneal graft acceptance in preimmunized rabbits [183]. In general, however, skin allograft rejection is naturally better in females than in males [184]. Estrogens regulate immunity by way of the thymus in rodents [185] and decrease the overall thymic population of small lymphocytes. Estrogen given prior to bone marrow transplantation results in increased graft failure. Estradiol and diethylstilbestrol (in concentrations of 10–50 mgm/ml) are known to reduce the phytohemagglutinin and concanavalin A response of lymphocytes *in vitro* [186]. The mixed lymphocyte reaction is enhanced by estradiol. Enhanced lymphocyte activity is observed at 200 ng/ml, whereas the effects are inhibited at 2000 ng/ml (thymidine incorporation). Fluctuant lymphocyte responses are observed during normal menses [74], during pregnancy, and during the use of oral contraceptives [187]. Castrated male and certain female mice display hyperplastic spleens and thymuses after challenge with thymic-dependent antigens, indicating an effect on thymic cell activity [188, 189]. Castration of males leads to accelerated allograft rejection. Syngeneic grafts of ovaries in males and grafts of testes in females have no significant effect on allograft rejection [190]. Sustained levels of estrogens in mice led to a marked reduction in natural killer cell activity. In other studies, estrogens have been found to depress cell-mediated immunity, natural killer cell function, and cancer cell immune surveillance. Estrogens also deplete thymic hormones and are known to produce a relative lymphopenia.

Estrogens are detrimental to animals with SLE and this refers not only to mice with SLE, but also other animals, such as dogs. In fact, tamoxifen and the antiestradiol antibody have beneficial effects on experimental SLE. This benefit occurs via cytokine regulation [191]. Men with prostatic cancer who are given diethylstilbestrol have markedly depressed cell-mediated immunity. Using normal lymphocytes, estradiol treatment of pokeweed mitogen-treated B cells shows an increase in plaque-forming cells (*in vitro*) [192, 193]. Estrogen receptors are found on $CD8^+$ T lymphocytes in some studies [194, 195], although data derived from more sensitive estrogen receptor CDNA probes have not confirmed these findings. Studies have shown that $CD4^+$ T helper cells increase after estrogen therapy [192]. By some studies, estrogens are thought to act by inhibiting $CD8^+$ suppressor T cells. Consequently, helper T cells would be enhanced with the resulting polyclonal B-cell immunoglobulin production. An exciting new direction is the inhibition of apoptosis *in vitro* using peripheral blood mononuclear cells from women with normal menses. The estradiol decreases tumor necrosis factor-α in SLE cells but not those from normal people.

Progestogens

Other sex steroids such as progesterone have been considered as effective therapeutic agents in diseases such as SLE. Progesterone is an immunosuppressive agent [41, 196], and levels of this substance rise during pregnancy when the placenta assumes an active role in its synthesis and secretion. At concentrations of 10–15 mgm/ml, this steroid reduces lymphocyte responses to phytohemagglutinin and to concanavalin A *in vitro*.

Other analogs (20α-hydroxyprogesterone) have similar effects [197].

Progesterone has been known to increase the relative amounts of $CD8^+$ suppressor cells and to decrease them in mice. In addition, progesterone has been invoked to explain many of the suppressive effects found in the sera of pregnant females.

SUMMARY

Sex steroids are potent modulators of immunity in all animal systems. They are very important in patients with SLE and may help explain the fluctuant activity in the disease lupus. Their role in the maturation of the immune system and their effect on the development of organs such as the brain could explain some of the abnormalities found in these systems.

GENES AND GENETICS OF MURINE LUPUS

Dwight H. Kono
Roberto Baccala
Argyrios N. Theofilopoulos

The genetic basis of systemic autoimmunity has now been clearly documented, and this progress has, ironically, also revealed the gaps in our understanding of this complex disease entity. Although the etiology of systemic lupus erythematosus (SLE) is still unknown, elucidation of the genes and their contributions to the development of lupus should reveal many of the fundamental events underlying the initiation and maintenance of systemic autoimmunity. Identification of the genes involved in the immunological and inflammatory processes that promote end organ damage will reveal the components crucial for disease manifestations, which can provide targets for therapeutic intervention. Delineating the genetic alteration that enhances susceptibility will define the causative mechanisms that lead to immune system-mediated self-destruction. The specific genes and pathways participating in immune system activation and homeostasis, along with gene manipulation approaches, have been investigated, and many new potential avenues for loss of tolerance and development of systemic autoimmunity have been identified. This chapter summarizes our current view of this rapidly evolving field.

MOUSE MODELS OF LUPUS

Spontaneous and induced mouse models of SLE have provided insights into the genetics and immunopathology of this disease (Table 1). The most commonly studied spontaneous models are the (NZB×NZW)F_1 (BWF_1) hybrid, MRL-*Fas*^{lpr}, and BXSB mice, strains that share characteristics, such as hypergammaglobulinemia, antinuclear antibodies (ANA), and glomerulonephritis (GN), and also possess unique features, such as arthritis and expanded $CD4^-CD8^-$ (double-negative, DN) T cells in MRL-*Fas*^{lpr} mice and hemolytic anemia in NZB mice. Details on the clinical manifestations and immunopathology for these and other spontaneous and induced models have been reviewed previously [1, 2].

Two new induced models of lupus-like disease have been added since the previous edition (Table 1). Nonautoimmune-prone galactose-α1-3-galactose-deficient mice exposed topically to commercial bovine thrombin preparations commonly used in human surgical procedures developed antibodies to the xenogeneic galactose-α1-3-galactose and, in a few cases, autoantibodies to clotting factors. Unexpectedly, they also produced anti-double-stranded (ds)DNA and anticardiolipin autoantibodies and developed immune complex-mediated GN with a higher frequency of disease in females [3]. The other model, type I diabetes mellitus-susceptible NOD mice, were given intravenous *Mycobacterium bovis* (bacillus Calmette–Guerin), which prevented diabetes but, surprisingly, induced systemic autoimmunity manifested by accelerated hemolytic anemia, antinuclear antibodies, exacerbation of sialadenitis, and immune complex-mediated GN [4]. Although it was initially hypothesized that susceptibil-

- Bovine thrombin-exposed galactose-α1-3-galactose-deficient mice [3]

ity to two different types of autoimmune diseases might be due to common autoimmune-predisposing genes, later mapping studies revealed no colocalization of loci predisposing to lupus or diabetes other than the MHC region [5]. These models provide striking examples of the complex interactions between genetic susceptibility and environmental factors that influence predisposition to SLE and other autoimmune diseases and demonstrate the utility of mouse models to help address this issue.

PREDISPOSING GENES IN SPONTANEOUS LUPUS MOUSE MODELS

The MHC genes, Fas receptor and ligand, and *Hcph* (hemopoietic cell phosphatase, SHP-1) (Table 2) are among the few genes identified as predisposing to spontaneous lupus. The Y chromosome accelerator of autoautoimmunity and lymphoproliferation (*Yaa*) gene, responsible for the male predisposition to lupus-like disease in the BXSB strain, has also been implicated using consomic mice (transfer of the Y chromosome), but the gene is not known.

MHC Region

In most lupus-prone strains, particularly BWF_1 [3, 4] and BXSB [5], the MHC complex has been strongly linked to the development of autoimmunity, but the contribution of MHC is highly dependent on other background genes, e.g., the specific haplotype that confers susceptibility depends on the lupus background, and autoimmunity does not develop when the predisposing MHC haplotypes are on normal backgrounds [2]. Although the actual gene(s) within the MHC complex that promotes lupus susceptibility still remains to be identified, class II molecules are strong candidates based on H-2 congenic studies [6–8] and their central roles in both repertoire shaping and antigen recognition. This does not exclude the participation of other, closely linked, immunologically relevant genes, which are numerous in this region. One of the strongest associations with lupus disease is the heterozygous H-2^z haplotype in combination with one of several different H-2 haplotypes, including d, b, and v [9–13]. Studies have attempted to directly implicate class II molecules by expressing I-A^z or I-E^z transgenes in the NZB × C57BL/6 background, but no increased susceptibility was found in mice expressing either of these transgenes [14, 15]. Although this suggests that class II molecules are not responsible, it is also possible that the transgene failed to adequately recapitulate the expression patterns required to promote autoimmunity, as it is known that slight changes in class II expression substantially affect disease susceptibility, e.g., homozygous versus heterozygous expression [16], or the presence or absence of I-E [17]. In this regard, transgenic mice would not have the same levels of class II molecules as wild-type mice as they would have normal levels of class II in addition to the transgene.

The role of I-E in lupus-prone mice has been investigated by expressing the Eα transgene in H-2^b BXSB mice [8, 17, 18]. Interestingly, high levels and, to a lesser extent, lower levels of I-Eα transgene expression suppressed lupus development, apparently because of competitive inhibition of autoantigen presentation by peptide fragments from processed I-Eα that bound effectively to H-2^b class II molecules.

Other potential lupus-predisposing genes within the H-2 complex include a polymorphic NZW tumor necrosis factor (TNF)-α gene that appears to promote lupus in BWF_1 hybrids [19, 20], complement components C2 and C4 [21], IEX-1 [22], and a recessive NZW locus (*Sles1*) that appears to suppress autoimmunity in NZW mice [23]. The relationship of *Sles1*, however, to the

known class II and TNF-α polymorphisms in the NZW strain has yet to be determined.

Fas and Fas Ligand

Fas (APO-1 or CD95) is a 306 amino acid, 45-kDa, cell surface membrane protein related to the TNF receptor superfamily of type I membrane glycoproteins. Fas is expressed on actively proliferating cells in the thymus, liver, ovary, heart, skin, and gut epithelium, with particularly high levels on $CD4^+CD8^+$ thymocytes, activated T and B cells, and some neoplastic cells [24, 25]. Following binding to its ligand, Fas transduces signals leading, in most instances, to apoptotic cell death [26, 27]. The ligand for Fas, FasL, is a 40-kDa type II transmembrane glycoprotein belonging to the TNF ligand family of proteins. It is expressed almost exclusively on T-cell lineages, primarily upon activation [28] and in certain immunologically sequestered sites, such as the testis, eye, and placenta [28–31]. In these areas, FasL may contribute to the maintenance of immune privilege by inducing Fas-mediated apoptosis in invading inflammatory cells [32], and in the case of the retina, may also control the growth of new vision-damaging subretinal blood vessels [33].

Two spontaneous loss-of-function mutations in Fas (*Fas*^{lpr} and *Fas*$^{lpr\text{-}cg}$) and one in FasL (*Fasl*^{gld}) result in similar autoimmune manifestations (Table 2). The *Fas*^{lpr} (lymphoproliferative) defect is caused by an early retroviral transposon (ETn) insertion within the second intron between exons 2 and 3, which causes aberrant RNA splicing, a frame shift, and premature termination of the mRNA at the long terminal repeat region of the ETn [34–38]. Low levels (~10%) of wild-type Fas mRNA and surface protein, however, are detectable [36–40], and recombinant *Fas* knockout mice, but not *lpr* mice, develop liver hyperplasia in addition to lymphoproliferation [41]. The *Fas*$^{lpr\text{-}cg}$ mutation (*lpr* complementing *gld*) [41] is caused by a single point mutation (T→A at nucleotide 786; isoleucine→asparagine; this residue is valine in humans) within the intracytoplasmic domain of Fas that modifies an amino acid in the so-called "death domain" essential for signal transduction [35]. Finally, the *Fasl*^{gld} allele (generalized lymphoproliferative disease) [42] is a point mutation in the carboxy-terminal extracellular domain (T→C at nucleotide 847, phenylalanine→leucine) of FasL on chromosome 1, which abolishes the binding of Fas to the FasL [43–45].

Homozygosity for these mutations promotes accumulation of $CD4^-CD8^-$ (double negative, DN), $B220^+$, $TCR\alpha\beta^+$ T cells and the induction or acceleration of systemic autoimmunity [1, 46], but both severity of the autoimmune disease and degree of lymphoproliferation depend on other background genes [1]. *Fas*^{lpr} does not complement *Fasl*^{gld}, whereas the *Fas*$^{lpr\text{-}cg}$ allele, as suggested by its name, can complement both the *Fas*^{lpr} allele and, to a slightly lesser degree, the *Fasl*^{gld} allele. Furthermore, in contrast to the recessive *Fas*^{lpr} mutation, autoimmunity and lymphoproliferation are observed in heterozygous MRL-*Fas*$^{lpr\text{-}cg/+}$ mice, although less severe and without the characteristic expansion of DN T cells [47]. In humans, defects in Fas have been identified as a cause of the rare autoimmune lymphoproliferative syndrome (ALPS or Canale–Smith syndrome) [48–50]. This syndrome has also been described with loss-of-function mutations in caspase 10, a cysteine protease involved in the downstream apoptosis-promoting pathway of Fas [51]. The majority of SLE patients, however, do not appear to have deficiencies or mutations in *Fas* or *Fasl* [52–55].

SHP-1

SHP-1 is a protein tyrosine phosphatase expressed ubiquitously in hematopoietic lineage cells. Two spontaneous recessive mutations, the motheaten (*me*) and motheaten viable (*me*^{v}), both lead to similar early lethal phenotypes, which differ slightly in severity because of more complete gene deletion in the *me* variant. Although increased immunoglobulin levels and autoantibodies are detected, the major disease manifestations arising from severe abnormalities in virtually all hematopoietic cell lineages are not similar to spontaneous lupus, nor are they mediated by autoantibodies or T and B lymphocytes [56–60]. The basis for the motheaten phenotype rests largely on the requirement for SHP-1 in inhibiting cell activation following its recruitment by negative regulatory molecules containing immunoreceptor tyrosine-based inhibitory motifs (ITIM) [61]. Autoantibody production is likely due to the inability of CD22, and possibly FcγRIIB, to negatively regulate the B-cell antigen receptor in the absence of SHP-1 [62].

Yaa Gene

BXSB mice have a marked male predilection to systemic autoimmunity in contrast to the female predominance in humans and other susceptible mouse strains. This striking sexual dichotomy is not due to hormonal factors, but to a gene on the Y chromosome, designated *Yaa* [63–65]. Because conventional genetic mapping approaches are not possible for the nonrecombining Y chromosome, *Yaa* has yet to be cloned. Nevertheless there is some information about its contribution to systemic autoimmunity.

[a] Includes only named loci with linkages $P < 0.01$ or lod > 1.9. Loci are listed by their approximate chromosomal locations based on the marker with the highest association. Chr, chromosome. cM distances are based on the Mouse Genome informatics (Jackson Laboratory).

[b] B, NZB; B6, C57BL/6; B10, C57BL/10; Ba, BALB/c; CAST, CAST/Ei; lpr, *Fas^{lpr}*; NOD, NOD/Lt; NZM, NZM/Aeg2410; PL, PL/J; W, NZW; (MRL-lpr×C3H-lpr)BC and F_2, both MRL-lpr×(MRL-lpr×C3H-lpr)F_1 and (MRL-lpr×C3H-lpr)F_2 crosses; (NOD×Ba)×NODBC, NOD backcrossed to (NOD×BALB/c)F1 in all four combinations.

[c] Original phenotypes that mapped to loci are shown; chr, antichromatin autoantibody; CL, anticardiolipin autoantibody; dsDNA, anti-dsDNA autoantibody; GN, glomerulonephritis; gp70IC, gp70 immune complexes; histone, antihistone autoantibody; LN, lymphadenopathy; Lprn, lymphoproliferation; MI, myocardial infarct; platelet, antiplatelet autoAb and thrombocytopenia; RBC, anti-RBC autoAb; spleen, splenomegaly. Autoantibodies are IgG unless otherwise specified. Does not include gp70 loci that were not linked to autoimmunity [357]. Induced or genetically modified models are indicated in parentheses; *M.bovis*, *M. bovis* iv; HgIA, mercury-induced autoimmunity.

[d] complex inheritance: either parental strain promotes GN, but heterozygosity protects.

Transfer of the *Yaa* gene (Y chromosome) to nonautoimmune and autoimmune mice has demonstrated that it contributes additively to lupus, but is dependent on other background genes. Nonautoimmune strains, such as CBA/J or C57BL/6, are largely unaffected by the *Yaa* gene, whereas all lupus-susceptible strains examined, including NZB, NZW, and MRL-*Fas*^{lpr}, have accelerated disease that generally maintains the clinical characteristics of the background strain [1, 66–68]. Mice with mild lupus appear affected more by the *Yaa* gene than strains with already accelerated disease [7]. This selective augmentation by *Yaa* contrasts with the induction of generalized autoimmunity by the *lpr* and *gld* mutations [68] and suggests that different mechanisms are involved. This is further supported by the findings that *lpr* and *Yaa* congenic mice with identical backgrounds have different phenotypes [1] and that the *lpr* and *Yaa* mutations are additive [69]. Interestingly, DBA/1.*Yaa* (consomic for the BXSB Y chromosome) were less susceptible to collagen-induced arthritis (CIA) than wild-type DBA/1 mice, suggesting that *Yaa* plays different roles in CIA and lupus [70].

Regarding the mechanisms responsible for the *Yaa* phenotype, double bone marrow chimera experiments using a mixture of *Yaa*$^+$ and *Yaa*$^-$ cells of different IgH allotypes revealed selective production of anti-DNA antibody and hypergammaglobulinemia by *Yaa*$^+$ B cells [71]. The antibody-promoting effect of the *Yaa* gene is applicable not only to self-antigens, but to foreign antigens [72], and, analogous to the effects in lupus mice, enhancement was observed mainly for antigens eliciting low, T-cell-dependent antibody responses and not for those eliciting high antibody responses [72]. Accordingly, the *Yaa* gene was postulated to increase the expression of an "intercellular adhesion molecule" on B cells, which promotes low-avidity, T helper–B-cell interactions [65]. Thus, nontolerant T helper cells normally quiescent in *Yaa*$^-$ animals because of insufficient antigen presentation become activated in *Yaa*$^+$ animals. Other mechanisms that increase antigen presentation, intracellular signaling, and coreceptor molecule expression can also be postulated and elucidation undoubtedly will require identification of the molecular defect. The *Yaa* gene has been found not to accelerate murine AIDS [73]. This was attributed to the already generalized activation of most lymphocytes, including B cells, that accompanies this disease.

Other mixed bone marrow chimera experiments with *Yaa*$^+$ and *Yaa*$^-$ T cells that express different Thy-1 allotypes revealed that autoimmunity developed regardless of whether *Yaa*$^+$ cells were present or eliminated by anti-Thy-1 antibodies [74]. Furthermore, similar degrees of homeostatic T cell proliferation and disease induction were observed when αβT-cell-deficient BXSB mice were reconstituted with either *Yaa*$^+$ or *Yaa*$^-$ T cells [75]. Thus, these findings indicate that the *Yaa* defect does not require expression in T cells. That B cells, but not T cells, from Yaa$^+$ mice have enhanced proliferative responses compared with cells from Yaa$^-$ mice is also consistent with this possibility [76].

LOCI PREDISPOSING TO SPONTANEOUS SLE IN LUPUS MOUSE MODELS

Identification of genes predisposing to quantitative traits, such as those predisposing to lupus, typically involve four major steps: (1) trait mapping performed by genome-wide scans using evenly distributed markers spanning the chromosomes. (2) Generation of interval-specific congenic strains containing an introgressed genomic fragment to confirm mapping and identify the major intermediate phenotypes; a relatively large region is generally taken to assure that the specific gene or genes are present within the interval. (3) Generation of panels of congenics with crossovers or smaller intervals to finely map the location of the susceptibility gene or genes; this may be achieved in one or two stages, i.e., localization to ~5 cM-sized fragments and then to <0.1 cM-sized fragments [77]. (4) The final step requires cloning, sequencing, and identification of genes within the fragment. Candidate genes can then be selected based on expression, structure, function, or other characteristics for screening the parental strains for polymorphisms. The completed sequence and annotation of the mouse genome should expedite this effort greatly.

Genome-wide scans to map lupus-related traits have utilized a variety of crosses that have included the three major lupus-prone strains and several induced or genetically manipulated models. To date, at least 70 named loci linked to one or more lupus traits distributed over all 19 autosomal chromosomes have been identified. These and additional unnamed loci are listed by chromosome and chromosomal location (distance in centimorgans from the centromere) in Table 2. Some of these loci, identified by different groups, appear to be identical, whereas others appear to represent unique loci. Overall, data suggest that susceptibility to spontaneous lupus in these strains is more likely due to different specific sets of a few major loci than to the presence of a large number of common predisposing loci.

Loci Derived from NZB and NZW Crosses

NZB and NZW mice have been the most extensively studied of the lupus-prone strains. Genome-wide scans

of intercrosses, backcrosses, and crosses to normal background strains have resulted in the identification of loci contributing to one or more lupus-related traits on 16 autosomal chromosomes (Table 2). Interestingly, lupus traits were also mapped to the nonautoimmune strain for 12 of the 57 loci reported and include regions derived from BALB/c, SWR, C57BL/6, C57BL/10, and C57L mice. Whether these loci are due to susceptibility alleles in the normal strain or suppressor genes in the lupus strains will need to be defined by allele distribution, type of mutation, and function of the alleles. Importantly, non-MHC loci confirmed in more than one cross include *Sle1/Cgnz1* (NZW derived) and *Lbw7/Nba2* (NZB derived) on chromosome 1, *Lbw2/Sle2/nba1/Imh1/Mott/Spm1* (NZB derived) on chromosome 4, *Lbw5/Sle3* (NZW derived) on chromosome 7, *Lbw8* (NZB derived) on proximal chromosome 8, and *nwa1* (NZW derived) on chromosome 16. According to mapping studies, inheritance of lupus traits is multiplicative and depends on the number and specific combination of susceptibility loci (epistasis). This indicates that different sets of loci contribute to different traits, i.e., lymphoid hyperplasia, autoantibody production, GN, and mortality [23, 78–80].

Interval-specific congenic C57BL/6 (B6) mice have been used to further define the roles of *Sle1*, *Sle2*, and *Sle3* in lupus pathogenesis. These mice contain introgressed genomic fragments of chromosomes 1, 4, or 7, respectively, from the NZB/NZW-derived recombinant inbred strain, NZM/Aeg2410 [81, 82]. *Sle1* congenic mice (B6.NZMc1) developed elevated IgG antinuclear antibodies (particularly targeting H2A/H2B/DNA subnucleosomes), but no GN [83]. Adoptive bone marrow transfer studies using combinations of B6.NZMc1, wild-type B6, B-cell-deficient, and αβT-cell-deficient mice revealed that *Sle1* is functionally expressed in both B and T cells [84]. In contrast, B6.NZMc4 congenic mice exhibited generalized B-cell hyperactivity, B1 cell expansion, and elevated levels of polyclonal IgM, but no increased IgG antinuclear antibodies or GN [85]. It was hypothesized that the expanded B1-cell population, which expressed higher levels of costimulatory molecules such as B7, might promote autoimmunity by facilitating the presentation of self-antigens to T cells [86]. B6.NZMc7 congenic mice developed elevated, but low, levels of antinuclear antibodies and a low incidence of GN. That *Sle3* might promote generalized T-cell activation was suggested by the observation of a marked increase in activated T cells, elevated CD4:CD8 ratios, and resistance to activation-induced cell death [87]. Based on these initial findings, a simple additive model was proposed wherein specific gene alterations resulting in a loss of tolerance to nucleosome components (*Sle1*) combined with a B- and a T-cell defect (*Sle2*, *Sle3*, respectively) lead to the development of lupus in NZM/Aeg2410 mice [80]. A more complex inheritance of lupus traits, however, has been indicated by studies involving crosses of these congenic mice that demonstrate epistatic interactions and the presence of NZW-derived suppressor loci present in the NZM/Aeg2410 strain [23, 88–90]. For example, bicongenic B6.*Sle1/Sle3* mice develop severe lupus with accelerated GN and early mortality, whereas B6.*Sle2/Sle3* mice exhibit much milder lupus manifestations [90]. Furthermore, when combinations of the three *Sle* loci were examined, *Sle1* appeared necessary for the development of early mortality.

Fine mapping revealed that *Sle1* is composed of a cluster of at least three (*Sle1a-c*) subloci [91], each of which independently caused a loss of tolerance to chromatin and evoked distinct serologic and cellular characteristics. However, these subloci alone do not induce severe nephritis when combined with other *Sle* loci, suggesting the presence of yet another major locus within the *Sle1* interval (*Sle1d* inferred). Overall, these findings demonstrate the complexity within a single locus and raise the possibility that complex trait loci may represent the sum of effects arising from clusters of closely situated lupus-predisposing allelic variants.

The complement receptor 2 (*Cr2*) gene has been identified as a candidate gene for *Sle1c* [92]. In mice, the *Cr2* gene encodes both CR1 and CR2 glycoproteins through alternative splicing (reviewed in Carroll [21] and Fearon and Carroll [93]). CR1/CR2 are expressed predominantly on the surface of mature B cells and follicular dendritic cells and bind C3 and C4 degradation products that have bound to antigen or immune complexes. CR2 reduces the threshold of B-cell activation and has been implicated in B-cell apoptosis and antigen processing and presentation, particularly in the germinal center. *Cr2*-deficient mice are defective in IgG responses to T-cell-dependent antigens, the generation of memory B cells, and the formation of germinal centers. CR2 also plays a significant role in the presentation of self-antigens to establish tolerance and, in fact, *Cr2* deficiency combined with the Fas^{lpr} mutation results in accelerated and more severe disease [94, 95]. Lower levels of CR1 and CR2 have also been reported in SLE [96]. When the *Cr2* alleles of NZM/Aeg2410 (NZW) and B6 strains were compared, they were found to be highly polymorphic, with differences in 16 nucleotide residues, including 11 that resulted in amino acid changes and a 3-bp insertion [92]. Of interest was a C→A (His→Asn) mutation at residue 1342 located in the external domain short consensus repeat 7 (SCR7) of CR1 and SCR1 of CR2, which introduced a new functional N-linked glycosylation site within the ligand-binding domain. This mutation was associated with

reduced C3dg binding, diminished CR1/CR2-mediated signaling, and reduced IgG response to T-cell-dependent antigens. Based on the three-dimensional structure, it was hypothesized that glycosylation of the Asn at residue 1342 disrupted the function of CR2 by altering its ability to properly dimerize [92].

Another candidate gene, *Ifi202*, for the *Nba2* locus on chromosome 1 has also been identified by comparing microarray expression profiles of spleen cells from B6 and B6.*Nba2* congenic mice [97]. Remarkably, greater than a 10-fold increase in *Ifi202* and a decrease in *Ifi203* were the only differences out of 11,000 genes examined, and both are part of the Ifi200 cluster situated within the *Nba2* interval. Increased expression of Ifi202 at both RNA and protein levels was also documented in NZB spleen cells compared with NZW. Several polymorphisms were identified in the promotor region of the *Ifi202* gene; however, the specific alteration responsible for the expression difference was not determined. *Ifi202* is an interferon-inducible family of two genes (*Ifi202a* and *Ifi202b*) that has been implicated in the regulation of cell survival, proliferation, and differentiation [98]. Which Ifi202 gene is responsible for the increased expression in NZB mice, or whether both are involved, is not known, nor is how Ifi202 predisposes to the splenomegaly and autoantibody production observed in B6.*Nba2* mice [97].

Two other potential NZ candidate genes have been studied: FcγRIIb [99] (discussed in a later section) and CD22 [100]. The $CD22^a$ variant is present in NZW mice and is located within the *Sle5* and *Lbw5* intervals [100]. $CD22^a$ mRNAs have aberrant alternative splicing due to the insertion in the second intron of a 794-bp pair cluster of short interspersed nucleotide elements. This is associated with B-cell expression of CD22 being reduced after LPS stimulation to about half the level observed with the $CD22^b$ (B6 mice) allele. It should be noted that while CD22 is a candidate gene for *Sle5*, it is not a candidate for *Lbw5*, as NZB mice are also $CD22^a$.

Loci in MRL-*Fas*^{lpr} Crosses

It is known that the *Fas*^{lpr} mutation promotes loss of tolerance and autoimmunity, but the manifestations and severity of lupus-like disease are highly dependent on background susceptibility genes. Several groups have defined lupus-related quantitative trait loci (QTL) in crosses of MRL-*Fas*^{lpr} mice, a strain that develops particularly severe spontaneous accelerated systemic autoimmunity (Table 2). QTL for one or more lupus traits have been identified on 14 of the autosomal chromosomes. This large number of loci may be partially attributable to the different strains of crosses utilized, as well as the variety of traits assessed, such as sialadenitis, GN, and vasculitis, which are most likely caused by overlapping, but distinct, sets of susceptibility genes. Nevertheless, several loci on chromosomes 4 (Arvm1, Lprm1), 5 (*Lmb2*, *Lprm4*), 7 (*Lmb3*, *Ldrm1*), and 10 (*Lmb4*, *Asm1*) had overlapping intervals and may be identical [101–104]. Interestingly, another locus, *Lmb1* (chromosome 4), which mapped to the nonautoimmune B6 background, had an additive effect on lymphoproliferation equal to the other *Lmb* QTL [101], indicating that nonautoimmune mice can harbor *bona fide* susceptibility genes, but presumably in numbers and combinations insufficient for disease induction. Such genes undoubtedly account for the background effects observed when using different strain combinations to map QTLs.

CD72 is a C-type lectin superfamily member expressed on the surface of B cells [105]. It is a negative regulator of B-cell activation and plays a role in B-cell development. Of interest, the $CD72^c$ variant in MRL mice, derived from the LG/J strain, was suggested as a candidate for the *Arvm1* locus, particularly since the $CD72^c$ allele compared with the $CD72^b$ allele (C3H strain) has 13 amino acid substitutions that include acidic, basic, and neutral changes [106]. This, however, is very tentative, as functional studies were not done.

Loci in BXSB Crosses

It is known that the presence of the Y chromosome *Yaa* gene [43] in BXSB male mice leads to the development of severe accelerated lupus, but other background genes are also clearly important, as indicated by the lack of significant autoimmune responses in consomic nonautoimmune background CBA/J.BXSB-Y [66] or B6.BXSB-Y [67] mice. Genome-wide searches have identified 12 BXSB-derived loci encompassing eight chromosomes in backcrosses of BXSB to C57BL/10 (B10) or to NZW strains (Table 2). In reciprocal BXSB×B10 backcrosses, five QTL were found to be linked to antinuclear antibodies, lymphoproliferation, and/or GN, of which four were located in different regions of chromosome 1 and one on chromosome 3 [107, 108]. In contrast, a different set of BXSB-derived loci linked to other traits (anticardiolipin antibodies, antiplatelet antibodies, thrombocytopenia, and/or myocardial infarction) were identified on chromosomes 4, 7, 8, 14, and 17 in the BXSBxNZW backcross study [109]. These findings, taken together with studies in other crosses discussed earlier, clearly demonstrate that the clinical heterogeneity of lupus in spontaneous mouse models is primarily the result of specific combinations of susceptibility genes rather than being influenced by the environment.

Conclusions from Studies on Susceptibility Loci in Spontaneous Lupus Strains

A number of generalizations can be made in assessing the results of mapping studies using different configurations of crosses among the four different lupus-prone background strains. (1) Although each strain apparently contains a few major susceptibility loci, overlap of susceptibility genes among the various lupus-predisposed strains is minimal, indicating a potentially large pool of susceptibility genes. (2) Different sets of genes apparently govern predisposition to different traits within a strain, although some traits share common genes. (3) In general, the genetic contributions are additive, but can depend on specific combinations (epistasis). This suggests that some immunopathologic manifestations require the parallel engagement of multiple genetic defects at the same time, intimating incremental effects on a common pathway or mechanism to a threshold that must be exceeded before the development of autoimmunity. Therefore, therapeutic intervention aimed at only one of these altered alleles might have a more profound effect than expected from the total number of susceptibility genes. (4) The manifestation of highly penetrant component phenotypes in interval-specific congenic strains clearly provides the opportunity to clone the underlying genes.

SYSTEMIC AUTOIMMUNITY IN NORMAL BACKGROUND GENE KNOCKOUT/MUTATED AND TRANSGENIC MICE

The role of specific genes in the immune system and possible mechanisms of systemic autoimmunity are being defined through genetic manipulation of nonautoimmune background strains. Deletion or overexpression of single genes results in remarkable examples of tolerance loss and systemic autoimmunity that have yielded valuable new models to detail SLE immunopathogenesis. Although the relevance of many of these models to spontaneous disease is uncertain, they have been particularly important in molecular studies of potential mechanisms of autoimmunity. Thus far, these gene defects have been shown to enhance B- or T-cell activation, inhibit certain apoptotic pathways, alter antigen presentation, reduce complement clearance of apoptotic bodies or soluble self-antigen, modify cytokine milieu, alter cell signal transduction, reduce glycosylation, and enhance cell cycling, as well as other mechanisms (Tables 3 and 4). Common mechanisms derived independently from different molecular defects have also emerged. These studies involve only a fraction of the total number of immunologically relevant genes, but extrapolation of their results suggests the potential that a large number of genetic defects can result in systemic autoimmunity and also indicates that many of these defects may involve common pathways or mechanisms. The relevance of these gene defects induced in mice by genetic manipulation to spontaneous SLE remains to be determined and is an area of significant ongoing research.

B-Cell Activation Genes

The fate of B cells following antigen receptor (BCR) engagement is a complex process that involves direct or indirect interaction of the BCR with numerous molecules that can promote or inhibit cell activation. Among these are several tyrosine kinases (lyn, fyn, Btk, Blk, Syk), phosphatases (CD45, SHP-1, SHP-2, and SHIP), and accessory molecules (CD19, CD22, FcRγIIB). Genetic manipulation of many of these B-cell regulatory molecules has resulted in mice with lupus-like characteristics, e.g., gene knockouts of lyn [110, 111] or CD22 [112–114], and spontaneous mutations of SHP-1 in motheaten mice [56, 57]. Lyn is a nonreceptor scr-related tyrosine kinase required for CD22-mediated negative regulation of BCR signaling. Although lyn also plays a role in positive signaling, this function appears largely redundant, as lyn deficiency results in hypersensitivity to BCR-mediated triggering. Homozygous deletion of lyn leads to increased activation and higher turnover rates of B cells, splenomegaly, elevated IgM levels, autoantibodies, and GN. Homozygous deficiency of CD22, a B-cell-specific cell surface sialoadhesin that binds specificially to asialoglycoproteins, has similar results, i.e., hyperresponsiveness to BCR signaling, expansion of the peritoneal B1-cell population, and autoantibodies. This similarity between lyn and CD22 knockout phenotypes arises from the inhibitory action of CD22, which requires recruitment and phosphorylation of lyn, followed by subsequent recruitment of SHP-1 into close proximity to the BCR, where it can dephosphorylate the BCR and downregulate the response. Heterozygous deletions of CD22, lyn, and SHP-1 were shown to have additive effects on B-cell abnormalities, consistent with the contention that they are limiting elements to a common pathway [115].

The functional cell surface receptor complex for C3 fragments, which promotes BCR signal transduction and is crucial for B-cell development and tolerance, is composed of CD19, CD21, and Tapa-1 (CD81) on B cells. Mice overexpressing a CD19 transgene develop hyperresponsive B cells to BCR cross-linking, marked expansion of the B1-cell population, hypergammaglobulinemia, and autoantibodies [116]. Moreover, anti-

TABLE 3 Genes Associated with Lupus-Like Manifestations in Knockout/Mutated and Transgenic Normal Background Mice[a]

Name	Gene	Chr	cM	Major autoimmune manifestations[b]	Ref.
Knockout/mutated					
CTLA-4	*Cd152*	1	30.1	Multiorgan lymphoproliferative disease, myocarditis, pancreatitis	147–149
CD45 (protein tyrosine phosphatase, receptor type C	*Ptprc*	1	74.0	Lymphoproliferation, dsDNA, splenomegaly, GN	181
Fasl (spontaneous)	*Fasl*	1	85.0	Lymphoproliferation, DN T cells, auto-Abs, GN (gld mutation)	44
Serum amyloid P component	*Sap*	1	94.2	Antichromatin Ab, GN, female predominance	216
PD-1 (programmed cell death 1)	*Pdcd1*	1	ND[c]	Proliferative arthritis, GN, glomerular IgG3 deposits	184
Mannoside acetyl glucosaminyltransferase 5	*Mgat5*	1	ND	Proliferative GN, enhanced EAE	239
IL-2Rα	*Il2ra*	2	6.4	Lymphoproliferation, hyper-IgG, auto-Ab, anti-RBC Ab	157
Nrf2 (nuclear, factor, erythroid derived 2, like 2)	*Nfe2l2*	2	45.0	Hyper-IgG, anti-dsDNA Ab, GN, splenomegaly	250
TYRO3 protein tyrosine kinase 3 (Tyro 3 family)	*Tyro3*	2	67.1	Triple knockout (*Tyro3*, *Axl*, *Mer*): lymphoproliferation, increased activated T and B cells, auto-Ab, GN	208
c-mer protooncogene (Tyro 3 family)	*Mer*	2	ND	Auto-Ab (*Mer* knockout alone) (also see TYRO3)	212
Bim (Bcl2 interacting mediator of cell death, Bcl2-like 11)	*Bcl2l11*	2	ND	Lymphoid/myeloid cell accumulation, auto-Ab, GN, vasculitis	195
IL-2	*Il2*	3	19.2	Lymphoproliferation, hyper-IgG, auto-Ab, anti-RBC Ab	156
GADD45 (growth arrest and DNA damage-inducible 45 alpha)	*Gadd45a*	3	70.5	Auto-Ab, GN, mortality	187
lyn	*Lyn*	4	0.0	Enhanced B-cell activation, splenomegaly, hyper-IgM, auto-Ab, GN	110, 111
C1q	*C1qa*	4	66.1	Auto-Ab, GN	215, 358, 359
	C1qb	4	66.1		
	C1qc	4	66.1		
SHP-1 (spontaneous)	*Hcph*	6	60.22	Auto-Ab (*me* and *me*^{v} mutations)	56, 57
AXL receptor tyrosine kinase (Tyro3 family)	*Axl*	7	6.0	See TYRO3	
TGFβ1	*Tgfb1*	7	6.5	Multiorgan lymphocytic and monocytic infiltrates	164
CD22	*Cd22*	7	9.0	Enhanced B-cell activation, auto-Ab	112, 360
Zfp-36 (tristetraprolin)	*Zfp36*	7	10.2	Complex systemic disease: cachexia, dermatitis, arthritis	225, 227, 361
LAT (linker for activation of T cells)	*Lat*	7	ND (tel)	Mutation inhibits T-cell development, but induces lymphoproliferation	189
fyn (+lyn ko)	*Fyn*	10	25.0	synergizes with the *Lyn* ko to accelerate disease	362
Aiolos (zinc finger protein, subfamily 1A, 3)	*Znfn1a3*	11	ND	Activated B cells, increased IgG, auto-Ab	131
G protein-coupled receptor G2A	*G2a-pending*	12	ND	Lymphoid hyperplasia, hyper-IgG, auto-Ab, GN	191
Protein kinase Cδ	*Prkcd*	14	11.0	Splenomegaly, lymphadenopathy, , hyper-IgM/IgG1/IgG2a, dsDNA GN	139
IL-2Rβ	*Il2rb*	15	43.3	Lymphoproliferation, hyper-IgG, auto-Ab, anti-RBC Ab	158

[a] Genes are listed in order of their chromosomal locations. Gene names and chromosomal locations are from the Mouse Genome Informatics or Locus Link (www.ncbi.nlm.nih.gov/LocusLink/).
[b] Ab, antibodies; dsDNA, anti-dsDNA auto-Ab.
[c] Not determined.

HEL antibodies resulted from expression of the CD19 transgene in antihen egg lysozyme Ig (HEL-Ig)/soluble HEL double-transgenic mice, suggesting that the underlying mechanism might be a defect in anergy to certain soluble antigens [117]. Apparently, lowering the BCR signaling threshold alters the tolerance/immunity balance in both CD19 transgene and CD22/lyn/SHP-1 knockout mice, leading to the development of autoimmunity.

The FcγRIIb on B cells also inhibits B-cell antigen receptor signaling [118], primarily by recruiting, through its intracytoplasmic immunoreceptor tyrosine-based inhibitory motif, the inositol phosphatase SHIP rather than the phosphotyrosine phosphatase SHP-1 [119, 120]. Gene knockout of FcγRIIb amplifies humoral and anaphylactic responses [121] and promotes the development of lupus-like disease [122], as well as type II collagen-induced arthritis [123] and type IV collagen-induced Goodpasture's syndrome [124]. Interestingly, two deletions in the promotor region of FcγRIIb in NZB mice have been identified that are associated with lower levels of FcγRIIb expression in germinal centers and hypergammaglobulinemia [99]. This polymorphism maps to NZB loci on chromosome 1 linked to autoantibody production (*Lbw7* and *Nba2*, see later and Table 4), but whether this is the actual allele remains to be determined. Complementation studies revealed that the FcγRIIb knockout synergizes with both the *Yaa* gene and, to a lesser extent, the *Sle1* locus, but not with the *Fas^{lpr}* defect, which was actually protective [125]. Back-

TABLE 4 Mechanisms for Induction of Systemic Autoimmunity

Enhanced B-cell activation[a]
- Lyn, CD22 or SHP-1 knockout
- FcγRIIb knockout
- Aiolos knockout
- PKCδ knockout (tolerance pathway)
- CD19 transgenic
- Tnfsf13b (BAFF, BlyS, TALL-1, or THANK) transgenic
- Fli-1 transgenic
- CD40L transgenic (B-cell-specific expression)

Enchanced T-cell activation
- CTLA-4 knockout
- IL-2 or IL-2R knockout
- CD45 E613R knockin mutation (B cells as well)
- PD-1 knockout (probably B cells as well)
- TGF-β deficiency (knockout/dominant negative)
- Cbl-b knockout
- *Gadd45a* knockout
- LAT Y136F knockin mutation
- G protein-coupled receptor G2A knockout

Defective apoptosis
- Fas or FasL mutations (lpr and gld mice, ALPS in humans; also caspase 10)
- Bim knockout (not related to Fas)
- Bcl-2 transgenic
- Flip transgenic
- IEX-1 transgenic

Enhanced antigen presentation
- Tyro3 family (*Tyro3*, *Axl*, *Mer*) triple gene knockout
- CD40L transgenic (keratin-14 promotor)

Complement and related genes
- C1q knockout
- C4 knockout
- SAP knockout

Cytokine-mediated activation
- IL-4 transgenic
- IFN-γ transgenic
- TTP (Zfp-36) deficiency (excessive TNF-α)
- TNF-α transgenic

Defective signal transduction
- Cbl-b knockout (enhanced activation of T cells, possibly B cells)
- $Pten^{+/-}$ knockout (defective Fas from increased PIP-3 elevating Akt levels)

Unopposed cell cycling
- $p21^{cip1/waf1}$ knockout (cyclin kinase inhibitor, primarily T cells)

Glycosylation enzymes
- α-Mannosidase II knockout
- *Mgat5* knockout (enhanced T-cell activation)

Other Mechanisms
- Dnase1 knockout
- Emk knockout
- Nrf2 knockout (antioxidant)

[a] Genes are categorized according to the most likely or predominant mechanism.

ground genes are also important, as only FcγRIIb-deficient B6, and not BALB/c, mice develop lupus-like disease. Genome-wide analysis revealed three regions, designated *sbb1–3* on chromosomes 9, 12, and 17, that were linked to ANA and/or proteinuria [125] (Table 3). Interestingly, one of these loci, *sbb1*, was derived from the nonsusceptible BALB/c genome. Overall, these studies suggest that enhancement of BCR signaling, as shown by overexpression of CD19 and knockouts of CD22, lyn, SHP-1, or FcγRIIb, may be a potential pathogenic mechanism for lupus, and they further document the complex interactions among genetic variants that can influence disease susceptibility.

Aiolos, a zinc finger DNA-binding protein that shares a common GGGA core sequence-binding motif with the closely homologous nuclear factor Ikaros [126], is highly expressed in mature B cells and, to a lesser extent, in developing bone marrow B cells and thymocytes. Aiolos is mainly localized to the 2 MD chromatin remodeling complex in the T-cell nucleus that also contains Ikaros, the Mi-2 ATPase, histone deacetylases, and other components of the nucleosome remodeling histone deacetylase (NURD) complex [126]. NURD complexes have been suggested as participants in transcriptional repression by promoting DNA methylation and allowing repressors to gain access to chromatin [127–129]. Ikaros has also been found to interact with the mSin3 family of corepressors [130]. These findings have led to the hypothesis that Ikaros family members regulate gene expression during lymphocyte development by recruiting certain histone deacetylase complexes to specific promotors [130]. Mice with homozygous deletions of the Aiolos gene develop defects primarily in the B-cell compartment, and these defects include hyperreponsiveness to BCR and CD40 stimulation and increased numbers of conventional B cells, a marked reduction in B1 cells, increased proportion of B cells with activated phenotype, hypergammaglobulinemia (particularly of IgE and IgG1), a three-fold reduction in IgM, and positive ANAs in about half of the mice studied by 16 weeks of age [131]. T-cell abnormalities were limited to a slight increase in the proliferative capacity of thymocytes and mature T cells. Thus, Aiolos deficiency apparently facilitates B-cell entry into cell cycle and maturation to germinal center lymphocytes, as well as a breakdown of B-cell tolerance. Whether overt autoimmune disease develops in these mice is the subject of ongoing long-term studies [131].

Tnfsf13b (also called BAFF, BlyS, TALL-1, THANK, or zTNF4) is a newly identified member of the TNF ligand superfamily expressed primarily on cells of myeloid origin, such as monocytes and dendritic cells [132–135]. Both the transmembrane protein and a

secreted homotrimeric form, released by cleavage at a furin canonical motif in the stalk region, are active in the costimulation of B cells, the main cell type known to express its receptor. Two other members of the TNF family, TACI and BCMA, have been identified as receptors for Tnfsf13b [136]. Overexpression of *Tnfsf13b* in the liver (α_1-antitrypsin promotor with the APO E enhancer) [137] or in multiple tissues (β-actin promotor) [138] resulted in similarly elevated B-cell numbers and, to a lesser extent, T cells, as well as increases in activated bcl-2-expressing mature B cells, memory/effector phenotype T cells, and syndecan-1-positive plasma cells. B cells from transgenic mice survived longer in culture than wild-type controls, and these mice further developed a lupus-like disease characterized by elevated levels of all immunoglobulin subclasses, rheumatoid factor, anti-DNA antibodies, circulating immune complexes, and kidney immunoglobulin deposits with proteinuria and elevated blood urea nitrogen. Importantly, elevations in *Tnfsf13b* have been shown in both BWF_1 and MRL-*Fas*^{lpr} mice, and blocking *Tnfsf13b* function in the former with a soluble TACI-IgGFc fusion protein inhibited proteinuria and prolonged survival [136].

Protein kinase Cδ (PKC-δ) is expressed in its highest levels in developing pro- and pre-B cells and is involved in B-cell receptor signaling. Mice homozygous for the null mutation in the PKC-δ gene developed splenomegaly, lymphadenopathy, increased numbers of B2 cells, germinal center formation and IL-6 production, mild increases of IgM, IgG1, and Ig2a, and antinuclear and IgG1 anti-DNA autoantibodies, as well as GN [139, 140]. Further studies in PKC-δ-deleted mice transgenic for the hen egg lysozyme (HEL) Ig receptor exposed to soluble HEL (as artificial autoantigen) indicated that the absence of PKC-δ prevented B-cell tolerance and allowed maturation and terminal differentiation of self-reactive B cells [139]. Because a deficiency of PKC-δ did not affect BCR-mediated B-cell activation *in vitro* and *in vivo*, it was concluded that PKC-δ plays a selective and essential role in tolerogenic, but not immunogenic, B-cell responses.

Reported aberrant expression of a transgenic *ets* family protooncogene, Fli-1, under the control of the MHC class I promoter, resulted in a constellation of lupus-like manifestations that included lymphoid hyperplasia, hypergammaglobulinemia, elevated antinuclear antibodies, and severe immune complex GN [141]. Fli-$1^{-/-}$ B cells were hyperresponsive to a variety of stimuli, showed resistance to activation-induced cell death, and had prolonged survival compared to nontransgenic B cells. Although these findings suggest an important regulatory function for Fli-1 in B-cell response and homeostasis, a more limited role was indicated by the finding that immunological defects in Fli-1 knockout mice were confined to a mild generalized thymic hypocellularity.

Ectopic expression of a transgenic CD40L on B cells (VH promoter, IgH intron enhancer and Ig 3′ enhancer) was shown to result in enhanced polyclonal IgG, anti-dsDNA, and, in about half of mice, the development of immune complex GN [142]. CD40L is a member of the TNF ligand family, expressed mainly on activated T cells [143]. It interacts with CD40 on B cells and plays a pivotal role in promoting B-cell proliferation and survival. Of interest, previous studied have reported B cell expression of CD40L in patients with SLE [144, 145] and in BXSB mice [146].

T-Cell Activation Genes

Knockout deletion of specific genes that primarily effect T-cell function results in systemic autoimmunity (Tables 3 and 4). CTLA-4, a surface glycoprotein expressed exclusively on T cells, acts as an inhibitor of the CD28-B7.1/B7.2 costimulatory pathway in part by binding with higher affinity to B7.1 and B7.2. As a result, a multiorgan lymphoproliferative disease associated with an increased frequency of activated B and T cells, hypergammaglobulinemia, and early mortality develops in mice with homozygous deletion of CTLA-4 at 3–4 weeks of age, accompanied by severe myocarditis and pancreatitis [147–149]. Altered thymocyte development is not, however, the cause of this abnormal T-cell expansion and disease manifestations [150], which rather arises from a failure to maintain homeostasis in activated peripheral T cells, primarily the $CD4^+$ subset [151, 152]. The precise mechanism through which this occurs has yet to be determined [153].

A similar syndrome results in gene knockouts of IL-2 [154–156] or either of its high (IL-2Rα) [157] or low (IL-2Rβ) [158] affinity receptors and includes late immunosuppression with defective antibody and CTL responses, as well as lymphoproliferation, expansion of memory/effector phenotype T cells, polyclonal hypergammaglobulinemia, autoantibodies, and immune-mediated hemolytic anemia. Mice lacking IL-2 [159] or IL-2Rα [157], but not IL-2Rβ [88], develop inflammatory bowel disease similar to human ulcerative colitis. Autoantibody production depends on the expanded $CD4^+$ T cells [158] and CD40/CD40L interaction [154]. The resistance of IL-2-deficient T cells to activation-induced cell death, at least partly from decreased Fas-mediated apoptosis, is the cause of the accumulation of T lymphocytes [160]. Other studies in mice maintained under germ-free conditions demonstrated that colitis,

but not other autoimmune manifestations, requires exposure to environmental pathogens [161].

Soon after birth, TGF-β1 gene knockout mice rapidly develop massive necrotizing lymphocytic and monocytic infiltrates in multiple organs and die by 3 weeks of age [162, 163]. Serum IgG autoantibodies to nuclear antigens, as well as Ig glomerular deposits, are detectable, but they appear to play a minor role in overall disease severity [164]. Although deficiencies of either class II or class I (β2m) molecules combined with TGF-$\beta1^{-/-}$ reduced both tissue inflammation and autoimmunity, implicating both $CD4^+$ and $CD8^+$ T cells in these processes, in both instances there was only partial improvement in survival because of the remaining lethal myeloproliferative abnormalities [165, 166]. The pivotal role of TGF-β in maintaining T-cell homeostasis and suppressing autoimmunity was highlighted by studies directly inhibiting TGF-β1 in T cells by a dominant-negative TGFβ receptor type II transgene under the control of a modified CD4 promotor specific for $CD4^+$ and $CD8^+$ T cells. This resulted in sickness, wasting, and diarrhea around 3–4 months of age, monocytic infiltrates in multiple tissues, enlarged peripheral lymphoid organs, increased percentage of memory/effector phenotype T cells, hypergammaglobulinemia, autoantibodies, and glomerular immune complex deposits [167].

The cbl family of adaptor proteins functions predominantly to inhibit receptor and nonreceptor tyrosine kinases [168, 169]. Two members, cbl-b and cbl, share a complex structure consisting of an amino-terminal phosphotyrosine-binding (PTB) domain, a C3HC4 RING finger, a proline-rich region capable of binding proteins with SH3 domains, several phosphotyrosine residues for binding SH2 domains, a ubiquitin recognition sequence, and, at the carboxy terminal, a putative leucine zipper. A smaller third member (cbl-c or cbl-3) has been identified that contains the PTB, RING finger, and a truncated proline-rich region, but is missing the rest of the carboxy portion [170, 171]. It is thought that cbl proteins suppress signaling by directly inhibiting PTKs via several possible mechanisms: (1) binding to negative regulatory sequences or induction of conformational changes, (2) sequestering molecules critical to cell activation, by recruiting distinct negative regulators, or (3) ubiquitination, internalization, and degradation of receptor PTKs [168, 172, 173]. Cbl-b is expressed in normal and malignant mammary epithelial cells, a variety of normal tissues, and in hematopoietic tissues and cell lines. In accordance with their negative regulatory role, T cells from mice homozygous for the cbl-b gene knockout exhibit enhanced proliferation to antigen receptor signaling and do not require CD28 costimulation for IL-2 production or generation of T-dependent antibodies [174, 175]. Significantly, enhanced basal and activated levels of Vav, a guanine exchange factor for Rac-1/Rho/CDC42, was the only alteration in TCR signaling identified in these knockout mice. This was consistent with previous findings that cbl-b binds to Vav and, when overexpressed, inhibits Vav stimulation of the c-Jun terminal kinase [176]. Cbl-$b^{-/-}$ mice exhibit an increased susceptibility to experimental autoimmune encephalomyelitis [174] and to a spontanous generalized autoimmune disease [175] involving multiorgan lymphoaccumulation of polyclonal activated B and T cells with parenchymal damage, increased plasma cells, and antibodies to dsDNA by 6 months of age. Curiously, spontaneous autoimmunity occurred in only one [175] of the two Cbl-b knockout studies, suggesting that background strain, environment, or other factors are also important factors.

CD45 is a receptor-like transmembrane protein tyrosine phosphatase (RPTP) expressed on all nucleated hematopoietic cells and is required for signal transduction through antigen receptors [177–179]. The activity of this molecule can be regulated negatively subsequent to dimerization by binding of the catalytic site from one molecule to a structural wedge from the acidic residue containing the membane-proximal region of the other [180]. It was, therefore, predicted that mutation of the inhibitory structural wedge would lead to inappropriate RPTP activation under normal dimerizing conditions, thereby causing inappropriate src-kinase activation with potentially pathological consequences. Indeed, "knockin" mice in which a single critical glutamate (aa613) in the inhibitory structural wedge was mutated to arginine developed, later in life, a lymphoproliferative syndrome with polyclonal B- and T-cell activation, splenomegaly, lymphadenopathy, increased IL-10 and IFN-γ, and premature death [181].

PD-1 is a 55-kDa ITIM-containing transmembrane cell surface glycoprotein expressed on activated T and B lymphocyes and monocytic cells [182]. Upon engagement of its ligands PD-L1 or PD-L2, it transmits a negative signal. Clues to its function have been gained from gene knockout experiments in mice deficient for PD-1, which are found to develop moderate hyperplasia of lymphoid and myeloid cells, increases in several Ig isotypes (particularly IgG3), enhanced responses to IgM cross-linking, and alterations in peritoneal B1 cells [183]. Older (14-month-old) C57BL/6-PD-$1^{-/-}$ mice spontaneously develop GN and proliferative arthritis, but not elevated anti-dsDNA antibodies or rheumatoid factor [184]. Further acceleration of GN and arthritis occurs when the PD-1 deletion is combined with the *Fas*^{lpr} mutation. Interestingly, manifestations appear highly dependent on background genes, e.g., in contrast to C57BL/6 mice, BALB/c PD-$1^{-/-}$ mice reportedly

develop lethal pancreatitis with massive thrombosis, indicating that PD-1 deficiency may accelerate background predisposition to autoimmunity, similar to the *Fas*^{lpr} and Yaa mutations. While the mechanistic details have not yet been elucidated, it seems that PD-1 plays an important nonredundant role in maintaining lymphocyte and myeloid cell homeostasis following activation.

The Gadd45 (growth arrest and DNA damage-inducible gene) family is composed of three members, α, β, and γ, which play pivotal roles in replication, growth arrest, and apoptosis [185, 186]. Of these, Gadd45a is the only member regulated by p53 and is an important molecule in several processes, including maintenance of genomic stability, cell growth control, nucleotide excision repair, chromatin accessibility, and apoptosis. Several of these effects may be mediated by interactions of the Gadd45a with Cdc2, PCNA, and the MEKK4/MTK1 kinases [187]. Studies in Gadd45a-deficient mice have shown that this molecule is a negative regulator of T-cell proliferation induced by antigen receptor-mediated activation, and that deletion of the Gadd45a gene leads to the development of a lupus-like syndrome, particularly when coupled with deletion of the p21 cyclin-kinase inhibitor [187]. While disease in Gadd45a-deficient mice was more severe in females than males, equal severity was seen when mice were deficient for both Gadd45a and p21.

LAT (linker for activation of T cells) is a transmembrane scaffolding protein that, after TCR engagement, becomes tyrosine phosphorylated and recruits multiple signaling molecules important for T-cell activation [188]. The distal four tyrosine residues of LAT (Y132, Y171, Y191, and Y226) are required for its activity. "Knock-in" mutation of LAT in mice in which the Tyr^{136} position was mutated to phenylalanine showed a severe, but incomplete, block in T-cell development associated with a marked reduction in immature $CD4^+8^+$ and mature $CD4^+$ and $CD8^+$ thymocytes and splenocytes [189]. However, by 4 weeks of age, homozygous mutant mice exhibited lymphadenopathy and splenomegaly with elevated markers of activated polyclonal $CD4^+$ T cells, B cells, macrophages and eosinophils, lymphocytic infiltrates in various organs, high production of IL-4, hypergammaglobulinemia (especially IgE and IgG1), and autoantibodies to nuclear antigens [189, 190]. These phenomena were attributed to defective PLCγ1-calcium signaling pathway in early T-cell development, leading to inefficient negative selection of self-reactive T cells and their exportation to the periphery wherein activation of these cells may not depend on LAT or PLC-γ1 [189].

G2A is an orphan G protein-coupled receptor expressed in various tissues, including lymphoid tissues [191]. A variety of studies have suggested that G2A is a negative regulator of proliferation and integration of extracellular signals with cytoskeletal reorganization. Mice with targeted disruption of the gene encoding G2A showed a normal pattern of T and B lineage differentiation. As they aged, however, they developed secondary lymphoid organ enlargement, expansion of T and B cells, enhanced T-cell proliferation responses, and, when over 1 year of age, a progressive wasting syndrome, lymphocytic infiltration into various tissues, hypergammaglobulinemia, immune complex GN, and antinuclear autoantibodies [191]. Although the molecular basis underlying the hyperresponsiveness of $G2A^{-/-}$ lymphocytes to TCR stimulation is presently unknown, the results reinforce the concept that lower thresholds for TCR activation can lead to overt autoimmune disease. Such a lower threshold for activation coupled with defective Fas-mediated apoptosis has also been considered to be a major contributor to the MRL-*lpr* lymphadenopathy and spontaneous lupus-like disease [192].

Apoptosis Genes

Bim is a proapoptotic ligand of the Bcl-2 family that shares homology with other members in only the short (nine amino acid) BH3 motif [193]. Through this domain, Bim binds to antiapoptotic Bcl-2 molecules and blocks their function. Bim is largely bound to the cytoplasmic dynein light chain LC8 normally sequestered in the microtubule-associated dynein motor complex [194]. Certain apoptotic signals release LC8, allowing it, together with Bim, to translocate to Bcl-2 and inhibit its function. Homozygous knockout of Bim resulted in an incompletely penetrant embryonic-lethal phenotype, apparently for nonimmunologic reasons. In the surviving offspring, however, alterations in the homeostasis of multiple hematopoietic cell lineages developed [195]. As anticipated, Bim-deficient B and T lymphocytes were resistant to certain apoptosis-promoting signals, but not to FasL. The knockout mice were found to have lymphoid hyperplasia with increased naive T and B cells, altered thymocyte subset composition, and increased granulocytes and monocytes in the peripheral blood. With age, these mice developed systemic autoimmunity manifested by progressive lymphadenopathy and splenomegaly, dramatic expansion of plasma cells, hyper-IgM, -IgG, and -IgA, antinuclear antibodies, immune complex GN, and vasculitis; the survival rate at 1 year was 55%.

Transgenic expression of the bcl-2 gene in B cells under the immunoglobulin enhancer resulted in similar lymphoid hyperplasia, hypergammaglobulinemia, high titers of antinuclear antibodies, and immune complex

GN [196]. Current studies suggest that constitutive bcl-2 expression may promote autoimmunity by blocking the apoptosis of autoantibody-producing B cells that normally arise spontaneously in germinal centers during the primary response to foreign antigens [197–199].

Chromosome 10q23 is associated with a wide range of malignancies, and the protein/lipid phosphatase PTEN was initially identified as a tumor suppressor gene on this chromosome [200, 201]. Germline mutations of PTEN cause Cowden disease, Lhermitte–Duclos syndrome, and Bannayan–Zonana syndrome, all autosomal-dominant disorders. Homozygous knockouts of PTEN are embryonic lethal, but heterozygous mice develop an autoimmune disorder characterized by severe polyclonal lymphadenopathy, diffuse inflammatory cell infiltrates of most organs, hypergammaglobulinemia, anti-DNA antibodies, immune complex GN, and decreased survival [202]. Females were affected more severely (mortality at 12 months vs 15 months in males). Defective Fas-mediated activation-induced cell death of T and B lymphocytes was observed in PTEN-deficient mice due to impaired Fas signaling associated with increases in the survival factor Akt. This suggests that uninhibited increases in phosphatidylinositol (3,4,5)-triphosphate (PIP-3), the major substrate for PTEN [203], leads to the recruitment and activation of Akt and possibly other factors, which then inhibit Fas-mediated killing [202]. PTEN-deficient mice, however, in contrast to *Fas*^{lpr} mice, had no increases in either B220^{+} or CD4^{-}CD8^{-} DN T-cell populations and, further, PTEN heterozygous knockouts had more severe disease than nonautoimmune background Fas-deficient mice. Thus, the development of autoimmunity in PTEN-deficient mice cannot be completely accounted for by Fas deficiency.

FLIP (gene name *Cflar*, for caspase 8 and FADD-like apoptosis regulator, also termed I-FLICE, CASH, Casper, CLARP, FLAME, MRIT) is a death effector domain-containing protein that is structurally similar to the apoptosis-promoting CASP8 (FLICE), but lacks a caspase domain. In contrast to FLICE, FLIP inhibits death receptor-induced apoptosis by blocking CASP8 recruitment and activation [204, 205]. Bone marrow cells, transfected retrovirally with FLIP prior to transplantation, resulted in B and T cell resistance to activation-induced cell death and expansion of these cell populations. In 4- to 6-month-old animals, hypergammaglobulinemia, anti-dsDNA autoantibodies, and glomerular immunoglobulin deposits with histologic evidence of GN characterized by glomerular sclerosis and thickening of mesangium and basement membranes were observed [206]. There was no accumulation of B220^{+} or CD4^{-}CD8^{-} DN T cells, or activated T cells despite the fact that FLIP blocks Fas signaling of activation-induced cell death, suggesting that Fas and/or FLIP may affect other nonoverlapping pathways.

IEX-1 (immediate early response gene X-1), also named IER3, p22/PRG1, Dif-2, or mouse homology *gly96*, regulates cell growth and apoptosis. Its expression is regulated by a variety of factors, such as X-irradiation, ultraviolet radiation, steroids, growth factors, inflammatory stimuli, and various activators of Nf-κB/rel transcription factors [207]. Mice transgenic for IEX-1 [under an H-2k^{b} promoter at the 5′ end and an Ig heavy chain (μ) enhancer at the 3′ end for specific expression in lymphocytes] were found to exhibit decreased apoptosis of activated T cells, increased duration of an immune response effector phase, splenomegaly, lymphadenopathy, accumulation of activated T cells, increased polyclonal IgG2a and anti-dsDNA autoantibodies, alopecia, arthritis, and immune complex GN [22]. These findings are particularly intriguing considering that the *IEX-1* gene maps within the MHC locus of humans and mice.

Enhanced Antigen Presentation

Mutant triple knockout mice lacking a group of closely related receptor tyrosine kinases, Tyro3, Axl, and Mer (the Tyro3 family, TAM), have been reported to develop severe systemic autoimmunity characterized by splenomegaly, lymphadenopathy, increases in activated T and B cells, autoantibodies to phospholipids associated with thromboses and hemorrhage, autoantibodies to collagen and dsDNA, and deposition of immune complexes in tissues [208].

The Tyro3 family of proteins is not expressed by quiescent lymphocytes, but are expressed by many other cell types, including antigen-presenting cells (APCs) (macrophages, dendritic cells). Macrophages freshly isolated from TAM-deficient mice have an increased expression of MHC class II molecules and produce elevated amounts of IL-2 and IFN-γ, suggesting their activation *in vivo*. Expression of these molecules and of CD86 (B7.2) was increased by these cells as well as by CD11c^{+} cells subsequent to *in vitro* incubation with LPS. Moreover, CFSE-labeled B and T cells transferred to TAM-deficient mice hyperproliferated compared to cells transferred in the wild-type controls. Although Tyro-3 receptors are known to convey growth-promoting and prosurvival signals to cells [209], findings with mutant mice suggest that these receptors are also able to activate negative feedback loops that attenuate the positive signaling pathways that they have activated, and that the loss of negative signals from these receptors has more profound effects than the loss of the positive growth-promoting signals. Another means by which absence of these receptors may promote auto-

immunity is by the ineffective removal of apoptotic cells, which are increased in TAM-deficient mice [210]. This latter possibility has been supported by the finding that mice with a cytoplasmic truncation of *mer* have macrophages deficient in the clearance of apoptotic thymocytes and develop a mild form of lupus-like disease with antibodies to chromatin [211, 212].

Targeted expression of CD40L to basal keratinocytes of the epidermis of mice using the keratin-14 promoter was reported to lead to the activation of resident tissue APCs (Langerhans cells) associated with dermatitis, lymphadenopathy, hypergammaglobulinemia, anti-dsDNA autoantibodies, and immune complex GN [213]. These findings are reminiscent of those observed in mice transgenic for IFN-γ under the involurin promoter [214]. Overall, they indicate that *in situ* activation of APCs in the skin can lead not only to local but also systemic, autoimmune, and inflammatory responses, presumably due to the migration of activated APC to the secondary lymphoid organs, and the engagement of preexisting, quiescent, nontolerant self-reactive T cells.

Complement Genes

Deficiencies of early complement components (C1q-s, C2, or C4) in humans are known to result in predisposition to SLE, indicating an important regulatory role in suppressing autoimmunity. This loss of tolerance to nuclear antigens cannot be fully explained by the inadequate clearance of immune complexes, and gene knockout mice for C1q and C4 were therefore generated to study this issue. Homozygous C1q-deficient mice recapitulated the human disorder with the development of mild, but typical, features of lupus, including autoantibodies and a 25% incidence of immune complex GN [215]. Furthermore, an atypical accumulation of apoptotic bodies in the glomeruli of C1q-deficient mice was observed, suggesting that C1q plays an essential role in the clearance of apoptosis by-products.

In C4 deficiency, the contribution to lupus susceptibility was evidenced only on the *Fas*^{lpr} background [94], indicating that lack of C4 alone cannot induce autoimmunity. B cells from C4-deficient mice were shown to have a tolerance defect to soluble HEL in experiments using a HEL Ig transgenic model, giving rise to the hypothesis that maintaining self-tolerance is crucially affected by the presentation of tolerizing antigens to B cells by early complement components.

This mechanism may be applicable to the unexpected development of lupus-like autoimmunity in mice homozygous for the deletion of serum amyloid P component (SAP), a highly conserved plasma protein originally named for its presence in amyloid deposits [216, 217]. In these mice, lupus manifestations included a clear female predominance of disease, autoantibodies to chromatin and its components (although not to other nuclear, tissue, or organ antigens), immune complex GN, and low mortality. In contrast to C1q deficiency, no accumulation of apoptotic bodies was detected in glomeruli. SAP binds to DNA and chromatin and can displace H1 histones, thereby increasing solubility and reducing the rate of degradation and clearance of chromatin [216]. It was hypothesized that SAP promotes self-tolerance to chromatin and its subunits by preventing immunogenic antigen processing and/or by tolerizing chromatin-reactive lymphocytes.

Cytokine Ligand and Receptor Genes

Systemic autoimmunity can also develop in mice transgenic for the major Th1 and Th2 cytokines, IFN-γ and IL-4, respectively, given the appropriate circumstances. Expression of IFN-γ in the suprabasal layer of the epidermis under the control of the involucrin promotor resulted not only in a severe inflammatory skin disorder, but also in the production of autoantibodies to dsDNA and histone, and an immune complex proliferative GN, particularly in females [214]. This suggests that presentation of nuclear antigen by skin Langerhans cells, and perhaps keratinocytes, may be sufficient for the production of antinuclear autoantibodies, which may explain the ultraviolet sensitivity of SLE patients. Similarly, C3H mice transgenic for the IL-4 gene under the control of the MHC class I promotor also developed systemic autoimmunity characterized by elevated MHC class II molecules and CD23, enhanced responses to polyclonal stimuli *in vitro*, increased levels of IgG1 and IgE, anemia, antinuclear antibodies, and immune complex GN [218]. It is thought that these manifestations result from direct IL-4-induced polyclonal activation of B cells, as $CD4^+$ T cells were not required and there was no evidence of inefficient B-cell negative selection. The role of IL-4 in promoting lupus, however, is more complicated, as autoimmunity was not observed in other transgenics expressing IL-4 on B or T cells [219–222] and in a spontaneous model of lupus expression of an IL-4 transgene did not exacerbate disease, but was protective [223]. This would imply that a number of factors, such as the level and site of IL-4 production and background genetic susceptibility, can modify the effects of IL-4 on systemic autoimmunity.

Tristetraprolin (TTP or Zfp-36) is a widely expressed zinc-binding protein initially throught to function as a transcription factor, particularly in lymphoid tissues, where high levels are found [224]. Mice with a homozygous knockout of TTP develop a complex syndrome consisting of cachexia, patchy alopecia, dermatitis, conjunctivitis, erosive arthritis, myeloid hyperplasia,

glomerular mesangial thickening, and antinuclear antibodies [225]. These manifestations are primarily the result of excessive TNF-α production by macrophages and are almost entirely reversed by anti-TNF-α antibody [225, 226], suggesting that TTP functions as a nonredundant negative regulator of TNF-α. The mechanism was later discovered to be the result of TTP binding to an AU-rich element in the TNF-α mRNA, which destabilizes the mRNA [227]. In contrast to the autoimmune-promoting effects of elevated levels of TNF-α, physiological amounts may, under certain circumstances, play a role in suppressing systemic autoimmunity. In studies of TNFR1 (p55) knockout mice, nonautoimmune mice did not develop defects in apoptosis or autoimmunity [228, 229], yet the same knockout in lupus-prone C57BL/6-*Fas*^{lpr} mice resulted in accelerated lymphoproliferation and autoimmune disease [230]. These findings may be attributable to TNF compensation for the lack of Fas in *Fas*^{lpr} mice, as TNF can induce the death of activated peripheral T cells [231].

Cell Cycle-Related Genes

Systemic autoimmunity was also reported to occur in mixed background C57BL/6 (B6) × 129/Sv mice deficient for the cyclin inhibitor p21$^{cip1/waf1}$ [232]. Disease was characterized by lymphoid hyperplasia, elevated IgG1, IgG antinuclear antibodies, GN, and early mortality. *In vitro* T-cell proliferation was enhanced in these mice, as was the accumulation of effector/memory phenotype (CD44^{high}) CD4$^+$ T cells, although levels of other activation/effector/memory cell markers, such CD25, CD62L, CD69, and CD45RB, were similar to wild-type mice. An increased proportion of splenic B cells also expressed an activated (HSA^{low}, IgG^{low}) phenotype. Interestingly, in this initial study, females were reported to have more severe disease than males. Based on these findings, it was suggested that p21 negatively regulates T-cell proliferation following long-term stimulation, as is presumably the situation for autoantigen-reactive CD4$^+$ T cells.

In contrast, another study of p21-deficient mixed background B6 × 129/Sv mice found increased *in vitro* and *in vivo* T-cell cycling and activation, enhanced homeostatic proliferation, moderate hypergammaglobulinemia, and low penetrant antichromatin autoantibodies, but only mild lymphoid hyperplasia, minimal immune complex GN, and no gender differences [233]. Furthermore, transfer of the p21 null mutation onto the BXSB background did not lead to accelerated disease in the lupus-prone females [234]. Importantly and relevant to most of the studies in this section, use of the mixed background 129/Sv × B6 to study the effects of specific genetic alterations may be confounded by the genetic heterogeneity of the host. It is therefore imperative that adequate controls, such as littermate controls or congenic strains with late-life lupus predisposition, should be employed.

Of interest, other studies in BXSB mice found increased p21 and other cyclin inhibitors in the expanded population of memory/effector CD4$^+$ T cells that are predominantly arrested in G1 [235]. This finding led to the opposite hypothesis that accumulating CD4$^+$ T cells are rendered incapable of entering the cell cycle after successive rounds of division and are resistant to apoptosis because of the buildup of cyclin inhibitors, a state similar to replicative senescence. Although no longer cycling, such cells may nonetheless secrete cytokines and activate B cells. Indeed p21-deficient male BXSB mice have reduced numbers of memory/effector CD4$^+$ T cells along with decreased autoantibody levels, GN, and mortality (Lawson, *et al*. unpublished observations).

Glycosylation Enzymes

The α-mannosidase II enzyme is encoded by a single gene in mammals and resides in the Golgi apparatus, where it trims two mannose residues from hybrid N-linked oligosaccharides. This trimming of the mannose residues allows the subsequent addition of multiple glycan branches by glycosyltransferases required for the generation of complex N-glycans found on mammalian cell surfaces [236, 237].

Mice rendered deficient in α-mannosidase II were reported to develop a lupus-like syndrome characterized by various autoantibodies, including anti-dsDNA, anti-Sm, and anti-histone, as well as hypergammaglobulinemia and immune complex GN [238]. Nevertheless, lymphoid cell development, composition, and responses were normal. No clear explanation for the appearance of systemic autoimmunity was evident, but a possibility is that alterations in N-glycan branching among some glycoproteins and tissues may lead to the formation of neoepitopes for which tolerance has not been established.

A related finding with a more clear explanation was the appearance of proliferative GN in mice deleted of the β1,6 *N*-acetylglucosaminyltransferase V (Mgat5), an enzyme in the N-glycosylation pathway [239]. An important mechanistic finding in this work was that absence of this enzyme led to lowering of the T-cell activation threshold by enhancing TCR clustering. Thus, T cells of deficient mice showed increased recruitment of TCRs to anti-CD3ε antibody-coated polystyrene beads and required lower concentration of anti-CD3 plus anti-

CD28 for efficient proliferation compared to control cells. Additional experiments showed that Mgat5 initiates GlcNAc β1,6 branching on N-glycans, thereby increasing *N*-acetylactosamine, the ligand for galectins, which are proteins known to modulate T-cell proliferation and apoptosis [239–241]. The findings indicate that a galectin–glycoprotein lattice strengthened by Mgat5-modified glycans restricts TCR recruitment to the site of antigen presentation, and therefore dysregulation of Mgat5 increases T-cell activation and susceptibility to autoimmunity.

Miscellaneous

DNase1 is a 32- to 38-kDa protein that is the major nuclease present in the blood, urine, and secretions. Interestingly, knockout of the DNase1 gene in nonautoimmune background mice has been reported to increase the incidence of SLE manifestations, including positive ANA, anti-DNA antibodies, and immune complex GN [242]. Although this suggests that accumulation of self-DNA may trigger the loss of tolerance and lupus, the precise mechanism is not known and other possibilities, such as a reduced degradation of exogenous nonmethylated CpG-rich DNA from pathogens, might also play a role. This observation is somewhat unexpected, as mammalian DNA alone is a poor immunogen for generating anti-DNA antibodies, and cell transfer studies in mice have suggested that genetic susceptibility to lupus is expressed in bone marrow-derived cells [1]. Nevertheless, reduced DNase1 activity, as observed in sera of lupus patients [243], may contribute to overall SLE susceptibility. Interestingly, an identical heterozygous nonsense mutation in *DNASE1* was detected in two SLE patients; however, the significance of this has yet to be determined [243].

ELKL motif kinase (Emk) is a serine/threonine kinase with a conserved region of about 100 amino acids that terminates with the sequence glutamate-leucine-lysine/asparagine-leucine (a region referred to as the ELKL domain) [244]. Emk has also been called MARK2 (microtubule affinity-regulating kinase 2) and mPar-1 based on homology with the Par-1 protein kinase of *Caenorhabditis elegans* [245]. Evidence suggests that Emk regulates cell polarity, cell cycle progression, and microtubule dynamics. It is expressed in several tissues, including the thymus and mature T and B cells [246]. $Emk^{-/-}$ mice showed growth retardation and hypofertility [246, 247]. In addition, deficient mice, as they aged, showed splenomegaly, lymphadenopathy, increased activated phenotype T cells ($CD44^{hi}CD62^{low}$, but no increases in IL-2R or CD69), increased responses to thymus-dependent antigens, lymphoid infiltrates in lungs, salivary glands, and kidneys, and membranoproliferative GN with immune deposits and proteinuria [246].

The basic leucine zipper transcription factor Nrf2 (NF-E2-related factor 2, or bZip-type transcription factor or NF-E2, nuclear factor-erythroid 2) regulates an antioxidant response element (ARE) or electrophile response element (EpRE), whose consensus sequence is found in the 5′ regulatory region of a number of genes encoding detoxifying and antioxidant enzymes [248, 249]. Nrf-2-deficient female mice over 5 months of age reportedly developed severe GN with immune complex deposits together with higher serum IgG, anti-dsDNA antibody, and slight splenomegaly [250]. In this regard, it is of interest that reactive oxygen species have been considered to be potential participants in the pathogenesis of lupus nephritis [251]. Moreover, homozygosity for glutathione-*S*-transferase *GSTM1* null alleles correlated with autoantibodies and lupus predisposition in humans [251] and mice deficient in heme-oxygenase-1 (HO-1) (a gene containing ARE) were noted to develop GN resembling that of the Nrf-2-deficient mice [252].

GENE KNOCKOUT AND TRANSGENIC LUPUS BACKGROUND MICE

Many investigators have directly examined the role of deleted or overexpressed immune-related genes in systemic autoimmunity in congenic lupus background mice (Table 5, listed by chromosome and chromosomal location). The effects of gene manipulation on different stages of the disease pathogenesis have provided important information on the crucial molecules and pathways, as well as a deeper understanding of the molecular basis for the diverse manifestations.

B-Cell-Related Genes

Studies in MRL-Fas^{lpr} mice with deletion of the Jh locus (no B cells) [253] have clearly shown the crucial role of B cells in lupus disease manifestations; despite the presence of lymphoproliferation, there were no signs of nephritis or vasculitis, confirming the theory that autoantibodies are central to these processes. Similar observations were made in Fas-intact MRL-+/+ mice deficient for the Jh locus [254], indicating that B cells are important not only for autoantibody production, but also for the spontaneous activation of $CD4^+$ and $CD8^+$ T cells [255, 256]. Moreover, genetic manipulation of MRL-Fas^{lpr} mice resulting in B-cell expression of surface, but not secreted immunoglobulin,

demonstrated that B cells alone could promote local cellular infiltration and inflammation, but not GN [257].

T-Cell-Related Genes

A wide diversity of intercross or congenic mice rendered defective for MHC, CD4, CD8, or T-cell receptor genes have been used to assess the role of helper and cytotoxic T cells and αβ- and γδT-cell subsets in lupus. In MRL-*Fas*^{lpr} mice, deletion of MHC class II [258] or CD4 [259] reduced autoantibodies and GN, but had no effect on lymphadenopathy, indicating that the class II-selected CD4 T cells are important for autoimmunity, whereas DN B220$^+$ T cells are not selected on class II molecules and are not necessary for autoimmunity to occur. In contrast, β2m- (class I) [260–263] or CD8-deficient [259] MRL-*Fas*^{lpr} or C3H-*Fas*^{lpr} mice showed reduced lymphoproliferation and expansion of DN B220$^+$ cells, but only partial diminution in autoantibody levels and GN. Combined with previous studies on TCR Vβ repertoires and anti-CD8 antibody treatment (reviewed in Theofilopoulos and Kono [2]), these findings indicate that DN B220$^+$ T cells in *Fas*-deficient mice are of CD8 origin.

Of interest, MRL-*Fas*^{lpr} mice deficient in β2m were shown to be discordant in skin and kidney disease, with the former accelerated and the latter ameliorated [264]. The skin disease was not accelerated in CD1-deficient MRL-*Fas*^{lpr} mice, thereby suggesting that the effect of β2m deletion (affecting both classical MHC class I as well as CD1) in this manifestation was not mediated by NK T cells that depend on CD1 or by CD1 expression itself on skin Langerhans or B cells. CD1 deficiency in itself also appears not to affect disease severity, including nephritis and vasculitis. The overall findings suggest that end organ disease is not an inevitable consequence of initial autoreactive cell activation in secondary lymphoid organs, but local conditions in target organs can control disease manifestations. In addition, a delayed onset and reduced incidence of anti-RBC antibodies were found in NZB mice deficient for CD4 [265] and even for β2m, despite the fact that in the littermate mice, the characteristic NZB thymic abnormalities and IgM or IgG autoantibody levels to ss or dsDNA remained unchanged [266].

Although the combined results clearly demonstrate the importance of TCRαβ cells in spontaneous lupus, TCRα gene deletion in MRL-*Fas*^{lpr} mice only partially

inhibited disease [267, 268]. Based on the fact that TCRαβ/TCRγδ double-knockout MRL-*Fas*^{lpr} mice fail to generate class-switched autoantibodies and immune complex GN [269, 270], this suggests that TCRγδ cells can also help drive the autoimmune B cells. Paradoxically, however, MRL-*Fas*^{lpr} TCRγδ-deficient mice showed disease exacerbation. Taken together, these results suggest that TCRαβ cells are important for cognate MHC-restricted autoantibody production and are the major provider of B-cell help in intact MRL-*Fas*^{lpr} mice, whereas TCRγδ cells suppress this process, but can concomitantly provide lesser degrees of non-MHC-restricted polyclonal B-cell help. In addition, knockout of the perforin gene in MRL-*Fas*^{lpr} mice resulted in disease exacerbation, suggesting that cytolytic cells may be involved in suppressing autoreactivity [271].

Costimulatory Molecules

Studies in MRL-*Fas*^{lpr} mice deficient for CD40L [272, 273] and CD28 [274] have clearly demonstrated the role of costimulation in lupus development, and the reduced disease progression was similar to that observed in BXSB and BWF1 mice treated with anti-CD40L or CTLA-4Ig (reviewed in Theofilopoulos and Kono [2]). MRL-*Fas*^{lpr} mice deficient for either B7.1 or B7.2 were used to further dissect the CD28-B7 axis [275]. Although neither of these deletions affected autoantibody levels compared to wild-type MRL-*Fas*^{lpr} mice, GN was substantially worse in B7.1-deleted mice, but less severe in B7.2 knockouts, consistent with findings in BWF1 mice showing that antibodies to B7.2, but not B7.1, suppressed disease [276]. Thus, B7.2 clearly plays a crucial role in lupus pathogenesis.

Cytokine Genes

Congenic cytokine knockout or transgenic lupus mice were used to investigate the effects of Th1 and Th2 cytokines, including IFN-γ, IL-12, IL-10, and IL-4. The results obtained in IFN-γ knockout mice clearly contradict the earlier notion that Th1-type responses primarily promote cellular immunity, whereas Th2-type responses promote mainly humoral immunity. There was a uniformly marked reduction of lupus in IFN-γ- or IFN-γR-deficient MRL-*Fas*^{lpr} or BWF1 mice [277–280], and this reduction even applied in the lupus-like mercury-induced autoimmunity model [281], which was previously considered to be a prototypic Th2-mediated disease. In fact, these results correlated well with previous observations of elevated IFN-γ levels in all lupus-prone strains, accelerated disease with IFN-γ treatment, and reduced severity following anti-IFN-γ treatment [2]. Thus far, data indicate that IFN-γ is important in at least two steps of lupus pathogenesis: (1) promotion of the response to self-antigens, perhaps because they are of low antigenicity [279, 281], and (2) promotion of the local inflammatory process, i.e., disease manifestations prevented, even in IFN-γ$^{+/-}$ MRL-*Fas*^{lpr} mice, which have autoantibody levels and glomerular immunoglobulin deposits similar to wild-type animals. The implied requirement for IFN-γ for the progression of local inflammatory responses [279] is supported by findings that IFN-γ signaling is critical for local production of the nephritis-promoting cytokines, CSF-1 and TNF-α [282]. Furthermore, IFN-γ may be responsible directly or indirectly for the apoptosis of kidney tubular epithelial and mesangial cells. This uncoupling of immune and inflammatory processes is reminiscent of FcRγ chain and MCP-1 deletions, as noted later. Clearly, intervention based on a blockade of IFN-γ action is warranted based on the central role of IFN-γ in the induction and effector phases of systemic autoimmunity. The finding that intramuscular injections of a plasmid encoding IFN-γ/Fc could significantly reduce and retard lupus in MRL-*Fas*^{lpr} mice even at advanced stage of disease strongly supports this possibility [283].

A variety of protooncogenes, kinases, and transcription factors have been implicated in the Th1 versus Th2 polarization process. These include the interferon regulatory factor 1 (IRF-1) and T box expressed in T-cell (T-bet, T-box 21) proteins for Th1 cells and, for Th2 cells, the c-Maf protooncogene and the GATA3 zinc finger protein [284]. T-bet regulates Th1 lineage commitment by CD4$^+$ T cells and selectively induces IFN-γ-mediated IgG2a class switching in B cells [285]. A deficiency of T-bet in lupus-prone mixed background MRL-*Fas*^{lpr} mice resulted in reductions in mortality, GN, autoantibody production, and hypergammaglobulinemia [285]. Interestingly, this was not associated with reduced Th1-related T-cell function, apoptosis, or disease manifestations (lymphocytic infiltrates). Instead, an *in vitro* intrinsic impairment of B cells in the production of IgG2a, IgG2b, and IgG3, along with an inability of B cells to generate germline or postswitch IgG2a transcripts in response to IFN-γ, was demonstrated.

IL-12 is an important regulator of Th1 cell differentiation and IFN-γ production [286]. In MRL-*Fas*^{lpr} mice, high levels of IL-12, hyperproduction of IL-12 by peritoneal macrophages after *in vitro* stimulation, acceleration of disease with recombinant IL-12 or intramuscular injection of plasmids encoding IL-12p40 or IL-12p70, and reduction of lymphoproliferation by neutralizing anti-IL-12 antibodies have suggested a major role for IL-12 in lupus [287–289]. However, although transgenic expression of the potent IL-12 antagonist, IL-12p40 in

lupus-susceptible MRL-*Fas*^{lprcg} mice, suppressed the production of Th1 cells, IFN-γ, and anti-dsDNA antibodies, it did not significantly improve clinical manifestations of disease, including lymphoproliferation, GN, and mortality [290]. Similarly, in a previous study, treatment of (NZB × NZW)F1 mice with antibodies to IL-12 inhibited the production of anti-dsDNA antibodies, but did not improve GN [291]. These studies suggest that IL-12 is important for autoantibody production, but that it may play a lesser role in end organ disease. In sharp contrast, intramuscular injection of MRL-*Fas*^{lpr} mice with a plasmid encoding the heterodimeric IL-12 was reported to inhibit disease manifestations, including GN, despite increased IFN-γ and unchanged IL-12 levels [292]. The reason for this discrepancy may be related to dose, timing, and type of treatment; however, if confirmed, it suggests a complicated relationship between IL-12 and the development of autoimmunity.

In contrast to the dramatic effects seen with |IFN-γ, deletion of IL-4 results in only partial or no reduction in disease, depending on the lupus-prone strain. IL-4$^{-/-}$ MRL-*Fas*^{lpr} mice produced less serum IgG1 and IgE (Th2-dependent subclasses), but maintained comparable levels of IgG2a, IgG2b, and autoantibodies [277], although reduced lymphoadenopathy and end organ disease were also observed. In contrast, IL-4-deficient male BXSB mice had similar autoantibody levels, GN severity, and mortality as their wild-type counterparts [293], suggesting that IL-4 plays little role in the immunopathogenesis of disease in this strain.

Previous studies have shown that administration of IL-10 accelerated disease onset and severity in (NZB × NZW)F1 mice, while repeated injections of anti-10 inhibited disease, presumably by the upregulation of endogenous TNF-α and preferential depletion of B1 cells [294, 295]. IL-10 has also been reported to promote autoantibody production by human SLE peripheral blood cells [296]. In contrast, studies in IL-10 gene-deleted MRL-*Fas*^{lpr} mice have shown that disease parameters (skin lesions, lymphadenopathy, increased IFN-γ levels, IgG2a anti-DNA autoantibodies, GN, and mortality) were increased, whereas administration of IL-10 was protective [297]. The protective effect of IL-10 in MRL-*Fas*^{lpr} mice was attributed to inhibition of the T_H1 responses that predominate in this mouse. In contrast, disease-promoting effects of IL-10 in the (NZB × NZW)F1 disease may be due to the importance of this cytokine for B1 cell generation and maintenance [298–300], thought to be a dominant autoantibody-producing cell type in New Zealand mice [1]. Furthermore, Fas-deficient mice expressing a transgenic antierythrocyte antibody develop autoreactive B1 cells that produce anti-RBC antibodies, leading to severe hemolytic anemia [300]. Treatment of these mice with anti-IL-10 antibody prevented autoantibody production and anemia. Because B-1 cells are the main source of B-cell-derived IL-10, it appears that IL-10 may act as an autocrine differentiation factor for these autoantibody-producing cells [301].

Eta-1 (osteopontin)-deficient normal background mice were shown to have reduced type 1 immunity for viral and bacterial infection attributed to diminished IL-12 and IFN-γ and increased IL-10 production [302]. C57BL/6-*Fas*^{lpr} mice rendered Eta-1 deficient were reported to display a delayed onset of polyclonal B-cell activation and somewhat delayed lymphoaccumulation and kidney disease [303]. Earlier studies have shown an increased expression of Eta-1 in MRL-*Fas*^{lpr} mice [304].

Cell-Signaling Molecules

A major pathognomonic finding in Fas deficiency is the expansion of DN B220$^+$ T cells derived predominantly from CD8$^+$ precursors. Although early *in vitro* functional studies suggested that these DN cells were inert, other characteristics, such as constitutive phosphorylation of the CD3ζ chain and increases in p59^{fyn}, certain oncogenes, and cell surface activation markers (TCR^{low}, CD44^{hi}), indicated otherwise. *In vivo* BrdU labeling confirmed the latter notion when DN B220$^+$ T cells were shown to be highly cycling early in life with an age-related decline in the frequency of cycling cells [305]. Furthermore, MRL-*Fas*^{lpr} fyn-deficient mice showed a reduced frequency of DN B220$^+$ T cells along with decreased autoantibody levels and immunopathology, indicating an essential role for fyn in signal transduction and expansion of DN B220$^+$ T cells [305]. Thus, DN B220$^+$ T cells are functional, but lose the capacity to proliferate as they accumulate, presumably due to replicative senescence (a loss of entry into cell cycle after a finite number of divisions). Replicative senescence has also been suggested to explain the rapid accumulation of apoptosis-resistant memory/effector (CD44^{hi}) CD4 cells in older BXSB male mice, perhaps a consequence of increased levels of cyclin kinase inhibitors [235]. Such senescent cells may secrete proinflammatory cytokines that contribute to autoimmunity.

Of interest, *Fasl*^{gld} mice with only one functional CD45 allelle (CD45$^{+/-}$) were reported to have a 10-fold reduction in DN T-cell population and decreased Ig and anti-DNA autoantibodies [306]. The finding suggests that CD45 plays an essential role in the activation of DN cells, which then accumulate due to the FasL defect.

Complement Components

MRL-*Fas*^{lpr} mice deficient for complement factor B (Bf) were utilized to investigate the role of the alternative pathway of complement activation in lupus pathogenesis [307]. Bf, produced by a variety of cell types, such as hepatocytes, phagocytes, fibroblasts, and endothelial cells, is an acute-phase reactant required to activate the alternative pathway. Local production of Bf can be detected in the kidneys of lupus-prone mice [308], where the homozygous deletion of Bf resulted in a significant reduction in GN severity and incidence of vasculitis, along with lower levels of anti-dsDNA, IgG3 anti-IgG2a RF, and IgG3 [307]. Serum C3 also remained at normal levels in Bf$^{-/-}$ mice. These findings support a significant role for Bf and the alternative pathway in the immune complex autoimmune pathology of these mice.

In contrast, MRL-*Fas*^{lpr} deficient for complement component C3 had the opposite effect, with slightly accelerated proteinuria and greater glomerular IgG deposition [309]. Thus, C3, instead of promoting the development of GN, may have a mild beneficial role possibly in the clearance of immune complexes. Similarly, disease severity was the same in mixed 129 × MRL-*Fas*^{lpr} C4 knockout mice with or without the C3 null mutation, suggesting little to no role for C3 [310].

MRL-*Fas*^{lpr} mice were made transgenic for overexpression of a soluble complement regulator, soluble CR1-related gene Y (*Crry*), both systemically and in the kidney [311]. Significant inhibition of complement activation led to reduced mortality, kidney disease, and C3 deposition. No effect was observed on lymphadenopathy, autoantibody production, or IgG kidney deposits. Thus, long-term complement inhibition reduces renal disease and increases the survival of MRL-*Fas*^{lpr} mice. Of potential relevance to these findings is a report [312] wherein normal mice deficient in factor H (Cfh$^{-/-}$; the main inhibitor of spontaneous C3 activation) were shown to develop membranoproliferative GN and to be hypersensitive to developing renal injury caused by immune complexes. In contrast, introduction of a second mutation in the gene encoding complement factor B, which prevents C3 turnover *in vivo*, obviated the phenotype of the Cfh$^{-/-}$ mice.

Local Immune and Inflammatory Response Regulation

Local upregulation of a variety of molecules, including MHC, ICAM-1, nitric oxide, and MCP-1, which may contribute to the immune and inflammatory responses essential for end organ damage, has been reported for lupus strains [2]. The role of such molecules in disease pathogenesis has been addressed by examining lupus-prone mice with homozygous deletions of these genes. MRL-*Fas*^{lpr} mice deficient for ICAM-1 showed improved survival, more as a result of reduced vasculitis than changes in autoantibody levels and GN [313, 314]. Similarly, deletion of the NOS2 gene in MRL-*Fas*^{lpr} mice resulted in partial disease abrogation, with a significant reduction in vasculitis and IgG rheumatoid factor, but anti-DNA antibody levels and GN were equivalent [315]. In contrast, deletion of the FcRγ chain in (NZB × NZW)F1 mice resulted in decoupling of the immune and inflammatory processes, resulting in similar autoantibody levels and glomerular deposits of immunoglobulin or complement, but siginificantly less glomerular destruction and mortality [316]. A similar result was demonstrated in the anti-GBM antibody model [317], wherein administration of the anti-GBM antibody bypassed the requirement for generating pathogenic autoantibodies. Thus, FcγRIII appears to play an important, nonredundant, role in the induction of local inflammatory glomerular injury. Similar decoupling was observed in MRL-*Fas*^{lpr} mice with deletion of macrophage chemoattractant protein-1 (MCP-1), a chemokine that recruits macrophages and T cells to tissues [318]. Thus, MCP-1 appears to be another factor critical for the progression from immune deposits to inflammatory tissue damage.

Miscellaneous Genes

Terminal deoxynucleotidyl transferase (TdT) is essential for adding nucleotides to the N regions at the V(D)J junctions during B- and T-cell antigen receptor rearrangement, which enhances B- and T-cell repertoire diversity both by the random addition of nucleotides and by disrupting the formation of repetitive homology-directed junctions [319–321]. Knockout of the *Tdt* gene in normal background mice resulted in reduced CDR3 region diversity with essentially fetal antigen receptor repertoires. Still, these mice were viable and responded effectively to a broad variety of immune challenges. Nevertheless, frequencies of anti-DNA-expressing B cells following LPS stimulation (natural antibody repertoire) were lower in TdT$^{-/-}$ mice, mainly due to a lower incidence of polyreactivity. In addition, the lack of N-region diversity appeared to reduce the affinity of anti-DNA antibodies [322]. Accordingly, TdT-deficient BWF_1 background mice had significant reductions in GN and mortality, but, curiously, no substantial differences in immunoglobulin levels or antinuclear antibody profiles. In contrast, TdT$^{-/-}$ C57BL/6-*Fas*^{lpr} mice had substantially lower anti-DNA and rheumatoid factor (RF) levels than their TdT$^{+/+}$ littermates [323]. Although

the mechanism(s) by which TdT enhances lupus remains to be determined, apparently it promotes autoreactivity by directly altering the fine specificies and affinities of autoantibodies and/or the T-cell receptor repertoire.

Protein kinase CK2 (casein kinase II) is a ubiquitous heterotetrameric serine-theonine kinase composed of two α or α′ catalytic and two β regulatory subunits [324]. It can phosphorylate a large range of protein substrates, including those involved in nucleic acid synthesis, nuclear transcription, signal transduction, protein synthesis, and the cytoskeleton. CK2 is active in proliferating cells, and high levels are found in certain human cancers. Mice transgenic for the α catalytic subunit of CK2 (CKα) show enhanced susceptibility to T-cell lymphomas in a stochastic manner [325], and overexpression of CK2 accelerates lymphoma development in myc or tal-1-transgenic or p53-knockout mice [326]. Crossing the CK2 transgene onto the MRL-*Fas*^{lpr} background did not change lymphoma incidence, but markedly accelerated lymphoproliferation and autoimmunity, with higher levels of serum IgG2a and earlier development of ANA positivity and proliferative GN [326]. CK2-mediated enhancement of T-cell proliferative responses was postulated to cause this disease acceleration.

Leukotrienes are potent proinflammatory lipid mediators produced through the 5-lipoxygenase pathway of arachidonic acid metabolism. Arachidonic acid metabolites, including leukotrienes, have been suggested to promote autoimmune pathogenesis in MRL-*Fas*^{lpr} mice [327], but 5-lipoxygenase deficiency in these mice resulted in a modest acceleration of mortality and a slight increase in the prevalence of arthritis in males only.

CONCLUSIONS

Advances in transgenic, gene knockout, and quantitative trait mapping have greatly aided identification of the genes and genetically related changes operative in murine models of spontaneous lupus. Genome-wide QTL scans of several lupus strains have resulted not only in the identification of multiple predisposing loci, but have advanced our understanding of the nature and complexity of genetic susceptibility. The relationship of these loci to component phenotypes and precise mapping of specific trait locations are being carried out in interval-specific congenic lines, which will eventually result in definitive characterization of the genetic alterations that predispose to autoimmune disease development. Studies in genetically manipulated normal background mice with an altered expression of specific immune-related genes have revealed a diversity of perturbations that can lead to tolerance defects and manifestations of systemic autoimmunity. Importantly, these findings suggest that spontaneous systemic autoimmunity can be induced by independent genetic abnormalities affecting the various checkpoints that normally control immune responses. Gene alterations affecting B- and T-cell activation, apoptosis, complement, clearance of self-antigens, certain cytokines, and the cell cycle have thus far been implicated. Similar studies assessing germline alterations in lupus-predisposing mice have also identified a variety of genes that are primarily inhibitory, although a few can enhance disease severity. The former are probably involved in downstream effector mechanisms, whereas the latter might play minor roles in lupus predisposition. Combined mapping and genetic manipulation studies have made it apparent that murine lupus susceptibility involves considerable genetic heterogeneity, which will complicate identification of the predisposing genes. Once accomplished, however, specific therapeutic interventions can be based on the individual genotypes and their associated traits.

Since submission of the manuscript additional genetic alterations were reported. Those promoting lupus include deletion of platelet endothelial cell adhesion molecule-1 (PECAM-1/CD31) (376), E2F2 knockout (377), STAT6 deficiency (378), deletion of decay-accelerating factor (CD55) in MRL-*Fas*^{lpr} mice (379), lack of TACI (380), transgenic expression of LIGHT (*Tnfsf14*) in T cells (381), and a targeted gain-of-function mutation of lyn (382). In contrast, deletions of the IFN-α/β receptor (383) or STAT-4 (378) in lupus-prone mice reduced disease susceptibility, A NZB polymorphism of C1q on chromosome 4 within the *Nba1/Lbw2/lmh1/Mott* interval was also reported (384).

SYSTEMIC LUPUS ERYTHEMATOSUS IN DOMESTIC ANIMALS

Richard E. W. Halliwell

INTRODUCTION

The study of spontaneous diseases of domestic animals is of great value in research into the pathogenesis and treatment of many spontaneous diseases of humans. Although generally more expensive than the use of traditional animal models, and despite mounting sensitivities regarding the use of dogs and cats in medical research, their close environmental proximity to humans and their outbred nature make them particularly appropriate for such investigations.

This is most certainly true in case of spontaneous autoimmune diseases. Investigations of canine immune-mediated thrombocytopenia, autoimmune hemolytic anemia, lymphocytic thyroiditis, rheumatoid arthritis, and systemic lupus erythematosus (SLE), to name but a few, have all contributed to better understanding of the counterpart disease in humans [1]. The most significant work, however, has probably involved investigations of canine SLE. Although contributions enhancing our knowledge of the clinical aspects of the disease continue on both sides of the Atlantic, in-depth investigations of the pathogenesis commenced in the United States in the late 1960s and in recent years has taken place largely in France and Scandinavia.

CANINE SYSTEMIC LUPUS ERYTHEMATOSUS

Introduction

The first suggestion that SLE occurred occur in dogs appeared in the 1960s with the work of Lewis and colleagues [2]. Seven cases were described, all of which suffered from autoimmune hemolytic anemia, and six of which in addition had immune-mediated thrombocytopenia and evidence of renal disease. A further report [3] detailed a case of erosive polyarthritis, which in addition suffered from anemia, leucopenia, amyloidosis, pleuritis, and whose serum had antinuclear antibodies (ANA). These workers utilized dogs suffering from SLE to create the first of three breeding colonies, details of which have appeared over the years [4] and also to conduct classical transmission experiments with cell-free filtrates [5].

Clinical Signs

As in humans, canine SLE is a multisystem disease, and the systems can be affected in random association and in random sequence. However, the appearance of

three or more signs simultaneously generally implies a poor prognosis [6]. The different studies, however, report varying incidence of the clinical signs, which is probably a reflection of the clinical bias of the clinician to whom the patients are presented. For example, the dermatologist is likely to receive a higher proportion of cases with skin disease, the orthopedic specialist will see mostly patients with joint disease, and the hematologist will see predominantly animals with anemia or thrombocytopenia. As in humans, canine SLE generally takes a chronic course, with periods of acute or subacute disease interspersed with periods of mild disease or clinical remission.

Joint Disease

Overall, this appears to be the most common presenting sign and is present in 40 to >90% of patients, and is multiarticular and generally symmetrical and nondeforming [1, 7–12]. The arthritis is almost always nonerosive, with <2% of cases being erosive arthritis. Affected animals have a sudden or gradual onset of generalized stiffness, and involved joints may be swollen and painful. In some advanced cases the temporomandibular joints become involved, leading to pain on eating and pronounced muscular wasting of the temporal muscles. Radiographic evidence of a bony change is usually minor to absent, with soft tissue swelling alone often being evident. Synovial fluid aspirates contain elevated neutrophil counts, and occasional LE cells are seen (Fig. 1). Histopathology of the synovial membrane reveals hypertrophy and hyperplasia of the lining cells, and a mixed cellular infiltrate with mononuclear cells predominating. Vasculitis is also commonly seen.

Polymyositis

This may accompany arthritis and, unless biopsies are taken routinely, may escape diagnosis. Occasionally it may be severe and lead to pronounced muscular atrophy, often involving the temporal muscles. It is reported in some 5% of cases.

When associated with arthritis of the temporomandibular joints, the resultant muscular wasting can be profound.

Skin Disease

The appearance of skin disease is highly variable and ranges from trivial, mild, alopecic, scarring lesion to severe and widespread ulceration [13]. Symmetry is a striking feature. Some cases present with a pruritic, generalized seborrhoeic dermatitis. In others, ulceration of the mucocutaneous junctions is apparent, which may spread to involve other parts of the body. Ulcerative and/or hyperkeratotic footpads may be seen. Focal areas of alopecia are often noted, which may extend to involve large areas. Apparent photosensitization may occur, with a history of lesions involving the hairless areas of the body flaring up following sunlight exposure. Loss of pigment from the nose and the eyelids may be apparent, and facial edema is sometimes noted. Some cases proceed to severe ulceration of the nose (Fig. 2).

Although vesiculation with subsequent ulceration is not reported as a feature of the cutaneous signs of canine SLE, a recent report features a bichon frisé with severe erosive lesions on the right elbow, axilla, and lateral thorax [14] (Fig 3). Histopathology revealed subepidermal clefting with an absence of dermal inflammation. Immunological studies revealed a circulating antibasement membrane antibody in a titer of >20,000, and the serum bound to the NC1 domain of recombinant human type VII collagen. In addition, the patient suffered from persistant proteinuria, a Coombs'-positive anemia, thrombocytopenia, pleuritis, and hepatitis. The authors proposed that this represented the canine equivalent of type 1 bullous SLE of humans [15]. Another report details a case of SLE showing a

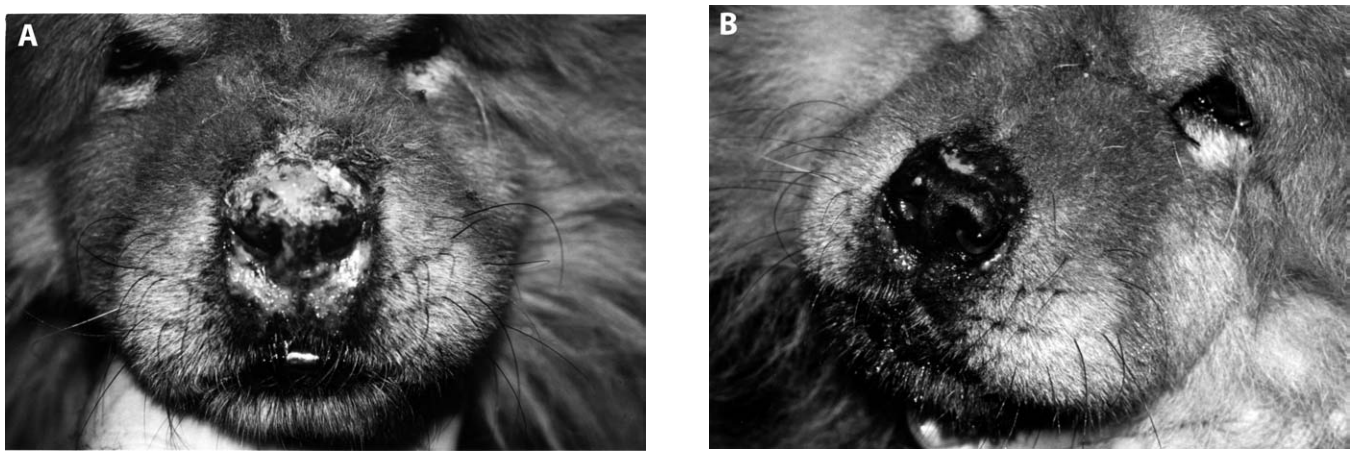

FIGURE 2 Depigmentation and ulceration of the nose of a chow (a). The dog also had oral ulcers and arthritis. There was a good response to prednisolone and azathioprine within 8 weeks (b).

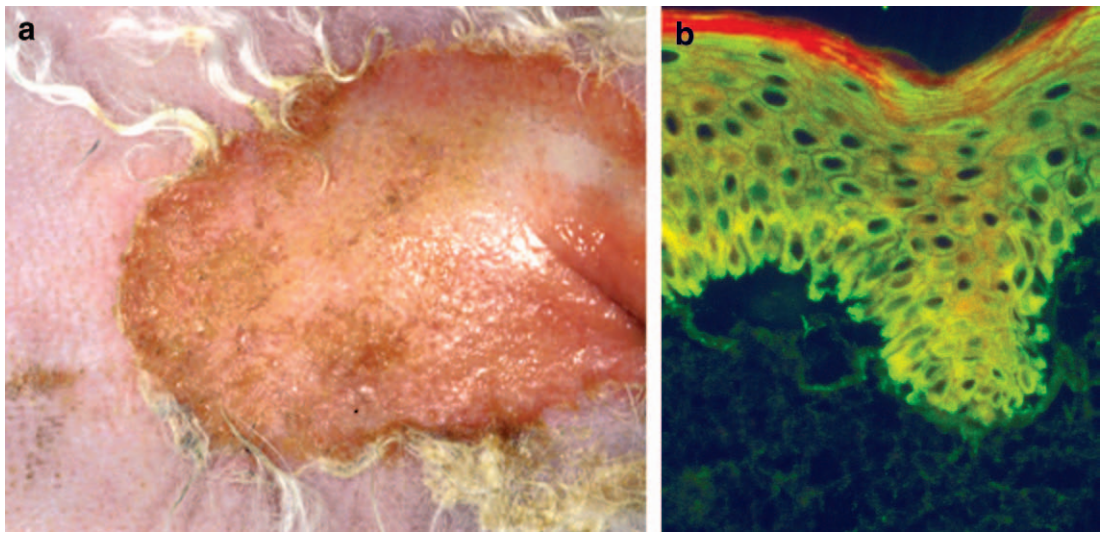

FIGURE 3 (a) Ulcerative lesions in a bichon frisé suffering from type 1 bullous SLE. (b) Indirect immunofluorescence in a case of type 1 bullous SLE using canine salt-spit lip. From Olivry *et al.* [4], with permission.

Coombs'-positive anemia, thrombocytopenia, and polyarthritis with an ANA titer of 10,240 [16]. However, instead of cutaneous signs of SLE, the patient had both clinical and histopathological signs suggestive of pemphigus foliaceus. Immunohistochemistry revealed desmosomal deposition of IgG. The dog subsequently developed a lymphoma. This appears to represent concomitant SLE and pemphigus—a phenomenon also reported occasionally in humans [15].

Histopathology of the cutaneous changes in SLE is ordinarily characterized by a lichenoid, largely lymphoid infiltrate that hugs the dermoepidermal junction (Fig. 4) [13, 17, 18]. Vacuolar alteration and apoptosis of basal cells are major diagnostic criteria, leading to the formation of colloid or Civatte bodies. Occasionally, this may lead to intraepidermal pustules. A leucocytoclastic vasculitis may be seen in the dermis, and thickening of the basement membrane with pigmentary incontinence is often a feature of chronic cases. Immunofluorescent studies reveal immunoglobulin deposits at the dermoepidermal junction (Fig. 5).

Dogs also suffer from discoid LE, or cutaneous LE, in which skin signs alone are noted and in which ANA is absent [19]. The predominant part of the body affected is the nose, with initial depigmentation being followed by erythema and ulceration (Fig. 6). Lesions are exacerbated by sunlight. Histopathology is similar to that of skin lesions in SLE, and immunofluorescent

studies reveal immunoglobulin deposits at the dermoepidermal junction.

An ulcerative dermatitis of Shetland sheepdogs and rough collies appears to represent a vesicular variant of cutaneous LE [20]. Affected animals showed ulceration of the hairless portion of the ventral abdomen and chest that was exacerbated in the summer (Fig. 7). Some also showed buccal ulceration. There were no systemic signs, except for evidence of granular casts in 4/8 cases that could represent early renal disease. Antinuclear antibody tests were negative, and the presence or absence of dermoepidermal junction immunoglobulin deposits was not examined.

Ulcerative Stomatitis

This is a feature of between 10 and 20% of cases. It may involve buccal mucosal surfaces, the hard or soft palate, and less frequently the tongue. Histopathology

FIGURE 6 Discoid LE in a dog. The depigmentation is followed by erythema and inflammation. The disease was exacerbated by sunlight, but ANA was negative and there were no other systemic signs.

FIGURE 7 Vesicular cutaneous LE in a Shetland sheepdog. From Jackson and Olivry [20], with permission.

of the affected areas reveals a similar picture to that seen in the skin, with an intense mononuclear cell infiltrate submucosally.

Hematological Changes

Some 30–60% of cases are presented with anemia. Of these cases, approximately half are apparently immune mediated, showing evidence of hemolysis with positive direct Coombs' tests or autoagglutination. The remaining patients are apparently suffering from anemia of

chronic disease. Leucopenia and leucocytosis are seen with approximately the same frequency, affecting 20–30% of cases each. In a proportion of the cases with leucopenia, the lymphoid series is preferentially reduced, leading to a marked lymphopenia.

In some cases of SLE, thrombocytopenia may be the initial cause for presentation to the veterinarian [21]. This may be manifested as petechial or ecchymotic hemorrhages, bleeding from any of the natural orifices, or excessive bleeding following minor surgery.

Renal Changes

Profuse proteinuria, as assessed by a four-plus reaction by the sulfosalicylic acid method, or quantitatively at a level >0.5 g/liter, is present in some 50% of cases. Azotemia may be present on presentation and is a frequent and often life-threatening complication of severe cases. Biopsies usually reveal a proliferative, membranous glomerulonephritis, and immune complexes are revealed readily using fluorescein-conjugated anti-IgG and anti-C3 (Fig. 8).

FIGURE 8 Immunoglobulin deposits in the renal glomerulus. Glomerulonephritis is associated with a case of SLE.

Neurological Abnormalities

These are recorded more rarely than in humans; however, psychological and behavioral abnormalities are identified less readily in dogs and may pass unnoticed or be ascribed to other causes. Polyneuropathies characterized by hyperesthesia, convulsions, and/or obvious behavioral changes are noted in some 2–5% of cases.

Lymphadenopathy

Lymphadenopathy is detectable in some 50% of cases and generally affects, symmetrically, the majority of the palpable nodes. It is often accompanied by splenomegaly.

Pleuritis/Pericarditis

This is not an easy diagnosis in dogs. It is reported as affecting some 5–10% of cases, but this is possibly an underestimate [7].

Pulmonary Disease

A chronic pneumonia has occasionally been reported, but is a rare complication [7].

Fever

Fever is present in a high proportion of cases, and indeed some authors contend that it is invariably present [6]. However, it tends to be intermittent and cyclical, and so may be missed unless repeated examinations are made. Characteristically, it is quite briskly responsive to corticosteroids.

Incidence of the Various Changes

Table 1 contains a composite of the various clinical and pathological changes as reported by seven studies over the years. In some studies, details given were less than in others, in which case the lack of information is given as not reported.

Immunological Findings

It is generally held that a diagnosis of SLE is untenable without serological evidence of antinuclear antibody activity. A variety of techniques have been employed to demonstrate this, and some studies have painstakingly addressed the antigenic specificity of the antibody activity.

TABLE 1 Incidence of Clinical and Pathological Sings in Canine SLE Derived from Published Case Studies

Criterion	Reference							Incidence[a] (%)
	17 (*n* = 29)	6 (*n* = 29)	7 (*n* = 30)	8 (*n* = 42)	9 (*n* = 13)	12 (*n* = 26)	11 (*n* = 75)	
Arthritis	17	29	23	25	13	10	69	76.2
Skin disease	13	3	9	19	4	14	45	43.8
Glomerulonephritis	6	15	7	22	2	12	49	46.3
Fever	12	NR[b]	28	NR	NR	8	75[c]	80.4
Central nervous system signs	2	3	0	4	1	0	1	4.5
Pleuritis	0	3	1	NR	1	0	6	5.4
Polymyositis	0	1	2	0	0	2	6	4.5
Pneumonia	0	1	2	0	0	2	2	2.9
Oral ulcers	0	0	5	7	0	10	8	12.2

Leucopenia	4	NR	NR	NR	NR	NR	15	14.4
Thrombocytopenia	4	1	NR	7	4	2	3	9.8

[a] Incidence as a percentage of those reports detailing that criterion.
[b] Not recorded.
[c] In this report, although fever was seen in 100% of cases, it was cyclical and not always present.

LE Cell Phenomenon

In earlier studies, the LE preparation, using either clotted or heparinized blood, was generally employed. However, difficulties in identifying LE cells accurately and a perceived lack of sensitivity in some hands have meant that this approach has been gradually abandoned.

Antinuclear Antibody by Immunofluorescence

Substrates employed have included mouse leucocytes, mouse and rat liver, and various tissue culture cell substrates, notably HeLa, Vero, and HEp-2 cells. The reported sensitivity varies between laboratories and with the substrate employed.

It is generally held that positive ANA are encountered in virtually every case of canine SLE—indeed, some hold that a definitive diagnosis of SLE in dogs is not tenable in the absence of supportive serology. However, it is also important to emphasize that, as in humans, positive ANA is by no means restricted to dogs with SLE. For example, positive ANAs are frequently encountered in leishmaniosis [22], a condition also associated with other immunological abnormalities, including circulating immune complexes and lymphadenoapthy. The dermatological signs of leishmaniosis are also strikingly similar to those seen in SLE.

As also is the case in humans, positive ANA may be found in sera from normal dogs. In one study, the incidence of ANA was assessed in sera from 100 normal dogs presented for routine heartworm prophylaxis using HeLa cells [23]. Two of these showed a titer of 320 and two of 80. In 19 animals a titer of 10 was recorded, 3 had a titer of 20, and 1 of 40. Forty-seven were negative when assessed undiluted. Another study examined the incidence in a line-bred colony of English cocker spaniels in which there was a high incidence of cardiomyopathy and in which the existence of at least one case of SLE had been confirmed [24]. Using Vero cells, the incidence in diseased dogs ranged from 47 to 60%. The incidence in 58 normal dogs in the same kennel was 46.5%. Antibody titers ranged from 10 to 2560. In contrast, none of 25 sera from English cockers from a control kennel yielded positive results.

A number of different patterns are seen. Commonest are homogeneous patterns and speckled patterns (which may be either fine or coarse), followed by homogeneous/speckled and homogeneous with large dots [25]. The large dot pattern is observed only when mouse leucocytes are employed as the substrate. However, in reality, a spectrum of patterns is seen, which in some instances fall descriptively in between. Membrane fluorescence is quite rare. Nucleolar fluorescence is occasionally noted, but is more often associated with unclassified immune-mediated diseases than with classical SLE.

Antigen Specificities of Canine ANA

Double-Stranded (ds)DNA

One of the greatest controversies in the field of canine SLE pertains to the frequency of occurrence of anti-dsDNA antibodies. It is now generally accepted that they are rarely encountered. The problem arises largely from the existence of an acidic β-globulin, which is not antibody and which binds to DNA and also to the synthetic double-stranded DNA analogue poly-deoxyadenylate-deoxythymidylate (dAdT) [26]. This protein is absent in primate sera, but has been found in bovine, equine, feline, mink, and canine serum. The highest levels of around 100 μg/ml are found in the latter species. This leads to false-positive reactions when techniques based on the Farr assay are employed [26–28].

Although the exact nature of this protein is still unknown, some features have been elucidated. It is heat labile and destroyed by heating for 30 min at 60°C, but not at 58°C [29]. It does not bind to protein A, would not appear to be a glycoprotein, as evidenced by a failure to bind to lentil lectin, and is partially inhibited by the addition of EDTA and more completely by the addition of dextran sulfate [29]. The interference can also be inhibited by the addition of sodium dodecyl sulfate [27] and by the use of increased ionic strength and pH of the buffers [30]. However, the use of the latter technique did give higher binding of sera from animals with not only SLE, but a variety of inflammatory diseases compared to normals. However, positive binding to dsDNA was not always correlated with binding to dAdT, and *vice versa.*

The detection of anti-dsDNA in canine sera is, therefore, not a simple matter. Other detection systems have included indirect immunofluorescence employing *Crithidia luciliae* or *Trypanosoma brucei* and ELISA techniques employing highly purified dsDNA. In all studies, immunofluorescent techniques show at best a low incidence of weak positive reactions using sera from dogs fulfilling the criteria of the American College of Rheumatology (ACR), although one study indicated weak positive reactions in 4/8 [31]. In two more studies using a combination of indirect immunofluorescence and ELISA, positive reactions were seen in only 2/100 and 0/43, respectively [25, 32], and reactions in ELISA were concordant with those using indirect immunofluorescence. It has been suggested that the DNA-binding protein in normal canine sera could, in addition to interfering with the Farr assay, also interfere with the binding of specific anti-dsDNA antibodies in an ELISA. However, in a study that addressed this question, none of the canine sera assayed were able to inhibit binding of a murine anti-DNA monoclonal antibody [32]. However, one study employing a commercial ELISA system showed relatively high DNA binding in sera from dogs with SLE, and to a lesser extent from dogs with other arthropathies [33]. These differences would appear irreconcilable on the basis of sample differences. The latter authors did, however, note that sera that gave high dsDNA-binding values also bound strongly to single-stranded (ss)DNA, which could suggest a possible contamination of the dsDNA substrate with ssDNA [33].

ssDNA

Demonstration of the presence of anti-ssDNA is of no value in the diagnosis of SLE in dogs. In one study, sera from 21% of 100 dogs with SLE gave positive results, as did 14% of dogs with positive ANA but less than four criteria for SLE, and 26.8% of 56 dogs with miscellaneous infectious diseases, including leishmaniosis [25]. This emphasizes the absolute necessity of utilizing highly purified and stable dsDNA preparations for all assays involving canine serum.

Histones

The presence of antihistone antibodies is highly correlated with a positive diagnosis of SLE [25, 32–35]. In the most extensive study, 71/100 sera from patients fulfilling at least four ACR criteria gave positive results, as compared with 6.7% of 120 normals [25]. In the case of dogs with one or more, but less than four criteria for SLE, 38% of 400 sera gave positive results. A number of these, of course, could later have fulfilled the four criteria. Of the 56 dogs with miscellaneous infectious diseases, 17.9% gave positive results.

The pattern of recognition, however, differs from that in humans. Using immunoblots, 54% of sera from dogs with SLE recognized H4, with the same number recognizing H3. Eight percent recognized H1, 22% H2A, and 20% H2B [25]. In another study, antibodies to H2B were not detected in any of 43 sera from dogs with SLE [32]. In contrast, H1 and H2B are more prominent autoantigens in humans [36, 37]. A further difference is that the histone determinants against which canine antibodies are directed are mostly trypsin resistant [25].

Other Antigens Recognized

Many of the other antigens that are recognized by sera from human patients with SLE are also recognized by canine sera. Some 7% of sera from dogs with SLE precipitate ribonucleoprotein (RNP), and a further 12% detected both RNP and Sm antigen [25]. High-motility group (HMG) proteins were recognized by 20% of sera, with HMG1 detected by 6% and HMG2 by 18%. No sera recognized HMG14 and HMG17. In

the aforementioned study, three sera also contained anti-Sjorgren's syndrome A antibody (anti-SSA), but anti-SSB has yet to be detected.

Of great interest are antibodies with a specificity that appears to be unique for sera from canine patients with SLE, which were initially termed anti-type 1 (or T1) and anti-type 2 (or T2) [25, 34]. These are reactive with soluble nuclear extracts, but the T2 antigen is absent from extracted nuclear antigen preparations. Anti-T1 is directed against a major nuclear antigen of 43 kDa [25]. Studies have confirmed that this is identical with the 43 kDa glycoprotein recognized by some canine SLE sera in the studies of Soulard *et al*. [38]. This has now been identified as hnRNP G [39]. Interestingly, many sera from dogs with SLE also react with a ribosomal antigen of identical molecular weight [40].

Antinucleolar Antibody

Four cases, with clinical signs compatible with SLE, have been reported in which a high-titer antinucleolar antibody was detected. In three of these, polyarthritis was a major presenting sign [41], although one case had concomitant immune-mediated thrombocytopenia, anemia, leucopenia, and skin eruption [42]. In view of the paucity of cases, assumptions regarding the disease associations cannot be made. The antibody specificity has been examined, and sera detect three polypeptides of 110,000, 95,000, and 45,000 kDa, which are antigenically cross-reactive [41].

Antibody Activity and Staining Patterns

A number of studies have attempted to correlate specific antibody activity with staining patterns. Early studies had demonstrated that anti-T1 (hnRNP G) gives a relatively fine speckled pattern, anti-Sm and anti-RNP give a coarser speckled, or reticulonodular pattern, and the antihistone antibody gives a generally homogeneous pattern [25].

More recent studies have employed immunodiffusion [43], ELISA, and immunoblots [44]. It was first shown that sera that exhibit chromosomal reactivity exhibit a homogeneous nuclear fluorescence pattern and fail to precipitate on immunodiffusion analysis using commercially available ENA preparations. Sera that show negative chromosomal reactivity are more likely to exhibit speckled patterns, and a proportion are positive on immunodiffusion. Lines of identity with human reactive sera were shown in the case of anti-RNP and anti-Sm only [43]. Some sera precipitated, showing partial identity with the homologous human protein, and in others there was a complete lack of identity. The autoantigen recognized most frequently in ELISA and immunoblots was hnRNP G—an antigen absent from the commercially available extract made for the examination of human sera. Examination of anti-RNP activity confirmed that canine sera react with the same full major antigenic region of the 70 K protein as human sera [44]. However, attempts to correlate staining patterns and/or antibody specificity with disease expression have thus far proved unsuccessful.

T-Cell Subsets in Canine SLE

A study of 20 dogs with SLE in differing stages showed striking abnormalities in lymphocytes and in T-cell subsets [45]. First, animals in the active phase showed marked lymphopenia, with mean counts of 1050×10^6/liter as compared with 2130×10^6/liter in controls. In the former, $CD4^+$ and $CD8^+$ cells comprised a mean of 56.7 and 10.9%, respectively. Comparative data for the controls were 40.5 and 18%, which implies a striking deficiency of cytotoxic/suppressor cells. Moreover, the percentage of $2B3^+$, or activated T cells, increased in the active phases of the disease from a mean of 46.5 to 64.1%. A combination treatment with prednisone and levamisole was quite effective in inducing long-term remission, and successful therapy was associated with normalization of the $CD4^+$:$CD8^+$ ratio.

Canine MHC Antigens, C4 Allotypes, and SLE

Possible associations between SLE and MHC class I and II antigens, as well as associations with C4 allotypes, have been investigated in two breeding colonies in which there is a high incidence of SLE [46]. There was a significant positive association of SLE with DLA-A7 (relative risk 11.93) and negative associations with both DLA-A1 and DLA-B5 (relative risks 0.06 and 0.05). No associations were found with class II antigens, and there were no associations with the C4 allotype. The latter finding contrasts with a previous study on eight dogs with polyarthritis, all of who had positive ANA, but only two of which satisfied the current ACR criteria for SLE [47]. Five (out of five studied) had the same C4 allotype, and three had markedly lowered C4 levels, which rose following corticosteroid treatment.

Lupus Anticoagulant

Although commonly encountered at some point in cases of SLE in humans, tests for the presence of this abnormality are not undertaken routinely in veterinary medicine. The literature lists just one case in a dog [48], with a further case in a cat [49].

Antithyroglobulin Antibodies

Hypothyroidism as a result of lymphocytic thyroiditis is a relatively common disease in dogs, and the pres-

ence of antithyroglobulin antibodies is a useful diagnostic aid [50]. However, although thyroiditis has been reported in cases of SLE [24], there have been studies that have investigated its incidence systematically.

Epidemiology of Canine SLE: Lessons for Human SLE

Breed and Sex Incidence

In most of the studies, the German shepherd breed appears to be overrepresented, and in a study at Lyon, France, German shepherds comprised 46.7% of 75 cases of SLE fulfilling at least four ACR criteria, as opposed to a 25% incidence of this breed in the base population [12]. In another study of 58 dogs in California, in which the diagnosis was aided by the application of log-linear and logistic regression models in disease prediction, 17.4% of 58 cases were German shepherds, as compared with a base clinic population of 7.8% ($P < 0.01$) [51].

The existence of a sex bias is controversial. A complicating factor in this analysis is that many bitches are spayed, and the proportion of spayed to intact females is not always noted. Also, to a lesser extent, some males may be castrated. At all events, most studies fail to show a female sex bias, which is in sharp contrast to cases of immune-mediated thrombocytopenia and autoimmune hemolytic anemia, occurring as single entities, in which a higher proportion of females than males is reported [1]. The only study showing a female predisposition was that of Drazner [8] in which 23/30 affected animals were female. However, two important points relating to the latter study are that some animal diagnosed as suffering from SLE satisfied only two ACR criteria, and it was also noteworthy that only 3 out of the 23 females were spayed. A male sex bias was shown in both the French study (51 males vs 24 females) and the Californian study in which intact males were significantly overrepresented ($P < 0.025$) [12, 51].

The Development of Breeding Colonies

A clear advantage offered by research using spontaneous animal models for human diseases is the ability to selectively inbreed such animals, and thus explore genetic aspects, as well as enabling the production of more clinical material. It can be argued that such models, occurring in an outbred animal, have more relevance to the human disease than do, for example, disease models employing highly inbred strains of mice.

The first of the canine SLE colonies was established by Lewis and Schwartz [4] in Boston by mating two dogs with SLE. The first significant conclusion was that the incidence of positive ANA could not be accounted for by any conventional mechanism of inheritance, and the authors hypothesized that it was the result of vertical transmission of an infective agent in a genetically susceptible animal. However, for many years, no animal in the colony developed disease, despite having high-titer ANA. Finally, after 10 years, and involving five inbred generations, SLE, autoimmune thyroiditis, and Sjogren's syndrome were all diagnosed [52].

Another colony was established by Monier and colleagues in France, starting with the mating of an affected German shepherd to an affected Belgium shepherd [53]. Both the incidence of positive ANA and clinical signs increased with each inbred generation. In the F1 family, the incidence of positive ANA and of clinical signs was 3/6 and 0/6, respectively. In the F2 it was 2/4 and 1/4, and in the F3 it was 5/6 and 4/6. Lymphocytes from affected animals showed higher sensitivity to concanavalin A (Con A) in lymphocyte blastogenesis assays, reduced Con A-induced suppression, lower levels of thymulin, and resistance to the induction of immunological tolerance using intravenous aggregate-free human IgG. In general, the appearance of ANA preceded that of clinical signs—in one case by as much as 3.8 years.

Hubert and colleagues [54] examined another colony of German shepherds that were being bred for show and sale. In contrast to the earlier study, the incidence of ANA and of clinical signs was reduced in each generation, which could be ascribed to the use of outbreeding rather than inbreeding once the clinical signs had become evident. It was of interest that of the 34 dogs that showed one or more ACR criterion for SLE, 22 were males and 12 were females. It was also noted that the appearance of the different clinical signs could be spread over some time. For example, in one animal, arthritis developed 16 months prior to the onset of proteinuria and cutaneous manifestations [54].

Conclusions of the three studies involving artificial or spontaneous breeding colonies are that the occurrence of SLE cannot be ascribed to genetic influences alone and that environmental influences must also play a role.

Possible Role of Transmissible Agents

The early investigations of Lewis and colleagues provided convincing evidence that serological abnormalities could be transmitted by a filterable agent [5]. Cell-free extracts of spleens from the offspring of dogs with SLE were injected into newborn puppies and into mice and rats. The dogs and the mice, but none of the rats, developed ANA. Some of the mice developed lymphoma, and cell-free extracts from the tumors induced

ANA when injected back into puppies. None of the animals, however, developed SLE. The occasional finding of normal animals with high-titer ANA and anecdotal reports of clusters of both dogs and cats with high-titer ANA are also supportive of the existence of a transmissible agent.

This has naturally led to a search for possible evidence of transmission of serological abnormalities from humans to dogs, and vice versa. The first report concerned two dogs living in a household where a number of family members had SLE [55]. Skin disease and arthritis were noted in the dogs, which were not subjected to detailed veterinary investigations. Both had anti-dsDNA when serum was subjected to the Farr assay.

The implication that a possible transmissible agent might be crossing the species barrier was refuted by three later better controlled studies involving investigation of a broader spectrum of autoantibodies and a greater number of individuals of both species [56–58].

The controversy was reawakened by study in which sera from 15 dogs living with patients with SLE were examined and compared with sera from 9 dogs with various immune-mediated diseases, not all of which were autoimmune in nature. Controls consisted of 10 laboratory-reared and -held Labrador retrievers and beagles [59]. The mean age of 10 of the household dogs living with SLE patients was 9.1 years and that of the control group was approximately 2 years. The control group was thus not matched for breed, age, or environment. Dogs from both the immune-mediated disease group and the SLE patient's group had abnormal serum electrophoretograms using criteria that were not defined. They also had higher levels of dsDNA binding as assessed by ELISA. It was noteworthy, however, that no sera from any group contained anti-dsDNA as assessed by indirect immunofluorescence using *Crithidia luciliae* and that none of the sera from the SLE patient's dogs had positive ANA as detected by indirect immunofluorescence employing both mouse liver and Hep-2 cells. Also, surprisingly, only 1 of the 9 dogs diagnosed as suffering from immune-mediated disease had ANA. Furthermore, no animals from any group had detectable antibodies to any extractable nuclear antigens. In view of the controversy that has surrounded the detection of anti-dsDNA in the dog, it would be important to show that the DNA preparation lacked detectable ssDNA in that there was no evidence of anti-dsDNA antibody using *C. luciliae.* Clearly, one can draw no conclusions from this study.

The issue, however, still fails to go away, and recent review again draws heavily on anecdotal observations [60]. Two dogs are described that lived in the home of a rheumatologist whose mother-in-law had suffered from SLE for >35 years. One of the dogs had clinical signs compatible with SLE, a positive ANA, and elevated anti-RNP as assessed by ELISA. The other dog, also a cocker spaniel, had an ANA titer of 25 and what was described as ocular Sjogren's syndrome. The existence of a true canine analogy of Sjogren's syndrome is quite controversial, and the dog probably was suffering from keratocunjunctivitis sicca, which is quite common in dogs as a stand-alone entity and may not have an immunological basis. It is indeed possible that the dog with SLE "caught" lupus from the mother-in-law. Clearly, the family should obtain a number of further dogs to see if the phenomenon is repeatable!

Diagnosis of SLE in Dogs

Over the years, this has caused just as much controversy as it has in human medicine. Some of the original ARA criteria [61] either did not occur in the dog or were difficult to evaluate. Raynaud's phenomenon and the serologic test for syphilis were among the former, and psychoses would be among the latter. With this in mind, criteria were proposed in which the presence of two major signs (polyarthritis, dermatological signs that cannot be ascribed to any other cause, Coombs' positive anemia, thrombocytopenia, glomerulonephritis, leucopenia, and polymyositis), together with evidence of antinuclear antibody by either immunofluorescence or LE cell preparation, justified a diagnosis of definite SLE [22]. Alternatively, the diagnosis could be made with the presence of one major sign, presence of an antinuclear antibody, and two minor signs (fever of unknown origin, pleuritis or central nervous signs, particularly seizures). A diagnosis of probable SLE was proposed if there was one major, two minor signs and positive serological evidence, or two major signs without serological evidence. The more recent findings that a high proportion of cases of canine SLE apparently suffer from anemia of chronic disease, which is not immune mediated, necessitates dropping the requirement that the anemia should be Coombs' positive. This approach has been found to have a high level of specificity and of sensitivity [49].

A better approach, however, is to adapt the revised ACR criteria [62] to the veterinary context as done by Chabanne and colleagues [63]. The major change is that criteria under immunological disorders are changed to incorporate one or more of

- Antihistone antibody
- Anti-Sm antibody
- Anti-hnRNP G
- A decrease in $CD8^+$ cells to $<200/mm^3$ or a $CD4^+ : CD8^+$ ratio higher than 4.0

The ANA specificities just noted are those associated most reliably with SLE. This approach has been widely commended and appears to represent the preferred way forward.

There remains the problem, as in humans, that the various signs can commence at random times and in random association. It is also clear that a positive ANA is frequently detectable prior to the onset of clinical signs or, rarely, after their onset [54]. However, although the use of such criteria is essential for defining the disease for the publication of data, clinicians continually encounter cases of immune-mediated disease covering a wide spectrum that require aggressive therapy, but whose precise nature will never be defined.

Treatment

Therapy of dogs with SLE generally involves the use of corticosteroids, initially in high doses, perhaps with concomitant use of cytotoxic drugs, such as azathioprine or chlorambucil. In cases where immune-mediated thromobocytopenia is part of the presenting signs, aggressive therapy, which may include the use of vincristine, is employed. Likewise, where the presenting signs include autoimmune hemolytic anemia and there is a life-threatening rapid fall in erythrocyte counts, intravenous cyclophosphamide is often employed. The disease can wax and wane, and there is a tendency to overtreat and maintain animals on continued therapy when it may not be required.

Plasmapheresis was used on four dogs with SLE that was refractory to conventional treatment [64]. Three of the four dogs had good responses lasting from 1 to 6 months. The therapy led to an appreciable fall in the ANA titer and to an increase in the levels of C3 and total hemolytic complement. The authors recommend the treatment only for severe cases that are minimally responsive to anti-inflammatory therapy and cytotoxic drugs. However the, dramatic response seen in some cases appears to emphasize the pathogenic role of the immune complexes.

Excellent results have been reported with the combined use of prednisone with levamisole [12]. In a comparative study, one group of dogs received initial treatment with 1–2 mg/kg of prednisone, which was gradually tapered once control was affected. The other received the same dose of prednisone with levamisole orally at a dose of 3–7 mg/kg/day on alternate days. The first group, continued to receive minimal doses of corticosteroids for maintenance, whereas in the case of the second group, prednisone was discontinued, with levamisole alone used when there was a recrudescence. In the group treated with corticosteroids alone, clinical improvement always occurred, but it was not maintained when prednisone was withdrawn. In the group in which combined therapy was used, prolonged remission was obtained in >50% of cases, which was as long as 9 years. When relapses occurred, levamisole alone was effective in achieving a further sustained remission. Successful treatment with levamisole caused a normalization of the lymphopenia, as well as a normalization in the abnormal $CD4^+$:$CD8^+$ ratio [45], making it tempting to speculate a cause-and-effect relationship between the disease and the underlying abnormalities in T-cell subsets.

SYSTEMIC LUPUS ERYTHEMATOSUS IN CATS

Introduction

As discussed, the dog suffers from a disease that is strikingly similar to that of humans. However, the situation with the cat is not so clear. Nonetheless, cats with a broad spectrum of clinical signs are encountered that are compatible with those found in SLE in humans and dogs; in some instances, the association of a number of these in the same patient is highly suggestive of the existence of SLE in this species.

In addition to the spontaneous disease, cats are of particular interest in the area of drug-induced lupus. This species suffers relatively commonly from hyperthyroidism, the etiology of which is obscure. Of the therapeutic approaches available, the use of propothiouracil leads to a high incidence of side effects in the form of a lupus-like syndrome [65]. In experimental studies, 53% of cats given 150 mg daily became ill within 4–8 weeks, manifesting weight loss and lymphadenopathy. Affected cats also showed a Coombs'-positive anemia and positive ANA [66]. It appears that the sulfur atom is critical in this phenomenon, as administration of propouracil is without effect. Drug-induced serological abnormalities have also been recognized in dogs following treatment with hydralazine, but in the latter case no clinical signs resulted [67].

Clinical Signs

The first report of an SLE-like disease in the cat appeared in 1971 and was described as a case of immune complex glomerulonephritis, which was accompanied by a positive LE cell preparation [68]. This was followed by papers detailing a cat with autoimmune hemolytic anemia [69] and one with immune-mediated thrombocytopenia [70], both accompanied by positive LE cell preparations

Scott and co-authors [71] described two cats whose presenting signs were dermatological and whose sera

showed low-titer positive ANA tests (10 and 40). One case was presented with recurrent fever and lymphadenopathy, paronychia, and a symmetric crusting alopecic rash involving the head and ears. Direct immunofluorescence revealed immunoglobulin deposits at the dermoepidermal junction. The second case had an extensive, ulcerative, crusting skin disease and anemia. Histopathology revealed striking hydropic degeneration of the epidermal basal cells.

A further report discussed results of ANA screening of sera from 107 cats presented to the University of Florida College of Veterinary Medicine over a 4-year period with signs suggestive of immune-mediated disease [72]. Five sera yielded titers >10. Two of the cats had ulcerative plasma cell pododermatitis accompanied by glomerulonephritis and anemia. Two other cats showed skin lesions that were histologically compatible with pemphigus foliaceous—one of which showed linear deposits of immunoglobulin at the dermoepidermal junction. The final case had a history of progressive, erosive polyarthritis and later developed erosive nasal lesions, perioccular erythema, and glomerulonephritis. Three of these cases satisfied the revised ACR criteria for a diagnosis of SLE.

Another report described 11 cats with a wide range of clinical signs, including various neurological and behavioral changes, glomerulonephritis, nonerosive arthritis, anemia, stomatitis, lymphadenopathy, and a range of skin changes [73]. Six of these cats satisfied the revised ACR criteria by showing at least four classical signs. ANA titers ranged from 40 to 1280.

The latest reports feature (i) a cat with symmetrical facial dermatitis (Fig. 9), thrombocytopenia, and an ANA titer of 160 [74] and (ii) a cat with autoimmune hemolytic anemia, thrombocytopenia, probable neurologic disease, and an ANA titer of 4096 [49]. The latter case did not fulfill the criteria for definite SLE. Histopathology of the skin in the former case showed an interface dermatitis and folliculitis with occasional basal cell vacuolation and necrosis and pigmentary incontinence. The cat responded to glucocorticoid therapy, but the skin disease relapsed following cessation of the treatment with, in addition, ulceration involving the hard palate. It was concluded that the cat had now satisfied four of the ACR criteria.

A summary of the incidence of the clinical signs ascribed to feline lupus is detailed in Table 2.

TABLE 2 Feline Systemic Lupus Erythematosus: Incidence of Clinical Sings from Case Reports in the Literature ($n = 23$)[a]

Glomerulonephritis	10
Neurological signs	10
Arthritis[b]	9
Anemia	10
Dermatological signs	8
Fever	4
Lymphadenopathy	3
Buccal or mucucutaneous ulcers	4
Thrombocytopenia	3

[a] Data from Refs. 49, 54–59, and 74.
[b] In some cases, no clinical signs were evident, but the diagnosis was made by joint tap cytology.

Diagnosis and Therapy

The approach to the diagnosis in the cat follows broadly the same principles as outlined for the dog. However, care must be taken to exclude two feline viral diseases, namely feline leukemia and feline infectious peritonitis, both of which can induce positive ANA tests [72].

High-dose prednisone or prednisolone represents the cornerstone of the therapeutic approach, with the addition of cyclophosphamide, chlorambucil, or gold salts if the former approach alone proves insufficient or where an alternate day regimen for the corticosteroids cannot be obtained. In comparison to dogs, cats are relatively resistant to the side effects of corticosteroids, which may reflect differences in plasma binding or in

FIGURE 10 Facial lesions of a horse with cutaneous LE. From Stannard [76], with permission.

tissue receptors. This also means that generally higher levels are required than in dogs.

SYSTEMIC LUPUS ERYTHEMATOSUS IN HORSES

SLE is rarely reported in horses [75]. The literature contains full descriptions of only two cases, although there are anecdotal reports of additional cases. The general clinical and dermatological signs are described elsewhere [76] and are depicted in Fig. 10.

The first report described a horse presenting with polyarthritis, proteinuria, thrombocytopenia, and a positive ANA test [77]. The second contained a very full description, with autopsy findings. The patient was presented with a history of weight loss, Coombs'-positive anemia, and bilaterally symmetrical alopecia [78]. Clinical examination in addition showed an ulcerative glossitis and generalized lymphadenopathy. Histopathological examination of skin biopsies showed a superficial and deep lymphocytic infiltrate, with hydropic degeneration and frequent single cell necrosis of the follicular and interfollicular basal cells. Immunoperoxidase staining of paraffin-embedded sections revealed linear deposits of immunoglobulin at the dermoepidermal junction, and the ANA was positive with a titer of 320.

Although the anemia responded to the administration of dexamethasone (0.2 mg/kg iv daily), the animal became recumbent and was euthanized. In addition to the findings noted premortem, an autopsy showed focal lymphoid infiltrates in the liver, a fibrinous synovitis, and a membranous glomerulonephritis accompanied by immunoglobulin deposits on the basement membrane. The diagnosis of SLE was convincingly made.

CONCLUSIONS

The current status of the knowledge of SLE in domestic animals has been presented. Particularly in the case of the dog, striking similarities with the disease in humans are evident.

A major controversy urgently in need of further investigation is the question of the possible transmission of serological abnormalities and/or clinical SLE between the species, especially between the human and the dog. It seems unfortunate that in some of the studies, veterinary involvement has been quite peripheral, which in turn has impacted negatively on the creditability of the data. Close working relationships between medical and veterinary scientists are a prerequisite for the optimal utilization of domestic animal models of human disease.

ANTI-DNA ANTIBODIES

Structure, Assembly, and Diversity

Elena Peeva
Betty Diamond

A diverse repertoire of antibodies is generated to ensure protection from the world of microorganisms and their toxins. Because mechanisms of diversity proceed randomly, autoantibody production occurs. Antinuclear antibodies are a hallmark of systemic lupus erythematosus (SLE), whereas anti-DNA antibodies are a very specific marker for this disease.

Low-affinity anti-DNA antibodies are nonpathogenic, whereas high-affinity anti-DNA antibodies correlate with disease activity, especially with renal involvement. Pathogenic anti-DNA antibodies are IgG antibodies and somatically mutated and have features suggesting selection in response to a specific antigen. Their pathogenicity may arise from their ability to form immune complexes that deposit in the kidneys, their cross-reactivity with renal antigens leading to direct binding to kidney cells, or their capacity to react with DNA or nucleosomes previously bound to the renal tissues. It has been hypothesized that anti-DNA B cells can be activated by bacterial DNA complexed to protein, environmental pathogens via a process of molecular mimicry, through B-cell somatic mutation, or through activation of novel B-cell costimulatory pathways mediated by toll receptors.

Anti-DNA B cells are normally downregulated by one of three basic mechanisms of tolerance: deletion, anergy, or receptor editing. Survival and activation or tolerance of autoreactive B cells is mediated by several genes, many of which regulate strength of signaling through the B-cell receptor. Dysregulation of any of these may contribute to the development of SLE.

A major goal of understanding of the structure, origin, and pathogenicity of anti-DNA antibodies is to develop novel targeted treatments for SLE.

The protective effects of humoral immunity are mediated by antibodies that cause destruction or inactivation of microbial organisms and their toxins. The immune system generates antibodies to a constantly changing array of foreign antigens, but not to self-antigens. Dysregulation of the immune system, manifested as a production of autoantibodies, leads to autoimmunity. Systemic lupus erythematosus is characterized by the production of high-affinity antibodies directed toward a variety of self-antigens, primarily nuclear antigens [1, 2]. Some of these autoantibodies, such as anti-Sm, anti-RNP, and antinuclear antibody are markers for disease, whereas others, such as anti-DNA, anticardiolipin, and anti-Ro, contribute to tissue damage [3–7].

Antibodies are glycoproteins produced by B lymphocytes in both a membrane-bound and a secreted form. Initially, antibodies serve as antigen receptors on the membrane of resting B lymphocytes. After B cells encounter antigen, they differentiate further to produce a secreted form of antibody. Each immunoglobulin (Ig) is composed of two heavy chains and two light chains. The two heavy chains are linked by disulfide bonds, and each heavy chain is linked to a light chain by a disulfide

bond. Together the heavy and light chains combine to form an antibody molecule with two functional regions: a constant region that determines its effector functions and a variable region that is involved in antigen binding and constitutes the amino-terminal domain. The light chains contribute solely to antigen binding, whereas the heavy chains constant region determines the isotype (IgM, IgD, IgG, IgA, or IgE) of the antibody [8]. A naïve B cell produces IgM antibodies. After encounter with antigen and T-cell help, it can switch to the production of other isotypes; IgG is the predominant isotype of the secondary (also called memory) immune response.

Each antibody molecule contains two identical antigen-binding sites composed of the variable regions of the heavy and light chains. Certain portions of the variable region are highly polymorphic and are known as complementarity-determining regions (CDRs); they serve as contact sites for antigen binding [9]. Other more conserved portions of the variable region are called framework regions (FRs). X-ray crystallographic studies have shown that the amino acids of the CDRs are arranged in flexible loops, whereas the FRs have a more rigid structure that contributes more to maintaining spatial orientation of the antigen-binding pocket than to antigenic specificity [10]. Each variable region of an antibody molecule is composed of four FRs and three CDRs. The most variable portion of the molecule is the CDR3 [11, 12]. The variable region of an antibody contains antigenic determinants defined as idiotype. Anti-idiotypic antibodies are antibodies that bind to specific determinants in the CDRs or FRs of another antibody [13, 14]; they can bind to membrane immunoglobulin and, like antigen, can either tolerize or activate the B cell. Thus, anti-idiotypic antibodies may be considered as a potential therapeutic to tolerize pathogenic autoantibody-producing B cells (see later).

The Ig light and heavy chain variable region genes, which encode the antibody molecules, are formed by a rearrangement of multiple gene segments. This process involves excision of DNA between various gene segments followed by their ligation. V (variable), D (diversity), and J (joining) segments are brought together to form a heavy chain variable region gene [15, 16], and V and J segments form a light chain variable region gene [17, 18]. V(D)J gene segments each come from gene clusters arranged tandemly in the heavy or light chain locus. In humans, the heavy chain gene segments come from the gene locus on chromosome 14, whereas κ and λ light chain gene segments come from gene loci on chromosomes 2 and 22, respectively. There are approximately 50 functional heavy chain V segment genes distributed randomly along the V locus. They share 80% identity at the nucleotide level primarily in FRs [19–22] thirty functional D gene segments and 6 J gene segments for the human immunoglobulin heavy chain have been described [21]. Each V, D, and J gene segment is flanked by a conserved heptamer–spacer–nanomer sequence, known as the recombination signal sequence (RSS) [23], which is esential for Ig rearrangement.

The first rearrangement occurs in the heavy chain locus and starts with the joining of a D segment from the D cluster to a J segment in the J cluster, which is mediated by excision and deletion of the DNA between the segments. Then, a V gene segment is rearranged to the already assembled DJ unit, forming a complete VDJ variable region [24]. The process of variable region recombination requires a complex of enzymes called V(D)J recombinase [25], most of which are present in the majority of cells because of their involvememt in the maintenance of double-stranded DNA. However, recombination activating genes, RAG-1 and RAG-2, are found only in lymphocytes [26]. RAGs start the process of VDJ recombination by generating double-stranded DNA breaks. Joining of the coding segments is mediated by several enzymes (Ku 70, Ku 80, DNA-PKs, XRCC4, ligase, Mre 11) [27–29], whereas the formation and stabilization of the cleavage synaptic complex are regulated by HMG1 and HMG2 from the high mobility group family of proteins [30]. During rearrangement, imprecise VDJ joining may result in junctions of variable length, and nontemplate–derived nucleotides may be inserted at the VD or DJ junctions of the heavy chain, generating CDRs of variable length and sequence. If the single-stranded DNA that is present after the break can form a hairpin loop, the resulting double-stranded (P, palindromic) sequences are added at the junction. Alternatively, N-nucleotides or nontemplate-encoded nucleotides are inserted randomly at the VD and DJ junctions by the enzyme terminal deoxynucleotidyl transferase (TdT) [31].

Light chain gene segment rearrangement can occur from the κ or λ locus and begins after a functional heavy chain is formed. Rearrangement starts in the locus, but if both rearranged κ alleles are not functional, the process will proceed to the λ locus. The ratio between κ and λ light chains varies among species: in humans it is 3:2 and in mice it is 20:1. The light chain variable region is composed of only two gene segments: V and J. The κ light chain gene locus on chromosome 2 contains approximately 40 functional V gene segments that are grouped into seven families and five J segments [32–34]. The λ light chain locus is on chromosome 22 and contains at least seven families with up to 70 members [35–37]. Similar to heavy chain gene rearrangement, V and J elements of the light chain loci also rearrange by recombination at heptamer/nonamer consensus sites. At the time of light chain rearrangement TdT is no longer expressed in the B cells; thus, only rarely are N

sequences inserted at the VJ junction of the light chain [38]. The rearranged heavy and light chain V(D)J segments contribute to antibody structure as follows: the V segments of both heavy and light chains encode FR1, 2, and 3 and CDR1 and 2; CDR3 is encoded by the heavy chain D region and the light chain VJ junction. The J segment from each chain encodes FR4. The rearranged heavy chain VDJ segment is initially associated with an IgM constant region gene, it can undergo a second kind of gene rearrangement during the secondary response to associate with downstream constant region genes in a process called heavy chain class switching [39, 40]. Switching is mediated by switch sequences located upstream of each constant region gene [41]. In general, heavy chain class switching occurs in B cells after they are activated by antigen.

There are two heavy chain loci and four light chain loci from each of which a functional gene can be derived. However, each B cell expresses only one rearranged heavy chain and one rearranged light chain gene through a process called allelic exclusion, in which a productive rearrangement on one heavy and one light chain locus inhibits rearrangements on other loci. Rearrangement on the first chromosome is often unproductive because of deletions, mutations, and DNA reading frame shifts that generate stop codons during recombination or because nonfunctional variable region gene segments called pseudogenes are used [42]. Nonproductive rearrangement on one chromosome permits Ig genes on the other chromosome to undergo rearrangement [8]. The first light chain gene rearrangements occur in the κ locus, but if they are nonproductive on both chromosomes, the V and J segments of the λ locus will rearrange to produce a light chain [42, 43]. If a functional antibody binds to self-antigen, additional rearrangements may take place to change its specificity and prevent autoreactivity. These additional rearrangements are termed receptor editing and occur frequently in developing B cells [44]. There are reports that receptor editing can also occur in mature B cells [45–48], demonstrated by increased RAG protein expression in germinal centers [45, 48], but this issue remains controversial.

The immune system has an ability to assure enormous B-cell diversity. The large antibody repertoire is a result of the process of recombination used to create complete Ig variable regions and is based on the following mechanisms: (1) random combinations of V, D, and J gene segments and V and J segments into heavy and light chain genes, respectively; (2) junctional diversity produced by N or P sequence insertion and/or imprecise joining of gene segments; (3) random pairing of heavy and light chains; and (4) somatic mutation of rearranged genes. The first three mechanisms occur before exposure to antigen and are potentially capable of producing a repertoire of $10^{9–11}$ different antibodies [8], whereas the process of somatic mutation occurs after antigen encounter. Somatic point mutations are single nucleotide substitutions that can occur throughout the heavy and light chain variable region genes, but are most numerous in certain hot-spot motifs [49–51]. They represent site-specific, differentiation stage-specific, and lineage-specific events [50]; they are important in the generation of high-affinity antibodies and their suboptimal frequency leads to immunodeficiency [52]. Mutated antibodies can also acquire novel antigenic specificities. For example, antibodies to foreign antigen can acquire autospecificity through somatic point mutation [53, 54]. Somatic mutation takes place in dividing centroblasts, whose rearranged Ig variable region genes undergo a much higher mutation rate than any other somatic cell (1 bp per 10^3 bp per cell division). The DNA mismatch repair system, which generally functions to correct point mutations in DNA, has been implicated in Ig gene mutation. Deficiency in mismatch repair enzymes MSH2 [55, 56] and MSH6 [57] causes altered nucleotide targeting for mutations. In both MSH2- and MSH6-deficient mice, the mutations are targeted to G and C nucleotides and to RGYW or WRCY hot spots [57, 58]. Controversy exists whether a deficiency in other mismatch repair enzymes PMS 2 and Mlh1 affects the process of somatic hypermutation [59, 60] or not [55, 60]. Activation-induced cytidine deaminase (AID), a putative RNA-editing enzyme discovered in germinal center B cells [61], is also critical for the process of somatic mutation [62]. It has been demonstrated that AID expression can induce hypermutation in hybridoma cells targeting to G/C nucleotides within RGYW or WRCY hot spots [63].

Because the process of somatic mutation occurs concurrently with heavy chain class switching, although by a different mechanism, hypermutation is more common in IgG than in IgM antibodies. Due to degeneracy of the genetic code, not every point mutation causes a change at the amino acid level. Mutations without consequent amino acid changes are termed silent (S). A point mutation that leads to a amino acid change, replacement (R) mutation, may result in an antibody with decreased or increased affinity for the triggering antigen. It is possible to indirectly analyze antigen selection during the course of the germinal center response by calculating the ratio of replacement (R) to silent (S) mutations in rearranged antibody genes. In a process referred to as affinity maturation, only those B cells making antibodies that bind to the eliciting antigen with a high affinity will be selected for proliferation [64]. B cells producing antibodies with low affinity rarely progress to plasma or memory cells, whereas B cells producing anti-

bodies of higher affinity will continue to be amplified. This selection for increased affinity may be reflected in a greater than random R/S ratio in the CDRs and a random or lower than random R/S ratio in the FRs of the selected antibodies [65].

In summary, multiple mechanisms exist for generating a diverse repertoire of antibody molecules and ensure the production of antibodies that are protective against microbial invasion. However, because these mechanisms of diversity proceed randomly in the absence of instruction from external antigens, they permit the production of autoantibodies, which must then be regulated.

DETECTION OF ANTI-DNA ANTIBODIES

Anti-DNA antibodies can be detected by several assays. Some of these assays are specific for high-affinity antibodies, whereas others detect low-affinity antibodies as well (Table 1). The most frequently utilized assays are the Farr assay, the Millipore filter assay, the enzyme-linked immunosorbent assay (ELISA), and the *Crithidia luciliae* assay [66–68].

In the Farr assay, radiolabeled single-stranded (ss) or double-stranded (ds) DNA is added to the sample to be tested for anti-DNA antibodies. The immune complexes can then be precipitated by ammonium sulfate and the results are expressed as a percentage of radioactivity that is present in the precipitate. This test, can detect both IgG and IgM anti-DNA antibodies but cannot distinguish between the two classes. The Farr assay is an excellent assay for the detection of high-affinity antibodies.

The Millipore filter assay also utilizes radiolabeled dsDNA that is added to the test serum and passed through a filter. Because the filters bind protein, but not dsDNA, DNA–antibody complexes are retained on the filter while free dsDNA passes through. The amount of radioactivity retained on the filter is proportional to the anti-dsDNA antibody in the test sample. This assay cannot be used to detect antibodies to ssDNA because ssDNA, unlike dsDNA, will bind directly to the filter. Neither the Farr assay nor the Millipore assay can distinguish between antibody–DNA complexes and complexes of other serum proteins with DNA.

TABLE 1 Assays for the Detection of Anti-DNA Antibodies

Assay	High-affinity anti-DNA antibodies detected	Low-affinity anti-DNA antibodies detected
Farr assay	+	–
Millipore filter method	+	–
ELISA	+	+
Crithidia lucilia	+	+

The ELISA is a rapid, simple, quantitative, and reproducible assay [69] that is now the most commonly used clinical assay. Microtiter plates are coated with ss or dsDNA. The serum is applied to the coated plates. Antibody in the serum is referred to as primary antibody. The presence of bound anti-DNA antibody can then be detected by an enzyme-linked anti-Ig antibody, or secondary antibody. Addition of a substrate that changes color in the presence of the enzyme allows the detection of anti-DNA antibodies. The color change can be read in a spectrophotometer. The advantage of this assay is the ease with which large numbers of samples can be screened. ELISAs are highly sensitive and have the advantage of being able to determine antibody isotype, light chain usage, and idiotypic specificity, depending on the specificity of the secondary antibody. It is currently the most popular assay in clinical use.

The most specific test for anti-dsDNA antibodies utilizes the flagellate *C. luciliae* as a substrate. This organism has a kinetoplast that contains circular dsDNA that is not associated with histone proteins. Test samples are incubated with the organism on a glass slide. The fluoresceinated anti-Ig antibody is then added. Detection of the fluorescent kinetoplast using a fluorescence microscope indicates the presence of anti-DNA antibodies. Although not as sensitive as the ELISA, this assay is highly specific for dsDNA binding and, like the ELISA, can distinguish structurally distinct subsets of anti-DNA antibodies, depending on the specificity of the secondary fluoresceinated antibody.

Accurate detection of high titers of anti-dsDNA antibodies has been shown to be useful in the diagnosis of SLE, and an increasing titer is generally correlated with disease flares [70]. Given the heterogeneity of the anti-DNA antibody detection assays available and their specific limitations, the utility of anti-dsDNA antibody detection in the diagnosis and treatment of SLE is enhanced in clinical decision making by a consideration of the sensitivity and specificity of the assay used.

CELLULAR ORIGIN OF ANTI-DNA ANTIBODIES

B1 cells comprise less than 10% of total B cells and are preferentially localized to the peritoneal and pleural cavity in mice [71], in contrast to conventional B cells, which populate peripheral lymphoid organs [72, 73].

Much controversy exists over the physiologic function of B1 cells. The autoimmune NZB mouse strain displays an increased number of B1 cells and antierythrocyte antibodies, and their elimination by hypotonic shock with intraperitoneal injections of distilled water significantly decreases the occurrence of hemolytic anemia [74]. The same method of elimination of B1 cells from the peritoneal cavity of NZB/W F1 lupus-prone mice leads to diminished anti-DNA serum titers with subsequent amelioration of the kidney disease [74]. Although an increased number of B1 B cells has been reported in some autoimmune diseases, the association with SLE is not firm [75–77]. Based on their membrane expression of the 67-kDa molecule CD5, B1 cells can be divided into two subsets: B1a and B1b. [78]. The functional significance of the CD5 surface marker has not yet been determined. It has been hypothesized that it may be a negative regulator of B-cell receptor signaling in B1 cells [79]. There is a long-standing notion that B1 cells represent a separate, self-replenishing B-cell population [78]. Evidence suggests that the strength of BCR signaling and the presence of particular costimulatory molecules strongly influence the fate of B cells and determine whether they will develop into B1, follicular B2, or marginal zone B cells [80, 81]. Mice with functionally inactive B-cell activating factor (BAFF), a member of the tumor necrosis factor family of proteins [82], or lacking BAFF [83] have a block in B-cell maturation in the periphery with a dramatic decrease in marginal and follicular B2 B cells, but with a normal number of peritoneal B1 B cells.

Although both B1 cells and conventional B2 cells can produce anti-DNA antibodies [77], the anti-DNA antibodies that have been termed natural autoantibodies are produced mainly by B1 cells [84]. They tend to be low-affinity, germline-encoded IgM antibodies [85, 86] that react preferentially with ssDNA, but are often polyreactive [87]. These anti-DNA antibodies are found in the sera of normal mice and humans and are believed to be nonpathogenic, but have been also postulated to help regulate the production of high-affinity pathogenic autoantibodies [88].

The autoantibodies of SLE differ from natural autoantibodies. Anti-DNA antibodies that are correlated with disease manifestations of SLE, specifically renal pathology, are encoded predominantly by somatically mutated Ig genes of the IgG isotype [89, 90] and have specificity for dsDNA or both ssDNA and dsDNA, although they may also exhibit polyreactivity (see cross-reactivity section and Table 2). In the NZB/W mouse, evidence shows that both marginal zone and follicular B cells contribute to anti-DNA antibody production. Follicular B cells are T-cell-dependent, and their involvement in the production of pathogenic autoantibodies is supported by the demonstration that $CD4^+$ T-cell depletion or blockade of B-cell/T-cell costimulatory pathways leads to decreased anti-DNA titers in NZB/W mice [91, 92]. However, NZB/W mice also demonstrate an expansion of marginal zone B cells [93]. Most marginal zone B cells express germline-encoded Ig VH genes [94] and are T cell independent for immunoglobulin production. Newly accumulating data demonstrates that marginal zone B cells may provide help to T-cell-dependent responses by acting as antigen-presenting cells (APCs) [95, 96] or by enhancing antigen presentation by follicular DCs [97]. Several studies have implicated marginal zone B cells in murine SLE. The increased number of autoreactive marginal zone B cells in NZB/W mice is linked to a chromosomal region that overlaps with Nba2, a genetic locus associated with lupus nephritis [98]. In a model of estrogen-induced lupus, the majority of anti-dsDNA antibody-secreting B cells are marginal zone B cells [99].

It becomes increasingly clear that SLE is a heterogeneous disease and that different B-cell populations may be responsible for the majority of autoantibody production in different patients.

TABLE 2 Antigens That Cross-React with Anti-DNA Antibodies

Antigen	Cross-reacts with anti-dsDNA	Cross-reacts with anti-ssDNA
Polynucleotides		
Z-DNA	+	+
Phospholipids		
Cardiolipin	+	+
Phosphatidyl glycerol		+
Bacterial antigens		
Bacterial phospholipids	+	+
Pneumococcal phosphorylcholine	+	
Mycobacterial glycolipid	+	+
Polysacharides of		
Klebsiella	+	+
Meningococci	+	+
Pneumococci	+	
E. coli	+	+
Extracellular matrix components

Chondroitin sulfate	+	
Heparan sulfate	+	
Laminin	+	+
Cellular components		
Cell surface proteins	+	
Vimentin	+	+
Ribosomal protein S1	+	
A and D SnRNP	+	

STRUCTURE OF ANTI-DNA ANTIBODIES

The anti-DNA antibody response resembles a normal antibody response in its shift from IgM to IgG [100] and in its pattern of somatic mutation [101, 102]. Both IgM and IgG anti-DNA antibodies [103] have features suggesting selection in response to a specific antigen (i.e., a greater than random ratio of replacement to silent mutations in CDRs). Sequence analysis has demonstrated a pattern of somatic mutation consistent with DNA, alone or in a complex, as the selecting antigen. Furthermore, some of the IgG anti-DNA-producing B cells that have been isolated are derived from the same clonal precursors as the IgM anti-DNA B cells, and progression of the isotype switch is paralleled by a greater affinity for dsDNA among IgG than IgM antibodies.

Extensive genetic characterization of anti-DNA antibodies from both lupus patients and mouse models of lupus has been undertaken in an attempt to understand the molecular basis for DNA binding. In general, the heavy or light chain V genes that are used to produce anti-DNA antibodies are used to encode anti-DNA antibodies that are also used in the response to foreign antigen [104–106]. Restriction fragment length polymorphism analysis comparing the Ig loci of lupus patients with those of nonautoimmune individuals shows that there are no apparent differences, such as gene loss or gene duplication, that distinguish the two groups [107]. Similar conclusions have been reached in mice [108], and it is clear from mouse studies that Ig genes of a nonautoimmune strain can encode pathogenic anti-DNA antibodies. When a mouse from the nonautoimmune SWR strain is mated to a mouse from the NZB autoimmune strain, the offspring produce pathogenic anti-DNA antibodies encoded by SWR Ig genes [109]. Similarly, when C57Bl/6 mice carry three lupus susceptibility loci derived from NZM mice, they develop anti-DNA antibodies and nephritis [110]. Two studies, however, suggest that polymorphisms in the Ig loci, although clearly not required for disease expression, may predispose to SLE. One study suggests that the heavy chain locus of 20% of individuals with SLE lacks a particular V_H3 gene [111], and the second study demonstrates that expression of the V_K gene, A30, seems to be unique to the antibodies of SLE patients with lupus nephritis [112]. Patients who do not express A30-encoded light chains, perhaps because they lack a functional A30 gene, have a lower incidence of lupus nephritis. Although genetic susceptibility to lupus has not been mapped to the Ig locus, the finding that there is preferential expression of some anti-DNA associated idiotypes in family members of patients with SLE also demonstrates that genetic factors may influence variable gene usage [113].

The process of Ig gene rearrangement is similar in autoimmune and nonautoimmune individuals. One notable exception is the suggestion that an uncommon reading frame of the D segment, D fusions and D segment inversions, may occur at a higher frequency in anti-DNA antibodies than in protective antibodies [114, 115]. These abnormal D regions display an increased number of arginines in CDR3 of the heavy chain. Arginine, along with other basic amino acids, is a potential DNA contact residue (discussed later). Finally, investigation of the process of somatic mutation in anti-DNA antibodies has led to conflicting data. Analysis of somatic mutation in 10 human anti-DNA antibodies showed no abnormality in the frequency of somatic mutation nor in the distribution of mutations in CDRs or FRs [116]. However, less targeting to mutational hot spots was found in the V_H genes encoding anti-DNA antibodies than in antibodies from nonautoimmune individuals encoded by the same V_H genes [116]. Decreased targeting of somatic mutations to hot spots was also detected in anti-DNA antibodies obtained from mice transgenic for the antiapoptotic gene bcl-2 [117]. This observation may suggest that B cells in SLE undergo somatic mutation at a different state of cellular activation. Other studies suggest other potential abnormalities in this process. Analysis of somatic mutations in the V_κ gene repertoire of B cells from one lupus patient showed an increased number of mutations and targeting of mutations to hot spots of FRs [118].

A large number of heavy and light chain variable genes can potentially encode anti-DNA antibodies [119], but some appear to dominate the response [120, 121]. Although IgM anti-DNA antibodies in humans are encoded by members of all seven V_H families [122], pathogenic IgG anti-DNA antibodies are biased toward members of the V_H3 and V_H4 families [123]. Although the overexpression of V_H3 family members may simply be a reflection of the large size of this V_H family, preference for the small V_H4 family is intriguing [123].

Light chain V gene use in both murine and human anti-DNA antibodies is more diverse than heavy chin V gene use [124]. There seems to be a preference for light chains that have long CDR1 loops containing basic amino acids, such as $V_\kappa1A$, $V_\kappa8A$, and Vk8B in the mouse [120]. The wider repertoire of light chains used to encode anti-DNA antibodies may be a reflection of the proposed dominance of the heavy chain in determining DNA reactivity [125] and may explain the polyreactivity of anti-DNA antibodies [126]. However, experiments pairing a murine anti-DNA heavy chain with different light chains demonstrate that light chain

identity can greatly influence the fine specificity of dsDNA binding [125].

Examination of the protein sequence of murine and human anti-DNA antibodies [120] has been fruitful in delineating features that are specific to these antibodies. Several basic amino acids, namely arginine, histidine, and lysine, and some polar amino acids, such as glutamine, tyrosine, and asparagine, have been found to contribute to DNA binding [127]. Arginine is the most versatile amino acid for DNA binding. It is a frequently used residue in protein–nucleic acid interactions [128] due to its potential to form electrostatic or hydrogen bonds with the DNA backbone and to its ability to interact with aromatic DNA bases [129]. Its importance in determining DNA reactivity is illustrated by the fact that somatic mutations to arginine are common among anti-DNA antibodies [130]. N base addition or unusual VDJ rearrangements that shift or invert the D reading frame are additional mechanisms by which anti-DNA antibodies may be enriched for arginine residues in CDR3 [129, 130]. Mutational analyses testing the relevance of arginine residues to DNA binding have yielded variable results, suggesting that other motifs as well play a significant role in DNA binding. The substitution of arginine 96 by glycine in one anti-DNA antibody resulted in complete loss of DNA binding; the addition of arginine at position 31 of CDR1, 56 and 64 of CDR2, and 76 of FR3 of this same antibody contributed to DNA binding both independently and additively [131]. In other anti-DNA antibodies, however, the mutation of arginine does not alter DNA binding or the removal of an arginine leads to an increase in DNA binding [132].

Molecular modeling has reinforced data obtained from anti-DNA antibody sequences. An early study investigated a complex of the anti-DNA antibody, D42, and poly(dT) and showed that the cleft of the antibody-binding site contains many arginine and tyrosine residues that make electrostatic and stacking interactions with phosphates and nucleic bases, respectively [114]. Homology modeling and molecular dynamic simulation of the antigen-binding site of anti-dsDNA monoclonal antibodies generated from a NZB/W mouse surprisingly suggest a significant increase in the flexibility of the antigen-binding loops in affinity-matured anti-DNA antibodies [133]. Only one anti-DNA antibody, BV04-01, has been crystallized both alone and in complex with ssDNA [134]. In complex with the trinucleotide, this antibody shows local changes in the conformation in CDR-H3, CDR-L1, and CDRl-L3 compared to its uncomplexed form; the interaction with DNA is achieved by four hydrogen bonds and an ion pair. The recently determined crystal structure of the complex of a murine anti-ssDNA antibody, DNA-1, with dT_5 shows that the structural stability of the antibody-binding site is maintained by the arginine side chains of the heavy chain CDR3 [135]. This observation extends previous information that ion pairs involving arginine are important for DNA recognition [129]. These few available crystal structures of anti-DNA antibodies have suggested that anti-ssDNA and anti-dsDNA antibodies may have distinct DNA-binding sites [136]; antibodies to ssDNA contain a deep cleft, whereas antibodies to dsDNA usually have a planar binding site [137, 138].

IDIOTYPES OF ANTI-DNA ANTIBODIES

Idiotypes are antigenic determinants located on an antibody molecule to which anti-idiotypic antibodies can bind. Idiotypes shared by multiple antibodies with distinct antigenic specificities are called cross-reactive idiotypes and may reflect the use of common germline genes used to encode these antibodies. Private idiotypes are unique to specific antibodies. Idiotypes can be antigenic epitopes formed by the heavy or light chain independently or may reflect an epitope formed by the association of both chains [139]. The idiotype network is a complex cascade of antibodies. Normally, after antibodies are produced in response to antigen, anti-idiotypic antibodies arise. These anti-idiotypes can bind to all antibodies bearing the specific idiotypic determinant, independent of their antigenic specificity. In this fashion, a network of interacting antibodies is produced [140].

Anti-DNA antibodies found in sera of lupus patients and lupus-prone mice have been demonstrated to express cross-reactive idiotypes [141–144]. These idiotypes are also present on serum Igs of nonautoimmune hosts, but in lupus patients they are present at increased titer. Some are directly correlated with disease activity and some are found in immune deposits in nephritic kidneys [145, 146].

The 16/6 idiotype, one of the most studied anti-DNA idiotypes, is expressed in a significant number of patients with SLE and is prevalent in patients with anti-cardiolipin antibodies [147]. It has been found at high titer in 50% of patients with active disease and in 40% of renal Ig isolates, and is associated with mesangial deposits [148]. The 9G4 idiotype is present at increased titer in the serum of 40% of SLE patients and correlates with cardiovascular, respiratory, and hematological disease manifestations, as well as with decreased complement component 3 [149]. 8.12 is a light chain-specific idiotype found in 50% of lupus patients with anti-DNA activity and is expressed on up to 30% of their serum

anti-DNA antibodies. 3I recognizes k light chains and, like 8.12, is elevated in a majority of SLE patients with anti-DNA activity and is present on a high percentage of anti-DNA antibodies. Both 8.12 and 3I idiotypes exist at low titer in normal individuals and both are elevated in relatives of SLE patients who have no evidence of clinical disease [113, 150].

Idiotypic analyses are of potential utility to the clinician, as anti-idiotypes may distinguish between pathogenic and nonpathogenic subsets of autoantibodies. For example, 3I, 8.12, 16/6, and 9G4 positive antibodies are all pathogenic. In a multicenter study of 19 anti-DNA associated idiotypes, an elevated expression of 3I positive antibodies correlated with active lupus and with nephritis [151].

Anti-DNA associated idiotypes are also present on antibodies that bind to microbial antigens. Both 3I and 8.12 are present on the antipneumococcal antibodies that arise in nonautoimmune individuals following vaccination with pneumococcal polysaccharide [152, 153]. Titers of 16/6 positive antibodies are elevated in patients with leprosy and with *Klebsiella* infection [154]. These observations have led to the suggestion that anti-DNA antibodies might arise as a response to bacterial antigen, either by somatic mutation of the antibacterial antibody or through an idiotypic network [155].

Immunization with the anti-idiotype 16/6 induces disease in mice [156]. This observation, along with multiple studies in mice showing that anti-idiotypic antibodies can regulate the expression of idiotype bearing antibodies, led to the hypothesis that the idiotypic network may play a role in triggering SLE or regulating disease activity and to the suggestion that therapy of autoimmune disease can be achieved through manipulation of idiotype–anti-idiotype interactions. An anti-idiotype can either mimic DNA and function as antigen by binding to the antigen-binding site or it can bind outside the antigen-binding site as a superantigen would. Like antigen, an anti-idiotype can induce or suppress an antibody response. One study has demonstrated that a SLE patient in remission has anti-idiotypic antibodies to anti-DNA antibodies, whereas the same patient experiencing flares lacks anti-idiotypic antibody [157]. In mouse studies, it has been suggested that NZB/W lupus-prone mice develop disease at the time they no longer produce anti-idiotypes to anti-DNA antibodies [158]. Furthermore, passive administration of anti-idiotypic antibodies has been shown to decrease anti-DNA antibody production and attenuate disease in mice for a short period of time [159]. There are also studies underscoring the importance of anti-idiotypic antibodies as stimulators of autoantibody production. Antibodies to the Ku protein, for example, which binds DNA and functions in the repair of DNA double-stranded breaks [160], are found with increased frequency among African-American patients with SLE [161] and are anti-idiotypic to anti-DNA antibodies [162]. Furthermore, immunization of mice with an anti-idiotypic antibody to an anti-DNA antibody induces autoantibody production [163]. An anti-idiotypic response to antibodies against p53, which acts as a tumor suppressor protein and binds DNA [164], leads to the production of antibodies to both DNA and p53. A specific class of anti-idiotypic antibodies that display specificity for both dsDNA and anti-DNA antibody has been identified. These anti-idiotypic antibodies arise naturally in SLE, may significantly stimulate production of anti-dsDNA antibodies, and consequently contribute to the development of lupus nephritis [165]. While these studies are provocative, the role of the idiotype network in SLE remains uncertain.

ANTIGENIC CROSS-REACTIVITY OF ANTI-DNA ANTIBODIES

The diversity of the autoreactivities found in lupus sera differentiates SLE from many other autoimmune disorders [166]. Although such diversity has been attributed to a polyclonal activation of B cells [167], studies show that the diversity of antigenic specificities may be due, at least partially, to the cross-reactivity of anti-DNA antibodies with a wide variety of molecules (Table 2). IgG anti-DNA-secreting B cells derived from SLE patients are much more cross-reactive than IgG anti-DNA-secreting B cells from nonautoimmune individuals and fail to show a normal decrease in cross-reactivity compared to IgM anti-DNA B cells [168].

Polynucleotides and phospholipids were the first molecules found to cross-react with anti-DNA antibodies. Immunization of autoimmune MRL mice with β2 glycoprotein I induced anti-DNA antibodies that could be inhibited with cardiolipin micelles, demonstrating that these antibodies bind both DNA and cardiolipin [169]. Using hybridoma technology as a means to isolate individual antibody molecules, it was demonstrated that monoclonal anti-DNA antibodies from lupus-prone mice bind not only to cardiolipin, but also to other phosphorylated molecules [170]. Analysis of the specificities of these antibodies, as well as these of human anti-DNA antibodies [171, 172], suggests that phosphodiester groups common to both DNA and phospholipids constitute the shared epitope recognized by these cross-reactive antibodies. Phospholipids lacking regularly spaced phosphate groups are not bound by anti-DNA antibodies.

Anti-DNA antibodies derived from naive lupus-prone mice can bind to the cell surfaces of murine

endogenous microbial flora [173]. This binding, which is unaffected by DNase treatment and is competitively inhibited by DNA, is due in part to the phosphodiester groups of bacterial cell walls. The human monoclonal IgM anti-DNA antibody DJ binds to human commensal bacteria, such as *L. acidophyllus*, *B. bifidum*, and *L. plantarum*; the cross-reactive epitope is phosphodiester groups [174]. Structural similarities between the sugar-phosphate backbone of DNA and lipid A, a common constituent of gram-negative bacteria [175], provide a possible explanation for the cross-reactivity of human IgM anti-DNA antibodies to these antigens. Antibodies binding both DNA and pneumococcal cell wall and capsular polysaccharide have been isolated from mice [176, 177] and humans [178]. Finally, a human monoclonal antibody that reacts with bacterial capsular polysaccharides of the human pathogens, group *B Meningococcus*, and *Escherichia coli K1*, also recognizes DNA [179]. Although many cross-reactivities of anti-DNA antibodies can be explained by their recognition of the phosphodiester groups common to the molecules they bind, the basis for other cross-reactivities is less apparent. For example, monoclonal anti-DNA antibodies derived from mice and humans with SLE bind to the glycolipid components of the mycobacterial cell wall [180].

Two explanations can account for the cross-reactivity observed between DNA and carbohydrate antigens. Either the binding site of anti-DNA antibodies may be able to accommodate a variety of antigenic structures or an as yet unidentified tertiary structure of these molecules may be the common epitope recognized by anti-DNA antibodies. Studies suggesting that negative charge distribution may be the key component responsible for the cross-reactivity between DNA and bacterial capsular polysaccharide support the latter possibility.

Anti-DNA antibodies have been shown to cross-react with a variety of extracellular matrix components, including proteoglycans. These molecules are rich in repeating, negatively charged units deriving from their glycosaminoglycan constituents hyaluronic acid, chondroitin sulfate, and heparan sulfate. Analysis of the interaction of several murine monoclonal anti-DNA antibodies with extracellular structures within both glomeruli and tubules of kidneys reveals cross-reactivity with laminin, a glycoprotein constituent of basement membranes [181]. This binding is inhibited by DNA and cannot be abolished by DNase treatment.

Anti-DNA antibodies have also been shown to interact with cell surface molecules expressed on several human and mouse cell types, including Raji cells [182], B cells [183], T cells, erythrocytes [184], neurons [185], epithelial cell cultures from human kidney and skin [183], and embryonal cells [186]. In general, pretreatment of target cells with proteases abolishes anti-DNA antibody binding whereas degradative enzymes targeting sugar moieties have no effect on binding [183], suggesting that the reactive cell surface components are proteins, not the sugar moieties of glycoproteins and proteoglycans. The identity of a majority of these proteins has not been determined yet, although studies have shown cross-reactivity with laminin [181]. Both murine and human anti-DNA antibodies cross-react with the NR2 subunit of *N*-methyl-D-asparate (NMDA) glutamate receptor on neurons, and cerebrospinal fluid of a lupus patient containing anti-DNA anti-NR2 cross-reactive antibodies induces neuronal apoptosis [185]. Because NMDA receptors are expressed on many cell types, this subset of anti-DNA antibodies may mediate injury in a variety of organs.

Anti-DNA antibodies can cross-react with intracellular proteins as well. Monoclonal human and mouse anti-DNA antibodies react with the intermediate filament vimentin, and possibly other cytoskeletal proteins, such as α-actinin [187] and tubulin [188]. Anti-dsDNA antibodies bind the ribosomal proteins S1 [189], P0 [190], and P1 [191] and the SnRNP polypeptides, A and D [192,193]. Phenylalanine in the C-terminal hydrophobic region of ribosomal protein P1 appears crucial for cross-reactivity with anti-dsDNA antibodies, which may be due to structural similarities between the aromatic ring of phenylalanine and the cyclic forms of a DNA molecule, such as nucleotide bases or pentoses in the backbone [191]. However, the shared epitope between intracellular proteins and nucleic acid is not always apparent. The cross-reactive epitope may also arise from the conformational apposition of negative charges in the tertiary structure of the cross-reactive proteins. For example, the S1 protein is devoid of stretches of negatively charged segments in its primary structure, but may resemble DNA in its tertiary structure [189]. Human anti-DNA antibodies have also been found to cross-react with lamin in the nuclear envelope [194].

The search for cross-reactive antigens continues, as these antigens may yield clues to the origin and pathogenesis of anti-DNA antibodies.

PATHOGENIC POTENTIAL OF ANTI-DNA ANTIBODIES

The presence of anti-dsDNA antibodies is virtually diagnostic of SLE and occurs only rarely in other conditions [195]. Over the past several years, it has been clearly demonstrated that anti-DNA antibodies have pathogenic potential. Clinical data demonstrate that anti-DNA antibody titers correlate with the disease activity in a significant number of patients with lupus

nephritis, and glomerular eluates from patients with active lupus nephritis contain anti-DNA antibodies [196]. Experiments in mice have also confirmed the pathogenicity of anti-DNA antibodies. For example, administration of anti-DNA antibodies into nonautoimmune mice has been shown to produce nephritis [197, 198], and transgenic mice expressing only the secreted form of an anti-DNA antibody develop lupus nephritis [199]. Moreover, perfusion of rat kidney with monoclonal mouse and polyclonal human IgG anti-DNA antibodies leads to proteinuria and decreased renal function [200]. However, not all anti-DNA antibodies are pathogenic. Although about two-thirds of lupus patients demonstrate anti-DNA antibodies in their serum, not all of them develop clinical manifestations related to these autoantibodies. The pathogenic potential of anti-DNA antibodies depends on their structural and molecular properties [197–201]. Nephritogenic anti-DNA antibodies are predominantly high-avidity, IgG, cationic antibodies that fix complement and show preferential reactivity to dsDNA [202, 203].

Within the kidneys of both SLE patients and mice with lupus-like disease, anti-DNA antibody deposition can be found at multiple sites, within the subendothelial and subepithelial spaces, in the mesangium, and along the basement membrane and tubules. These differing sites of antibody deposition result in variable disease severity among patients and murine lupus strains [204] and reflect a complicated disease process. Although studies on the mechanisms of pathogenesis by anti-DNA antibodies agree that the formation of glomerular immune complexes is the initial event in the inflammatory process [204, 205], there are different explanations for the origin of these immune complexes. There are, at present, three hypothesized mechanisms to explain the deposition of anti-DNA immune complexes in the kidney. The circulating immune complex hypothesis states that immune complexes preformed in the periphery are passively trapped within glomeruli. The second model suggests that direct binding of cross-reactive anti-DNA antibodies to glomerular antigens is the leading mechanism of immune deposit formation. The third is the "planted" antigen hypothesis that suggests that intracellular antigens released into the circulation after cell death bind to certain sites within the glomerulus and serve as antigenic determinants to which anti-DNA antibodies can bind, initiating immune deposit formation.

It has been demonstrated that some anti-DNA antibodies can penetrate living cells [206, 207], but whether these antibodies are pathogenic and how often they arise remains to be determined.

Hypothesis 1: Circulating Immune Complexes

Sera from patients with lupus nephritis contain high levels of circulating immune complexes [208–211]. Because anti-DNA antibodies are one of the major pathogenic antibodies in lupus nephritis, it was hypothesized that DNA–anti-DNA antibody complexes preformed in the circulation deposit in the renal parenchyma causing disease. Although it has been reported that the presence of DNA–anti-DNA antibody complexes in lupus sera correlates with disease activity [212, 213], the pathogenicity of such complexes has not been confirmed [214]. DNA–anti-DNA complexes formed *in vitro* and injected into mice are cleared rapidly by the liver [215] and show no affinity for the glomerulus [216], whereas unbound anti-DNA antibodies injected into mice deposit in glomeruli. Nevertheless, data that anti-DNA circulating immune complexes are present preferentially in lupus patients with nephritis and are associated with immunoglobulin deposition in the subendothelial area of the renal glomeruli [217] cannot be ignored.

To reconcile these findings, it has been suggested that circulating anti-DNA antibodies are bound to histones or nucleosomes rather than naked DNA [218, 219]. When perfused into a rat kidney, nucleosome–antibody complexes are able to deposit in kidneys and fix complement following their deposition [220], suggestive of the nephritogenic potential of such immune complexes. Finally, nucleosomes complexed with anti-DNA antibodies bind to heparan sulfate, a constituent of the glomerular basement membrane (GBM) [221].

Hypothesis 2: Cross-Reactivity with Renal Antigen

Nephritogenic anti-DNA antibodies are highly polyreactive. A comparison of anti-DNA antibodies derived from normal individuals, patients with active lupus, or renal eluates of patients with active lupus nephritis showed that anti-DNA antibodies eluted from the kidney were the most cross-reactive, binding to polynucleotides, phospholipids, and the SmRNP complex [222]. Similar observations were also made in a lupus mouse model [223]. The observation that anti-DNA antibodies are cross-reactive for cardiolipin and other negatively charged phospholipids [170–172] gave rise to the suggestion that anti-DNA antibodies may exert their pathogenic effect by reacting with renal tissue antigens that share common epitopes with DNA. Support for this hypothesis came from studies showing that an exogenously administered murine monoclonal

anti-DNA antibody formed immune deposits by binding directly to the GBM antigens and that this binding was not inhibited by DNase [224]. In addition, mouse and human anti-DNA antibodies cause renal dysfunction in the perfused rat kidney through direct interaction with glomeruli and subsequent fixation of complement [200]. Finally, observations on mutated anti-DNA antibodies have suggested that binding to DNA is not the sole determinant of pathogenicity. Mutants of anti-DNA antibodies with decreased binding to DNA are nevertheless pathogenic [225]. Furthermore, small numbers of amino acid changes in the V region of a monoclonal anti-DNA antibody that increase DNA binding can be associated with a decrease in glomerular binding.

Clues to the identity of the glomerular antigens to which anti-DNA antibodies bind have come from several investigators who found anti-DNA antibodies to be cross-reactive with important constituents of the GBM and the mesangium, including hyaluronic acid, chondroitin sulfate, heparan sulfate [226], laminin [181], and α-actinin [187, 227]. Heparan sulfate is the major glaycosaminoglycan constituent of GBM and has been shown to play a leading role in the maintenance of the charge [228] and size-selective barrier of the GBM [229]. Masking of glycosaminoglycan polyanionic sites occurs following the deposition of cross-reactive anti-DNA antibodies, resulting in proteinuria [228] and influencing the intraglomerular handling of circulating antigens, antibodies, and immune complexes [230]. This observation, therefore, presents at least two possible mechanisms by which the cross-reaction of anti-DNA antibodies with glomerular antigens might lead to lupus nephritis. Binding of anti-DNA antibodies to renal antigens may disrupt the normal physiologic function of the kidney, may trigger local inflammation and tissue damage, or both.

In addition to reacting with extracellular components of the kidney, direct cell membrane binding of anti-DNA antibodies has been shown to be a potential mechanism of immune deposition. For example, human and mouse anti-DNA antibodies that cross-react with A and D SnRNP polypeptides exert their deleterious effects by binding directly to kidney cells. Some of these antibodies have been demonstrated to penetrate the cells and localize to the cytoplasm or nucleus [192, 207]. Whether they interfere with intracellular processes *in vivo* in SLE patients is not known.

Hypothesis 3: Planted Antigen

In contrast to the cross-reactivity theory of anti-DNA antibody-induced nephritis, the planted antigen hypothesis states that the major mechanism by which anti-DNA antibodies form immune deposits is by binding to autoantigens, either DNA or nucleosomes, that have been bound previously to renal tissue [219]. Both DNA and nucleosomes have been shown to have an affinity for the GBM [231] and glomeruli [232, 233]. Specifically, DNA has been shown to interact with collagen [234], fibronectin [235], and laminin [181], whereas nucleosomes have an affinity for the GBM component heparan sulfate [221].

The observation that DNA already bound to collagen can be recognized by anti-DNA antibodies and lead to the formation of immune complexes, whereas preformed DNA-antiDNA complexes do not bind to collagen to the same extent, provided a rationale for the local formation of DNA–antiDNA complexes in lupus nephritis [231]. Further support came from *ex vivo* perfusion studies showing that anti-DNA antibodies do not bind directly to renal antigens, but that binding to the GBM is mediated through histones and DNA [233]. Furthermore, some IgG from patients with SLE nephritis bound human glomerular extracts only in the presence of either DNA or nucleosomes [236].

Although the apparent disparity in data supporting each of the aforementioned hypotheses may at first be disconcerting, it must be kept in mind that all the studies have been performed with distinct sets of antibodies. Therefore, these seemingly contradictory results may simply be a reflection of the diversity of the anti-DNA antibodies present in the sera of lupus patients and mouse models, in addition to antigenic differences in the target organs in each assay. The three models of pathogenesis presented earlier may not necessarily be mutually exclusive. Rather, it is possible that different pathogenic mechanisms may be operative simultaneously or successively in the same lupus patient or different mechanisms may be at work in different patients. This may explain the observation that the glomerular lesions of SLE represent several distinct forms of nephritis that often differ from patient to patient.

ACTIVATION OF ANTI-dsDNA B CELLS

In order to understand how the production of anti-DNA antibodies might occur, it is necessary to briefly review the process of B-cell activation. B cells are activated when they encounter an antigen that cross-links membrane Ig. In addition, an activated T cell must provide costimulatory signals to the activated B cell.

Costimulation occurs through several different pathways, such as the interaction of CD40 on the B cell with the CD40 ligand on the T cell, B7 or ICOS on the B cell, and CD28 or CTLA-4 on the T cell, as well as BAFF and its B-cell receptors, TACI, BAFF-R, and BCMA (Fig. 3). Interaction of the B cell and T cell is further dependent on the T-cell receptor-binding major histocompatiblity complex (MHC) class II molecules on the B cell. These class II molecules are complexed to a peptide from self or foreign proteins that have been bound and internalized by the B cell. Thus, the B cell binds antigen and presents peptides from that antigen to T cells. The T cells that recognize a class II-peptide complex on the B cell then activate that B cell. In this way, B and T cells interact in the presence of antigen and costimulatory signals to generate an immune response. Generally, when B or T cells encounter antigen in the absence of costimulatory molecules, as is often the case with self-antigens, tolerance is induced [8].

Although it is clear that anti-dsDNA antibodies are involved in disease pathogenesis, it is not known how they arise and whether they are elicited by self or foreign antigens. A number of theories have been proposed to explain their induction and it is likely that more than one event can trigger their production. Some investigators have suggested that self-antigens presented in an immunogenic manner induce SLE, whereas many believe that the initial event is a response to foreign antigen. Multiple models thus exist to account for anti-DNA antibody production: (1) a novel association between DNA and a foreign antigen such as a viral protein may establish a hapten–carrier complex that can trigger a T-cell-dependent anti-DNA response; (2) an antibody elicited in response to a microbial antigen may cross-react with DNA because of certain shared epitopes between the microbial antigen and DNA (molecular mimicry); (3) somatic mutation of an antimicrobial antibody may give rise to an autoantibody; (4) cells undergoing apoptosis and releasing enzymatically degraded DNA and nucleosomal complexes may present novel (cryptic) epitopes of self-proteins that may be immunogenic [237]. These may activate T cells that in turn provide help to anti-DNA B cells; and [5] polyclonal activation of either T or B cells may induce anti-DNA antibody production. The first three models propose a role for foreign antigen, which are described in detail later. If the response to foreign antigen activates T or B cells that are cross-reactive with self-antigen, an immunologic cascade, termed epitope spreading can ensue, leading to autoantibodies against multiple self-antigens. This secondary amplification of target antigens is also discussed.

Immunogenicity of DNA

Hypothesis 1: DNA as a Hapten

In order to understand the etiology of the pathogenic anti-dsDNA antibodies found in SLE, several laboratories have tried to induce similar anti-dsDNA antibodies in mice. Early attempts to generate anti-dsDNA antibodies by immunizing mice with native eukaryotic B-DNA were unsuccessful [238]. Immunization with Z-DNA can induce anti-dsDNA antibodies [239], but these antibodies are specific for Z-DNA and do not cross-react with native B-DNA [238]. Bacterial DNA complexed with BSA is more immunogenic than eukaryotic DNA. When autoimmune NZB/W mice are immunized with *Escherichia (E.) coli* DNA complexed with methylated bovine serum albumin they develop antibodies that bind both *E. coli* and mammalian DNA [240]. These antibodies, like those that arise spontaneously in this strain, display similar V_H CDR3 arginine content and V gene utilization, and bind preferentially to adenosine thymidine (AT)-rich sequences [241]. These studies have led to speculations that *E. coli* DNA can elicit an anti-DNA response because it bears unique antigenic epitopes. It has been suggested that bacterial DNA may be more immunogenic because of a high guanosine cytodine (GC) content, the presence of methylated adenosine residues [242, 243], or the abundance of unmethylated cytodine guanosine dimers [244]. However, immunizaton of nonautoimmune mice with *E. coli* DNA results in an antibody response restricted to bacterial DNA and rarely cross-reactive with eukaryotic DNA [245]. These data indicate that bacterial DNA can elicit lupus-like antibodies in a host lacking intact mechanisms of self-tolerance, but will only induce antibodies specific for bacterial DNA in a host maintaining self-tolerance.

Based on the poor immunogenicity of DNA, it has been hypothesized that the immunogen in lupus is not naked DNA but consists of DNA complexed to DNA-binding proteins [246]. To determine whether DNA in association with protein might induce anti-dsDNA antibodies, nonautoimmune mice were immunized with a highly immunogenic peptide, Fus 1 (derived from the protozoan *Trypanosoma cruzi*), complexed with calf thymus DNA [246]. In this model it is helpful to consider DNA as a hapten recognized by B cells and the peptide as a carrier recognized by T cells. Mice developed low titers of antibodies to calf thymus DNA, suggesting that DNA can be somewhat immunogenic when presented in a complex with a highly immunogenic carrier. DNA coupled to viral proteins can also induce anti-DNA antibodies. Nonautoimmune mice hyperimmunized with polyoma BK virus T antigen develop antibodies to both mammalian and viral DNA. The

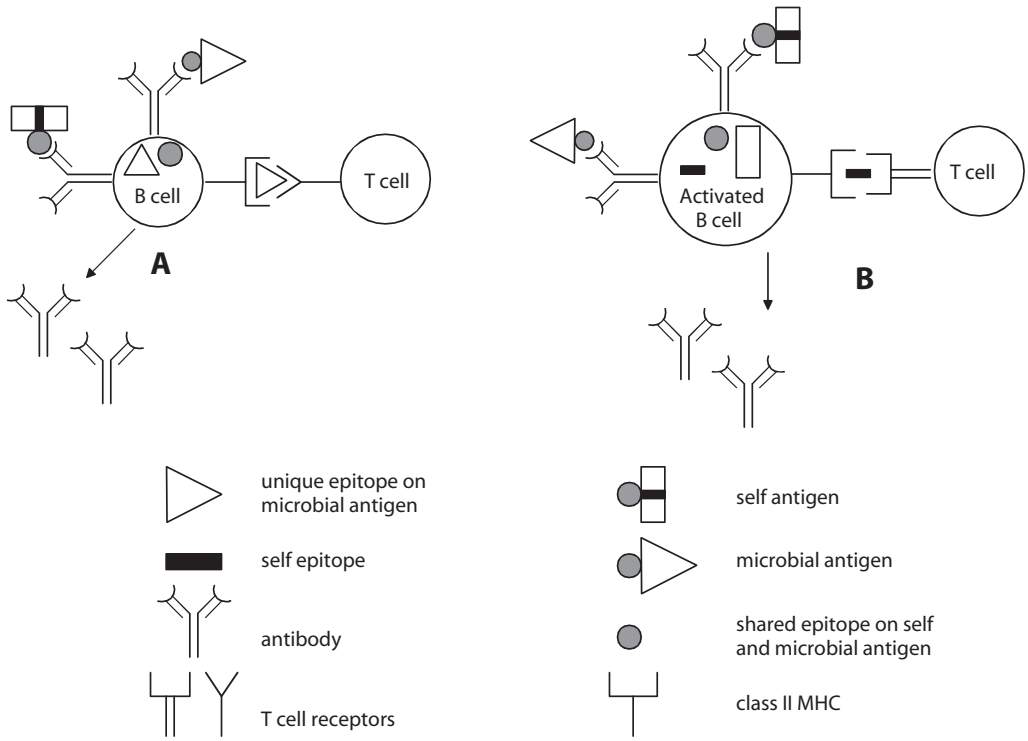

FIGURE 1 Molecular mimicry and presentation of self-epitopes can perpetuate an autoimmune response. (A) A B cell specific for a determinant shared by a microbial and self-antigen is triggered by a T cell specific for a unique determinant on the foreign antigen. (B) The activated B cell internalizes, processes, and presents epitopes of the self-antigen. A T cell that has never seen this epitope before, and has therefore not been tolerized to it, is now activated and continues to provide help to the autoreactive B cell and to other B cells with this autospecificity.

anti-dsDNA response has been shown to depend on the DNA-binding property of the T antigen, which serves as the carrier protein for the DNA hapten [247–249]. By establishing hapten–carrier complexes with DNA, viruses may initiate the production of anti-dsDNA antibodies *in vivo* and persistent viral infection may lead to autoimmunity.

Hypothesis 2: Molecular Mimicry

Environmental pathogens have long been suspected to be inducers of autoimmune disease. Autoimmune NZB mice raised in a germ-free environment develop reduced titers of autoantibodies, and elevated titers of anti-DNA antibodies can be found in patients with microbial infections, suggesting that microbial stimulation of the immune system helps stimulate the induction of autoantibodies in some way [250, 251]. Similarly, mice transgenic for an antibody to red blood cells do not develop autoimmune hemolytic anemia if they are bred in pathogen-free conditions. In conventional breeding conditions, however, many develop anemia, demonstrating that bacterial exposure plays a role in activating the autoreactive B cells [252, 253]. Studies of human and murine monoclonal anti-DNA antibodies have demonstrated extensive cross-reactivity with bacterial antigens (discussed earlier), suggesting that bacterial antigens may elicit these antibodies. This cross-reactivity, known as molecular mimicry, offers a potential explanation for the development of autoimmunity (Fig. 1). Alternatively, T cells cross-reactive with self-antigen may be activated during the response to microbial antigen and subsequently provide help to B cells specific for the self-antigen (Fig. 2).

Hypothesis 3: B-Cell Somatic Mutation

The majority of pathogenic anti-dsDNA antibodies in human and murine lupus are encoded by somatically mutated Ig genes [254–260]. The importance of somatic mutation in generating pathogenic anti-DNA antibodies is illustrated by experiments that show that transgenes coding for anti-ssDNA antibody can gain specificity for dsDNA by somatic mutation. Also, treatment with a costimulatory blockade in NZB/W mice leads to a decreased frequency of somatic mutations in

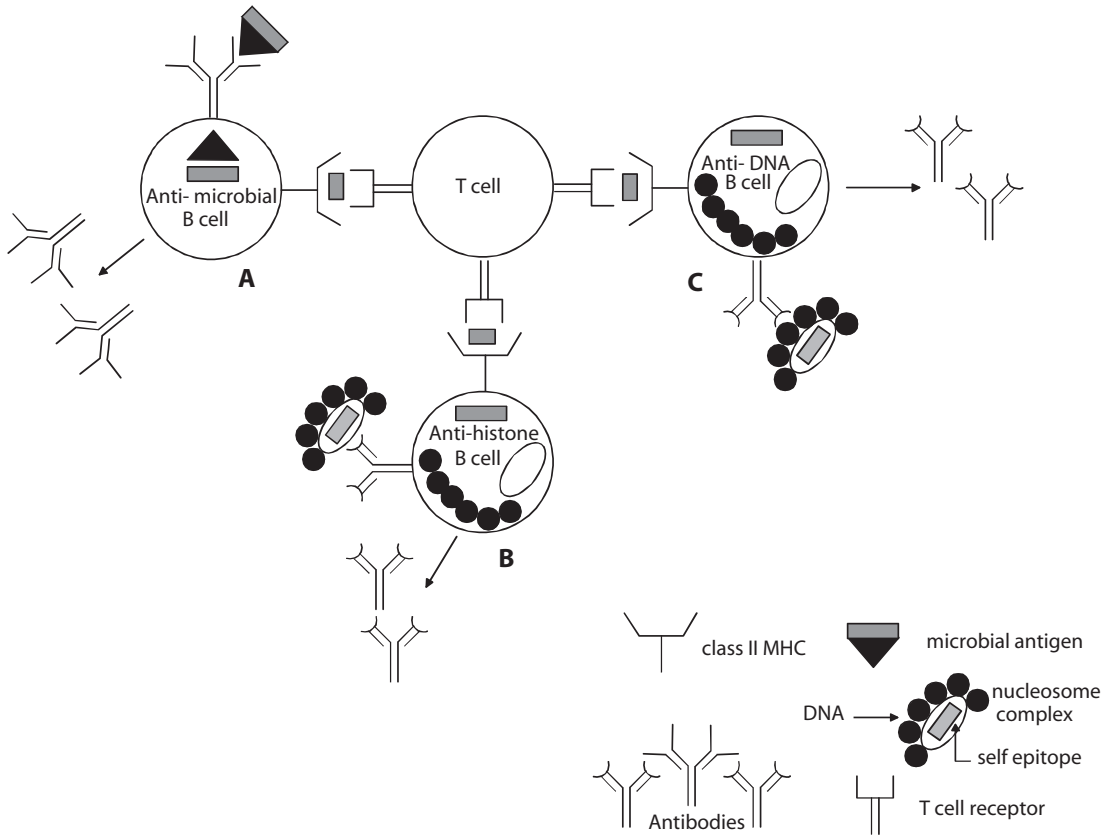

FIGURE 2 Epitope spreading leads to the production of anti-dsDNA antibodies. (A) A B cell specific for a microbial antigen internalizes, processes, and presents epitopes from the foreign antigen to T cells. (B) A T cell recognizing an epitope on a microbial antigen cross-reacts with a self-epitope and therefore activates both antimicrobial- and antihistone-specific B cells, causing them to secrete antibodies. (C) An anti-dsDNA B cell recognizes DNA in the nucleosome complex and presents the same histone epitope that has been presented by the antihistone B cells to activated T cells. These T cells can now activate anti-dsDNA B cells, causing them to secrete anti-dsDNA antibodies.

the VHBW-16 gene that encodes pathogenic anti-DNA antibodies, contributing to decreased anti-dsDNA antibody titer and prolonged survival [92].

The observation that many anti-DNA antibodies cross-react with microbial antigens suggests that antibodies to dsDNA may arise from antimicrobial antibodies undergoing somatic mutation. Support for this hypothesis was obtained in an *in vitro* culture system in which spontaneous mutation of an antibody to phosphorylcholine (PC) resulted in an antibody with specificity for dsDNA [53]. To determine if anti-dsDNA antibodies routinely derive from antimicrobial antibodies following mutation, efforts were made to generate anti-dsDNA hybridomas from nonautoimmune mice immunized with PC. Only rarely is it possible to obtain anti-dsDNA antibodies that cross-react with PC [176] unless splenocytes from PC-immunized mice are fused with a B-cell fusion partner transfected with the anti-apoptic gene bcl-2 [54]. Bcl-2 promotes B-cell survival and is upregulated in B cells destined to become plasma cells or memory B cells. Many hybridomas generated from these latter fusions cross-react with dsDNA [54]. These display somatically mutated genes, suggesting that autoreactive B-cell clones arise routinely following exposure to a bacterial antigen, but are deleted in normal mice.

Perhaps the most convincing data suggesting that anti-dsDNA antibodies can arise by somatic mutation following a response to bacterial antigen come from a study of human antibodies. Nonautoimmune patients given a polyvalent pneumococcal polysaccharide vaccine developed antipneumococcal antibodies bearing the anti-DNA-associated idiotypes 3I and 8.12 [104, 152]. In contrast, 3I+ and 8.12+ antibodies obtained from a combinatorial library derived from a lupus patient given pneumovax prior to splenectomy bind

both pneumococcal polysaccharide and dsDNA [177]. DNA binding appears to correlate with an increased frequency of somatic mutation, supporting the hypothesis that a bacterial antigen can trigger the development of anti-DNA antibodies through somatic mutation. In normal individuals, these antibodies are downregulated, but may escape regulation in autoimmune individuals.

There are conflicting data about the process of somatic mutation in SLE. An analysis of 10 human antibodies with a F4 idiotype that is highly associated with specificity for dsDNA demonstrated a decrease in targeting of mutations to mutational hot spots, but no change in the number of somatic mutations or their distribution in CDRs or FRs [116]. Analysis of V genes from B cells from one lupus patient demonstrated an increased frequency of mutation in both CDRs and FRs, with targeting to hot spots in FRs [118].

Epitope Spreading

The production of a diverse repertoire of autoantibodies can begin with the activation of a single autoreactive lymphocyte, either a B cell (Fig. 1) or a T cell (Fig. 2), followed by the diversification of the initial immune response. Native DNA is a component of many multimolecular complexes whose subunits are often targets for autoantibody production in SLE. DNA associates with histone proteins to form a nucleosome, and antibodies to nucleosomes and histones as well as DNA are found frequently in patients with lupus [261–263]. DNA also associates with replication/repair proteins, the Ku protein, and transcription factors. Antibodies to several of these DNA-binding proteins are also often present in SLE patients [261]. Cryptic or novel epitopes derived from the protein subunits in DNA protein complexes may be presented by B cells, activate autoreactive T cells, and so perpetuate and expand an autoantibody response (Fig. 1). This process is termed epitope spreading.

Evidence for epitope spreading exists in animal models [264–267]. It has been observed for some time now that lupus patients who have antibodies to Sm often develop antibodies to RNP and DNA over time [193, 266, 268]. Both RNP and Sm are components of the spliceosomal complex. To test whether epitope spreading occurs between Sm and RNP, rabbits and mice were immunized with peptides derived from the Sm B protein and control peptides. Animals immunized with the Sm peptides developed antibodies to Sm as well as to other components of the splicesome, including U RNAs and nRNPs [266, 269]. In fact, a few rabbits and mice also developed antibodies to dsDNA, exemplifying how anti-dsDNA antibodies may arise even when DNA is not the eliciting autoantigen as long as there is physical linkage between the immunizing protein and nucleic acid.

T CELLS INVOLVED IN ANTI-DNA ANTIBODY PRODUCTION

Most pathogenic anti-dsDNA antibodies in lupus are IgG and are somatically mutated. Because isotype switching and somatic mutation require T-cell help, it is clear that T cells have an important function in the production of autoantibodies [270–273]. The role of T cells in lupus has been demonstrated in autoimmune mouse models, and interfering with T-cell–B-cell interactions has been successful in ameliorating disease activity [274–276].

T cells from SLE patients display an activation defect that arises from altered expression of different signaling molecules. For example, an aberration in the protein kinase C- mediated activation pathway has been identified [277]; lupus T cells have an impaired protein kinase C response to integrin-mediated activation, diminished proliferation in response to anti-CD3 and anti-integrin antibody, and diminished adhesion to fibronectin [278]. Studies have also shown that lupus T cells exhibit a decreased expression of the TCR ζ chain, a crucial signaling molecule, caused by an increased frequency of mutations and polymorphisms in the TCR ζ chain-untranslated region [279]. These T cells also display increased phosphorylation of downstream signaling molecules and increased free intracellular calcium concentrations, demonstrating that alternative signaling pathways substitute for the deficient TCR ζ chain. It has been demonstrated that lupus T cells have an increased expression of the Fc ε receptor γ chain on both $CD4^+$ and $CD8^+$ T cells; its increased expression may contribute to the abnormal T-cell activation in SLE patients [280].

In recent years, attention has focused on the antigenic specificity of T cells involved in murine and human lupus, and it has been observed that autoreactive T cells may recognize either self-peptides that derive from a nucleoprotein complex or peptides derived from the autoantibodies themselves. An analysis of 15 autoreactive T-cell clones derived from five patients with SLE demonstrated that autoreactive T cells support the polyclonal activation of B cells [281]. Autoantibody secretion did not occur when antigen presentation was blocked with anti-HLA class II antibodies, demonstrating that T-cells engage in cognate interactions with autoreactive B cells. Histone-specific T-cell clones generated from autoimmune mice are able to augment the production of anti-DNA antibodies *in*

vitro and induce anti-dsDNA production when transferred into autoimmune hosts prior to disease onset [264]. Because DNA and histones are components of the same nuclear complex, a histone-specific T cell can activate anti-DNA B cells. Similarly, in a peptide-induced model of SLE, activation of class II-restricted $CD4^+$ T cells is necessary for the breakdown of tolerance and autoantibody production [282]. B cells can process their own immunoglobulin molecules and present immunoglobulin-derived peptides in the context of MHC class II molecules [283–286]. Peptides derived from anti-dsDNA antibodies can prime autoreactive T cells in autoimmune NZB/W mice, lead to activation of anti-dsDNA B cells, and hasten the onset of disease [287]. Although some studies have suggested that autoreactive T cells have anionic residues in the CDR3 of their T-cell receptor that are capable of binding to cationic residues present in nucleosomes [266], others have not confirmed the preferential usage of anionic receptors [287].

The majority of T cells express a T-cell receptor composed of an α chain and β chain, which are covalently linked to one another. These T cells are required for the development of autoantibodies and the onset of autoimmunity. A small subset of T cells (less than 5% in humans) expresses a T-cell receptor consisting of a γ chain and a δ chain. Some studies suggest that γδ T cells may play an important regulatory role in SLE. Autoimmune MRL/lpr mice deficient in γδ T cells have higher titers of autoantibodies and exacerbated disease compared to mice in which both αβ and γδ T cells are present [288]. The importance of γδ cells in SLE is also supported by human data. A decreased number of γδ T cells has been reported in SLE patients and correlates inversely with markers of inflammation [289].

REGULATION OF ANTI-DSDNA B CELLS

Tolerance Induction

Autoreactive B cells can be downregulated by one of three mechanisms of tolerance: deletion, anergy, or receptor editing. Deletion refers to the death of the cell through apoptosis or programmed cell death. Anergy is a state of functional paralysis in which the normal signals for B-cell activation will no longer activate the cell. Anergy can be reversed by exposure to B-cell mitogens, such as bacterial lipopolysaccharide (LPS). Receptor editing is a mechanism by which a B cell can attempt to change its specificity and avert autoreactivity by undergoing additional V region rearrangements.

The advent of transgenic technology has enabled investigators to follow the fate of autoreactive B cells and to learn more about the maintenance of tolerance. A number of laboratories have generated transgenic mouse models to study the regulation of anti-DNA B cells [290–292]. These studies have led to the development of a model for tolerance induction. B-cell activation depends on stimulation by two signals: antigen and a costimulatory molecule. B-cell tolerance occurs when the cell encounters antigen in the absence of costimulatory molecules. As inflammation is needed to induce the expression of costimulatory molecules, an encounter with antigen in a noninflammatory setting will, in general, lead to tolerance. Because most encounters with self-antigen occur under noninflammatory conditions, B cells reactive with self-antigen are generally tolerized. When a B cell encounters self-antigen in the bone marrow, RAG genes are reexpressed and receptor editing occurs. If this process does not lead to successful production of a new nonautoreactive antibody, then deletion or anergy will ensue with deletion occurring under conditions of extensive cross-linking of membrane Ig and anergy under conditions of more modest cross-linking. Some autoreactive B cells will have an affinity for antigen below a threshold for tolerance induction or will encounter too little antigen to trigger tolerance induction and willl remain activatable in the periphery [293].

Anti-DNA Antibody Transgenic Mice

Two transgenic mouse models expressing either the heavy chain of an anti-DNA antibody or both the heavy and the light chain have been analyzed in some detail. In one transgenic system, nonautoimmune BALB/c mice were made transgenic for the heavy chain of an IgM anti-DNA antibody that arises spontaneously in MRL/lpr lupus-prone mice. Pairing of the heavy chain with different endogenous light chains resulted in either antibodies that recognized ssDNA only or those that also recognized dsDNA. Analysis of anti-DNA B cells suggested that anti-ssDNA B cells are anergized, whereas B cells with an affinity for dsDNA are deleted [290]. Subsequent studies using mice transgenic for IgM heavy chain, as well as particular transgenic light chains, confirmed these results [294, 295]. Transgenic anti-ssDNA B cells display functional defects, such as decreased total surface Ig and suboptimal response to T-dependent and T-independent stimuli, but have a normal life span compared to nontransgenic B cells. Further analysis revealed that receptor editing was responsible for a shift in specificity of the B-cell receptor from dsDNA binding to non-dsDNA binding [295, 296]. Definitive studies have not yet been performed to

determine whether receptor editing is less efficient or defective in human SLE. Of interest, however, is one study suggesting that B cells from several patients with SLE were unable to edit a particular V_κ gene that is frequently associated with a cationic anti-DNA antibody whereas normal B cells appear capable of editing this light chain [297].

In another transgenic system, both nonautoimmune BALB/c mice and autoimmune NZB/W mice were made transgenic for the heavy chain of an IgG anti-dsDNA antibody [126, 291]. In these mice, the transgenic heavy chain can pair with the spectrum of endogenous light chains to produce B cells with DNA-binding and non-DNA-binding specificities. Although nonautoimmune mice display negligible titers of transgene-encoded anti-dsDNA antibody due to the induction of tolerance, the autoimmune mice secrete elevated titers of transgene-encoded anti-dsDNA antibody. Analysis of autoimmune and nonautoimmune mice revealed the presence of three populations of anti-dsDNA B cells, each of which is subject to a different mechanism of regulation in nonautoimmune hosts. One population with high affinity for dsDNA is anergized; a second population that also has high affinity for dsDNA is deleted; and a third population producing low-affinity anti-dsDNA antibodies escapes regulation and is termed indifferent. It has been demonstrated that some members of the low-affinity subset of anti-dsDNA B cells differ from the high-affinity subsets by a single base substitution, resulting in a single amino acid replacement [298]. Thus high-affinity pathogenic anti-DNA B cells may arise when low-affinity anti-dsDNA B cells, making "natural autoantibody," undergo somatic mutation.

Genes That Regulate B-Cell Tolerance

Several molecules are involved in setting thresholds for the survival, activation, or tolerance of autoreactive B cells. The MRL/lpr mouse model of lupus has a defect in the Fas gene [299–301] that inhibits activation-induced T- and B-cell death, which results in severe lymphoproliferation. MRL/lpr mice transgenic for an IgM anti-DNA antibody fail to display tolerance and do not delete anti-dsDNA B cells [302]. These mice allow anti-DNA B cells to enter the B-cell follicles, from which they are normally excluded [303]. The lpr mutation does not require the MRL background for the induction of anti-dsDNA antibodies; C57BL/6J, AKR/J, and C3H/HeJ strains of mice bearing the lpr mutation are all capable of producing anti-DNA antibodies; however, they develop lower titers of autoantibodies and less severe glomerulonephritis than MRL mice [304]. Although the Fas mutation leads to a lupus-like syndrome in mice, the same mutation in humans leads to lymphoproliferation without the autoantibody specificities that characterize lupus [305].

The bcl-2 gene product promotes B-cell survival in both the bone marrow and the periphery [306–308]. Overexpression of bcl-2 in nonspontaneously autoimmune mice transgenic for the heavy chain of a pathogenic anti-DNA antibody leads to survival of anti-dsDNA B cells that normally would be deleted [309] and "rescue" of cross-reactive anti-DNA/anti-pneumococcal B cells in nonautoimmune mice during a primary response to PC [310, 311]. The hormones estrogen [312, 313] and prolactin (E. Peeva, unpublished data) promote the survival of anti-dsDNA B cells and upregulation of the bcl-2 gene. The phenotypic impact of bcl-2 overexpression depends on the genetic background; bcl-2 overexpression induces a lupus-like syndrome in some mouse strains [309], but not in others [314]. A spontaneous overexpression of bcl-2 has not been observed in patients with lupus.

Several regulatory molecules are involved in signaling B cells to proliferate and secrete antibody or undergo apoptosis. These molecules include cell surface receptors, such as CD19, CD45, and CD22, and their intracellular components, such as Lyn, Fyn, Btk, and the tyrosine phosphatase SHP-1. Alterations in expression or function of any of these molecules can be associated with abnormal B-cell function and development of a lupus-like phenotype. Motheaten mice spontaneously develop an autoimmune syndrome characterized by the production of anti-dsDNA as well as other autoantibodies [315]. These mice have a mutation that ablates the activity of SHP-1 phosphatase, which helps regulate B-cell activation [316–318]. B cells producing autoantibodies in motheaten mice are $CD5^+$ B1 cells. It has been shown that a death signal can be delivered through ligation of the CD5 molecule [319, 320]. CD5 is, therefore, thought to play a role in negative signaling, and it has been suggested that its mechanism of action requires the recruitment of SHP-1 phosphatase. Hence, in SHP-1-deficient mice the absence of a CD5–SHP-1 interaction may lead to the accumulation of $CD5^+$ B cells. Lyn is a tyrosine kinase associated with membrane Ig that downmodulates B-cell responses. Lyn deficiency results in increased anti-DNA titers and immune complex deposits in the glomeruli [321]. Lyn is also important in determining B-cell development, as demonstrated by the absence of marginal zone B cells in Lyn-deficient mice [322, 323]. CD22 is another transmembrane molecule that associates with SHP-1 phosphatase that can negatively regulate antigen receptor signaling [324]. Mice deficient in CD22 expression also display elevated titers of anti-DNA antibodies due to an expanded B1 cell population [325–328]. In some SLE patients, a sig-

nificant decrease in the expression of Lyn in resting as well as in anti-IgM-stimulated B cells was observed, but the expression of CD22 was intact [329]. A newly discovered molecule called BAFF plays a pivotal role in B-cell activation, maturation, and proliferation. BAFF transgenic mice develop an increased number of mature B cells and T cells, and hypergamaglobulinemia. These mice have a lupus-like illness characterized by anti-DNA antibodies and Ig deposits in the kidney [330, 331]. NZB/W lupus-prone mice exhibit increased levels of BAFF.

CD45 or B220 is a transmembrane tyrosine phosphatase involved in B-cell activation [332]. Mice deficient in CD45 display a hyporesponsiveness to antigen receptor cross-linking and display diminished signaling in response to an autoantigen. This leads to a need for more autoantigen to be present to signal the elimination of autoreactive B cells. When the concentration of autoantigen is low, only those B cells with the highest affinity for autoantigen are eliminated. CD45-deficient mice, therefore, have an increased number of autoreactive B cells and an enhanced incidence of autoimmunity [333]. Human studies also suggest a decreased expression of CD45 on B cells of SLE patients [334]. The cell surface molecule CD19 has also been observed to alter signaling thresholds, and mice with an increase in CD19 expression have elevated titers of anti-dsDNA antibodies that are predominantly of the IgG isotype. B1 cells are upregulated in these mice, but it is not clear whether these cells or conventional cells are the source of anti-DNA antibodies [335]. Even 15–29% increases in CD19 expression in C57Bl/6 mice can induce autoantibody production, suggesting that subtle changes in the levels of expression of signaling molecules may lead to autoreactivity [336].

Expression of molecules that are involved in the costimulation of B cells may also influence the induction of anti-DNA antibodies. As stated earlier, two signals are required for B-cell activation: (1) ligation of surface immunoulobulin with antigen leading to BCR signaling and (2) engagement of costimulary receptors on the surface of B and T lymphocytes. Costimulatory signals are delivered by the binding of the B-cell surface molecules CD40, B7, or TACI/BCMA/BAFF-R with the T-cell surface molecules CD40 ligand (CD40L), CD28/CTLA-4, or secreted molecule BAFF, respectively (Fig. 3). Lpr/lpr mice deficient in CD40L have been observed to have lower titers of IgG anti-DNA antibodies [337], and BAFF-deficient mice display a severe B-cell depletion [83]. Studies such as these have led to speculations that costimulatory molecules are upregulated in SLE patients and lupus-prone mice, resulting in an increased production of autoantibodies. Indeed, there is an increased expression of CD40 ligand on both B and T lymphocytes [338] and an increased expression of CD86 on peripheral blood cells in lupus patients [339]. Cytokines and hormones may also play a role in the development of lupus. Interleukin (IL)-10, for example, has been shown to activate B cells to secrete autoantibodies, and treatment with the anti-IL-10 antibody delays the appearance of autoantibodies in lupus-prone NZB/W mice [340] and provides some therapeutic benefit in humans [341]. Mice lacking expression of transforming growth factor-β produce anti-DNA antibodies and develop glomerulonephritis [342]. Finally, elevated estrogen and prolactin levels lead to elevated titers of anti-DNA antibodies and a lupus-like phenotype in certain genetic backgrounds.

The importance of dysregulated innate immunity has been emphasized as a factor in the etiopathogenesis of SLE. Impaired clearance of apoptotic material from the circulation plays a significant role in the breakdown of tolerance and induction of anti-DNA antibodies [343]. Apoptotic cells given intravenously induce anti-DNA antibodies in nonautoimmune mice [344], whereas an increased expression of the soluble complement inhibitor prolongs survival in autoimmune MRL/lpr mice [345]. The lupus susceptibility locus Sle1c includes genes encoding complement receptors CD21/CD35; a single nucleotide polymorphism of CD21 that affects the glycolysation and dimerization of the molecule that is necessary for the binding of C3d results in a lupus-like phenotype [346]. A decreased expression of both CD21 and CD35 has been observed in MRL/lpr lupus-prone mice [347]. The importance of complement in the maintenance of tolerance is further supported by the association of lupus and deficiency of the early complement components. C1q deficiency accelerates disease progression in MRL/lpr mice [348], whereas C4-deleted lpr mice and mice lacking complement receptors 1 and 2 demonstrate high titers of antinuclear and anti-DNA antibodies and severe glomerulonephritis [349]. Clearance of apoptoic debris through Fcγ receptors also seems to regulate the development of autoimmunity. Fcγ receptors bind pentraxins involved in the clearance of nuclear proteins, serum amyloid protein (SAP), and C-reactive protein (CRP), allowing phagocytes that express these receptors to ingest SAP and CRP-coated apoptotic material directly [350]. Utations of FcRIIIA causing decreased uptake of immune complexes are observed in patients with SLE [351]. Toll-like receptors (TLR) are also implicated in autoimmunity. Cross-linking of the BCR and TLR9 activates B cells; thus, chromatin alone can activate anti-DNA B cells [352].

Dysregulation of either the innate or the adaptive immune system may lead to the development of autoantibodies against nuclear components, including DNA.

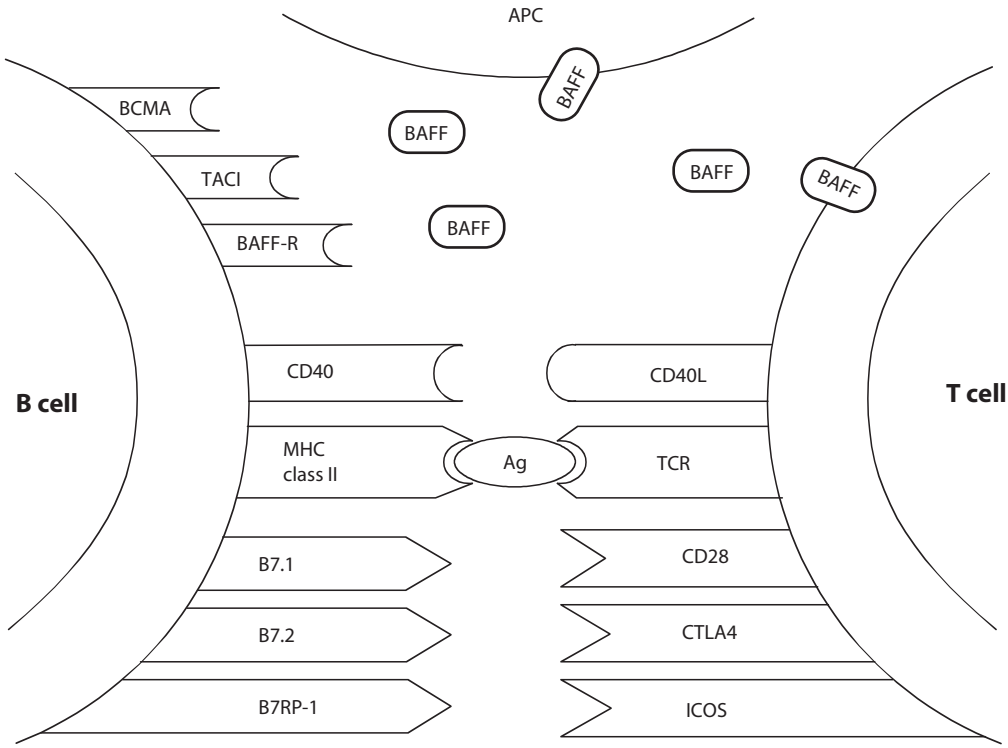

FIGURE 3 B-cell–T-cell costimulation is dysregulated in SLE and leads to enhanced autoantibody production. An antigen-presenting cell (APC) processes antigen (Ag) and presents it in context of MHCII to a $CD4^+$ T cell via an interaction with the T-cell receptor (TCR). Costimulatory molecules including B7 family members (B7.1, B7.2, and B7RP-1) on the B cell bind to T-cell receptors CD28 and ICOS, and tumor necrosis factor family members that include CD40L and BAFF bind to B-cell surface molecules CD40 and TACI, BAFF-receptor and BCMA, respectively. B-cell/T-cell costimulatory augmentation is negatively regulated by the interaction of B7 molecules with CTLA4 on $CD4^+$ T cells. Aberrant costimulatory processes appear to exist in SLE. For example, there is an increased expression of soluble and T-cell membrane-expressed CD40L and BAFF in lupus patients, as well as an increased expression of B7.1/2 on the surface of lupus B cells.

It is clear that aberrant expression of a variety of different molecules may result in the production of anti-DNA antibodies and in the development of a lupus-like phenotype in mice with a particular genetic background. Defects in expression of more than one of these molecules are required to sustain the autoimmune response.

THERAPY

A major goal of understanding the structure, origin, and pathogenicity of anti-DNA antibodies is to develop therapies that will be less harmful than the current nonselective immunosuppressive regimens used to treat lupus patients. Several novel approaches to therapy of SLE have been proposed based on our growing understanding of B-cell activation. This section briefly mentions only the novel therapeutic approaches that are specific to anti-DNA antibodies.

The association of anti-DNA antibodies with pathologic events in SLE, especially with lupus nephritis, suggests that removal of anti-DNA antibodies, or blocking their production or activity, may be beneficial. Many anti-DNA antibodies in SLE arise from T-cell dependent responses in which costimulation between B and T cells is mediated through the CD40-CD40 ligand and B7-CD28 pathway (Fig. 3). Blocking the costimulatory pathways, independently or collectively, prevents the generation of a second signal, which is necessary for B-cell proliferation, differentiation, and antibody production. Monoclonal antibody to the CD40 ligand leads to improved survival in the NZB/W and SNF mouse models of SLE. Inhibition of the B7-CD28 costimulatory pathway by CTLA-4 Ig, a fusion molecule constructed of CTLA-4 and the Fc portion of an

immunoglobulin, also blocks anti-DNA antibody production and prolongs life in NZB/W mice [353]. Simultaneous treatment with anti-CD40 and CTLA-4 Ig or cyclophophosphamide and CTLA-4 Ig provides greater benefit than either intervention alone [92, 354]. However, clinical trials with anti-CD40 ligand in patients were less successful. It remains a question whether blockade of the CD40-CD40 ligand or B7-CD28 costimulatory pathways or other costimulatory pathways will be useful therapeutic modalities for SLE.

Idiotypic interventions may be used to deplete specific antibodies or specific B-cell populations. For example, patients have been subjected to the extracorporeal depletion of antibodies bearing the 3I idiotype that are present on anti-DNA antibodies and associated with lupus nephritis. These patients showed a marked diminution in DNA binding. The patient number was, however, too small and the duration of the study too short to determine if there was a lasting effect of this therapy [355]. Two new techniques to remove anti-DNA antibodies from the blood of lupus patients based on immunoadsorbtion of DNA have been developed [356, 357]. Both techniques lead to significant declines in the anti-DNA titer, but neither has entered into a clinical trial.

It has been suggested that anti-idiotype administration *in vivo* might alter the disease course. Preparations of IVIG containing anti-idiotypic activity to anti-DNA-associated idiotypes were reported to be more likely to induce disease remission than IVIG preparations that lack anti-idiotypic activity [358]. It has also been suggested that anti-idiotypic antibodies can be complexed to cytotoxic drugs to target specifically anti-DNA B cells [359].

Understanding mechanisms of tolerance induction in B cells has led to the design of a novel therapeutic for SLE, LJP 394, a conjugate constructed from a polyethylene glycol and tetrameric oligonucleotides [360]. This reagent is designed to provide antigen signaling through the BCR in the absence of costimulation, thus leading to B-cell deletion or anergy. In BXSB male lupus-prone mice, treatment with LJP 394 led to a significant decrease in proteinuria and increased survival [361], but results in a preliminary study in patients showed only a modest, if any, benefit [362]. A second antigen-based heteropolymer has been developed to bind anti-DNA antibodies [363], but it has not been tested in animal studies yet.

Another novel therapeutic approach to SLE in mice is based on the observation that peptides derived from anti-DNA antibodies can activate T cells that regulate autoantibody production. Treatment of NZB/W mice with peptides derived from an anti-DNA antibody demonstrated a beneficial effect with a delay in the development of autoantibodies and prolonged survival [364].

SUMMARY

All individuals have the potential to produce high-affinity potentially pathogenic anti-DNA antibodies. Anti-DNA antibodies are encoded by genes that are present in nonautoimmune individuals and that are used routinely to encode protective antibodies. The mechanisms of somatic diversification of the immunoglobulin repertoire appear to be normal in lupus patients. It has been demonstrated that anti-DNA antibodies arise in nonautoimmune hosts during microbial infection, but that tolerance is restored when microbial antigens are eliminated. Therefore, it appears that the critical defect in SLE is not in the formation of the B-cell repertoire, but in the regulation of autoreactive B cells.

The antigenic stimulus for anti-DNA antibody production is not known, nor is it clear whether a self or foreign antigen begins the process. There are probably several triggers for anti-DNA antibody production. Just as the antigenic trigger for anti-DNA antibody production may not always be DNA, the antigenic target may also not be DNA. It is apparent that at least some anti-DNA antibodies can cross-react directly with tissue antigens and so mediate tissue damage. On the near future, transgenic models and human genetic studies in combination should elucidate the defects in B-cell repertoire selection and tolerance induction that can lead to SLE. Major questions need to be addressed in future studies: (1) What abnormalities of B-cell function alter tolerance induction in SLE? (2) What genetic defects underlie these abnormalities? (3) How do anti-DNA antibodies cause tissue injury, (4) What differences in target tissue regulate susceptibility to anti-DNA-mediated tissue damage? Such studies in turn will suggest new and specific therapies.

ANTICYTOPLASMIC ANTIBODIES IN SLE

Antibodies to Cytoplasmic Antigens

Morris Reichlin

The hallmark of the autoimmune response in patients with systemic lupus erythematosus is the presence of antibodies to nuclear antigens. These include native and denatured DNA, histone, the DNA–histone complex, and some soluble nuclear RNA proteins, termed *Sm* and *nRNP* [1]. As many as 95% of active untreated SLE patients are found to have positive antinuclear antibody tests by indirect immunofluorescence when their sera are tested with rodent liver or kidney tissue as substrate. However, about 5% of the SLE population consistently lack such ANA, but their sera frequently contain antibodies to soluble antigens that are not well represented in the standard substrates used for immunofluorescence. SLE patients also produce antibodies to a number of cytoplasmic antigens, and investigation has sought to ascertain the clinical and biological significance of these reactions.

Antibodies to cytoplasmic constituents were recognized in early studies, but individual antigen–antibody reactions were not defined [1–4]. This chapter describes progress in the immunologic and biochemical study of these systems and the numerous clinical phenomena now recognized as being associated with these immune responses.

Two sets of antibodies are discussed. The first comprises two soluble antigens, *Ro* and *La*, which form precipitates with SLE sera and are RNA protein conjugates. While conflicting data exist regarding their cellular localization, substantial data support a cytoplasmic locus for at least part of their lifetime in cells. The second set of antibodies are those directed to cytoplasmic ribosomal constituents. Finally, the significance and possible origins of these responses as they relate to the spectrum of autoimmune responses exhibited by SLE patients are explored.

ANTIBODIES TO Ro AND La: METHODS OF DETECTION

The initial method used for the detection of antibodies to Ro and La was agar diffusion by Ouchterlony's method. This method and the independence of the two antigen–antibody reactions are illustrated in Fig. 1. In well 1 is a partially purified human spleen extract containing both Ro and La antigens. Well 2 contains a monospecific anti-Ro serum. Well 3 contains an undiluted serum with both anti-Ro and anti-La antibodies. Well 4 contains a one-third dilution of the same serum as in well 3. Note the complete independence of the Ro–anti-Ro and the La–anti-La precipitin lines, which suggests that the two antigens shared no epitopes. Subsequently, both a radioimmunoassay method [5, 6] and an enzyme-linked immunosorbent assay (ELISA) method were developed to measure anti-La.

Antibodies to the soluble antigens Ro and La were originally described in patients with SLE and Sjögren's syndrome [7, 8]. The antigens were thought to be cytoplasmic in origin because they were quantitatively recovered from the cytoplasmic fraction of cells

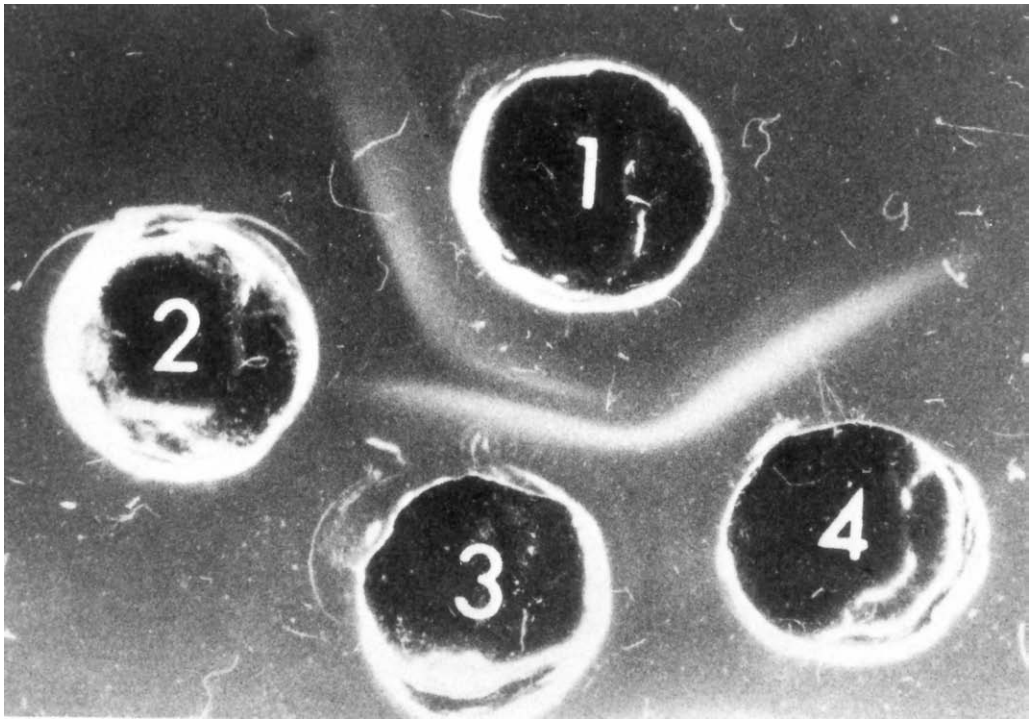

FIGURE 1 Well 1 contains a partially purified human spleen extract containing both Ro/SSA and La/SSB antigens. Well 2 contains a monospecific anti-Ro/SSA serum. Wells 3 and 4 contain a serum with both anti-Ro/SSA and anti-La/SSB undiluted and at one-third dilution, respectively.

prepared in strong sucrose solutions. Moreover, specifically purified antibodies to the Ro antigen stained predominantly the cytoplasm of KB (a human tissue culture line) cells, thymocytes, and Wil_2 (a lymphoblastoid B-cell line) cells, whereas specifically purified antibodies to La stained both the nucleus and the cytoplasm of these cells (P.J. Maddison and M. Reichlin, unpublished data). Alspaugh and Tan [9] described two nuclear antigens extracted from Wil_2 cells, termed *SSA* and *SSB*, that precipitated with the sera of patients with Sjögren's syndrome. Akizuki *et al.* [10] described a soluble nuclear antigen, termed *Ha*, that precipitated with the sera of patients with SLE–Sjögren's syndrome overlap. Interlaboratory exchange of sera and antigen extracts has clearly shown that Ro and SSA, on the one hand, and La, SSB, and Ha, on the other, are antigenically identical. Problems still remain about the cellular localization of Ro/SSA and La/SSB/Ha, but as is elaborated in a later section, these antigens are both RNA protein conjugates [11].

The clinical specificity of antibodies to these antigens in North American populations is that they occur principally in two diseases: SLE and Sjögren's syndrome. Antibodies to Ro/SSA occur in 25–40% of unselected SLE patients when the assay used is the relatively insensitive agar diffusion method. Antibodies to La/SSB/Ha occur in 10–15% of SLE patients, all of whom also have antibodies to Ro/SSA in their sera. In a large survey of hospitalized patients without rheumatic diseases, the false-positive rate for anti-Ro/SSA was found to be approximately 1/1000, as only 6 positive reactions were found in the sera of over 6000 patients [12]. There are differing data about the occurrence of these antibodies: (1) in primary Sjögren's syndrome when keratoconjunctivitis sicca (KCS) occurs alone and (2) in secondary Sjögren's syndrome when KCS occurs with a connective tissue disease, usually rheumatoid arthritis (RA). Studies of Alspaugh *et al.* [13] found anti-Ro/SSA and anti-La/SSB/Ha almost exclusively in primary Sjögren's syndrome. Subsequent studies from Scotland [14] and Baltimore [15] failed to exhibit this specificity; 40–50% of the patients with both primary and secondary Sjögren's syndrome have antibodies to these antigens. A unifying feature noted in the Baltimore patients, which may be relevant in this regard, is that the presence of anti-Ro/SSA is tightly linked to vasculitis and extraglandular disease whether these complications occur in the presence or absence of RA.

When KCS occurs with SLE [15] and scleroderma [16], at least one-half of the patients with anti-Ro/SSA also have anti-La/SSB/Ha in their sera. In patients with primary biliary cirrhosis (PBC) who have Sjögren's

syndrome, only anti-Ro/SSA is found in such sera. Sera from 12 such cases with anti-Ro/SSA were found in a series of 63 PBC patients (E. Penner *et al.*, unpublished data).

Of considerable interest is the vastly different frequency of occurrence of anti-Ro/SSA in Japanese patients with connective tissue diseases. The frequency of occurrence in SLE is 58%, whereas the frequencies in RA, scleroderma, polymyositis, and undifferentiated connective tissue diseases are 24, 29, 15, and 45%, respectively [17]. These frequencies are much higher than those exhibited by North American patients [12] with these same diseases, and the differences are not explained by a more frequent occurrence of Sjögren's syndrome in the Japanese population. Analysis of this difference in anti-Ro/SSA frequency in Japanese versus North American patients with connective tissue diseases should yield important clues to the genesis and regulation of this specific immune response.

CLINICAL ASSOCIATIONS

A number of clinical phenomena have been recognized to be associated with the presence of anti-Ro/SSA in patients with SLE. These are listed in Table 1 and are discussed in the following sections.

ANA-Negative SLE

When the ANA test is performed on cryostat sections of mouse liver or kidney and standardized commercially available fluorescent conjugates of antihuman gammaglobulin are employed, about 95% of active untreated SLE patients will have positive tests. The liters will vary greatly but at least 50% of the liters will exceed 1/100 and a small proportion (≤1/10) will be positive only at the screening dilution (1/10–1/20 in most laboratories). If the screening test is performed on commercially available human tissue culture lines, such as KB or Hep2 cells, the percentage of positive tests approaches 98% of active untreated SLE patients. The difference between the two substrates largely represents the poor representation of the Ro/SSA antigen in mouse or rat liver and kidney sections and its presence in the tissue culture lines.

TABLE 1 Clinical Subsets Associated with Anti-Ro/SSA in SLE and Sjögren's Syndrome[a]

	Anti-Ro/SSA precipitins (%)
SCLE	63
Neonatal SLE[a]	>90
Homozygous C2 and C4 deficiency[b]	85
ANA-negative SLE	65
Vasculitis of Sjögren's syndrome	86
Interstitial lung disease	83
Photosensitivity	90

[a] Prevalence of anti-Ro/SSA in mothers who have children with neonatal SLE.

[b] Prevalence of anti-Ro/SSA in symptomatic patients with lupus-like syndrome.

These sera occur in patients with "ANA-negative SLE," i.e., patients with typical clinical findings of SLE and negative ANA tests on cryostat sections of rodent epithelial tissues [18–20]. Almost two-thirds (41 of 66) of these patients have antibodies to Ro/SSA and/or La/SSB in their sera; of the remainder, the great majority have antibodies to single-stranded DNA (ssDNA) demonstrable by radioimmunoassay. Reexamination of these patients by sensitive ELISA techniques with affinity-purified Ro/SSA reveals that all 66 patients have elevated anti-Ro/SSA levels [21]. These issues have been described and discussed in an analytical review [22]. These negative ANA tests are found in active untreated patients and persist for long periods of clinical follow-up [22]. The clinical picture in these patients is notable for an increased frequency of photosensitive dermatitis and rheumatoid factor tests and a low frequency (10%) of neuropsychiatric and renal disease. It should be noted that some ANA-positive, anti-Ro/SSA-positive SLE patients who enter a steroid-induced remission frequently become ANA negative (on mouse liver or kidney sections) while maintaining substantial titers of anti-Ro/SSA demonstrable by immune precipitation. Indeed, in the author's experience, it is unusual if not rare for anti-Ro/SSA to disappear completely from the sera of SLE patients, whatever the clinical activity of their SLE. The issue of whether anti-Ro/SSA fluctuates with disease activity is still under study in various laboratories, but one report describes a correlation between anti-Ro/SSA titers and disease activity [23].

Differences between SLE Patients with Anti-Ro/SSA and Those with Both Anti-Ro/SSA and Anti-La/SSB

Within the ANA-positive subset of SLE patients who have anti-Ro/SSA, important clinical and serologic differences distinguish patients who produce anti-Ro/SSA alone from those who produce both anti-Ro/SSA and anti-La/SSB [24]. There is a great similarity in nonrenal findings in these two groups of patients but a striking difference in the frequency and severity of renal disease. Thus, 16 of 30 (53%) anti-Ro/SSA patients had one or

more of the following three findings: a serum creatinine level greater than 3.0 mg%, proteinuria exceeding 1.5 g in 24 h, and cellular casts in the urine. Only 2 of 23 (9%) of the anti-Ro/SSA and anti-La/SSB patients had such evidence for nephritis. The serologic correlation of this difference in renal disease was a 77% prevalence of anti-DNA in the anti-Ro/SSA group and a 30% prevalence of such antibodies in the anti-Ro/SSA and anti-La/SSB group. Details of the titers and specificities of these antibodies to DNA have been published, but the titers of both anti-dsDNA and anti-ssDNA were higher in the anti-Ro/SSA-alone group than in patients who had both anti-Ro/SSA and anti-La/SSB in their sera [24]. At least part of the reason for the increased frequency of nephritis in the SLE patients who produce only anti-Ro/SSA is to be found in the usual presence and high titers of antibodies to DNA in this group.

Groups defined by the serologic findings described earlier are stable. Patients producing anti-Ro/SSA alone have never been observed to produce anti-La/SSB. Conversely, patients with both anti-Ro/SSA and anti-La/SSB in their sera have never been observed to lose one or the other of the two. The great difference in frequency of renal disease correlates with a more serious prognosis in the anti-Ro/SSA-alone group compared with patients producing both anti-Ro/SSA and anti-La/SSB. These findings have now been confirmed in two additional cohorts of SLE patients [25, 26].

A possible mechanism for this paucity of anti-dsDNA and nephritis in anti-La/SSB-positive patients has been proposed in which a subset of anti-La/SSB has been shown to be an anti-idiotype to anti-dsDNA [27].

Antibodies to Ro/SSA Are Enriched in Glomerular Eluates from Nephritic SLE Kidneys

Two SLE patients were observed whose progressive renal failure was accompanied by declining serum titers of anti-Ro/SSA [28]. Acid eluates from the postmortem kidneys of these patients revealed enrichment of anti-Ro/SSA by 200- and 12-fold, respectively. These studies provide evidence for the selective deposition of anti-Ro/SSA and participation of these specific antibodies in the nephritis of these patients. The high frequency of nephritis in patients producing anti-Ro/SSA in the absence of anti-La/SSB may, in part, reflect deposition of the Ro/SSA–anti-Ro/SSA immune complexes in renal tissue.

SUBACUTE CUTANEOUS LUPUS ERYTHEMATOSUS

A subset of lupus patients with a characteristic non-scarring dermatitis, subacute cutaneous lupus erythematosus, has been described [29, 30]. The skin disease is intermediate in severity between the acute erythematosus eruption of SLE and the chronic indolent scarring lesions of discoid lupus erythematosus (DLE). Patients exhibit a wide distribution of lesions on the face, arms, and trunk. These lesions are always accompanied by telangiectasia, and there is less hyperkeratosis and follicular plugging than in DLE. There are two morphologic types of lesions: papulosquamous and annular. Primary skin lesions are the same in both, featuring erythematous scaling papules or small plaques. Histopathologically, the two lesions exhibit identical features. Morphologically, the papulosquamous lesions feature merging of the small papules or plaques into large psoriasiform plaques, which can progress to a confluent or retiform array. In annular lesions, the primary active lesions expand peripherally and leave a central inactive zone, resulting in a red scaling ring with a gray–white center. These latter lesions may form a polycyclic array.

Eighty percent of these patients are ANA positive on KB cells and have a mild systemic illness very similar to that described in the so-called ANA-negative SLE patients [22]. When a positive ANA test was taken as a criterion for SLE, 78% of these patients (21 of 27) satisfied at least four American College of Rheumatology criteria for the diagnosis of SLE [31]. The clinical picture is dominated by skin disease, mucosal ulceration, and polyarthritis. Serositis, central nervous system, and renal disease are uncommon. The common factor shared by ANA-negative SLE patients and SCLE patients that may relate to their mild disease and to the low frequency of nephritis is the low frequency (about 10%) of antibodies to dsDNA. Of great interest are two findings that further characterize these patients. One is that 77% of patients with SCLE carry the DR3 antigen, a substantial increase over the 22% frequency found in the control population. The other finding is the presence of antibodies to Ro/SSA, La/SSB, or both in the sera of these patients. While only 25–30% of unselected SLE patients and 3% of DLE patients have anti-Ro/SSA precipitins in their sera, 63% of SCLE patients have anti-Ro/SSA precipitins in their sera. Similar to the findings in ANA-negative SLE, sensitive ELISA tests for anti-Ro/SSA reveal that virtually all are positive for anti-Ro/SSA [21]. Only two SCLE patients had anti-nRNP in their sera, and a single patient had antibodies to Sm. An even tighter linkage of anti-Ro/SSA and DR3 has been observed by Bell and Maddison [32]. In their SLE population, all the anti-Ro/SSA patients (10/10) were positive for the DR3 antigen. The frequency of DR3 in their control populations was 26%. These data suggest that a set of genetic determinants (immune response genes) in the major histocompatibility complex is associated with the production of anti-Ro/SSA.

HOMOZYGOUS C2 = C4 DEFICIENCY

Further data supporting a genetic influence on anti-Ro/SSA production comes from the study of patients with homozygous C2 deficiency. Genes for C2 are known to reside in the major histocompatibility complex on chromosome 6. Antibodies to Ro/SSA were detected in 10 of 20 such C2-deficient sera and were the only precipitins detected. Interestingly, none of these patients produced anti-La/SSB, their sera containing only antibodies to Ro/SSA.

Of even greater interest is that of 12 of these patients with an SLE picture, 9 possessed anti-Ro/SSA and the remaining anti-Ro/SSA-positive patient had DLE. Therefore, all of the 10 homozygous C2-deficient, anti-Ro/SSA-positive patients were symptomatic [33]. Furthermore, 75% of the C2-deficient SLE-like patients were positive for anti-Ro/SSA. No asymptomatic C2-deficient patients were found to have precipitating antibodies to Ro/SSA.

SLE patients with C2 deficiency have a clinical picture very similar to that described for patients with ANA-negative SLE and SCLE described in preceding sections. They have extensive skin disease and polyarthritis; their sera often fail to have demonstrable ANA by indirect immunofluorescence when tested on mouse tissues and only 10% of such patients have antibodies to native DNA. The serologic link of ANA-negative SLE, SCLE, and SLE in C2-deficient patients is anti-Ro/SSA. As it is known that many homozygous C2-deficient patients studied thus far carry the A10, B18, DW2 haplotype, it appears that antibodies to Ro/SSA can be associated with either the DR2 or the DR3 antigen. Although much rarer, homozygous C4 deficiency is also associated with anti-Ro/SSA precipitins. Genes for C4 are also located on chromosome 6 [34].

NEONATAL SLE

It has long been known that in children who develop neonatal SLE, the major clinical features are dermatitis and complete heart block. Studies show that antibodies to Ro/SSA, La/SSB, or both have been found in virtually every child and mother examined in this clinical setting [35–40]. Dermatitis and anti-Ro/SSA disappear with the same time course, suggesting the possible participation of anti-Ro/SSA in the pathogenesis of the dermal lesion. Some of the mothers have not been clinically ill, and anti-Ro/SSA and anti-La/SSB have been demonstrated in their sera in the course of evaluating the clinical and serologic status of the children.

Long-term follow-up of the asymptomatic mothers who gave birth to children with complete congenital heart block (CCHB) reveals that a proportion develop Sjögren's syndrome and a smaller number develop SLE [41].

Three kinds of data implicate placentally transferred anti-Ro/SSA in the pathogenesis of CCHB: (1) the virtual uniform presence in the mothers and children with CCHB, (2) the selective depletion of anti-Ro/SSA in a child with CCHB whose asymptomatic fraternal twin had a serum level identical to the mother, and (3) the enrichment of anti-Ro/SSA in the acid eluate of the heart of a child who died with CCHB [43]. Demonstration of an idiotype characteristic of anti-La in myocardial fibers from a child who died with CCHB suggests that in some cases anti-La/SSB may also participate in the development of CCHB [44].

SEROLOGIC PHENOMENA IN SLE PATIENTS WITH ANTIBODIES TO RO/SSA AND LA/SSB

A number of serologic phenomena have been noted in SLE patients with anti-Ro/SSA, La/SSB, or both; these are listed in Table 2. Rheumatoid factors have been found in 30–40% of unselected SLE patients but are greatly enriched in SLE patients with anti-Ro/SSA, occurring in 75–80% of such patients [16]. This enrichment for rheumatoid factors in anti-Ro/SSA-positive patients may be another manifestation of the linkage antibodies to Ro/SSA form between SLE and Sjögren's syndrome. Further genetic and clinical associations have been noted in a group of patients with SLE–Sjögren's syndrome overlap [45, 46].

A striking linkage of antibody precipitin titers has been noted in SLE patients producing both anti-Ro/SSA and anti-La/SSB. Antibodies to Ro/SSA either equal or exceed La/SSB as determined by counterimmunoelectrophoresis. In 13 instances, the anti-Ro/SSA liters were observed to be greater than the anti-La/SSB titers. Since it has been shown that these precipitins are independent and one can be absorbed out without

TABLE 2 Serologic Phenomena Associated with Anti-Ro/SSA and Anti-La/SSB

1. Rheumatoid factor occurs in 75–80% of anti-Ro/SSA–positive SLE patients
2. In SLE patients producing both anti-Ro/SSA and anti-La/SSB precipitin, titers of anti-Ro/SSA are either equal to or greater than anti-La/SSB titers
3. Homozygous C2-deficient patients [33] and primary biliary cirrhosis patients [24] who produce anti-Ro/SSA have not been observed to have anti-La/SSB in their sera

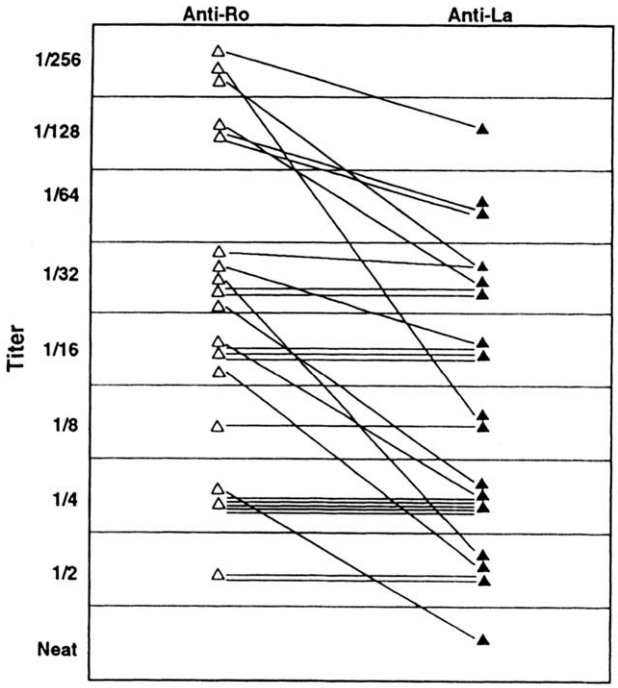

FIGURE 2 Quantitative titers of precipitating antibody to anti-Ro (△) and anti-La (▲) measured by counterimmunoelectrophoresis. Note that the titers to the two antibodies for each patient are connected by a line.

affecting the titer of the other, interesting questions have been raised about the joint regulation of the production of these antibodies. This has also been suggested indirectly by the facts that (1) patients producing both anti-Ro/SSA and anti-La/SSB rarely produce anti-DNA (in contrast to patients producing only anti-Ro/SSA) and (2) both C2-deficient SLE patients and those with primary biliary cirrhosis who produce anti-Ro/SSA (10 and 12 instances, respectively) have rarely been observed to produce anti-La/SSB. These data suggest not only joint regulation of the production of anti-Ro/SSA and anti-La/SSB in patients producing both antibodies, but also independent factors (possibly genetic) controlling the production of anti-Ro/SSA alone as opposed to the joint production of anti-Ro/SSA and anti-La/SSB [25]. This titer linkage is illustrated in Fig. 2.

MOLECULAR BIOLOGY OF RO/SSA AND LA/SSB ANTIGENS

Lerner *et al.* [11] launched a new era in the study of antigens reactive with the sera of patients with SLE and related diseases by a molecular biologic approach. Using intrinsically labeled RNA as the probe, they showed that anti-Ro/SSA and anti-La/SSB are directed to RNA protein particles. Anti-Ro/SSA is directed against cytoplasmic particles containing protein and five small RNAs, designated Y_1–Y_5, containing 80–140 bases. The Ro/SSA particle has been implicated in the discard pathway for 5S RNA [47].

The La/SSB/Ha antigen has proven interesting in at least two regards. Antibodies to La/SSB bind a particle containing a very heterogeneous set of small RNAs and protein from normal cells, but they also bind to an RNA particle containing V_A RNA, encoded by adenovirus, and Epstein–Barr virus-associated RNA particles $EBER_1$ and $EBER_2$, which are encoded by the Epstein–Barr virus [48]. In addition, it appears that anti-La/SSB reacts with predominantly nuclear particles whose RNA components are all products of RNA polymerase III, including pre-tRNA, pre-5S rRNA, and, as mentioned, certain viral transcripts. It may be that the La/SSB protein plays a special role in the processing of RNA that are products of RNA polymerase III [48, 49].

These studies suggest that the La/SSB protein is involved in RNA processing and perhaps that the anti-La/SSB response is a marker for previous viral infection. Of great interest in this regard will be the demonstration that the La/SSB protein is the same or different in normal and virus-infected cells. Should the La/SSB protein be the same in these two circumstances, binding of the relevant RNA protein conjugates in normal and infected cells by anti-La/SSB might simply reflect the uniform role of the La/SSB protein in processing certain RNA classes in both normal and infected cells.

HETEROGENEITY OF Ro/SSA ANTIGEN AND ANTI-Ro/SSA

It has become clear that sera with anti-Ro/SSA precipitins react with at least seven different molecules, some of which bind the HY RNAs and all of which bind autoantibodies in Western blot analysis. These are listed in Table 3, and a detailed discussion of these Ro/SSA molecules is given elsewhere [50]. There appear to be related but different 60-kDa Ro/SSA molecules in lymphocytes and red cells and a completely different set of related smaller molecules of 52 and 54 kDa in lymphocytes and red cells, respectively. In platelets, both 60- and 52-kDa forms of Ro/SSA are present and only HY3 and HY4 Ro/SSA RNA are found. Finally, a 47-kDa Ro/SSA molecule different from all of those just mentioned and related to calreticulin has been reported [51].

It is now thought that only the 60-kDa Ro/SSA molecules within nucleated or nonnucleated cells bind HY RNAs, and past perceptions of such binding by the 52- and 54-kDa forms of Ro/SSA were incorrect [50].

TABLE 3 Molecular Forms of Ro/SSA Antigen[a]

Tissue source	Molecular Mass (kDa)	RNA type
Lymphocytes, HeLa cells	60 52	HY1, 3, 4, 5
Red cells	60 54	HY1, 4
Platelets	60, 52	HY3, 4
Wil_2 cells (calreticulin)	47	HY1, 3, 4, 5

[a] See Reichlin [50] for details.

ANTIBODIES TO RIBOSOMES

Antibodies to ribosomes in SLE patients were first clearly demonstrated by precipitins in agar gel [52]. RNA and protein were both involved in the antigenic determinant(s), and all 11 patients had nephritis and severe disease. In that study, such precipitins were present in 11 of 85 SLE patients. In other studies, antibodies to ribosomes were demonstrated by bentonite flocculation [53] and a fluorescence spot test [54]. In these studies, 25 and 51% of SLE sera contained such antibodies, and in both instances, RNA and protein were both required for full antigenicity. In another study, purified ribosomal RNA was shown to react directly in precipitin reactions with some sera from SLE patients [55].

The most sensitive assay for antibodies to ribosomes has been developed by Koffler *et al*. [56], who reported on the use of intrinsically labeled HeLa cell polysomes in a Farr-type radioimmunoassay. Using this approach, 70% of SLE patients were found to have antibodies to ribosomes [56]. Sera from patients with RA and chronic active hepatitis contained antibodies to ribosomes in 24 and 27%, respectively, and the titers were lower than in SLE patients. More recently, the fine specificity of antibodies to ribosomes was examined by inhibition of the binding of labeled ribosomes to antibody by ribosomal ribonucleoprotein and free RNA [57]. The findings suggested that antibodies to ribosomal ribonucleoprotein correlated most closely with active disease.

ANTIBODIES TO THE RIBOSOMAL P PROTEINS

The first definition of a specific ribosomal polypeptide antigen was reported in 1985 when three related phosphoproteins, P_0, P_1, and P_2 of molecular masses 38, 19, and 17 kDa, were shown to be targets of autoimmunity in SLE patients [58]. An immunodominant 22 amino acid peptide was shown to be shared among these polypeptides [59], and an association was demonstrated between antibodies to the ribosomal P proteins and lupus psychosis [60]. A more recent report utilizing an assay employing the measurement of antibodies to the immunodominant carboxyl-terminal P peptide has shown an even closer association of ribosomal anti-P antibodies with depression in SLE patients [61]. In addition, such autoantibodies to the ribosomal P peptide were shown to occur in 15% of SLE patients [61]. Two additional findings of interest were that antiribosomal P antibodies fluctuated with the clinical neuropsychiatric diseases [60, 61] and that markedly less antiribosomal P antibodies was demonstrated in the cerebrospinal fluid than in the serum [61]. Definition of a specific reaction between a defined ribosomal protein has permitted elucidation of an important link between clinical neuropsychiatric disease and antibody to the ribosomal P proteins. These findings have sparked some controversy, and some studies, but not all, show this linkage between neuropsychiatric disease and anti-P proteins. These matters are the subject of an analytical review [62].

Three studies report new findings suggesting an association of ribosomal P protein with unexplained hepatitis [63, 64] and an even stronger association with lupus nephritis [64–66], an association foreshadowed in 1967 when precipitating antibodies to ribosomes were uniformly associated with the 11 patients who were first described with these precipitins, all of whom undoubtedly had antibodies to the ribosomal P proteins [52].

These latter findings take on added meaning now that it is clear that antiribosomal P antibodies bind to living cells in culture, penetrate these cells, and profoundly affect protein synthesis [67]. Antiribosomal P antibodies are the only specific autoantibodies characteristic of SLE that uniformly behave this way, although a subset of anti-dsDNA antibodies also behave this way [68]. Nonetheless, the ability of anti-P antibodies to bind a variety of living cells may position such autoantibodies uniquely to participate in immunopathogenesis of SLE.

SIGNIFICANCE OF THE AUTOIMMUNE RESPONSE TO CYTOPLASMIC CONSTITUENTS

In the most general sense, antibodies to cytoplasmic constituents in SLE patients are a part of the spectrum of autoimmune responses so characteristic of this disorder. Antibodies to nuclear antigens in SLE have received the greatest attention, but antibodies to both cytoplasmic constituents and lymphocyte membranes occur in a substantial number of patients. The

antibodies discussed in this chapter are part of a general autoimmune response in SLE patients to polynucleotides and protein polynucleotide conjugates. Clearly, however, in the case of antibodies to Ro/SSA and La/SSB, reactivity has only been demonstrated conclusively on the protein moieties of the RNA–protein conjugates known to possess antigenicity. In the case of antibodies to ribosomes, antigenicity resides in free RNA, on RNA–protein conjugates, and on the specific polypeptides P_0, P_1, and P_2.

Genetic factors clearly play a role in the production of anti-Ro/SSA and anti-La/SSB. Strong linkage of these antibodies to DR3 in SLE and to DR2 in homozygous C2 deficiency supports the idea that immune response genes are involved in the production of these antibodies. Are these genes responsible for loss of antigen-specific T suppressor clones, enhancement of antigen-specific T helper clones, or some other as yet unrecognized functional aspect of the D region on chromosome 6 that modulates immune function in SLE patients? Only further research can sort out these possibilities. Finally, the fact that antibodies to La/SSB bind viral-specific RNA–protein conjugates raises anew the possibility that viral infection may provide an etiologic trigger for some patients with SLE. Structural elucidation of the La/SSB protein in antigens derived from normal and virus-infected cells should shed light on this possibility.

There is no doubt that anti-Ro/SSA antibodies are linked to a subset of SLE patients with shared features described previously as ANA-negative SLE, SCLE, the SLE-like disease of homozygous C2 deficiency, and neonatal SLE. In addition, antibodies to ribosomes and Ro/SSA may participate in immune complex disease, and antibodies to the ribosomal P proteins may play a role in the pathogenesis of not only neuropsychiatric disease in SLE patients, but hepatitis and nephritis as well. One can expect further correlations of anticytoplasmic antibodies with disease expression in the future.

ANTIHISTONE ANTIBODIES

Robert L. Rubin

HISTORICAL PERSPECTIVE

Histone-reactive antibodies hold a preeminent position in the history of fundamental discoveries in autoimmunity. The first indication that autoimmunity may underlie diseases such as systemic lupus erythematosus is generally attributed to the observations of Hargraves *et al*. [1] on the lupus erythematosus (LE) cell phenomenon in which *in vivo* polymorphonuclear leukocytes (PMN) were deduced to have phagocytosed nuclear material derived from dead cells. This phenomenon was produced *in vitro* by Hamburger [2] and Miescher and Fauconnet [3] by mixing normal PMNs with SLE plasma. Holman and Deicher [4] showed that the responsible factor in SLE plasma was an antinuclear antibody (ANA) but not anti-DNA (as demonstrated by absorption experiments) and was capable of fixing complement when bound to nuclei [5]. Absorption of sera with calf thymus nucleohistone and histone–DNA complexes greatly reduced the LE cell phenomenon [6], suggesting that the fine specificity of this ANA was that of histone-reactive antibodies. LE cells have also been observed in drug-induced lupus (DIL) [7], a syndrome invariably associated with antihistone antibodies [8].

The necessity for the presence of histones in maintaining the antigenicity of nuclei for the LE cell factor was verified by a number of studies published in 1959. Holborow and Weir [9] demonstrated that these antibodies bound to spermatocyte nuclei, but after histones are replaced by protamines during the formation of mature sperm, antibody binding was no longer detected. The LE cell factor was absorbed out and could be eluted from a histone-containing, DNase predigested residue of nucleoprotein [4]; binding of antibody to nuclei was also not diminished after DNase pretreatment [10]. Direct demonstration of the antigenicity of free histones was obtained by Holman *et al*. [11] and Kunkel *et al*. [12] using a complement-depletion assay.

Much of the subsequent, older work on histone-reactive antibodies in SLE was restricted to histone-containing nucleoproteins. Complexes of histones with sonicated DNA were shown to form immunoprecipitins with SLE sera using classic Ouchterlony analysis [13]. Many SLE patients had complement-fixing anti-DNA and anti-(histone-DNA), which tended to increase along with clinical disease [14]. Various immunofluorescence patterns (rim, fibrillar, homogeneous) were attributed to antibodies to nucleoprotein [13, 14]. Over 50% of SLE sera had antibodies to soluble nucleoprotein that were not removed by absorption of sera with DNA [15], but the fine specificity of these autoantibodies was not determined until years later [16]. It was generally inferred from these early studies that antibodies that bind nucleoprotein are antibodies to histone–DNA complexes, and this specificity is equivalent to the LE cell factor. More recent studies by Hannestad *et al*. [17] and Rekvig and Hannestan [18] suggested that a complex of histones in the absence of DNA possessed antigenic activity for the LE factor. Precisely what specificities determine the LE factor activity have still not been completely resolved, although studies have demonstrated that antibodies to histone H1 are a major contributor [19]. Nevertheless, the recognition that LE cells in SLE and DIL are caused by histone-reactive antibodies not only led to numerous studies on the significance of these antibodies, but also

opened up the laboratory investigation of autoimmunity in general.

HISTONE STRUCTURE AND FUNCTION

Histones are normally found in eukaryotic cells associated with DNA, and this nucleoprotein is the major constituent of chromatin. Chromatin is insoluble in physiologic solutions, but histones dissociate from DNA in 2 *M* NaCl or dilute acid. Acid-solubilized histones are monomeric, and five major polypeptides can be distinguished by polyacrylamide gel electrophoresis (Fig. 1). These proteins can be separated by gel permeation chromatography [20], and individual histone classes can be purified readily on a preparative scale. The amino acid sequences of all five histones and numerous variants from many animals and plants have been determined [22, 23].

Primary Structures and Histone Variants

Histones H3 and H4 are two of the most conserved proteins in evolution [24]—bovine H3 and H3 from the pea plant differ by only 4 of 135 amino acids, and bovine and pea H4 are identical, except for two conservative amino acid substitutions. Human and calf H4 are identical, including the presence of three posttranslationally modified residues [25]. The primary structure of human spleen H3 is identical to calf thymus H3 except for serine in the place of cysteine at position 96 and for the presence of two minor variants in the human histone [26]. The primary structure of H2B also displays remarkable similarity in the C-terminal half of the molecule among a wide variety of animals, but considerable variation in the amino acid sequence of the N-terminal half of H2B has been detected within the animal kingdom [23]. However, human spleen H2B is identical with calf thymus H2B except for two minor variants in human H2B, each of which has a single amino acid substitution [27]. The entire molecule of H2A appears to be more highly conserved than H2B. Calf thymus H2A is identical to human spleen H2A except for a minor variant having a histidine deletion at residue 123 or 124 [28]. The vast majority of histone variants are identical among mammalian species, suggesting their importance in the biology of the cell. Because of this near identity between human core histones and the respective histones from calf thymus (the source tissue of choice for its high nuclear/cytoplasmic mass ratio), bovine histones can generally be considered as valid autoantigens for analyzing human autoantibodies.

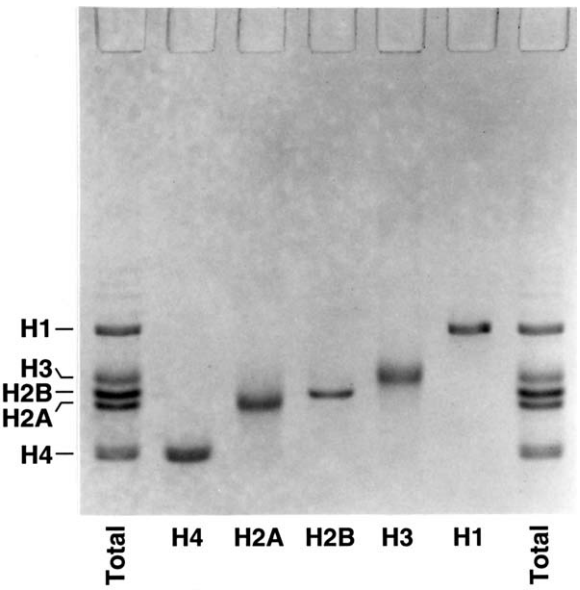

FIGURE 1 The five major histone classes. Total histones derived by the acid extraction of chromatin were separated by gel exclusion chromatography [20] and subjected to polyacrylamide gel electrophoresis [21].

The H1 class of histones is considerably more complex and heterogeneous. An internal segment of approximately 70 amino acids displays extensive homology among the animal H1 histones sequenced, but the N-terminal 40 residues and C-terminal half of the protein show substantial primary structure divergence [23]. H1 includes at least eight variants, which differ in primary structure (see later), and many of these, especially human [29–33], have only recently been sequenced. Mammalian H1° is present mainly in terminally differentiated, quiescent cells and shows extensive homology with histone H5, which is found in phylogenetically lower animals and is generally isolated from avian-nucleated erythrocytes. Human H1° and chicken H5 share eight essentially identical segments of 6–21 amino acids long if only one amino acid deletion, addition, or substitution is allowed per segment [31]. However, these histones show less than 10% homology with the main H1 class [34]. The nomenclature for the H1 family of histones has not been formally standardized, so structural comparisons between species are presently ambiguous. However, all the H1 histones, including H1° and H5, share a nearly identical 16 amino acid long region in the globular domain (human H1.1 94–108, human H1.2 91–105, human H1° 79–94, bovine H1.1 91–106, chicken H5 80–95), as well as a highly conserved octapeptide in the C-terminal domain (human H1.1 151–158, H1.2 153–160, and H1° 152–159, chicken H5 148–155) [33]. Although extensive antigenic cross-reactivity can be expected among H1 variants within an

animal and between species, the complexity of this histone class and the difficulty in physically separating and identifying these variants presently confounds the interpretation of studies involving antibody to the H1 family of histones.

The different histone classes have very limited amino acid sequence similarities [35, 36], but these may account for some cross-reactions among antihistone antibodies. H2A shows homologies with H4, H2B, and H3, each in different parts of the H2A molecule, an octapeptide in H3 is similar to a decapeptide in H4, and H3 and H2B share an identical tetrapeptide (see Rubin [37] for exact sequence). Although all the histones are rich in basic amino acids, especially in their amino-terminal regions, extensive, uninterrupted strings of such residues are generally not observed. A pentapeptide in H2B and H4 consisting of only basic amino acids can be found, but an array of greater than three lysine, arginine, or histidine residues does not occur in any histone, including H1. This may explain why naturally occurring antihistone antibodies display only weak or negligible cross-reactivity with basic homopolypeptides.

Within each class of histones, numerous subtypes or variants have been identified [38]. Variants occur among different species as well as within a species, such as between stages of development, among different tissues, and even within a homogeneous cell type. This heterogeneity in primary structure can be the result of transcription from multiple genes for a histone class with slightly different coding sequences or due to postsynthetic modifications. Posttranslational modifications occur on only a portion of the total histone pool of a cell or tissue, resulting in a variety of subtypes being present simultaneously. Phosphorylation occurs on certain serine residues of all histones, threonine on H3 and H1, histidine on H4, and lysine on H1. H1 is phosphorylated extensively during the S phase of cell division [39]. From two to four lysine residues may be acetylated in histones H3, H4, H2A, and H2B, as is the amino terminus of H2A, H4, and H1 [39]. A portion of all the histones is methylated at certain lysine residues and probably at the guanidine nitrogen of arginine. Poly(ADP-ribose) has been found covalently linked to H1, and ADP-ribose was present on up to 15% of H2B when nuclei were incubated *in vitro* with ^{14}C-NAD^+ [40, 41]. However, definitive evidence for ADP-ribosylation of histones *in vivo* is lacking [38]. Approximately 10% of calf thymus H2A (and 1% of H2B) is covalently associated at lysine 119 with ubiquitin, a protein of 76 amino acids, resulting in a variant of H2A possessing an electrophoretic mobility equivalent to twice the size of the parent molecule [42–44]. As mentioned earlier, there are at least six H1 variants in addition to H1° and H5, some of which have been identified only by deduction from the nucleotide sequence of cloned genes. The significance of the H1 variants has been the subject of intensive study for years and appears to be related to the role of H1 in affecting the higher order structure of chromatin (see the following section) and consequently the overall transcriptional activity of the genome.

Clearly, very subtle variants as well as highly altered forms of histones have been identified among higher organisms. Even single amino acid differences in histone variants could potentially be recognized immunologically [45], and many of the side chain modifications of histones are biochemically profound. Phosphorylation introduces a charge, lysine acetylation neutralizes a charge, and poly(ADP-ribose) or ubiquitin is obviously a very bulky modification. Autoantibodies to poly(ADP-ribose) [46] and to ubiquitin [47] have been reported, but because these modifications are found on many other proteins, their relationship to antihistone antibodies is unclear. The significance of posttranslationally modified histones as well as of the variants with different amino acid sequences in the elicitation of antihistone antibodies or the antigenicity of the targeted histones is unknown.

Higher Order Structure Comprising the Nucleosome

Histones are not randomly associated with DNA in chromatin but are organized into a well-defined subunit called the nucleosome [48–51]. The nucleosome consists of two molecules of each of the "core" histones, H2A, H2B, H3, and H4, along with one H1 molecule, and DNA of approximately 200 bp in length. DNA of 146-bp-long wraps with 1.75 superhelical turns around an octamer of histones H2A, H2B, H3, and H4, and this core particle is connected to the adjacent core particle by the linker segment of DNA. Histones H1 or H5 appear to bind close to the exposed face of one of the two H2A molecules, creating asymmetry in the nucleosome that provides a ramp where DNA exits and is directed to the adjacent nucleosome [52]. The amount of linker DNA shows wide interspecies and even intertissue variation so that nucleosomes may contain from 166 to 231 bp of DNA. The linear array of nucleosomes held together by a continuous strand of approximately 2×10^7 bp of DNA forms the primary chromatin fiber of approximately 100 Å in diameter. This thin filament has a tendency to supercoil into higher order solenoid-like structures of increasing diameter [53], compacting the DNA 5000- to 10,000-fold as depicted in Fig. 2. In a typical chromosome, approximately 7 m of DNA is condensed to 1 μm by the organizing capacity of about 100,000 nucleosomes.

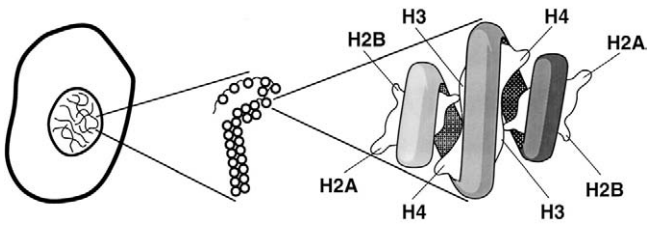

FIGURE 2 Higher ordered structure of histones in chromatin. (Right) A diagrammatic representation of the core particle of the nucleosome in which two turns of DNA wrap around an octamer of histones consisting of two H2A-H2B dimers flanking an H3-H4 tetramer. Separation of dimers from the tetramer is exaggerated for clarity—the native core particle is a compact structure stabilized by noncovalent bonds [54, 55]. Association with H1 completes the nucleosome, and an array of polynucleosomes supercoil into a solenoid-like structure depicted in the middle diagram. Additional supercoiling into even higher ordered structures is presumed to take place until chromatin fibers are eventually visible in the light microscope as mitotic chromosomes.

The natural tendency of histones to interact with each other is of fundamental importance in the generation of the core particle. A tetramer of histones H3 and H4 is stable under physiologic conditions, as is a dimer of H2A and H2B, and the H3–H4 tetramer can be readily separated from the H2A–H2B dimer by ion-exchange chromatography on carboxymethylcellulose [56]. Two H2A–H2B dimers and the H3–H4 tetramer self-assemble to form an octamer, stable at high salt concentration. The octamer stability is due largely to contacts of residues 16–25 and 71–92 of the two H4 molecules in the H3–H4 tetramer with residues 76–97 of H2B in each H2A–H2B complex, but other interactions occur within the octamer, including H3–H2A′, H4–H2A′, H2A–H2A′, and H2B–H2B′ [55]. All the histones participate in limited contacts with DNA at 10-bp intervals whenever the minor grove of the double helix faces the histone core [57–59], resulting in 14 regions on the twisting DNA anchored to arginine side chains of the histones [55]. These multiple interactions account for the stability of the nucleosome and constrain the DNA to curve tightly around the octamer. As discussed later, the discovery of autoantibodies specific to certain histone–histone and histone–DNA complexes suggests that histones in the form of nucleosomes drive these autoimmune responses.

Domain Structure of Histones

Histones in chromatin (but not the individual proteins) show a remarkable resistance to trypsin digestion considering their high content of lysine and arginine, the amino acids immediately N-terminal of the specific cleavage site of trypsin. The trypsin-resistant "limit digest" products can be separated by sodium dodecyl sulfate (SDS) gel electrophoresis, and their compositions are shown in Table 1. Because similar polypeptide products are observed after trypsin digestion of nuclei, chromatin, or core particles but not of histones in low ionic strength environments, resistance is attributed to the protection of potential cleavage sites by the tertiary or quaternary conformation of the histones in the nucleosome. DNA does not afford principal protection of histones from trypsin because the DNA-free octamer in 2 *M* NaCl displays a similar resistance to trypsin digestion. [In fact, the trypsin-sensitive sites are the highly positively charged regions believed previously (incorrectly) to be bound stably to the DNA phosphates: the 11–30 amino acid residues of the N-terminal ends of the four core histones and the C-terminal 11 residues of H2A and six residues of H3.] Biophysical studies on trypsinized core particles indicate that they are largely indistinguishable from their native counterparts [61]. The trypsin-sensitive tails are highly mobile with no stable conformation or binding sites on DNA, although they have been suggested to provide relatively nonspecific electrostatic shielding of DNA phosphates, stabilizing the higher order chromatin structure [62]. Apparently, these domains are accessible to the enzymes involved in histone posttranslational modification because almost all the sites for phosphorylation, acetylation, methylation and ubiquitination are at the trypsin-sensitive regions. It has also been claimed that these domains comprise the predominant epitope for antihistone antibodies in SLE, but as discussed in a later section, this is an oversimplification.

The protruding histone tails may make contact with DNA and/or histone of the adjacent nucleosome, and a candidate site of interaction between a seven acidic residue region on the outward face of the H2A–H2B

TABLE 1 Structural Domains within Histones[a]

Histone	Number of residues in parent molecule	Major trypsin-resistant domain	
		Residue number	Designation
H3	135	27–129	P1
H2A	129	12–118	P2′
H2B	125	21–125	P2
		24–125	P3
H4	102	18–102	P4
		20–102	P5
H1	212–222	36–121	P0 (G-H1)

[a] Compilation is based on Böhm and Crane-Robinson [60] and refers to calf thymus histones. Histones are arranged in order of increasing electrophoretic mobility of the trypsin-resistant domain.

dimer and the amino-terminal tail of H4 from the adjacent nucleosome has been identified [55]. These kinds of interactions may "lock" the DNA into a higher order structure (Fig. 2) that suppresses transcriptional activity. Transcription factors associated with histone acetyltransferase activity can add acetyl groups to the protruding histone tails, disrupting this compact structure, thereby allowing access to transcriptional machinery [63].

All the H1 variants, including H5 and H1°, bear a similar three-domain structure as described previously. The highly conserved central globular domain is involved in the critical function of redirecting the DNA as it exits the core particle, and the flanking regions, which are rich in the basic amino acids arginine and lysine, presumably play a role in internucleosomal interactions involved in chromatin condensation into higher order structures [52]. Histone H5 possesses an unusually large arginine-rich C-terminal domain believed to condense chromatin to the transcriptionally inactive form present in avian erythrocytes. The otherwise closely related H1° retains lysines in the C-terminal domain characteristic of the main H1 family, but is associated with chromatin in terminally differentiated cells, which have only selected genes that are transcriptionally active. The highly conserved 16-mer in the globular domain and octamer in the C-terminal region of all members of the H1 family are presumably involved in critical structural/functional roles. Although autoantibodies to H1 have been frequently reported (see later), the domain structure and the complexity of the H1 family complicate interpretation of these data.

ASSAYS FOR ANTIHISTONE ANTIBODIES

The measurement of antihistone antibody has had a tortuous history. Application of conventional immunoassay techniques such as Ouchterlony immunodiffusion, immunoprecipitation, or Farr ammonium sulfate assay for detection of antihistone antibodies is complicated by the tendency of histones to aggregate and to interact with nonimmune IgG and IgM and other serum proteins such as α_2-macroglobulin [64]. The quality of histones used as antigens is highly variable, and commercial sources are often degraded or contaminated with nonhistone proteins. Inhibition of endogenous proteolysis during histone isolation is necessary to obtain intact histones, as shown in Fig. 1. Complete sets of individual histones or of subnucleosome complexes are not widely available commercially and require a biochemistry laboratory for preparation. It is difficult to remove all traces of DNA, a serious problem when assessing sera that may also contain anti-DNA antibodies. In addition, the propensity for histones to bind DNA in biological fluids can result in artifacts such as false-positive reactions with anti-DNA antibodies (see later).

The first assay for antihistone antibodies was an adaptation of the microcomplement fixation method using lysis of sensitized red blood cells as the indicator [12, 65]. Antihistone antibodies were reported to be infrequent in SLE using this assay [66] and reactive predominantly with histone H1, although a few sera displayed binding to all histones [65]. It was also inferred from these and other studies [13–15, 67] that a complex of histones with DNA was required to generate antigenicity. The stringent requirements of this assay [68], the procomplementary nature of histones [69], and its apparent insensitivity [64] have led to abandoning the complement fixation assay for detecting antihistone antibodies.

An immunofluorescence procedure was modified to render it specific for histone-binding antibodies [70]. Histones can be extracted from mouse kidney tubule nuclei by 0.1 *N* HCl, preventing the binding of antihistone antibodies. The histone content of such nuclei can be partially "reconstituted" by incubation with a histone solution. Sera with antihistone activity display binding to histone-reconstituted nuclei and to untreated mouse kidney but not to acid-extracted sections. This assay is highly specific for antihistone antibodies but cannot be used with sera that contain anti-DNA antibodies, which display background binding to acid-extracted nuclei. Furthermore, sera with antihistone activity predominantly to H3 and H4 displayed negligible reaction in the immunofluorescence assay [71, 72], presumably because of the failure of these histones to bind to DNA with this technique. Thus, the immunofluorescence assay is largely selective for antibodies reactive with H1, H2A, and H2B and may preferentially detect epitopes requiring a histone–DNA complex.

Solid-phase assays have largely replaced conventional assays for antihistone antibodies. Histones, histone complexes, and chromatin adsorb readily to polystyrene, and antibody binding can be quantified with a class-specific enzyme-, fluorescent-, or radiolabeled anti-immunoglobulin. The first solid-phase assays detected antibodies to histones raised in rabbits [73, 74], in human SLE [72, 75, 76], and in murine lupus [77]. Most studies on antihistone antibody in the past decade have relied on purified histones in solid-phase enzyme-linked immunosorbent assays (ELISA) or on immunoblots (Western blots) of histones separated by SDS polyacrylamide gel electrophoresis. Subnucleosome structures have also been adapted to

ELISA formats [78], which allow measurement of autoantibodies requiring these higher ordered structures.

PREVALENCE AND SPECIFICITY OF ANTIHISTONE ANTIBODIES

Overall Disease Association

Reports of antihistone antibodies in various diseases are listed in Table 2. Although antihistone antibodies have been observed in a variety of (generally rheumatologic) diseases, most of the studies have focused on SLE or DIL. Reported prevalences ranged from 17 to 95% in SLE (average = 51%) and 67 to 100% in DIL (average = 92%). Antihistone antibodies have also been consistently observed in rheumatoid arthritis (RA) (average prevalence = 11%) and juvenile rheumatoid arthritis (JRA) (average prevalence = 51%). RA patients with ANA were two to seven times more likely to have antihistone antibodies [110–112] than ANA-negative RA patients. Other than SLE in which other ANA commonly coexist, the bulk of the ANA in sera with antihistone antibodies is probably due to these antibodies, although this relationship has been formally demonstrated only in DIL and drug-induced autoimmunity [133].

Limited studies on antihistone antibodies in various other syndromes have appeared. In some cases, remarkably high prevalences of antihistone antibodies were observed, especially in primary biliary cirrhosis [124, 125], autoimmune hepatitis in all immunoglobulin classes [127], ANA-positive neoplastic diseases [109], RA-related diseases, and patients with undifferentiated connective tissue disease who develop predominately IgM anti-H3 producing a variable large speckled ANA pattern [134, 135]. Antichromatin antibodies were reported in 53% of patients with autoimmune hepatitis type I [136]. In addition to DIL, there have been isolated case reports of unusual antihistone antibodies such as anti-H1° in patients with sensory neuropathy [137, 138] and antibody to chymotrypsin-digested H2B in a patient with vasculitis [139]. However, antihistone antibodies have generally not been observed in signifi-

TABLE 2 Reported Prevalences of Histone-Reactive Antibody in Human Disease

Disease/syndrome	Method[a]	Prevalence[b]
Systemic lupus erythematosus	IF	24% [79], 35% [8], 46% [80]
	RIA	48% [75], 55% [81]
	FIA	83% [82]
	ELISA	8%(M) [83], 17% [84], 21%(G) [85], 27%(G) [83], 28%(M) [86], 36% [87], 42% [88], 43%(G) [89], 43%(M) [90], 44% [76], 45%(G) [91], 50%(G) [92], 52% [93], 52% [94], 55%(G) [90], 57%(G) [95], 57% [96], 60% [97], 61% [98], 68%(M) [16], 74% [99], 77% [100], 80%(A) [86], 84%(G) [86], 8%(G) [16], 95% [101]
	WB	38%(M) [90], 46% [102], 52% [103], 53%(G) [90]
Drug-induced lupus	IF	67% [104], 96% [8]
	RIA	100% [71]
	ELISA	82% [101], 100% [88], 100% [105], 100% [106], 100% [107]
Drug-induced ANA	ELISA	22% [88], 24% [108], 39% [109], 67% [105], 81% [106], 79–95% [107]
Rheumatoid arthritis	IF	8% [109], 14% [110], 24% (ANA+) [110], 36% [80]
(RA)	ELISA	0% [91], 5% [87], 5% [98], 5% [97], 9% [83], 11% [100], 13% [111], 33% (ANA+) [111], 80% (ANA+) [112]
RA-vasculitis	FIA	75% [82]
RA-Felty's	ELISA	79% [111]
Juvenile RA	ELISA	44% [113], 48% [114], 72% [115], 72% [116, 117], 75% [118]
	WB	42% [119], 47%(G) [120]
Inflammatory bowel disease	ELISA	13–16%(G anti-H1) [121]
Neoplastic diseases	ELISA/IF	14% [122], 17–78% (G anti-H2B) [123], 79% (ANA+) [109]
Primary biliary cirrhosis	ELISA	50% [124], 60% [125], 81% [94]
Liver cirrhosis/hepatitis	ELISA	35% [126], 40% [127], 50% [124]
Scleroderma disorders	ELISA	29–44% [128], 42% [129], 47% [130], 62% [131]
Poly/dermatomyositis	ELISA	17% [132]

[a] A, IgA antibodies; ANA, antinuclear antibody; ELISA, enzyme-linked immunosorbent assay; FIA, solid-phase fluorescence immunoassay; G, IgG antibodies; IF, histone reconstituted immunofluorescence assay; M, IgM antibodies; RIA, solid-phase radioimmunoassay; WB, Western (immuno-)blot.

[b] Elevated IgG and/or IgM antibody to total histone or to at least one histone class.

cant prevalences in other rheumatic diseases, including Sjögren's syndrome, progressive systemic sclerosis, and mixed connective tissue disease; a low prevalence of predominately anti-H1 antibodies has been reported in patients with dermatomyositis/polymyositis [132]. However, reports have found antihistone antibodies in a substantial proportion of patients with scleroderma-related disorders [128, 130, 131, 140], especially localized scleroderma with generalized morphea [129, 130]. In addition, anti-H2B antibodies were reported in over half of HIV+ patients with persistent lymphadenopathy [141] or patients with squamous cell carcinoma [123], but these results have not been reproduced. Although approximately 11% of patients with RA have antihistone antibodies, these tend to be low level (low titer). Therefore, most studies have concentrated on antibodies in DIL, drug-induced ANA, and SLE, diseases in which antihistone antibody levels are generally high.

The basis for the discrepancies in the reported prevalences of antihistone antibodies shown in Table 2 is probably multifactorial. Certainly, methodology can affect both sensitivity and specificity of the immunoassay. For example, the immunofluorescence histone reconstitution assay tends to produce false negatives because of its insensitivity to antibodies reacting with histones H3 and/or H4 or with epitopes that are blocked by DNA as discussed previously. Thus, this assay cannot detect some antihistone antibodies in hydralazine-induced lupus, whereas these antibodies can be detected readily in solid-phase and Western blot assays using DNA-free histones [71, 72, 142–144]. Methodological differences among the various studies include the nature of the detecting reagent (polyvalent vs immunoglobulin class-specific vs protein A from *S. aureus*, which selects predominantly IgG1, IgG2, and IgG4), serum dilution, and quality and quantity of the antigen on the solid phase. A collection of normal human sera generally establishes the cut-off value used to assign an experimental sample to a positive category, but borderline values are always difficult to interpret in quantitative immunoassays and these low-level reactivities may sometimes be due to increased nonspecific binding as a result of elevated γ globulins commonly observed in sera from patients with rheumatic diseases. Antibody binding to histones appears to be more prevalent in elderly, healthy people [145], making the need for aged-matched controls important. Finally, ethnic or regional genetic differences in the patient samples, diagnostic criteria for patient selection, or the therapeutic regimen (especially the use of corticosteroids, which may suppress immune responses) can account for discrepancies. Considering these potential variables and excluding the extreme reports, there is fairly good agreement on the prevalence of antihistone antibodies in various human diseases.

TABLE 3 Prevalence of IgG Anti-[(H2A-H2B)–DNA] in Idiopathic and Drug-Induced Lupus

Disease	Prevalence of anti-[(H2A-H2B)–DNA]
SLE, Oriental sample, untreated	70% [16]
SLE, American samples, treated	59% [16], 31% [131]
Procainamide-induced lupus	96% [107, 146]
Lupus induced by penicillamine, isoniazid, acebutalol, methyldopa, timolol, sulfasalazine	Very common[a] [146–151]
Quinidine-induced lupus	53% [107, 146]
Hydralazine-induced lupus	43% [107]

[a] All patients with lupus induced by these drugs had anti-[(H2A-H2B)–DNA] reactivity, but few patients have been tested because lupus induced by these drugs is rare.

In addition to the occurrence of antibodies reactive with isolated histones, patients with lupus-like disorders commonly have autoantibodies to histone–DNA complexes, and the (H2A-H2B)–DNA complex largely accounts for reactivity to these higher order structures in chromatin. Table 3 summarizes this information. Anti-[(H2A-H2B)–DNA] antibodies were found in over two-thirds of untreated (Oriental) patients; a somewhat lower prevalence and titer were observed in (American) SLE patients under medication [16]. Anti-nucleosome (and anti-nDNA) appear to be particularly sensitive to corticosteroid therapy [152]. Most patients with lupus induced by procainamide, penicillamine, isoniazid, acebutolol, methyldopa, timolol, and sulfasalazine also have strong reactivity with the (H2A-H2B)–DNA complex, although a substantial number of patients have only been examined with lupus induced by procainamide. Drug-induced lupus related to quinidine and hydralazine was associated with anti-[(H2A-H2B)–DNA] in 53 and 43%, respectively.

The overall relationships among these histone-dependent antibodies are depicted in Fig. 3 and are detailed further elsewhere [153]. In SLE, antibodies requiring native forms of nucleohistone dominate the autoantibody serology, although antibodies to DNA-free histones (really anti-*denatured* histone antibodies) are commonly present at lower titer. Antichromatin (which is synonymous with antinucleosome) antibodies were found in 72 to 88% of SLE patients from three separate sources [16, 155, 156], although the prevalence of this type of serological abnormality in SLE ranged from 31 to 56% in three other studies [131, 157, 158]. Anti-[(H2A-H2B)–DNA] antibodies are a major component of antichromatin, and antinative (n) DNA antibodies can be considered a subset of the antichromatin response. Drug-induced lupus is more restricted to

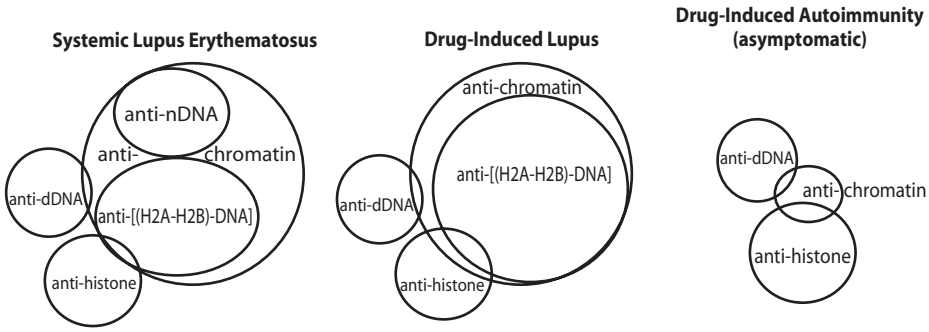

FIGURE 3 Venn diagrams depicting relationships among the major autoantibodies to chromatin components in patients with SLE, DIL, and DIA. Not included are antibodies to high-mobility group proteins, which are present in the three patient groups [91, 154], as well as other important autoantibodies in SLE that react with antigens not stably bound to chromatin. In contrast to epitopes for antinative DNA antibodies (anti-nDNA), epitopes on denatured DNA (dDNA) and some individual histones are probably not expressed on truly native chromatin. However, some of these antibodies may bind chromatin because of localized denatured regions or partial degradation of isolated chromatin.

antichromatin, as anti-nDNA (and other types of autoantibodies) are generally absent. Anti-[(H2A-H2B)–DNA] largely accounts for the antichromatin activity, and, as in SLE, anti-(denatured) histone antibodies are often present at lower titer. In patients who remain asymptomatic during treatment with lupus-inducing drugs, chromatin-reactive antibodies rarely develop and antihistone antibodies account for the bulk of the autoimmune serology. Antibodies to denatured (d) DNA are common in all forms of lupus (and in asymptomatic, drug-treated patients), and these antibodies generally do not bind chromatin unless it contains regions of single-stranded DNA.

Associations with Clinical Disease Activity and Symptoms

Systemic Lupus Erythematosus

Studies on the association of antihistone antibodies with disease activity or severity, with the predominant organ system affected, or with specific clinical features have been inconsistent. Some reports showed no association between the presence or the amount of antihistone antibodies and any measure of disease activity [80, 82, 85, 88, 152, 159] with the exception of a history of photosensitivity in one report [82]. However, in one of the earliest reports on histone-reactive antibodies, Rothfield and Stollar [14] observed that 14 out of 15 patients with active lupus contained antibodies to histone–DNA complexes, whereas only 4 of 26 patients in remission had these antibodies. Subsequently, associations of antihistone antibodies with active disease were observed with solid-phase [93] and histone-reconstituted immunofluorescence assays [109]. The presence of anti-[(H2A-H2B)–DNA] antibodies was significantly correlated with glomerulonephritis [16, 160] and the antihistone antibody level with the renal activity score [95], supporting the older study on association with renal manifestations [14]. Population correlations of the presence of antihistone antibodies with neuropsychiatric involvement [79], skin and joint symptoms [92], or overall disease severity have been reported [86]. However, no quantitative association has been observed between the level of antihistone antibodies and any specific array of clinical symptoms or the overall disease activity. Perhaps variants of SLE characterized by increased disease severity commonly display antihistone antibody because of the general linkage between symptoms and signs in SLE. This view is supported by the association of antihistone or antinucleohistone antibodies with antibodies to native DNA [85, 95, 97, 161], a well-established correlate of disease activity. Taken together, these studies indicate that antihistone antibodies are generally not a useful independent parameter for the clinical form or the activity of disease in SLE, but high levels of antihistone antibodies tend to be linked with active disease.

Drug-Induced Lupus

Rheumatologic symptoms associated with DIL are strongly correlated with the presence of IgG anti-[(H2A-H2B)–DNA] antibodies (Table 3 and Rubin [162]). In contrast, patients remaining asymptomatic for lupus-like disease during treatment with procainamide or chlorpromazine [107] or isoniazid [108] develop antihistone antibodies that are generally inhibited by DNA.

Thus, although antibodies to total histones and to non-native preparations of H2A-H2B do not show a strong correlation with symptomatic drug-induced lupus [106, 163, 164], IgG antibodies to the native H2A-H2B complex [106], especially when bound to DNA [107], are highly correlated with symptomatic disease. In fact, anti-(H2A-H2B) has been observed to precede overt clinical symptoms and therefore may have predictive as well as diagnostic value [165, 166]. Anti-(H2A-H2B) has a sensitivity of 100% and a specificity of >90% for symptomatic procainamide-induced lupus compared to asymptomatic procainamide-treated patients [106] and an even higher specificity when an (H2A-H2B)–DNA complex is used as the screening antigen [107].

Rheumatoid Arthritis

RA patients with antihistone antibodies did not display more active disease than antihistone antibody-negative RA patients [112]. However, in Felty's syndrome, which is considered to be a severe form of RA, antihistone levels were considerably higher than in non-Felty's RA, especially of the IgG isotype [111].

Juvenile Rheumatoid Arthritis

Antihistone antibodies were reported in 93% [114] and 67% [120] of JRA patients with uveitis compared to 33% of patients without uveitis [114]. However, associations with uveitis were not observed in other studies [113, 119, 167], although patients with uveitis (active or inactive) tended to have higher levels of antihistone antibody compared to those JRA patients with no history of uveitis [118]. Antihistone antibodies tended to be more common in pauci- or poly-articular types of JRA compared to systemic onset JRA [119, 120]. These antibodies react preferentially with DNA-free histones [115, 167], similar to those in asymptomatic drug-treated patients, so may not contribute substantially to the ANA commonly occurring in these children.

Isotypes of Histone-Reactive Antibodies

Antihistone antibodies can be found in all the major immunoglobulin classes in patients with SLE, but as discussed in detail [37], there is little agreement as to the predominant isotype. There appears to be a significant correlation between the amount or at least presence of IgG (but not IgM) antihistone antibody and overall clinical disease activity [83, 86], although there was no correlation between isotype and predominant organ system involvement [86]. The isotype profile tended to remain constant over time [81] and for IgG antibodies consisted mainly of IgG1 and IgG3 with notably negligible amounts of the IgG2 antihistone antibody [81, 168]. IgG1 and IgG3 are strong complement-fixing subclasses, implicating these antihistone antibodies in pathogenic processes. A broader distribution of the IgG subclasses was observed in drug-induced autoimmunity in which antihistone activity commonly occurred in all four IgG subclasses [168]. These patients, as well as patients with frank drug-induced lupus, are more likely than SLE patients to have IgG, IgA, and IgM antihistone and anti-[(H2A-H2B)–DNA] antibodies. These autoantibody isotypes often appear to arise simultaneously during procainamide treatment, although patients who remain asymptomatic fail to develop *IgG* anti-[(H2A-H2B)–DNA] [166]. Interestingly, as treatment with the lupus-inducing drug continued, a gradual shift to predominantly IgG1 antihistone antibodies occurred [168], similar to the isotype profile in idiopathic SLE. The substantial IgA autoantibody levels in procainamide [166]- and isoniazid [108]-treated patients is remarkable, suggesting induction of autoantibody synthesis within the gastrointestinal mucosal immune system where drug concentration is presumably highest. The rather slow development of autoantibodies, the apparent concordance of IgG, IgA, and IgM isotypes, and the perpetuation of IgM autoantibodies for many years in asymptomatic, procainamide-treated patients suggest that the mechanism underlying drug induction of autoantibodies is unlike a classical immune phenomenon.

Fine Specificities of Autoantibodies to Individual Histones

Histone heterogeneity and chromatin structure (see the previous section on *histone structure and function*) raise the possibility that useful information may be derived from examining antibody activity to individual histones, domain regions within individual histones, or to subnucleosome particles. Most studies have focused on the five major histone classes, although antibody activity to histone variants such as H1° [137], H5 [120], and ubiquitinated H2A [169] has been reported. The methods employed have been either analytical separation of total histones by gel electrophoresis followed by Western blot or ELISA using biochemically purified histones or histone complexes.

Data on antibody activity to a panel of histones have been reported in various ways. In many studies, antibody binding to each histone is averaged over the entire sample of patients. More informative is the profile of reactivity of individual patients with a panel of histones. The former analysis results in information on the average prevalence or level of antibody activity to the tested histones in a patient sample. In general, SLE

TABLE 4 Antibodies to Histone Classes in Individual Patients[a]

Disease	Method	Immunoglobulin class	Histone class reativity (ranking order)	Ref.
SLE	ELISA	G, M	Variable	75, 90, 99, 170
	ELISA	G	H2B ≥ H2A > H3 = H4	91
	WB	Undefined	H1 = H2B > H4 > H3 > H2A	102, 103
	FIA	Undefined	Variable	82
	WB	G, M	H1 = H2B = H3 > H2A = H4	90, 142
	ELISA and WB	G	Variable H1 = H2B > H2A > H3 > H4	92
DIL-PA	RIA/ELISA	G	H2A-H2B	71, 105, 106
	WB	Undefined	Complex > > H2A = H2B	143
	WB & ELISA	Undefined	H2B > H3 = H1 > H4 = H2A H2A-H2B Complex > H2A = H2B > H4	142
DIL-HY	FIA	Undefined	Variable	144
	WB	Undefined	H3 > H2B = H2A = H1 > H4	143
	WB and ELISA	Undefined	H3 > H4 > > H2B > H2A	142
DIA-PA	ELISA	M	Relatively uniform	105, 170

[a] Abbreviations as in Table 2; DIL-HY, hydralazine-induced lupus; DIL-PA, procainamide-induced lupus; DIA-PA, procainamide-induced ANA in asymptomatic patients.

patients with antihistone antibodies tended to have antibody to all histones, especially H1 and/or H2B [82, 89, 91, 92, 97, 101, 102, 144]. However, there has been only modest agreement within these studies in that anti-H1 [89, 144] or anti-H2B [159] was sometimes observed to be a minor antibody or that other histones, especially H3 [82, 83, 89], were major antigenic targets for antihistone antibodies in SLE sera. Biases in assays, differences in patient population, and small sample size contribute to these discrepancies. Furthermore, patient-to-patient variability is obscured by this type of analysis.

Table 4 summarizes the reported average profiles in individual patients of antibody activities to a panel of histones. The aforementioned predominance of anti-H1 and anti-H2B in SLE can be observed in the patient profiles of only half the reports; the other studies showed no particular profile because of substantial patient-to-patient variability. Many of these studies used a nonclass-specific immunoglobulin-detecting reagent, adding additional ambiguity because the specificity of antihistone antibodies may depend on the immunoglobulin class being examined. Considerable disagreement on the characteristic antihistone antibody profile in DIL is also apparent (discussed in Rubin [37]). With procainamide-induced lupus, a discrete profile of reactivity was only discernible when the dimer of histones H2A and H2B was included as a test antigen, although reactivity with the H2A-H2B complex may also be due to antibody binding to the individual, constituent histones [163, 164].

H2A and H2B

There is good agreement that antibody to H2A and/or H2B in most SLE sera does not bind in Western blot to the large trypsin-resistant domain of these histones (Table 1). Thus, only 15% [142], 8% [101], and 0% [171] of SLE sera with anti-H2B retained activity on the C-terminal H2B polypeptide [21–125), i.e., when the N-terminal 20 amino acids were removed. Direct evidence that the N-terminal region of H2B contained a predominant epitope was obtained by Hardin and Thomas [102], who showed that 63% of sera with anti-H2B reacted with the N-terminal cyanogen bromide polypeptide (1–59), whereas there was no reactivity with the C-terminal (63–125) polypeptide. Studies on monoclonal anti-H2B antibodies from the lupus-prone MRL/*lpr* mouse also demonstrated predominant reactivity with the amino terminus of H2B [172]. Similarly, removal of the N-terminal 11 and C-terminal 11 amino acids from H2A reduced its antigenicity dramatically so only 20% [101] 15% [142], and 11% [171] of anti-H2A in SLE retained activity on the H2A polypeptide (12–118). These studies would suggest that the major epitope on H2B contains peptide (1–20) and on H2A peptide (1–11) and/or (119–129). In fact, in ELISA, H2B (1–25) did have antigenicity for 38% of SLE sera [96]. Gohill *et al.* [101] reported that the H2A 38-mer (91–129) retained good antigenicity for SLE sera having anti-H2A activity, but Muller *et al.* [96] found that the smaller C-terminal H2A peptide (116–129) and N-terminal H2A peptide (1–15) displayed only weak

antibody binding for 13 and 29%, respectively, of SLE sera. There are considerable discrepancies in DIL as to the predominant epitopes within the trypsin-resistant domains, as discussed previously [37]. However, the trypsin-resistant domains of H2A and H2B are clearly important because these regions contain the amino acid residues responsible for H2A complex formation with H2B [60, 173] creating the highly antigenic H2A-H2B dimer [71, 105, 106, 142].

H3 and H4

The effect of trypsin digestion on the antigenicity of both H3 and H4 is similar. In Western blot, the H3-derived P1 domain ("A" band [101, 143, 171]) and the H4-derived P4/P5 domain ("C" band [101, 143, 171]) retained antigenicity for fewer than 10% of SLE and procainamide-induced lupus sera having anti-H3 and/or H4 activity [101, 142, 143, 171]. This would suggest that the major epitope for SLE anti-H3 and anti-H4 antibodies resides in the N-terminal 26 amino acid and/or C-terminal six amino acids of H3 and the N-terminal 17 amino acids of H4, assuming no tertiary interaction between these and other regions of the molecules, as would be expected [60, 173]. In fact, in ELISA, H3 peptide (1–21) and (130–135) bound 76 and 39% of SLE sera, respectively, and 54% of SLE sera bound H4 (1–29) [96]. However, the H3 peptide (40–45) was also antigenic [96], and absorption experiments showing that these activities were related to antibody to the parent molecule were not reported.

In contrast to SLE and procainamide-induced lupus, 80% [143] or 100% [142] of hydralazine-induced lupus sera reacted with the trypsin-resistant domains of H3 and H4 to an extent similar to that of the parent histones. The dichotomy between the reactivity of antibodies in hydralazine-induced lupus with those in procainamide-induced lupus and SLE is also manifested on subnucleosome particles (see the preceding section on *overall disease association*) and would suggest a difference in the immunogenic stimulus driving the autoimmune responses in these disease groups.

H1

Chymotrypsin cleaves accessible peptide bonds on the C-terminal side of aromatic amino acids, and brief digestion splits H1 approximately in the middle of the central, globular domain at phenylalanine 106. In Western blot the C-terminal polypeptide (107–220) retained full antigenicity for 100% [92, 98, 174] or 86% [102] of SLE and 100% of procainamide-induced lupus sera [174] having anti-H1 antibodies (both IgM [174], and IgG [98, 143, 174]). In contrast, the N-terminal half (1–106) displayed lower antigenicity in most (but not all [92]) studies in showing reaction with only 28% [98], 16% [174], and 14% [102] of SLE sera with anti-H1 activity. When Gohill and Fritzler [174] tested the antigenicity of the globular domain (36–121) (generated by trypsin digestion of H1) using ELISA, no SLE or procainamide-induced lupus serum reacted. These results suggested that the bulk of H1 antigenicity lies in the C-terminal hydrophilic domain. In a study using synthetic 15-mer peptides, Stemmer *et al*. [175] observed definite skewing of reactivity of SLE sera with C-terminal peptides of human H1b, although N-terminal and globular domain peptides were occasionally antigenic as well. Nevertheless, these data suggest that the apparent lower antigenicity of the N-terminal domain reported using bovine [92, 98, 174] or chicken [102] H1 fragments applies to human H1 as well, presumably the bona fide immunogen driving the autoimmune response. The highly conserved octapeptide in the C-terminal region (see earlier section on *primary structure and histone variants*) might be a candidate epitopic region that would cross species barriers and is included in the second most antigenic peptide in H1b [175]. It is unlikely, however, that there is an immunodominate epitope in H1, consistent with the heterogeneity of anti-H1 antibodies in murine lupus [176]. In addition, SLE sera appear to have substantial antibody heterogeneity within the H1 variants; of nine SLE sera examined, H1.5 was recognized by all nine patients, but from none to all of the five other H1 variants showed antigenicity by Western blot [177].

Antibodies to H1 from JRA sera have also received considerable attention. Of particular interest was the report by Pauls *et al*. [120] that a small proportion (5 of 51) of JRA patients had antibody activity to chicken histone H5 without concomitant reactivity with the major H1 class. A similar preferential reactivity with H5 compared to H1 with SLE sera was observed by Stemmer *et al*. [175]. Because H5 is not present in human tissues, it was suggested that the anti-H5 immune response was driven by an unknown non-histone cross-reacting antigen. However, as discussed in the section on *primary structure and histone variants*, H5 has extensive homology with H1°, the variant found in terminally differentiated cells. In fact, Monestier *et al*. [118] showed that JRA sera with anti-H5 had even higher reactivity with human brain H1°. Antibody binding to H1° from human brain without binding to the major H1 fraction was also detected in a patient with sensory neuropathy [137]. There are seven sequences in human H1° not present in H1 that are nearly identical to sequences in chicken H5, which are distributed mainly in the globular and N-terminal region [31], possibly accounting for cross-reaction between H1° and

H5. In fact, epitope mapping demonstrated that peptides within the globular domain of H5 had the highest antigenicity in SLE and procainamide-induced lupus [178]. Antibodies in JRA displayed poor binding to the central globular domain of H1 whether or not the amino terminal segment (1–32) was also present, whereas the highest reactivity was observed on the C-terminal segment containing the globular domain (33–220) [118]. This reactivity appears to be similar to that of SLE sera, but coblocking studies between IgM antibodies in JRA and IgG antibodies in SLE have not been performed.

Significance of Antihistone Antibody Fine Specificity

The specificity of histone-reactive antibodies in SLE and in lupus induced by most drugs is consistent with some form of chromatin being the predominant *in vivo* immunogen driving these B-cell responses. Antibodies in SLE and DIL that react with intact histones but not with histones from trypsinized chromatin can be explained most readily as having been elicited by chromatin rather than by free histones because the trypsin-resistant domain structure of histones is preserved in the form of chromatin and nucleosomes but not in individual histones. However, subnucleosome particles and histones in the form of the DNA-free H2A-H2B dimer and the H3-H4 tetramer are also resistant to trypsin digestion. Furthermore, the argument that chromatin drives the autoantibody response is weakened by observations that antibodies reacting with the trypsin-resistant cores of H2A and/or H2B also occur in some SLE sera and were the predominant activity in procainamide-induced lupus [107, 142]. This discrepancy is especially pronounced with antibodies in hydralazine-induced lupus, which retain reactivity with histones after trypsinization of chromatin [142, 143]. IgM antibodies from patients taking hydralazine or chlorpromazine [107], as well as IgG antihistone antibodies from patients with JRA [115], bound strongest to DNA-free histones, less to subnucleosome structures, and very little or not at all with chromatin. Thus, immune tolerance to more native forms of nucleohistone is largely preserved in JRA and with antibodies induced by chlorpromazine, isoniazid, and IgM antihistone antibodies in hydralazine-induced lupus. This is the same pattern of antibody binding found when normal mice were immunized with histones [179] and is more consistent with some unknown form of DNA-free histone driving the immune response to histones in these patients.

A more convincing argument that chromatin drives the bulk of the histone-reactive antibody response in SLE and most DIL can be made from data that compare the antigenicity of various forms of histones. As discussed earlier, antibodies from patients with SLE and lupus induced by 10 drugs (**Table 3**), as well as antibodies from murine lupus, bound prominently to a structural epitope in the (H2A-H2B)–DNA complex. Some patients with SLE also bound native DNA and the $(H3\text{-}H4)_2$–DNA subnucleosome, but reactivity with individual histones was much lower [16, 152, 157]. In murine lupus, antibodies to (H2A-H2B)–DNA were found early in disease, before antibodies to native DNA and $(H3\text{-}H4)_2$–DNA arose [180]. Absorption with chromatin removed most of the antibody reactivity to subnucleosome structures, indicating that regions buried in chromatin were not antigenic in SLE, DIL, or murine lupus. Thus, histone-reactive antibodies in SLE can be explained most readily by a autoimmunization with chromatin accompanied by a sequential loss of tolerance first to the (H2A-H2B)–DNA region and then to $(H3\text{-}H4)_2$–DNA and native DNA. Loss of immune tolerance to epitopes on DNA-free histones, which can be considered "denatured histones," and to denatured DNA (and to other nuclear antigens) may accompany the immune disregulation associated with lupus-related disorders, but because of the complexity of these epitopes and the heterogeneity of this immune response, only with nucleosome-reactive antibodies can a strong case be made for the putative *in vivo* existence of a chromatin-like immunogen.

Artifactual Antihistone Antibodies

Special problems arise when measuring antihistone antibodies in complex biological fluids. Three features of this antigen–antibody system contribute to ambiguous results: (1) histones have a net positive charge and readily bind soluble polyanions such as DNA in physiological medium or sulfated macromolecules on membranes, (2) DNA and/or histones are not uncommon contaminants of antibody-containing fluids or of other components of the assay, and (3) anti-DNA and antihistone activities commonly coexist in SLE sera. Soluble DNA in human serum can be responsible for false-positive antihistone antibody signals by forming a macromolecular bridge between anti-DNA antibodies and histone bound to the solid phase. These interactions result in anti-DNA antibody binding to histones, indistinguishable from bona fide antihistone antibody activity (see the following section on *antilymphocyte antibodies*). This phenomenon can be clearly seen when harvesting tissue culture supernatants from a hybridoma secreting anti-DNA antibodies [181]. DNase treatment of the antibody preparation removes the antihistone activity, consistent with the involvement of DNA in the generation of artifactual antihistone activity.

Similar artifacts can occur in serum. Subiza *et al*. [182] demonstrated that DNase pretreatment of SLE sera resulted in a significant decrease in antihistone antibody activity in 7/11 sera. Affected sera invariably had anti-DNA antibodies (whose activity increased after DNase digestion) and the histone-binding activity could be regenerated by the addition of DNA. These results would suggest that a significant portion of the antihistone activity in SLE might actually be due to DNA–anti-DNA immune complexes. However, Suzuki *et al*. [90] observed a DNase effect on the antihistone activity in only 27% of SLE sera; this decrease was relatively small and uniform across all histone classes. Therefore, it appears that measurement of antihistone activity in well-prepared samples of SLE sera gives largely valid results even in the presence of anti-DNA antibodies.

Nucleohistone in bovine milk (a common blocking medium) or serum can bind to histone bands transferred to nitrocellulose, introducing artifacts [183]. Histones were isolated from bovine serum and milk by affinity chromatography on DNA-cellulose [184], and this material mediated the binding of antihistone antibodies to solid-phase DNA [181]. Indirect evidence strongly suggests that DNA exists in serum in the form of mono- and oligonucleosomes [185, 186], which can be immunoprecipitated with antihistone antibodies [186]. Therefore, blocking media from these natural biological fluids should be avoided when measuring antihistone antibodies. This type of phenomenon may also have pathologic significance, as suggested by the report of Schmiedke *et al*. [187] that circulating nucleohistone binding to the negatively charged residues on heparin sulfate in the glomerular basement membrane (GBM) may mediate the binding of DNA and anti-DNA antibodies to the glomerulus.

Cross-Reactions of Antihistone Antibodies

Rheumatoid Factors (RF)

Polyclonal IgG RF with ANA activity were first clearly demonstrated by Hannestad and Johanessen [188], and an IgM RF with the capacity to bind nucleosomes containing core histones was isolated from another RA patient [189]. Several subsequent studies verified and extended these findings [110, 190–194], suggesting that RF with histone-binding activity was quite common. Trivial explanations such as contaminating immune complexes were ruled out by the discovery of monoclonal RF produced in tissue culture with similar properties [195]. Although the structural basis for these cross-reactions is unclear, it is possible that the combining site of an antibody is considerably larger than that needed to accommodate a single epitope, permitting distinct regions within the Fab part of an antibody molecule to react with unrelated epitopes.

Antilymphocyte Antibodies

Of 27 LE factor-positive sera, 26 contained ANA that bound to and could be eluted from viable leukocytes [196]. These "X-ANA" reacted with nucleosomes [197], and absorption experiments indicated that ANA, LE factor, and antilymphocyte activities were properties of the same antibody population [18]. In addition to human leukocytes, LE factor also bound to mouse and rabbit splenocytes, rat hepatocytes, and human endothelial cells but not human or chicken erythrocytes [198, 199]. X-ANA behaved as a subset of the cold reactive antilymphocyte antibody repertoire [198]. The related capacity of anti-DNA antibodies to bind a "lupus-associated membrane protein" (LAMP) has been shown to be mediated by DNA or nucleohistone debris contaminating the anti-DNA preparations [200, 201], although apparently DNA-independent anti-DNA antibody binding to cell membranes has been described [202]. The capacity of mononuclear cells or granulocytes to bind X-ANA was not mediated by the Fc region of IgG or by the Fc or C3 receptors on leukocytes, and, in contrast to anti-LAMP antibodies, nuclei derived from dead cells appeared not to be responsible for the capacity of leukocytes to immunoadsorb X-ANA [197, 203, 204]. The cell membrane antigen is similar to an epitope in the core histone octamer (in the presence or absence of DNA) but not in nucleosomes depleted of H2A and H2B [196], and solid-phase H2B or H2B peptide (6–18) reacted with antibody affinity purified on leukocytes [205]. A peptide derived from H2B also appears to be present on murine B cells [206]. However, studies with a panel of histones, as well as antihistone and anti-DNA antibodies, failed to detect other chromatin-related antigens on cell membranes [207]. In addition, Holers and Kotzin [208] detected antihistone antibody binding to mononuclear cells only after overnight culture at 37°C. Apparently activation of monocytes by endotoxin in the medium induces expression of a nucleohistone receptor that binds chromatin debris released into the medium [209]. This receptor may be a 94-kDa protein in a cell membrane extract, which bound DNA and nucleohistone [200], a 30-kDa protein, which is a component of a DNA receptor on mononuclear cells [210, 211], or a 50-kDa protein that acts as a nucleosome receptor on a fibroblast cell line [212]. However, there is no evidence that SLE patients, in which anti-H2B and/or anti-DNA antibodies are commonly observed, display membrane-associated antibody on circulating mononuclear cells *in vivo*.

MURINE EXPERIMENTAL MODELS WITH ANTIHISTONE ANTIBODIES

Strains of mice in which serum antihistone antibodies appear spontaneously during their natural life history include (NZB × NZW)F1 [77, 176, 213, 213–215], MRL-*lpr/lpr* [87, 176, 180, 214–217], MRL-+/+ [215, 216, 218], BXSB [180], (SWR × NZB)F1 [219, 220] Palmerston North [87], Swan [87], NZB [176, 216, 217], ddY [221], and (C57Bl/6 × DBA/2)F1 mice undergoing chronic graft-vs-host (GVH) disease after injection of DBA/2 T cells [179, 214, 222–226]. As with most human SLE and some DIL, predominant reactivity with linear epitopes in the trypsin-sensitive region of the core histones was also observed with spontaneously arising antibodies in murine lupus [213, 224]. Many monoclonal histone-reactive antibodies have been derived by the hybridoma technique from autoimmune mice [181, 218, 223, 227, 228] and subjected to comparative sequence analyses [217, 218, 220, 229, 230]. Monoclonal antibodies to (H2A-H2B)-DNA obtained from MRL-+/+ mice were clonally related and possessed numerous charged residues in the heavy chain as a result of somatic mutations and various $V_H DJ_H$ rearrangement processes [218, 229], indicating antigen selection rather than polyclonal activation. However, the replacement/silent mutation ratios even in the complementarity-determining regions were much lower than the ratio expected for random mutations [229], suggesting that once B cells with sufficient avidity for chromatin arise, something else, presumably T-cell help, causes their expansion. This view is supported by the detailed sequence comparisons of anti-(H2A-H2B) antibodies derived from an (SWR × NZB)F1 [220] and an (NZB × NZW)F1 [231] mouse; these antibodies showed very few somatic mutations, suggesting that chromatin-reactive T cells selected a single precursor of these B cells for expansion at an early stage in their development and limited further V region mutations to an extent corresponding to only 1 week of antigen-driven autoimmunization.

When the kinetics of autoantibody appearance in the lupus-prone MRL-*lpr/lpr* and BXSB mouse were examined over short time intervals, the earliest autoantibodies detected reacted with native chromatin rather than its constituents such as histones and DNA [180, 232]. Anti-[(H2A-H2B)–DNA] accounted for the bulk of the early antichromatin activity [180]. This serology was similar to that observed in 14 out of 40 newly diagnosed SLE patients, and the mouse and human sera efficiently coblocked, indicating a similar target epitope [16]. Another 14 SLE sera had elevated reactivity to multiple antigens in chromatin, including (H2A-H2B)-DNA, native DNA, H3-H4 tetramer, and various individual histones [16]. This serology, in turn, was very much like that in older lupus mice, which had rapidly developed antibodies to multiple epitopes on chromatin [180]. These data suggests that, as in DIL, the autoimmune response in human and murine SLE is initially directed to the (H2A-H2B)–DNA component of chromatin, but unlike DIL spreads to other regions in chromatin (and to other nuclear antigens).

HISTONE-REACTIVE T CELLS

Lymphocytes from 54% of SLE patients showed a proliferative response to nucleosomes *in vitro* [158]. Chromatin-specific T cells were isolated from mouse [219] and human [233] SLE, and histone-reactive T-cell lines were obtained from SLE and a normal individual [234]. T-cell clones derived from lupus-prone (SWR × NZB)F1 mice displayed proliferative and cytokine responses to nucleosomes but not their component macromolecules. Of the clones that could be mapped, five reacted with peptides corresponding to H4 (13–39) and/or H4 (73–90) and one with H2B (10–33) [235], and their specificity seemed to be conferred primarily by the α chain of the T-cell receptor [236]. Interestingly, these T-cell epitopes were similar to those commonly recognized by T cells from SLE patients; human lupus T cells also recognized H3 (91–105 or 100–114), H2A (34–48), and H4 (49–63) [237]. Nucleosome-reactive clones provided helper activity to primary B cells for secretion of IgG anti-"histone/DNA" *in vitro* [235]. A controlling role for such chromatin-specific T cells in the humoral response of BXSB mice was the demonstration that injection of chromatin *in vivo* directly into thymic lobes delayed the appearance of antichromatin and anti-DNA antibodies, probably due to the enhanced deletion (negative selection) of autoreactive T cells [238]. Histone-reactive T-cell lines have been developed from normal individuals after stimulation with nucleosome–polyomavirus T antigen complexes [239, 240], demonstrating that quiescent (anergic) histone-reactive T cells may be part of the normal T-cell repertoire.

The notion that the antichromatin response is limited by the availability of T_H cells is supported by immunization studies. Normal mouse strains generally fail to produce autoantibodies reactive with native self-antigens using various immunization protocols [241]. Thus, host B cells from (C57BL/6 × DBA/2)F1 mice produce anti-[(H2A-H2B)–DNA] antibodies after *in vivo* transfer of DBA/2 T cells due to the GVH reaction [222, 242], but only antibodies to nonative regions in chromatin can be detected after immunization of this strain with various chromatin-related antigens [179]. These results are consistent with the findings that immunoglobulin receptors for (H2A-H2B)–DNA are

derived by limited somatic mutations of the normal B-cell repertoire [218, 220, 229], but these cells or their precursors remain quiescent until appropriate T-cell help becomes available. Apparently, DBA/2 T cells provide this help in the GVH model, but direct immunization does not break T-cell tolerance to chromatin. However, when a reactive metabolite of the lupus-inducing drug procainamide was injected into the thymus of (C57BL/6 × DBA/2)F1 mice, anti-[(H2A-H2B)–DNA] antibodies arose [243], consistent with the view that chromatin-reactive T cells, created by disruption of central T-cell tolerance, have sufficient helper capacity to drive precursors of [(H2A-H2B)–DNA]-specific B cells to somatically mutate, expand, and secrete autoantibodies.

PATHOGENIC POTENTIAL OF ANTIHISTONE ANTIBODIES

The pathogenic mechanisms in SLE and DIL have not been clearly elucidated, but there is a general consensus that complexes between autoantibody and its cognate antigen play at least a contributing role. Anti-nDNA antibodies have a long history of being implicated in glomerulonephritis in murine and human SLE [244], but serum anti-nDNA is not closely correlated with renal disease (reviewed in [153, 245]), and anti-[(H2A-H2B)-DNA] activity was a better statistical correlate of lupus nephritis than anti-nDNA [16]. The presence of antichromatin was also strongly linked to early death in the progeny of (NZB × NZW)F2 intercross mice [246], and IgG antichromatin antibodies showed a strong statistical correlation with the SLEDAI score of disease activity in SLE [161]. Although one study found that anti-DNA antibodies correlated better with lupus nephritis than anti-[(H2A-H2B)-DNA] activity [156], the predominance of antinucleosome antibodies and their correlation with active lupus nephritis were demonstrated in large samples of SLE patients from France and Brazil [157]. IgG3 antinucleosome antibodies were found to be an overrepresented subclass in SLE patients with renal disease, further implicating immune complex-mediated pathology involving this strong complement-fixing isotype [155].

A pathogenic role for chromatin-reactive antibodies in lupus nephritis, but not antibodies to (denatured) histones [247], is suggested by studies in experimental animal models of nephritis and *in vitro* assays for glomerular-binding immunoglobulin. Antinucleosome–nucleosome immune complexes bound to the glomerulus *in vivo* and to the GBM *in vitro* [248], and immunoglobulin eluted from glomeruli of MRL/*lpr* mice reacted most strongly with histones in the nucleosome core particle [249]. However, in SLE, circulating, preformed immune complexes appear to be of minor importance [250]. Although serum from 81% of SLE patients with nephritis showed elevated IgG binding to a preparation of basement membranes isolated from human glomeruli in an ELISA format [250], GBM-binding activity was decreased substantially by DNase treatment of the GBM (but not the sera), and nucleosome preparations were especially potent in restoring antibody binding to GBM. These and other data [187, 248, 251–255] demonstrate that chromatin or nucleosome core particles readily adhere to type IV collagen and/or heparin sulfate in the GBM (but less so to other types of basement membranes), providing an *in situ* surface for binding chromatin-reactive antibodies. Approximately 20% of SLE patients have increased levels of circulating nucleosomal material, although plasma chromatin did not correlate with disease activity or SLEDAI score [161].

Of SLE patients with active nephritis, those with the highest GBM-associated immunoglobulin showed more severe clinical disease, especially hypocomplementemia and poorer prognosis than SLE patients with low GBM-binding activity [256]. Although there are some data to the contrary [80, 257], complement proteins C3, C4, and properdin deposited on nuclei of HEp-2 cells preincubated with histone-reactive antibodies [258], consistent with the finding that IgG1 and IgG3, potent complement-fixing immunoglobulins, are the predominant isotypes of these antibodies in SLE and DIL [155, 168]. In fact, depressed complement levels have been detected in patients with lupus induced by procainamide [259] and hydralazine [260], and a prospective study of a patient with procainamide-induced lupus demonstrated elevated C4d/C4 ratios during symptomatic disease [165], indicating activation of the classical pathway *in vivo*. It is highly likely, therefore, that complement activation and its accompanying inflammatory mediators are a consequence of the appearance of histone-reactive antibodies in SLE and DIL.

It could be envisioned that anti-nDNA, anti-[(H2A-H2B)–DNA], and other chromatin-reactive antibodies cause nephritis by binding to nucleosomal material that deposited in the glomerulus from the circulation [186]. However, sera from a substantial proportion of SLE patients without nephritis also showed a capacity to bind glomerular structures [256] or GBM [250] *in vitro*. Furthermore, sera from patients with DIL displayed a range of *in vitro* GBM-binding capacity similar to that of SLE sera [250]. As SLE but not DIL patients develop glomerulonephritis, anti-[(H2A-H2B)–DNA] antibodies cannot be sufficient to cause this pathology.

Collectively, these observations suggest that kidney damage in SLE requires not only chromatin-reactive

antibodies (including anti-DNA) but also at least another abnormality, such as a compromised capacity to clear immune complexes after chromatin followed by antichromatin antibodies are deposited in the kidney. Patients with drug-induced anti-[(H2A-H2B)–DNA] antibodies presumably have adequate capacity to remove immune complexes involving these antibodies from the kidney, but the systemic symptoms of DIL [162] may be a consequence of the operation of the inflammatory machinery involved in clearance of these immune complexes. The strong correlation between anti-[(H2A-H2B)–DNA] antibodies and both nephritis in SLE and rheumatologic symptoms in DIL suggests that there is a general intolerance of these antibodies, contributing to symptomatic disease.

ANTIBODIES TO NONHISTONE ANTIGENS IN SYSTEMIC LUPUS ERYTHEMATOSUS

Marvin J. Fritzler
Edward K. L. Chan

INTRODUCTION

Systemic lupus erythematosus (SLE) is a disease in which an unbalanced immune response is invoked on the background of susceptibility genes and environmental stimuli. One manifestation of this response is the presence of serum autoantibodies directed against intracellular and extracellular antigens. Autoantibodies directed against nuclear (ANA) and other intracellular components predominate in SLE, and for that reason they have achieved clinical importance. The past three decades have witnessed a tremendous increase in our knowledge of the clinical relevance and complexity of ANA in SLE. This has made it necessary to know that antinuclear antibodies are present in serum and to determine the immunologic specificity of the autoantibody responses.

There are several reasons why the determination of autoantibody specificity is important. First, a positive ANA is no longer considered a specific test for any systemic rheumatic disease because ANA occur in high frequency in several of them as well as in nonrheumatic conditions. Second, important diagnostic and prognostic information can be gained from determining autoantibody specificities because certain autoantibodies are specific for SLE while others are specific for other diseases [1–4]. Moreover, some ANA specificities are closely related to certain clinical manifestations of SLE. Therefore, autoantibodies to a variety of nuclear antigens, including nonhistone macromolecules, have served as extremely useful aids in differential diagnosis and in the detection of early forms of several diseases, including SLE.

The importance of ANA was recognized in the 1982 revised criteria for the classification of SLE [5] where they are identified as an independent criterion. Anti-double-stranded DNA and anti-Sm were included with lupus erythematosus (LE) cell test and biological false-positive test for syphilis as subitems in a second immunological criterion. This has underscored the diagnostic significance of autoantibodies directed against several autoantigens.

An understanding of the clinical relevance of ANA has been the result of intensive study over the past three decades. From these studies it has been appreciated that ANA specificities can be divided into three general categories: antibodies directed against DNA (see Chapter 10), those directed against a family of basic nuclear proteins or histones (see Chapter 12), and those directed against nonhistone proteins. Although most autoantibodies in SLE react with intranuclear antigens (ANA), many sera also react with cytoplasmic antigens [2, 6] (see Chapter 11). Some antibodies that stain both the cytoplasm and the nucleus are directed against ribosomal proteins, various RNA species, and other cytoplasmic antigens [6, 7]. The discussion in this chapter is limited to autoantibodies directed against nonhistone proteins (Table 1).

TABLE 1 Autoantibodies in SLE: Clinical Association and Biochemical Identity[a]

Autoantigen	Prevalence in SLE (%)	Molecular characteristic
DNA		
dsDNA	40–60	Double-stranded DNA
Histones	60–80	H1,H2A,H2B,H3,H4,H5
Nonhistone nuclear antigens		
nRNP		
Sm	10–30	Proteins 28,29,16, and 13 kDa complexed U1,U2,U4,U5,U6 RNAs
U1 RNP	30–40	Proteins 33 and 22 kDa complexed U1 RNA Protein 68 kDa
hnRNA	15–25	Heterogeneous nuclear RNA
hnRNP A2/RA33	20–25	33-kDa protein of hnRNP complex
Ribonuclease P (RNase P)	25	400 bases RNA; 38-kDa protein
Nuclear and cytoplasmic RNPs		
SS-A/Ro	30–40	Proteins 60 and 52 kDa complexed to Y1–Y5 RNA
SS-B/La	15–25	Phosphoprotein 48 kDa complexed to RNA pol III transcripts—ATPase/dATPase
LSm4	<10	15-kDa protein complexed to U4/U6 snRNP
DNA/chromatin-binding antigens		
PCNA	<5	Protein 36 kDa—auxiliary protein of DNA polymerase δ
Ku p70/p80	10–20	70 and 80 kDa
Poly(ADP-ribose) polymerase (PARP)	35–45	116 kDa
Poly(ADP-ribose)	40–70	Branched homopolymer
DEK oncoprotein	10–25	45 kDa
Transcription activator Sp1	<10	95-kDa component of terminal repeat-binding protein
HMG-17	30–70	9-kDa high-mobility group protein
SSRP1	28	HMG protein involved transcription and repair of DNA and RNA
Ubiquitin	80	Ubiquitin-H2A branched peptide
Nucleolar and ribosomal proteins		
Ribosomal P proteins	10–20	P0, P1, P2 phosphoproteins
L7 eukaryotic protein	30–75	29-kDa large ribosomal subunit
L12/S10 protein subunits	2–40	L12 = 20 kDa (60S); S10 = 20 kDa (40S)
Nucleolar organizer NOR-90	<5	90-kDa upstream binding factor
RNA helicase (Gu)	<20	100 kDa
ASE-1	20	90-kDa protein antisense to ERCC-1
Mitotic spindle-associated proteins		
NuMA-1	<5	235-kDa protein
HsEg5 (NuMA-2)	<10	130-kDa protein
Other nuclear antigens		
p53	25–30	53 kDa regulates cell proliferation and apoptosis
Ki/SL	10–30	~31-kDa protein
Ki-67	3–30	Two isoforms: 315 and 350 kDa
Lamins	<10	Lamins A,B1/B2,C
p80-coilin Cajal/coiled bodies	<10	80-kDa protein in nuclear
Cytoplasmic antigens		
pp75	16[b]	75-kDa protein complexed to SS-A/Ro
20S proteasome	50	Nonlysosomal protein degradation
p57	?	57-kDa protein
Golgi complex	<10	67-, 97-, 160-, 245-, 376-kDa proteins
Endosome	<10	160-kDa early endosome antigen 1
Mitochondria	<10	DNA, cardiolipin, pyruvate dehydrogenase complex
Carbonic anhydrase I, II	20–45	34-kDa protein in erythrocytes

[a] ADP, adenosine diphosphate; HMG, high mobility group; hnRNP, heterogeneous nuclear ribonucleoprotein; NuMA, nuclear mitotic apparatus; PCNA, proliferating cell nuclear antigen; RNP, ribonucleoprotein; scRNP, small cytoplasmic ribonucleoproteins; snRNP, small nuclear ribonucleoproteins; SSRP 1, structure-specific recognition protein 1.

[b] Refers to frequency in neonatal lupus syndrome.

NOMENCLATURE AND MOLECULAR BIOLOGY OF NONHISTONE AUTOANTIGENS

The significance of antibodies directed against nonhistone protein antigens has increased with the ability to characterize their respective antigens at the molecular level. The pioneers in this work, Steitz and colleagues, introduced the techniques of immunoprecipitation of radioisotope-labeled cellular macromolecules and immunoblotting of cell extracts for the identification of intracellular autoantigens [3]. These techniques are now widely used for the characterization of autoantigens and for the recognition of nucleic acids, particularly RNAs. These RNAs are complexed to a number of protein antigens in a highly specific and characteristic association. The technology being applied to the study of nonhistone antigens also includes cloning of these antigens, the isolation of cDNA probes to study their role in cell biology, and the use of recombinant proteins in antigen arrays and other assays to detect autoantibodies [8–10].

Studies of RNA and protein antigens by immunoprecipitation and immunoblotting techniques have suggested that autoantigens reacting with SLE autoantibodies are frequently coupled as supramolecular complexes such as RNA–protein (RNP, spliceosomes), DNA–protein (DNP, nucleosome), and protein–protein (70/80 Ku subunits, ribosomal P proteins) complexes [11–14]. This discussion focuses on RNPs because they are the most prevalent nonhistone autoantigens described in SLE.

A review of Tables 1 and 2 reveals that an understanding of molecular biology and biochemistry is required to understand the nomenclature used in the identification of nonhistone antigens. Therefore, a brief overview of molecular and cell biology is presented to help the reader understand the nomenclature of autoantibodies seen in SLE and to appreciate basic concepts of cell biology.

TABLE 2 Clinical Features Associated with SS-A/Ro Antibodies

	Ref.
Neonatal lupus syndrome	134–136
Photosensitive skin rash/subacute cutaneous lupus	137–140
Interstitial pneumonitis	141, 142
Homozygous C2 deficiency	143, 144
Thrombocytopenia purpura	145–147
Vasculitis	132, 148
Lymphopenia	149
With anti-SS-B/La = decreased frequency of nephritis	149–151
ANA-negative lupus	169, 170

RNA

The RNA molecules that make up RNP complexes in eukaryotic cells can be categorized as messenger RNAs (mRNA), heterogeneous nuclear RNAs (hnRNA), large ribosomal RNAs, and several classes of low molecular weight RNA [13, 15]. Low molecular weight RNAs can be subclassified into uncapped small cytoplasmic RNAs (scRNA) and capped small nuclear RNAs (snRNA). snRNAs typically have a high content of uridine and are therefore designated UsnRNA. At least 12 UsnRNAs have been identified. UsnRNAs are, for the most part, transcribed by RNA polymerase II, whereas scRNAs are transcribed by RNA polymerase III. Transfer RNA (tRNA), ribosomal 5S RNA, 7SK RNA, the 7SL RNA of the signal recognition particle, translational control RNA, and 4.5S RNA are all examples of scRNA. A common feature of scRNAs is the addition of a few uridine residues to the 3′ terminus by RNA polymerase III at the termination of transcription. scRNAs include a class of low molecular weight molecules of 83–112 bases referred to as yRNA. The y designates their primary cytoplasmic localization. When yRNA are extracted from human tissues, they are given the additional designation of hyRNA. There are four classes of hyRNA: hy1, hy3, hy4, and hy5. hy2 is a breakdown product of hy1.

Some snRNAs are independently associated with their own RNP particle so that each snRNP particle contains only one snRNA. An exception is U4/U6 snRNAs, which are present in the same complex. A schematic representation of the RNA molecules precipitated and bound by RNP and Sm sera is shown in Fig. 1. Figure 1 shows that anti-Sm sera coprecipitate snRNAs U1, U2, U4, U5, and U6. However, the antibody to nuclear RNP only coprecipitates U1 RNA. Although autoimmune sera target predominantly the protein component of RNPs, autoantibodies directed against the RNA molecules themselves have been detected in association with autoantibodies to snRNP and scRNP [16–22]. For example, up to 60% of sera reactive with U1-RNP have autoantibodies directed against U1-RNA, and this reactivity is correlated with the HLA marker DR2/DR4, Raynaud's phenomenon, and synovitis [22].

Proteins

Identification and characterization of the proteins associated with RNPs have been aided greatly by

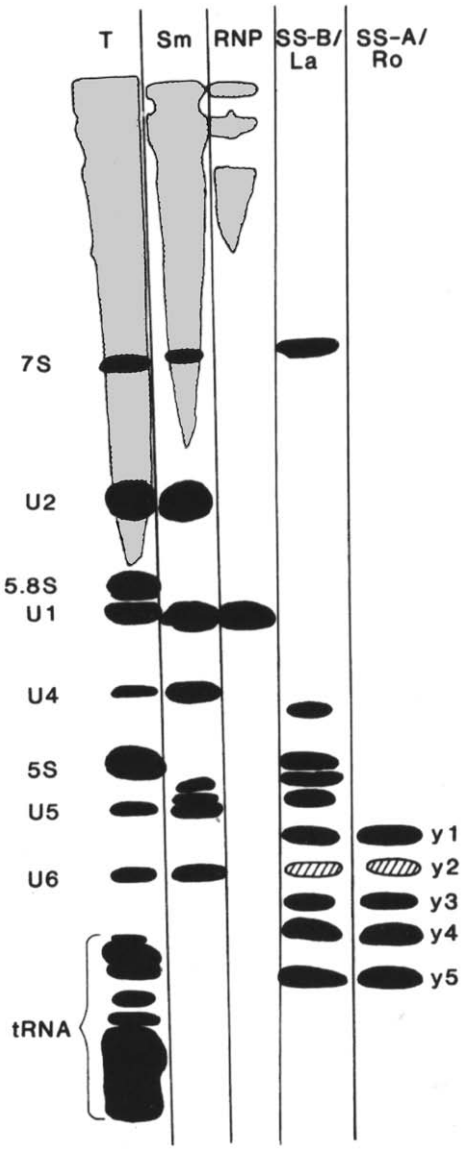

FIGURE 1 Schematic representation of small nuclear RNAs (snRNAs) immunoprecipitated by anti-Sm and anti-nRNP sera and small cytoplasmic RNAs (scRNAs) immunoprecipitated by anti-SS-B/La and anti-SS-Ro sera. HeLa cells are labeled with ^{32}P, and the soluble extract of these cells immunoprecipitated with anti-Sm (lane 2), anti-U1-RNP (lane 3), anti-SS-B/La (lane 4), and anti-SS-A/Ro (lane 5). Total RNA of the cell extracts is displayed in lane 1 (T). Anti-Sm precipitates five species of uridine-rich snRNA (U1, U2, U4, U5, and U6), whereas anti-U1-RNP precipitates only U1 RNA. Anti-SS-B/La sera precipitates 7S, 5S, 4.5S, y1, y3, y4, and y5 scRNAs, whereas anti-60-kDa SS-A/Ro precipitates only y1–y5 scRNAs. Stippled areas represent other high molecular weight RNA coprecipitated by the sera. The shading of the y2 RNA band is used to indicate that it is a breakdown product of y1.

autoantibodies from SLE patients. Immunoaffinity, immunoprecipitation, immunoblotting, other biochemical techniques, and molecular cloning have been used to identify polypeptides that are the constituents of the major human snRNPs U1, U2, U4, U5, and U6 [1, 15, 23]. At least seven of these core proteins are present on all the snRNPs. These have been designated by the letters B/B′ (27/28 kDa), D1/D2/D3 (14 kDa), E (12 kDa), F (11 kDa), and G (9 kDa). Analysis of individual snRNPs has disclosed that in addition to shared peptides, there are some proteins specific for certain snRNAs. U1 snRNPs contain three such proteins designated 70k (68/70 kDa), A (32 kDa), and C (22 kDa). The 70k protein is bound to the nuclear matrix and is associated with newly transcribed messenger RNA [24, 25]. U2 snRNPs have at least two unique proteins: A′ (29 kDa) and B″ (27 kDa). Two-dimensional electrophoretic gel and biophysical analyses of these proteins have shown that, except for the F protein, they are all basic (p*I* 8–10). The 70k protein, for one, has additional heterogeneity that is likely based on varying degrees of post-translational modifications such as phosphorylation. Several proteins have been shown to be associated with hyRNAs. A 60-kDa protein recognized by anti-SS-A/Ro sera interacts directly with one of the hyRNAs, and the 52-kDa SS-A/Ro polypeptide has been reported to be associated to this protein [26]. Finally, the 48-kDa phosphoprotein SS-B/La has been shown to be associated with RNA polymerase III transcripts, including hyRNAs [27]. A profile of some proteins that react with SLE sera is shown schematically in Fig. 2.

BIOCHEMICAL AND CLINICAL ASPECTS OF NONHISTONE ANTIGEN/ANTIBODY SYSTEMS

Sm

The Sm antigen is a complex system consisting of different proteins (Fig. 2) associated with the small nuclear RNAs (snRNA) U1, U2, U4/U6, and U5 (Fig. 1). These RNA polymerase II transcripts are complexed with proteins to form small nuclear ribonucleoproteins (snRNP). With the aid of immunoblotting and immunoprecipitation techniques, most investigators have come to the conclusion that five or six proteins in these complexes are the primary target antigens of human anti-Sm antibodies [15, 23, 28–31]. These are the Sm core proteins B/B′, D1, D2, D3, E, F, and G proteins described earlier [15, 23, 30, 32]. These proteins share a common sequence motif in two short polypeptide segments, Sm1 and Sm2, separated by a short variable linker. Crystal structures of two Sm protein complexes,

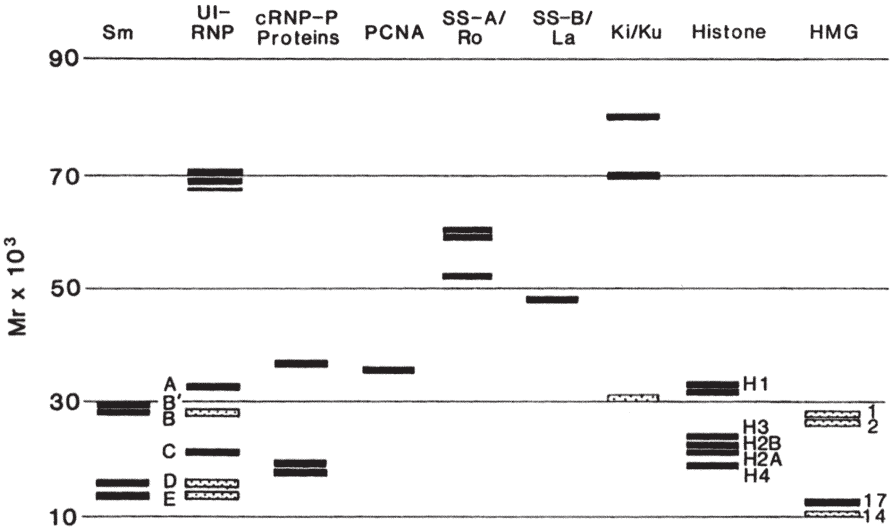

FIGURE 2 Schematic representation of [^{35}S]methionine-labeled HeLa cell proteins immunoprecipitated with various sera and analyzed on SDS polyacrylamide gels. The first two lanes show the typical pattern of polypeptides 70 k and A through E immunoprecipitated by anti-Sm and anti-U1RNP sera. The 70 k antigen is represented by a triplet of 68–70 kDa. Ribosomal RNP P proteins are identified as 38- 19- and 17-kDa polypeptides. Anti-PCNA antibodies precipitate a single 35-kDa protein. When extracts of nucleated mammalian cells are used, antibodies to SS-A/Ro precipitate 60- and 52-kDa proteins. Monospecific anti-SS-B/La sera precipitate a 45- to 48-kDa phosphoprotein. It should be understood that virtually all SS-B/La sera are not monospecific and usually precipitate some of the proteins in the adjacent SS-A/Ro lane. Ku antibodies precipitate proteins of ~80 and 70 kDa. Ki antibodies bind to a ~31-kDa protein (shaded). Histone proteins H1, H2A, H2B, H3, and H4 are bound by some SLE sera. SLE sera with HMG antibodies immunoprecipitate HMG-17 (~17 kDa), HMG-1 (~28 kDa), HMG-2 (~26 kDa), and HMG-14. Mr, relative mobility.

D3/B and D1/D2, suggest that the seven Sm core proteins could form a closed ring and the snRNAs may be bound in the positively charged central hole [33]. These core proteins are common to all major snRNPs, and for that reason a wider range of snRNAs are immunoprecipitated by Sm antibodies than are precipitated by U1RNP antibodies.

Anti-Sm produces a speckled staining pattern on HEp-2 cells by standard indirect immunofluorescence (IIF) assays but it cannot be detected with certainty by this technique [1]. Immunodiffusion, immunoblotting, analysis of precipitated RNAs (see Figs. 1 and 2), or enzyme-linked immunoassays are preferred to definitively identify this autoantibody. Advances in cloning and epitope mapping of Sm-related peptides have led to the use of synthetic peptides in clinical studies [34–37]. The techniques required to demonstrate antibody to Sm necessitate the use of standard reference sera. These prototype sera are available through the Centers for Disease Control [38].

The antibody to Sm was the first nonhistone antibody reported in what has become an expanding list of autoantigens (Table 1). Over the years, it has been confirmed repeatedly that this antibody is present almost exclusively in SLE and is considered a diagnostic marker for the disease to the extent that it is included in criteria for the classification of the disease [5]. Although anti-Sm is present in only 10–30% of patients with SLE, it is a highly specific disease marker. It has not been detected in normal sera or in patients with other systemic rheumatic diseases such as Sjögren's syndrome (SS), mixed connective tissue disease (MCTD), scleroderma, polymyositis, or drug-induced LE [39, 40]. Rising titers of anti-Sm have been correlated with more active disease [41] and disease flares [42]. This tends to support other studies that showed that anti-Sm was associated with milder renal disease and a less central nervous system disease [43–45] despite a high prevalence of late-onset proteinuria and a poorer prognosis than patients without Sm autoantibodies [44]. Because SLE sera tend to have multiple autoantibodies and more sensitive techniques using recombinant and highly purified proteins are under development, it could be concluded that the ability of anti-Sm antibodies to predict the clinical course of SLE is not clearly defined [46]. For example, van Venrooij and associates have reported that SLE sera have a prevalent and unique reactivity to a complex of RNP E-F-G proteins [47]. In

this study, individual snRNP proteins E, F, and G were synthesized and then allowed to form complexes. Although the individual proteins were not recognized in immunoblots, the E-F-G complex was immunoprecipitated preferentially by all anti-Sm sera but not sera from other diseases. These observations suggest that many anti-Sm sera recognize unique conformational epitopes in the E-F-G complex.

As noted earlier, anti-Sm reactivity is characterized by reactivity to several proteins (see Fig. 2), including the A, C, and 70k proteins of U1 RNP [1, 12]. Because U1RNP antibodies are considered to be a serological feature of MCTD, some investigators have questioned if unique serological profiles could distinguish MCTD from SLE. Analyses of SLE sera that contained both anti-Sm and anti-U1RNP antibodies have shown that some SLE patients have antibodies that bind to U1-U6 RNA-associated proteins, but they lack antibodies to the 70k protein [24, 48]. The importance of these observations is discussed in more detail in the next section.

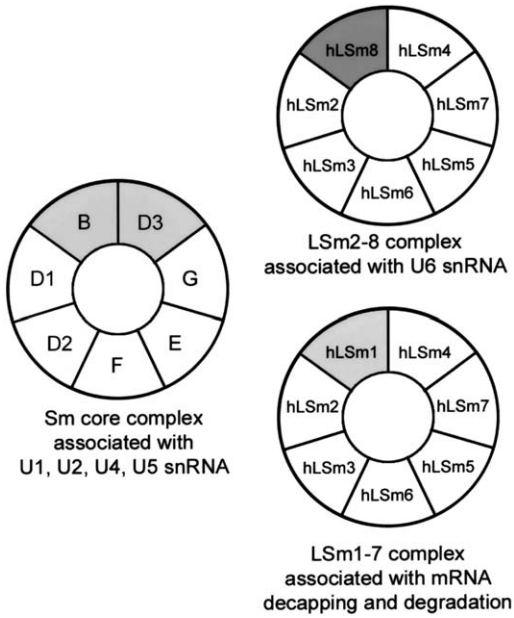

FIGURE 3 Diagrammatic representation of Sm core and hLSm protein complexes illustrating the proposed structural similarity among these seven protein doughnut-shaped structures. For both Sm core and LSm complexes, it has been proposed that the center space of the doughnut shape is involved in RNA binding.

LSm4 and LSm Complex

Studies have identified complexes composed of Sm-like proteins that form complexes distinct from Sm core snRNP complexes. They have been named like-Sm proteins, or LSm proteins (LSm1 to LSm8), as they each bear sequence homology with one of the seven Sm core proteins [49, 50]. For example, LSm4 was found to have the highest sequence similarity to SmD3, whereas hLSm1 and LSm8 have the highest similarity to the core domain of B/B′ [51]. Likewise, D1, D2, E, F, and G are most similar to LSm2, LSm3, LSm5, LSm6, and LSm7, respectively. The complexes they form with each other are postulated to have the same seven member ring doughnut configuration as the Sm protein complexes (Fig. 3) [33, 50]. The LSm complex, therefore, appears to exist in at least two configurations: the LSm2–8 complex associated with U6 snRNA and pre-mRNA splicing and the LSm1–7 complex that is involved in mRNA decapping and degradation [50, 52].

In one report [53], autoantibodies to LSm4 were detected using immunoprecipitation and *in vitro*-translated LSm4 in ~80% of all anti-Sm sera analyzed. A small fraction (7.2%) (28/391) of the same group of anti-Sm sera immunoprecipitated LSm4 together with the LSm complex from HeLa cell extracts. These findings document IgG autoantibodies to LSm4 are detected in a large overlapping subset of anti-Sm positive SLE. Interestingly, a small subset of anti-Sm sera LSm complex can be recognized independently of the Sm core protein antigens. Data suggest that the hLSm complex can be a separate, independent autoantigenic complex distinct from snRNP core complexes. LSm4 could be immunoprecipitated from a few lupus sera that contain little or no coprecipitating anti-Sm core proteins. Thus the presence of autoantibodies to hLSm4 or the hLSm complex may not be readily explained by epitope spreading via the association of LSm with the snRNP complex. The clinical significance of anti-LSm antibodies remains to be determined.

U1RNP

The target proteins of autoantibodies to nuclear U1RNP are predominantly the 70k (68/70kDa), A (32kDa), and C (22kDa) proteins (Fig. 2) [28–32, 48, 54]. Some sera containing antibody to nuclear RNP have been shown to have antibodies directed against the U2 snRNA-associated A′ (29kDa) and B″ (27kDa) proteins [55–57].

The antibody to U1 RNP was first reported by Sharp *et al.* [58, 59] in mixed connective tissue disease, a syndrome characterized by symptoms and signs mimicking SLE, scleroderma, and polymyositis. The main clinical features of MCTD are a high prevalence of Raynaud's phenomenon, edema of the fingers, arthritis/arthralgias, myositis, serositis, and a relative absence of renal disease [58, 59]. The characteristic feature of MCTD is the presence of high titers of U1 RNP antibodies and, with

the possible exception of anti-A2/RA33 (discussed later), no other types of ANA. This is unlike SLE where multiple other autoantibodies are characteristically observed.

In contrast to anti-Sm, anti-U1-RNP antibodies were also found in patients with a variety of systemic rheumatic diseases, including SLE, rheumatoid arthritis, systemic sclerosis, Sjögren's syndrome, polymyositis, discoid LE, and following procainamide therapy [1, 39, 40]. From these data one may conclude that the antibody to U1 RNP is not an exclusive serological marker for MCTD. The observation that anti-U1 RNP occurs with high frequency in patients with anti-Sm may be a reflection of autoimmune responses directed to macromolecular complexes [20, 60] through a process called "epitope spreading" [61–64]. It is clear that genetic influences are involved in regulating these autoantibody responses since they are correlated with HLA-DR4 [65] and are found in higher frequency in Black SLE patients than in patients of European extraction [66].

It is important to appreciate that some SLE and MCTD sera bind most of the snRNP polypeptides (as shown in Fig. 2), whereas others bind to little, if any, 70k or C polypeptides. In one study, only 8% SLE sera containing U1 RNP antibodies bound to the 70k antigen, but 76% of MCTD sera bound this protein [54]. The higher frequency of anti-70k antibodies in MCTD has been reported in several studies to be as high as 95% in MCTD while the range of reactivity in SLE is 20–50% [48]. The reported frequency of autoantibody frequency is highly dependent on the assay employed because when recombinant 70k protein was used in an ELISA, up to 85% of SLE patients showed elevated antibody levels [37]. It has been suggested that the presence of anti-70k provides a positive indicator for the presence of Raynaud's phenomenon, esophageal dysmotility, and myositis and as a negative indicator for the presence of renal disease. Taken together, data suggest that antibodies to the 70k protein may distinguish SLE from MCTD. These may be important observations for the clinician who attempts to identify patients at high risk of developing end organ disease when they present with only a few features (e.g., Raynaud's phenomenon, myositis) of other systemic rheumatic diseases.

Although antibodies to the 70k protein vary during the disease course [67], there is little evidence that they correlate with disease activity or that they are involved in disease pathogenesis [37, 45, 54, 68]. Evidence has renewed interest in the possibility that anti-U1 RNP antibodies have a unique property of being able to "penetrate" living cells [69, 70]. This property of U1 RNP antibodies may account for other occasional observations that anti-U1 RNP antibodies appear in nuclei of patients' tissue specimens [71].

Antibodies to the A and C proteins are found in approximately 25% of unselected SLE cohorts and in 75% of SLE patients preselected for antibodies to U1 RNP [30, 37, 45, 54, 72–75]. Like antibodies to the 70k protein, titers may vary during the course of the disease but there is no clear evidence that they predict disease activity or that they are involved in the pathogenesis [37, 45].

Heterogeneous RNP

As described earlier, heterogeneous nuclear RNA and heterogeneous nuclear ribonucleoproteins are intermediate components between gene transcription and translation [76]. Like snRNPs, hnRNP are associated with unique protein components that have a role in the processing, alternative splicing, and transport of larger hnRNA (pre-mRNA) transcripts [77]. Autoantibodies from patients with mixed connective tissue disease and SLE have been shown to bind hnRNA [25] and protein components [78–81] of hnRNP. One of these studies has demonstrated that approximately 20% of SLE, 35% of rheumatoid arthritis, and 50% of mixed connective tissue disease patients have antibodies to the A2/RA33 protein [79]. Unlike rheumatoid arthritis patients where antibodies to snRNPs are relatively rare, antibodies directed against the A2/RA33 protein in SLE and MCTD are often accompanied by anti-U1 RNP. This has led to the conclusion that when antibodies to A2/RA33 occur in the absence of antibodies to U1-RNP, there is 96% specificity for the diagnosis of rheumatoid arthritis [82]. By comparison, one study showed that anti-RA33 antibodies distinguish erosive arthritis in patients with SLE and RA [83]. Both SLE and RA sera bind to a conformational epitope in the RNA-binding amino terminus of the A2/RA33 protein, whereas MCTD sera tend to recognize another epitope [79]. The recognition of RNA-binding domains as major epitopes has been observed in other autoantigens, including the SS-B/La and the 70k and A U1-RNP proteins [84].

U2 RNP, RNase P, and Other nRNP

U2 RNP

Autoantibodies directed against U2 RNP react with the A′ and B″ proteins of the U2 particle [56, 57, 85]. Because U2 RNP antibodies were often accompanied by U1RNP antibodies, reactivity to the 70k and C proteins was also observed. It has been reported that up to 15% of SLE sera have autoantibodies directed against

U2 RNP [31]. In one study, antibodies to U2 RNP were not seen in 141 SLE patients but were identified in 8 patients with an overlap syndrome that most commonly included features of myositis [85]. Two of these 8 patients had features of SLE. One of the SLE patients also had features of scleroderma and an erosive arthropathy.

Ribonuclease P and tRNA

Ribonuclease P (RNase P) is an enzyme that cleaves precursor tRNA molecules to yield the correct 5′ terminal sequences of the mature tRNAs [86, 87]. Because this enzyme is complexed to a 400 nucleotide RNA molecule known as *H1RNA*, it is classified as a RNP particle [87]. Although some sera containing RNase P antibodies bind a 38-kDa protein [88], the identity of RNase P in immunoblots has not been clearly established. An interesting feature of this molecule is that the catalytic activity resides in the RNA subunit of the enzyme [87].

RNase P antibodies were first identified in approximately 25% of selected SLE sera [89]. Antibodies to the Th RNP/RNase MRP antigen are a common accompaniment of RNase P antibodies, suggesting that these two antigens are associated *in vivo* [90]. More recently, two antigens that copurify with RNase P have been shown to react with systemic sclerosis antibodies [91]. Studies have shown that some SLE sera bind tRNA itself [92, 93].

Other nRNP

Serum autoantibodies from a variety of systemic rheumatic diseases bind proteins that are components of U4/U6 [31, 94, 95], U5 [96], U7 [97], and U11 [98] snRNPs. These autoantibodies appear to be rare in SLE and tend to immunoprecipitate specific snRNPs because of their unique reactivity with snRNP particles. By comparison, nucleolar snRNPs (U3, U8, U13) do not contain the common Sm proteins but they do have the 35-kDa polypeptide fibrillarin in common. Hence, U3, U8, and U13 RNPs can be immunoprecipitated by antibodies directed against fibrillarin [99].

SS-A/Ro

There are two main classes of ANA in patients with SLE that are related to ANA seen in patients with Sjögren's syndrome. These two antigens were termed SS-A and SS-B by Alspaugh and Tan [100] because they were precipitated with the sera of patients with Sjögren's syndrome. Another group of investigators described a soluble nuclear antigen, termed Ha, that was precipitated with the sera of patients with SLE—Sjögren's overlap syndrome [101]. It was shown that SS-B and Ha were identical to La, another antibody system demonstrated by the same individuals. Through interlaboratory exchange of sera and antigen extracts, it was determined that SS-A was identical to Ro, an antibody system described in 1974 by Mattioli and Reichlin [102] and by Alspaugh and Madison [103]. Anti-SS-A/Ro antibodies are rarely found in normal individuals [104] or in hospitalized patients without systemic rheumatic diseases [105].

Studies of the molecular characteristics of the SS-A/Ro antigen have generated much interest. The reactive antigen has been described as various molecular species ranging from 50 to 150 kDa [1, 27, 106, 107]. An RNP particle composed of a 60-kDa protein and human cytoplasmic RNAs (hyRNA) was the first antigenic moiety described [108, 109]. The 60-kDa protein was thought to be the site of antibody binding, as SS-A/Ro sera did not bind to hyRNA alone. Some sera bind to unique determinants expressed when hy5RNA is complexed to the 60-kDa protein [110, 111]. Besides the 60-kDa protein, greater than 80% of SS-A/Ro sera identified in conventional double immunodiffusion assays bound a 52-kDa protein [106]. The reason this protein was not detected in earlier studies was likely due to the coexistence of SS-B/La antibodies and the incomplete separation of the 52-kDa SS-A/Ro and 47-kDa SS-B/La polypeptides by gel electrophoresis [112]. Expression cloning of cDNAs for the 52-kDa [113–115] and 60-kDa proteins [115, 116] and gene structure analysis showed that these two antigens are encoded by distinct genes on human chromosomes 1 and 11, respectively [117, 118]. The predominant cellular 60 kDa has a RNA recognition motif and has been shown to bind hy RNAs directly in an *in vitro* reconstitution assay [116]. The RNA-binding domain is conserved among human, mouse [119], and *Xenopus* 60-kDa protein [120]. A zinc finger was originally postulated in the center domain of the 60-kDa protein [115, 116], this putative zinc finger is not conserved in the mouse homologue [119]. The 60-kDa protein has been proposed to function as part of a novel quality control or discard pathway for 5S rRNA precursors in *Xenopus* oocytes [121]. Because 5S RNA is not known to be associated with the 60-kDa protein in mammalian cells, the function of the 60-kDa protein in mammalian cells remains to be determined.

Based on the N-terminal zinc finger domains and two coiled-coil regions, including a leucine zipper identified in the 52-kDa protein, the function for the 52-kDa protein has been implicated in transcription regulation because both of these structural motifs are found in transcription factors [113]. Furthermore, the overall structure of the 52-kDa protein is highly homologous to

the rpt-1 protein, a protein that downregulates the expression of the α chain of the IL-2 receptor and the human immunodeficiency virus type 1 proteins [113]. It has been shown that the leucine zipper of the 52-kDa protein is responsible for self-dimer formation [122]. Two forms of the human 52-kDa SS-A/Ro protein autoantigen, 52α and 52β, are products of alternative mRNA splicing [123]. The 52α form is expressed ubiquitously, whereas 52β, lacking the central leucine zipper domain, has been detected at higher levels than 52α during certain stages of fetal development [124]. In cell transfection transcription reporter assays, a six fold increase in transcription activity of the reporter was detected with the 52β construct compared to 52α or the empty vector control [122]. It is speculated that the ratio of cellular 52α and 52β may play an important role in regulating gene expression as a potential repressor and activator, respectively [122].

The consensus is that SS-A/Ro antibodies recognize both the 60- and the 52-kDa protein independently with at least two or more autoepitopes for each protein [125, 126]. Cross-reactivity of these two antibodies has not been observed consistently [127]. It has been shown that the immune response to 52- and 60-kDa proteins is linked in experimental mice when they are immunized with one or the other antigens [128, 129]. These data provide a confirmation that the linked response in human disease can be reproduced *in vitro*. The question whether the 60-kDa protein is directly complexed to the 52-kDa protein has been disputed. Boire *et al*. [130] have not been able to observe the association of the 52-kDa protein with biochemically purified hy RNPs. Work suggests that, in K562 cells, RoRNPs, especially hy3 RNPs, were immunoprecipitated effectively by certain anti-52-kDa SS-A/Ro peptide antibodies, indicating that the 52-kDa SS-A/Ro protein is associated with at least a subset of RoRNP particles [131].

Antibodies to SS-A/Ro occur in 60–70% of patients with Sjögren's syndrome, 5–10% of other connective tissue diseases, and 40% of patients with SLE [27, 132, 133]. SS-A/Ro antibodies are closely associated with disease subsets (Table 2) such as neonatal lupus erythematosus syndrome (NLS) [134–136], a photosensitive skin rash and subacute cutaneous lupus erythematosus [137–140], interstitial pneumonitis [141, 142], homozygous deficiency of complement proteins C2 and C4 [143, 144], idiopathic thrombocytopenic purpura [145–147], and the purpuric vasculitis typical of Sjögren's syndrome [132, 148]. Titers of SS-A/Ro antibodies have been correlated with lymphopenia [149], and when SS-B/La accompanies SS-A/Ro, the patients have an apparent decreased frequency of nephritis [149–151]. The impression that anti-SS-A/Ro antibodies fluctuate with disease activity [152, 153] is still open to debate and may depend on the assay being used. A new 75-kDa phosphoprotein (pp75) that binds to the carboxyl domain of the 60 kDa SS-A/Ro has also been shown to be an autoantigenic target in 17% of mothers of children with NLS and 6% of Sjögren's syndrome [154].

A study of 60 primary Sjögren's syndrome patients and 90 SLE patients showed that there is a dissociation of the immune responses to the 52- and 60-kDa antigens [155]. In this study, SS-A/Ro immunoprecipitins were identified in 78% of SS patients and in 57% of SLE sera. Of note, 13% of Sjögren's syndrome patients and 35% of SLE patients did not react with either protein in immunoblots. One explanation for this finding is that the immunoblotting techniques abolish epitopes that are expressed in the native protein, a finding in keeping with those of Boire *et al.* [60, 110, 111]. In addition, some patients react primarily with the deproteinized hy5 RNA [18, 60].

Studies of SS-A/Ro have also received much interest in the context of the NLS, a condition that occurs in approximately 1 of every 20,000 births and is characterized by a typical rash and/or congenital heart block (CHB) [156]. This interest was generated when it was noted that in three infant–mother pairs, both infants and their mothers had anti-SS-A/Ro in their serum [135]. In follow-up studies it was noted that anti-SS-A/Ro disappeared from the sera of the children, but continued to be present in the mothers. This suggests transplacental passage of antibody from mother to infant. The high association of isolated congenital complete heart block and anti-SS-A/Ro has been verified in a study of sera banked in the European Registry of CHB [136] (Table 3) and in a large study of CHB cases. There are several cases in which an alert physician aware of the association between anti-SS-A/Ro and NLS identified asymptomatic SLE in a mother who had circulating anti-SS-A/Ro antibodies. It has been suggested that NLS is characterized by antibodies directed against the 52-kDa protein [157, 158] and the concomitant occurrence of SS-A/Ro and SS-B/La [159]. Of interest, both SS-A/Ro and SS-B/La antigens have been detected on

TABLE 3 Serologic Findings in 21 Children with Isolated Congenital Complete Heart Block[a]

Age at time of serum collection	Number of children		No. of mothers with anti-SS-A/Ro
	Total	With anti-SS-A/Ro

the surface of myocardial fibers in CHB [160], and the 52β isoform of SS-A/Ro is highly expressed in heart tissue during embryogenesis [124]. In other studies, anti-SS-A/Ro has been shown to alter the transmembrane action potential of isolated cardiac cells [161] and Langendorff preparations of adult rabbit hearts [162]. These studies have added evidence that anti-SS-A/Ro autoantibodies play a pathogenic role in congenital heart block.

The availability of cDNAs encoding SS-A/Ro antigens and their respective recombinant proteins has permitted studies that defined the fine specificity of SS-A/Ro autoantibody reactivity. The expression of recombinant SS-A/Ro fragments has facilitated the definition of epitopes on the 60-kDa [125, 163, 164] and 52-kDa [113] antigens. Curiously, some antigenic peptides of the 60-kDa antigen tend to show short sequence homology with vesicular stomatitis virus nucleocapsid protein [165, 166]. Humans infected with vesicular stomatitis virus have low titers of anti-SS-A/Ro [167], and animals immunized with vesicular stomatitis nucleocapsid produce antibodies that react with 60-kDa SS-A/Ro [168]. These interesting studies will need to be reproduced and the association of stomatitis virus and SLE should be examined in the context of the pathogenesis and antibody production in SLE.

There has been some controversy concerning the question of ANA-negative lupus and the observation that many ANA-negative lupus patients have anti-SS-A/Ro [169, 170]. Several studies have clarified some of this controversy. One explanation is that ANA detected by IIF vary in sensitivity from one laboratory to the next [171]. A second explanation is that the concentration of SS-A/Ro antigen varies remarkably from one animal species to the next [172]. In species such as human, monkey, dog, and guinea pig, the SS-A/Ro antigen is present in higher concentrations than in species such as mouse, rat, and hamster. Therefore, when tissues from species such as rat or mouse are used as substrates in indirect immunofluorescence, a serum containing anti-SS-A/Ro antibody may not show reactivity. However, when human or guinea pig tissues are used, the serum would be positive. These observations are supported by studies showing that SS-A/Ro proteins extracted from human tissues demonstrate preferential reactivity with human SS-A/Ro antibodies [107, 173]. Thus ANA-negative lupus may be related to the high solubility of the antigen that can be washed away during tissue processing rather than the absence of ANA in the serum [6]. Therefore, it is important to use a known positive anti-SS-B/La control with each assay to be certain the antigen has not been solubilized.

Some dilemmas of using the ANA test to screen for SS-A/Ro antibodies in human serum are being resolved by using the transcribed recombinant 60-kDa DNA transfected into mammalian cells as an substrate for indirect immunofluorescence [174–180]. Alternatives are to use immunoblotting as a technique [112] and ELISA techniques that are able to identify reactivity that is undetected by conventional serological assays [173, 181, 182]. At present, the commercial kits designed to detect SS-A/Ro are known to have high sensitivity but may suffer from lack of specificity. In addition, there appears to be considerable variation in results obtained from kits supplied by different commercial vendors [182, 183]. It is clear that these techniques require considerable expertise and use of carefully controlled protocols [112, 182].

SS-B/La

The SS-B/La protein, a 46/48 kDa phosphoprotein [27, 184, 185], is highly conserved in mammals and is mainly associated with precursor forms of RNA polymerase III transcripts such as tRNAs, 7S RNA, and 5S RNA (Fig. 1). SS-B/La is increased in transformed cells [186], and virus-encoded RNAs, such as adenovirus-encoded VAI and VAII RNAs [187, 188], Epstein–Barr virus-encoded EBER RNAs [189, 190], and leader RNAs of some negative stranded viruses, are associated with the SS-B/La antigen [191, 192].

The SS-B/La antigen has RNA recognition motifs that bind to uridine-rich residues on the 3′ terminus of scRNAs [27] and may act as a shuttle to carry RNA transcripts from the nucleus to the cytoplasm [193]. The sequence of the antigen predicts a nuclear localization sequence and a putative ATP-binding site. One study has shown that SS-B/La is a nucleic acid-dependent ATPase/dATPase [194]. This enzyme can "melt" or separate the DNA/RNA hybrids that form during transcription and, along with SS-B/La, serves as a transcription initiation [195] and termination factor for RNA polymerase III [196]. All of these features may account for the observation that SS-B/La also increases the efficiency and fidelity of mRNA translation [197–199].

Epitopes of the SS-B/La antigen have been mapped to the RNA-binding domain [84] and a number of other regions [34, 200–204]. Of interest, peptides in the 88–101 segment bear sequence similarity with a retroviral *gag* protein [201], but the significance of this remains to be determined.

The antibody to SS-B-La is detected in 15–20% of SLE and in 45–60% of SS patients [1, 205]. Except for the overlapping presence of Sjögren's syndrome in patients with SLE, there does not appear to be any other distinguishing clinical features associated with the presence of anti-SS-B/La.

As with anti-SS-A/Ro, anti-SS-B/La is frequently detected by precipitin assays in sera yielding a false-negative ANA by IIF techniques [6]. Here it was felt that because of the high solubility of the SS-B/La antigen, it may be solubilized from tissue sections during the processing of the slides. Thus, it is important to use a known positive anti-SS-B/La control with each assay to be certain that the antigen has not been solubilized from the tissue and inadvertently washed from the slides. Such a positive control serum is available from the CDC reference bank in Atlanta, Georgia [38]. As with other autoantigen systems, the use of recombinant proteins in ELISA techniques may provide a more sensitive method to detect SS-B/La autoantibodies [206].

TABLE 4 Functions of Nuclear Autoantigens Inhibited by Autoantibodies[a]

Autoantigen	Function inhibited
Sm/nRNP (U1,2,4–6 snRNP)	Pre-mRNA splicing
PCNA (DNA pol δ auxiliary protein)	DNA replication and repair
Scl-70 (topoisomerase I)	DNA replication and transcription
RNA polymerase I	Transcription of rRNA
Centromere proteins CENP-A,B,C	Chromosome movement in mitosis
DNA polymerase II	DNA replication
tRNA synthetases	Amino acylation of tRNAs

Proliferating Cell Nuclear Antigen

Autoantibody to a nuclear antigen in proliferating cells was initially detected by positive immunofluorescence staining of scattered cells in the interstitial tissue of kidney and liver and negative reactions with nuclei of renal tubular, glomerular, or hepatic parenchymal cells [207]. The autoantibody did not react with nondividing interphase cells, but did react with rapidly proliferating or mitogen-stimulated cells, and the nuclear antigen was called *proliferating cell nuclear antigen* (PCNA). This antigen was not restricted to a specific cell type and was found in activated T and B lymphocytes [208]. PCNA was soluble in saline and was immunologically distinct from DNA and other known nuclear antigen–antibody systems such as Sm, U1 RNP, or SS-B/La.

Early studies focused on characterization of the antigen and the discovery that PCNA was identical to a protein referred to as cyclin [209–212]. It is important to note that the usage of the term "cyclin" in the current literature is reserved for a different family of proteins with regulatory roles for the cell cycle [213]. After that, the pure protein was isolated, the amino terminus was sequenced [214], and monoclonal antibodies were produced [215–217]. Eventually a rat cDNA [218] and a full-length cDNA encoding human PCNA [219] were isolated. Shortly after the description of a 36-kDa protein that was required for chain elongation in DNA synthesis mediated by DNA polymerase δ [220], it was reported that PCNA is identical to the auxiliary protein of DNA polymerase δ [221].

The determinants recognized by human autoantibodies and monoclonal antibodies directed against PCNA protein are different [222]. Other studies have shown that human antibodies can inhibit oligonucleotide synthesis *in vitro* whereas monoclonal antibodies cannot [223] (Table 4). These observations are concordant with observations that other autoantibodies directed against nonhistone proteins are able to inhibit the function of the cognate antigens (Table 4) and this feature is not generally shared by monoclonal antibodies binding to the same protein [224].

Antibodies to PCNA are detected in less than 5% of patients with SLE [207, 208, 225]. However, despite its low frequency, it is regarded as a highly specific marker antibody for SLE [1, 6]. Because of the somewhat low frequency of these antibodies, it has been difficult to determine if they serve as a marker for a distinct clinical subset of patients. One study has suggested a high frequency of diffuse proliferative glomerulonephritis in anti-PCNA-positive patients, and the somewhat low frequency of the antibody may be due to high sensitivity to immunosuppressive therapy [225]. Another study [208] did not identify unique clinical features, except for a higher frequency of lymphadenopathy.

Ku, Sp1

Different investigators in the same laboratory [226, 227] identified the Ku and Ki antibody systems almost simultaneously, and initially it was thought that Ki and Ku were identical [228, 229] (see Fig. 4). Subsequently, distinct antigens were cloned and identified [230]. In immunoprecipitation with [^{35}S]methionine labeled cells, the Ku antigen system has been shown to consist of a pair of ~70- and 80-kDa proteins designated p70/p80. Unlike other nonhistone proteins (i.e., Sm, U1 RNP, SS-A/Ro), p70/p80 are not bound tightly to RNA but form heterodimers and bind tightly to free ends of DNA [229, 231] where they serve as an anchor for a 350-kDa catalytic peptide with DNA-dependent protein kinase activity [232]. This complex appears to be involved in the repair of DNA double helix breaks and in VDJ recombination [233]. The association of these proteins

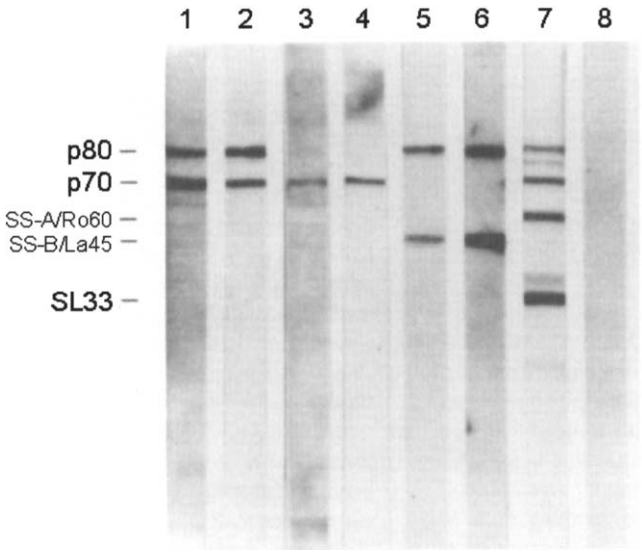

FIGURE 4 Immunoblotting studies showing five autoantigen systems. The HeLa cell extract was separated in SDS polyacrylamide gels and transferred to nitrocellulose. The first two antibody systems are represented in lanes 1 and 2 and show reactivity with both of the Ku p70 and p80 proteins. As illustrated in lanes 3 and 4, some sera react only with the p70 Ku antigen. In lanes 5 and 6, sera with reactivity to the p80 antigen but not the p70 Ku antigen are shown. In lane 7, a serum with reactivity with both Ku antigens and the Ki/SL (SL33) antigen is shown. Some sera with anti-Ku activity also bind SS-A/La (lanes 5 and 6) and 60-kDa SS-A/Ro (lane 7). Lane 8 is normal serum.

in vivo was demonstrated by colocalization of the antigen on early prophase and late telophase chromosomes. Curiously, these antigens appear to dissociate from chromosomes in metaphase and anaphase of the cell cycle, although they are reassociated to the nucleoplasm and nucleolus in interphase [229]. Analysis of anti-Ku sera by IIF demonstrated a speckled pattern of nuclear staining, and the nucleoli were stained in the G1 phase of the cell cycle [234, 235].

Patients with anti-Ku were initially characterized clinically by a predominance of arthritis, pericarditis, and pulmonary hypertension, but since then, antibodies to the Ku antigen have been described in a variety of conditions [230, 236]. In Japanese patients, anti-Ku is commonly associated with overlap syndromes, especially polymyositis/scleroderma and also in SLE/scleroderma [226]. One study used immunopurified p70/p80 antigen in sensitive ELISA or immunoblotting assays to identify Ku antibodies in 20–40% of SLE patients, 15–40% of scleroderma patients [229, 235], ~10% of myositis patients [235], 20% of Sjögren's syndrome patients [235], and 55% of MCTD patients [229]. The variation in antibody frequency in these studies is likely related to differences in the selection of sera, the assays employed, and the racial background of the patient [198].

Most patient sera recognize both Ku polypeptides in immunoblots, but the ratio of the intensity of reactivity of antibodies to the p80 and p70 antigens vary from serum to serum [235]. This suggested that the two proteins were the product of separate genes [237, 238], a theory that was supported when it was demonstrated that the cDNA sequence of the two proteins shows no amino acid sequence homology [239]. Nonetheless, some evidence has suggested that there are both unique and shared determinants on the p70 and p80 proteins. Because there is no amino acid homology between these two peptides, it is suggested that the shared determinants are conformational epitopes on these proteins. A study has shown that some autoantibodies bind to a presumably conformational epitope on the p70/p80 complex [240].

Many autoantibodies tend to be associated as "linked sets" [11], and in that context, it is interesting that there is a high frequency of anti-Sm antibodies in anti-Ku-positive sera [228, 235]. Although patients with anti-Sm frequently have concomitant anti-U1RNP antibodies, it appears that the "linked set" of anti-Ku/anti-Sm is to the exclusion of anti-U1RNP [235].

Sp1 and Ku are components of macromolecular complexes referred to as terminal repeat binding proteins (TRBP) [241]. Sp1 is phosphorylated by Ku, is characterized by a zinc finger domain, and serves as an RNA polymerase II transcription activator [241]. A study of eight patients who had antibodies directed against Sp-1 as determined by an electrophoretic mobility shift assay and immunoprecipitation showed that the majority had features of SLE (i.e., arthritis, fatigue, photosensitivity) but only one met the diagnostic criteria for SLE [241]. In addition, antibodies to a phosphorylated form of RNA polymerase II has also been shown to be an autoantigenic target in SLE [242].

Ki/SL

The Ki antigen is a ~31-kDa protein [238, 243, 244] that has sequence homology with topoisomerase IIα [245]. The sequence is highly conserved and has a predicted nuclear localization sequence [244]. ELISA has been used to detect anti-Ki/SL antibodies in up to 12% of SLE sera and overlap syndrome sera [246]. More recently, it was shown that an epitope recognized by SLE sera has sequence identity with the SV40 large T antigen nuclear localization signal [247]. This 31-kDa Ki antigen should not be confused with the nuclear proliferation-associated Ki-67 antigen [248, 249].

Ribosomal RNP and P Proteins

The mammalian ribosome is a cytoplasmic organelle consisting of 28S, 18S, 5.8S, 5S RNA, and some 80 different proteins [250, 251]. Because ribosomal RNP, (rRNP) antigens are cytoplasmic and nucleolar in location, a discussion of their biochemical characteristics and clinical relevance is included in this chapter. Although many of the ribosomal proteins are basic, the rRNP-P antigens (P0, P1, P2) are acidic phosphoproteins of 36, 19, and 17 kDa [252, 253]. The phosphoprotein moiety may account for observations that some high-affinity antibodies to dsDNA can also bind to these P proteins [254, 255]. P1 and P2 are involved in three steps of polypeptide synthesis: initiation, translocation, and termination [256]. Autoantibodies to other constituents, such as L12, the 20-kDa 60S subunit, S10 the 20-kDa 40S subunit, L5 the 35-kDa protein of the 5S subunit, and 28S ribosomal RNA have been described in SLE [257–260].

Autoantibodies from SLE patients cross-react with similar antigens present in rodent, brine shrimp, and yeast cells, demonstrating that the proteins and their epitopes have been conserved. Although the major epitope recognized by SLE sera resides within a 22 amino acid domain in the carboxyl-terminal region common to P0, P1, and P2, additional epitopes are recognized because the carboxyl peptides do not absorb the reactivity of some human sera to the native protein [253, 261]. It is possible that conformational epitopes not detected using short peptides are also recognized by SLE sera [261]. A mouse monoclonal antibody [262] and spontaneously arising autoantibodies in MRL/lpr mice recognize the same spectrum of rRNP-P proteins that are recognized by human autoantibodies [263].

The IIF staining pattern on HEp-2 cells is characterized by homogeneous or finely granular cytoplasmic, with or without nucleolar, staining [264] but it should be noted that at least 50% of sera with anti-P proteins do not show any staining on conventionally prepared tissue substrates. Immunoassays employing the recombinant P2 fusion protein or synthetic constructs of the dominant epitope have been developed and were found to correlate with immunoblotting and ELISA of the intact proteins [261, 265]. Also, anti-rRNP antibodies are associated more frequently with anti-Sm antibodies (present in 20% of sera containing anti-Sm) than with any other autoantibodies of the lupus profile [252].

Antibodies to ribosomal P proteins, ribosomal ribonucleoprotein (rRNP), 28S ribosomal RNA, and the L12/S10 subunits have been identified in the sera of 3–70% of SLE patients. Antibodies to the L12 subunit were found in higher frequency in juvenile SLE [266]. Antibodies to the S10 subunit appear to be less common than anti-L12 [258, 266, 267] and may be related to anti-Sm activity [266]. Reichlin and collaborators showed that patients with anti-rRNP appear to identify a subset of SLE patients with liver and kidney involvement, although some of their patients also had concomitant antibodies to native DNA [268–270]. It has been reported that 30–90% of patients, including children, with neuropsychiatric lupus have P protein antibodies [270–277] and the titers fluctuate in concert with disease activity [278]. Other studies [41, 271, 277] have not confirmed these clinical correlates.

HIGH MOBILITY GROUP PROTEINS

High mobility group proteins (HMG) are chromosomal proteins that are defined by their extractability with 0.35 *M* NaCl, solubility in 2–5% perchloric acid, a high content of charged amino acids, and a molecular mass of less than 30 kDa. They possess an extraordinary amino acid composition of 50% acidic and basic residues and a somewhat high content of proline. There are three distinct families of HMG proteins; the HMG-1/-2 family, the HMG-14/-17 family, and the HMG-I family. HMG-1 and HMG-2 comprise most HMG protein in the cell and have four domains: an unstructured N terminus, two basic folded regions containing many hydrophobic amino acids (DNA-binding domains), and a highly acidic carboxyl terminus (histone-binding domain). HMG-17 and HMG-14 are characterized by a highly basic amino terminus and a highly acidic carboxyl terminus. HMG-1 and HMG-2 bind to the linker DNA in chromatin, whereas HMG-17 and HMG-14 bind primarily to nucleosomes, especially those associated with transcriptionally active chromatin [279]. Of interest, binding of these HMGs may increase the susceptibility of chromatin to digestion by DNase I. The HMG-I family includes the HMG-I protein (also called a-protein) and its isoform HMG-Y. The amino acid composition of these proteins resembles HMG-14/-17 proteins but they appear to bind preferentially to A-T-rich DNA and are found in highest concentrations in rapidly dividing cells.

In one study, antibodies to calf thymus HMGs were found in 13/29 (45%) SLE sera and of these, 10 reacted with HMG-17, 3 with HMG-1, and 2 with HMG-2 [280]. In contrast, HMG antibodies were found in only 1/11 MCTD and in 0/14 RA patients. This study agrees with studies showing that antibodies to HMG-17 are prominent in SLE [281]. Of interest, there was a high correlation between the presence of HMG antibodies and histone antibodies, an observation that lends additional

evidence to the concept that intact nucleosomes serve as the autoantigenic stimulus in some SLE patients [282]. Further, some studies have suggested that HMG-17 resides on a subset of nucleosomes that are located in transcribable regions of the genome [283–285]. This suggests that one of the immunogens in SLE may be a subset of nucleosomes that contain specialized DNA sequences involved in the processing of messenger RNA. This possibility brings into sharper focus the recurring "theme" of autoantibodies in SLE that are characterized by their binding to various macromolecules involved in gene expression. Other studies have shown that HMG antibodies are found in drug-induced lupus [286], systemic sclerosis [287], idiopathic pulmonary fibrosis [288], and juvenile rheumatoid arthritis where they are correlated with a positive ANA [289, 290]. A study using ELISA and immunoblotting techniques showed that over 28% of SLE sera react with the HMG-associated protein known as structure specific recognition protein 1 (SSRP1) [291].

Ubiquitin and Proteasome

Ubiquitin is a low molecular weight, highly conserved eukaryotic protein that exists as a free molecule or as a protein linked covalently to a variety of cytoplasmic, nuclear, and cell membrane proteins [292, 293]. Most proteins that are degraded in the cytosol are delivered to a large protein complex called the proteasome [294]. In this organelle, degradation proceeds by a ubiquitin- and ATP-dependent mechanism. Histones H2A and H2B, which are targets of SLE autoantibodies [295, 296], are ubiquitinated during the cell cycle and during stress responses. Antibodies to ubiquitin and a synthetic fragment of ubiquitin were found in up to 80% of SLE patients and in 16% of other systemic rheumatic diseases [297, 298]. Further analysis of antibody reactivity to ubiquitin–protein conjugates has shown that 95% of SLE sera that bind ubiquitin contain antibodies specific for the branched ubiquitin-H2A peptide [299] and may have a role in the pathogenesis of lupus nephritis [300]. The α type subunit C9 of the 20S proteasome complex has been shown to be a SLE target antigen as well [294, 301].

Nuclear Lamins

The nuclear envelope is composed of four major structural components: a double membrane consisting of an inner laminar layer, an outer layer that is continuous with the endoplasmic reticulum, nuclear pores where the outer layer abuts the inner layer, and the interlaminar "space," also known as the *nuclear lamina* [302–304]. Electron microscopic analysis of the nuclear lamina reveals a meshwork of intermediate filaments that line the inner surface of the inner nuclear membrane [304, 305]. The nuclear lamina is rich in three structural proteins of 74, 68, and 60 kDa also called A, B, and C proteins. It is thought that lamins A and C serve as anchoring sites for interphase chromatin, whereas lamin B binds to the inner nuclear membrane [306]. Analysis of the amino acid sequence of the lamins shows similarity to the cytoskeletal intermediate filament proteins [307, 308].

Autoantibodies to nuclear lamins are characterized by linear staining of the nuclear envelope that clearly delineates the nucleus from the cytoplasm [309], and in some laboratories this is called a *peripheral* or *rim* pattern of staining [310]. After the introduction of IIF for the identification of antinuclear antibodies, it was felt that the rim pattern of staining represented antibodies to dsDNA [311]. Although these sera often contained anti-DNA antibodies, it is probable that the rim pattern of staining represented antibodies directed against other components of the nuclear membrane. It was suggested that sera containing monospecific antibodies to DNA can be differentiated from sera containing anti-lamin antibodies based on these staining patterns on IIF [309]. However, if the DNA and lamin antibodies occur in the same serum, a distinctive staining pattern is less apparent. Because most studies of the frequency of lamin antibodies have been based on sera selected for specific staining patterns, the frequency of lamin antibodies in systemic rheumatic diseases may be underestimated.

Nuclear lamin antibodies have been described in a variety of autoimmune diseases, including systemic lupus erythematosus [312–314], linear scleroderma [315], autoimmune (lupoid) hepatitis [312, 316, 317], chronic fatigue syndrome [318], rheumatoid arthritis [319], and primary biliary cirrhosis [320, 321]. An analysis of the patients in these reports suggests that common clinical features in patients with lamin antibodies are the presence of "lupoid" or chronic active hepatitis [317, 320] and the lupus anticoagulant [322]. In addition, diseases may be differentiated based on antibodies that bind to specific lamin proteins and epitopes [80]. For example, sera from SLE patients (particularly those with cytopenias) react predominantly to a unique domain on the B protein, whereas patients with autoimmune liver diseases bind to A and C proteins. This is of interest because the sequences of lamins A and C differ only at the carboxyl terminus, whereas the B protein appears to have less sequence similarity to the others. However, the observation that monoclonal antibodies can recognize all three lamins suggests that they bear similar epitopes [323].

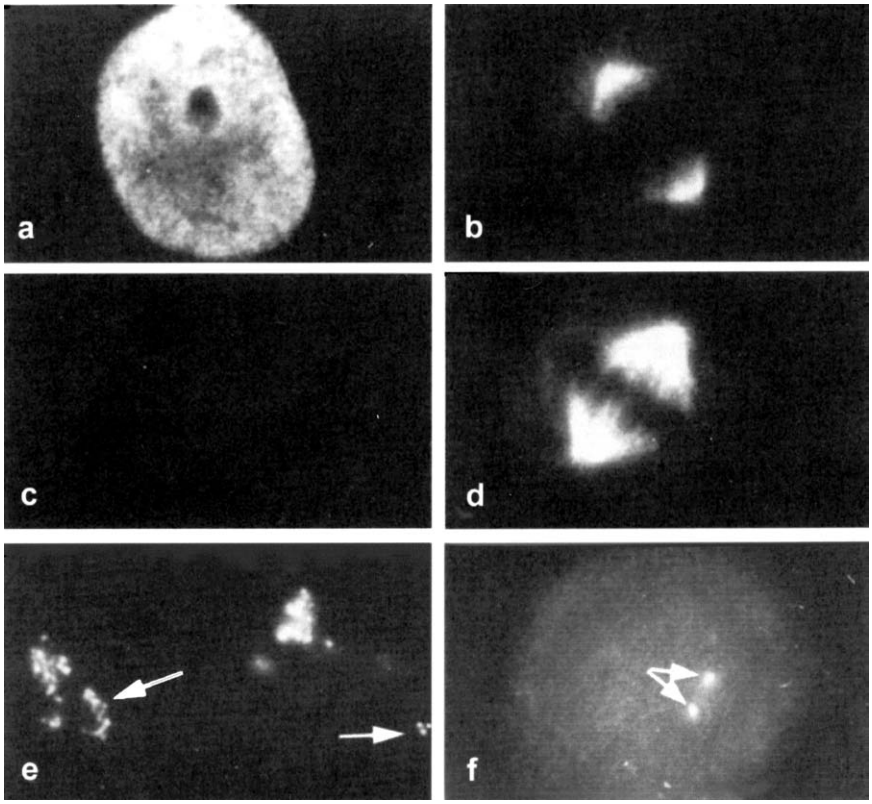

FIGURE 5 A comparison of the IIF patterns of human antibodies to NuMA (**a** and **b**), HsEg5 (**c** and **d**), and ASE-1 (**e** and **f**). In interphase cells, NuMA is represented by a fine speckled staining pattern (**a**) and bright staining of the centrosome and the spindle fibers proximal to the centrosomes (**b**). In comparison, antibodies to HsEg5 show no staining of interphase cells (**c**) but bright staining that extends along kinetochore-to-pole microtubules in metaphase cells (d). ASE-1 antibodies stain discrete foci in the fibrillar centers of interphase nucleoli (**e**, arrows) and the nucleolar organizer regions of condensed metaphase chromosomes (**f**, arrows).

Mitotic Spindle Apparatus

A number of autoantigens that reside in the mitotic spindle apparatus (MSA) have been described [324]. These include the nuclear mitotic apparatus (NuMA) [325] and the human spindle kinesin-like (HsEg5) [326] proteins. NuMA, also referred to as mitotic apparatus antigen I (MA-I) by Andrade *et al.* [325], is a 235-kDa protein characterized by IIF as a finely speckled nuclear pattern in interphase cells and bright staining of the spindle poles and associated fibers during metaphase (Figs. 5a and 5b). By comparison, HsEg5 is a ~130-kDa protein that does not appear in interphase nuclear IIF staining but is characterized by intense staining of the spindle fibers at metaphase, the interpolar fibers at anaphase, and intercellular bridge staining in telophase (Figs. 5c and 5d) [326]. When autoantibodies directed against HsEg5 occur in isolation, the distinctive IIF pattern is easily identified. However, in a few patients, autoantibodies to HsEg5 and NuMA have been found to coexist, making the distinction of the two autoantibodies in the same serum difficult. A study of 7 patients who had antibodies to HsEg5 showed that 6 had SLE and 1 had Sjögren's syndrome, and the autoantibody to HsEg5 was only found in 6% of an unselected cohort of SLE patients [326]. In this same study, only 1 of 52 SLE patients had anti-NuMA. In another study of 17 patients with antibodies to NuMA, 9 (53%) had Sjögren's syndrome and none had SLE [325]. Antibodies to NuMA have also been reported in patients with systemic sclerosis and other diseases [327, 328].

Other Antigens

Autoantibodies in SLE directed against other nonhistone intracellular antigens include the Golgi apparatus [329–331], endosomes [332, 333], mitochondria [334–341], a multicatalytic protease [342], red blood cell carbonic anhydrase [343, 344], RNA polymerase I [160],

[a] Dermatomyositis/polymyositis antigens include Jo-l, Mi2, and Pl-7.

Alu RNA–protein complex [345], a 90-kDa nucleolar organizer upstream binding factor for RNA polymerase I [346, 347], p53 [348, 349], p57 [350], calreticulin [351, 352], and a number of proteins related to DNA binding and DNA metabolism [241, 353–356]. More recently described autoantibodies in SLE sera include those directed against a 100-kDa RNA helicase (Gu) [357], the DEK oncoprotein [358, 359], and ASE-1, an antigen in the fibrillar center of nucleoli that has a distribution and molecular mass similar to NOR-90 (Figs. 5e and 5f) [360]. In SLE sera, ASE-1 tends to be commonly associated with sera that also have anti-Sm antibodies [360, 361]. Cross-reacting antibodies and molecular mimicry have been areas of some interest, and it has been shown that a subset of anti-DNA antibodies bind to a molecular mimic pentapeptide Asp/Glu-Trp-Asp/Glu-Tyr-Ser/Gly found in the NR2 glutamate receptor [362].

SUMMARY: SLE IS CHARACTERIZED BY DISTINCT AUTOANTIBODY PROFILES

Distinct profiles of ANA have been found in different systemic rheumatic diseases, characteristics of which include the presence or absence of certain antibodies and differences in mean titers of these antibodies. Table 5 outlines the ANA profiles of SLE and four other systemic rheumatic diseases: Sjögren's syndrome, MCTD, myositis, and scleroderma. The following conclusions can be made from these profiles: (1) multiple ANA are found frequently in SLE; (2) anti-Sm, anti-PCNA, and anti dsDNA are distinctive markers for SLE; (3) anti-U1-RNP is present in several diseases but in different frequencies; (4) anti-Scl-70 and anticentromere are distinctive for scleroderma; and (5) anti-Jo-1 and anti-Pl-7 antibodies are distinctive for polymyositis.

IMMUNE COMPLEXES

Mark H. Wener
Mart Mannik

Systemic lupus erythematosus (SLE) is the prototype of human diseases that are principally mediated by immune complexes. The evidence for tissue injury by immune complexes in SLE is marshaled from many observations. The recognition of a number of autoantibodies in this disease served as an important initial finding. The presence of immunoglobulin and complement deposits in target organs and the characteristics of pathologic changes allowed the comparison of SLE to experimental models of serum sickness [1]. The conclusive evidence of the involvement of immune complexes in the genesis of tissue lesions, however, was provided by the identification of specific antibodies in the glomeruli of patients with SLE [2].

Injury to specific target organs in immune complex-mediated diseases results from the presence of antigen–antibody complexes in tissue. Immune complex deposits activate complement and interact with cell receptors, leading to the release of cytokines from cells and culminating in tissue damage and organ dysfunction. Antigen–antibody deposits in tissue may arise from deposition in tissues of circulating immune complexes, from formation of immune complexes at the site of their existence in tissues, or a combination of both.

This chapter reviews the nature of immune complexes, considers the biologic properties of immune complexes in relation to pathogenic processes, and discusses the clinical application of tests for the detection of immune complexes.

CHARACTERISTICS OF IMMUNE COMPLEXES

Immune complexes are composed of antigens and antibodies. The chemical features and physical characteristics of antigens can be quite variable, ranging from simple molecules to complex macromolecules or tissue components. The nature of an antigen in immune complexes may influence the biologic properties of the complexes. Antibodies in immune complexes may belong to any of the classes of immunoglobulins and endow the complexes with biologic properties unique to the particular class of immunoglobulin. In addition, the nature of the union between the antigen and the antibody influences the biologic properties of the resultant immune complexes, particularly the number of antibodies in a given immune complex.

Antigens

Antigens are substances that interact specifically with available antibodies or with receptors on sensitized lymphocytes. The term *immunogen* is used for substances that upon administration to a suitable host will elicit an immune response. The two concepts are separated, as antigens that can be shown to react with specific antibodies or with specifically sensitized lymphocytes do not necessarily induce an immune response. The actual portion of an antigen molecule that interacts with the

antibody-combining site or with a specific receptor of a sensitized lymphocyte is an *antigenic determinant* or *epitope*. The epitope is of limited size. For example, an epitope consists of five to six amino acids or of six to seven monosaccharide units. Furthermore, the antigenic determinant may consist of a sequence of amino acids or of a particular conformation of the protein so that the actual epitope is formed by amino acids from various areas of the polypeptide chain, or the epitope may be formed by the proximity of amino acids from separate polypeptide chains. Antigens may be proteins, polysaccharides, nucleic acids, lipoproteins, phospholipids, or other chemicals.

The number of antigenic determinants on a given molecule defines its valence for the interaction with specific antibodies. Small molecules with a single antigenic determinant are called *haptens.* Proteins or other substances of larger molecular size may possess multiple epitopes. The number of antigenic determinants on the molecule for a given antibody specificity defines the valence of that antigen for that antibody specificity. Most proteins and other macromolecules possess multiple epitopes with variable valence. As discussed later, the valence of antigens profoundly alters the nature of immune complexes formed upon interaction with antibodies.

The chemical features of an antigen may significantly influence the biologic properties of immune complexes, independent of the properties provided by antibodies in the complexes. This point can best be made by several specific examples. Highly cationic (positively charged) antigens can interact with fixed negative charges in glomeruli and thereby influence the localization of immune complexes in these structures. The clearance of immune complexes from the circulation can be altered by the nature of antigens present in immune complexes. For example, small-latticed immune complexes prepared with orosomucoid persisted in circulation similar to other small-latticed immune complexes. In contrast, when similar small-latticed immune complexes were prepared with asialo-orosomucoid with exposed galactose, the removal of these small-latticed immune complexes from circulation was hastened by the interaction of galactose with galactose receptors on hepatocytes [3]. In a similar manner, large molecular weight DNA is removed quickly from circulation by the liver because of the presence of specific receptors for DNA on nonparenchymal cells [4]. As a consequence, immune complexes containing such DNA are also removed faster from circulation than immune aggregates with comparable numbers of antibody molecules and protein antigens [5]. These studies performed in experimental animals emphasize the potential role of antigens on the biologic properties of immune complexes.

Whereas in the classic serum sickness immune complex model, the antigen in the immune complex (often heterologous serum albumin in experimental systems) bears little relevance to the resultant pathology, in SLE and other human immune complex diseases the antigen constituents within the immune complex could influence the pattern of clinical sequelae. For example, immune complexes containing lipids could augment the risk for cardiovascular disease. The uptake of lipids and the formation of foam cells is enhanced if the lipids are bound to IgG, i.e., as an immune complex [6]. This uptake is mediated, at least in part, by Fcγ receptors (FcγR) [7–9]. The FcγR-mediated uptake of lipids can lead to the formation and activation of the lipid-laden macrophage [10], including promotion of an atherogenic, oxidative phenotype of the macrophage [11]. Serum from patients with SLE has been reported to contain LDL-bearing immune complexes, which enhanced the uptake of lipids into macrophages [12], although similar findings were also found in patients with coronary artery disease [13].

Some antiphospholipid antibodies bind to other families of lipids, including oxidized low-density lipoproteins, (LDL) [14]. Immune complexes containing antibodies to lipoproteins known to be associated with atherogenesis could play a role in the development of coronary artery disease. Hasunama *et al*. [15] found that the anticardiolipin cofactor β_2-glycoprotein I (β_2-GPI) bound preferentially to oxidized plasma lipoproteins, i.e., oxidized (ox)VLDL, oxLDL, and oxHDL, in comparison with the native forms of the lipoproteins [15]. Antibodies to β_2-GPI bound to the β_2-glycoprotein I–oxLDL complex. Whereas binding of β_2-GPI to oxLDL inhibited the uptake of oxLDL by macrophages, the uptake was enhanced in the presence of immune complexes containing anti-β_2-GPI and β_2-GPI–oxLDL. Uptake of oxLDL by macrophages predisposes to the formation of foam cells, leading to intimal disease and atherosclerosis, thus the enhanced uptake caused by lipoprotein-containing immune complexes could contribute to accelerated atherosclerosis [16] as well las immune complex disease. Given the growing importance of coronary disease and of the antiphospholipid syndrome in SLE, the role of immune complexes in those manifestations bears further investigation.

Evidence has accumulated that immune complexes containing nucleosomes are important in the pathogenesis of lupus nephritis, and the antigen within those complexes may play a critical role, leading to the localization of immune complexes in the glomerular basement membrane. Renal biopsies from patients with diffuse proliferative lupus nephritis and membranous lupus

nephritis were found to contain nucleosomes and histones [17]. DNA found in the blood of patients with SLE is probably nucleosomal [18]. Furthermore, immune complexes containing nucleosomes are found circulating in MRL/lpr mice [19]. Clearance of chromatin by the liver is mediated in part by charge–charge interactions with heparan sulfate proteoglycans on hepatic Kuffper cells [20]. It has been suggested that nucleosomes can also interact with heparan sulfate proteoglycans in the kidney, promoting the glomerular deposition of circulating nucleosome–antinucleosome immune complexes or *in situ* formation of immune complexes after the initial deposition of nucleosomes in the glomerulus [21, 22]. Reasoning that heparin injections can compete with glomerular basement membrane structural heparan sulfate for binding to nucleosomes, van Bruggen and colleagues [23] treated MRL mice with heparin and demonstrated that heparin treatment led to less severe nephritis compared with untreated MRL mice [23]. Collectively, these data suggest that nucleosomes within immune complexes of lupus patients could influence the deposition of those immune complexes and again demonstrate that the antigen within an immune complex can contribute to the pathogeneticity of an immune complex.

Antibodies

Antibodies are the other essential constituent of antigen–antibody complexes. Detailed discussion of the antibody structure is beyond the scope of this chapter. Antibodies may belong to the IgG, IgA, IgM, IgD, or IgE classes of immunoglobulins. Most antibody molecules have two combining sites and hence a valence of 2 (IgG, monomeric IgA, IgD, and IgE). Dimeric IgA has a valence of 4, and IgM molecules exhibit a valence of 10 for small antigenic molecules or a valence of 5 for some large antigenic molecules. The distance between the two antibody-combining sites can also alter the nature of the formed complexes. In a given antibody molecule, this distance is somewhat variable, depending on the flexibility of the two Fab arms at the hinge region. The flexibility of the hinge region depends substantially on the isotype of the immunoglobulin, with human IgG3 having a long, flexible hinge region and IgG2 having a shorter, more constrained hinge region. Effector functions of the antibody molecules are localized in the constant regions of the two heavy chains. The important effector functions in relation to immune complexes are complement activation and interaction with specific cell receptors. Detailed reviews of immunoglobulin structure and effector functions are available [24, 25].

Nature of the Antigen–Antibody Union

The interaction of antigens and antibodies leads to the formation of immune complexes. A variety of immune complexes can be formed, ranging from the union of one antigen molecule and one antibody molecule to interactions of many molecules of each of the reactants. The *lattice* of immune complexes is defined as the number of antigens and the number of antibody molecules in a given immune complex. Such unions may be designated Ag_1Ab_1, Ag_2Ab_1, Ag_1Ab_2, Ag_2Ab_2, and so forth. A number of variables alter the lattice formation of immune complexes. In turn, the lattice of immune complexes influences the biologic properties of the complexes.

The valence of antibodies and the valence of antigens, among other variables, dictate the nature of the formed lattice. As already pointed out, most antibodies have a valence of 2. A monovalent antigen can maximally form Ag_2Ab_1 complexes, and larger lattices and immune precipitates cannot be formed. Bivalent antigens, depending on the distance between the antigenic determinants, may form Ag_1Ab_1, Ag_2Ab_2, circular Ag_3Ab_3, or larger open or closed complexes. Multivalent antigens may form increasingly larger complexes with high degrees of lattice formation, and immune precipitates may form. The presence of multiple different antigenic determinants allows the formation of complex and large lattices as well as precipitation. When an antigen is polyvalent with an appropriately spaced, repeating antigenic determinant, both antibody-combining sites of a bivalent antibody molecule preferentially react with the same antigenic molecule because of the formation of two antigen–antibody bonds between the reactants. This type of reaction is termed *monogamous bivalent reaction* and does not favor the formation of immune complexes with many antigen and many antibody molecules [26]. Antibodies to DNA, for example, may bind with monogamous bivalent interactions to DNA of appropriate size, and the cross-linking of DNA strands by antibody molecules is not favored by this interaction [27]. Of considerable interest is the finding that the strand of DNA bound with antibodies to DNA by monogamous bivalent binding was protected from degradation by DNase. The protected length of DNA corresponded to the distance between the two combining sites of an IgG molecule [28].

Another variable in the nature of antigen–antibody union is the molar ratio of the reactants; this is well illustrated by the classical precipitation curves. For example, when an increasing amount of antigen is added to a constant amount of antibody, then an increasing amount of precipitate is formed in the antibody excess zone. The maximum amount of precipitate is formed at the point

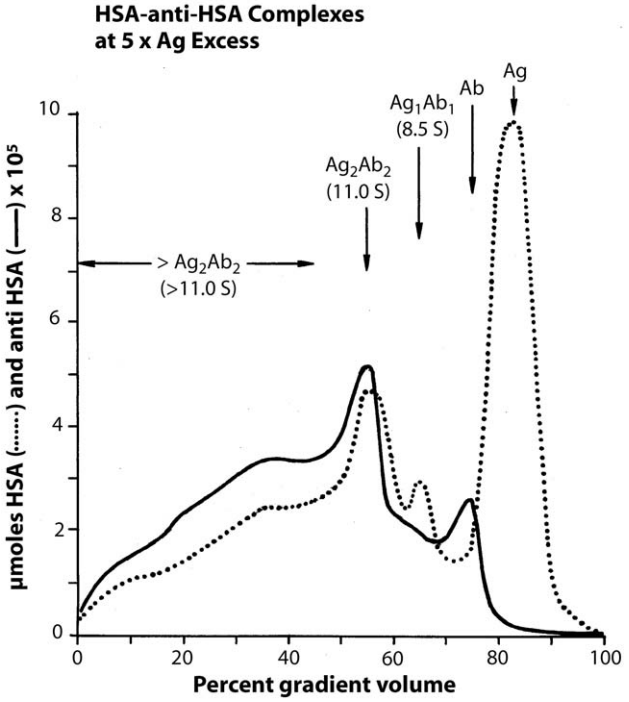

FIGURE 1 An example of the lattice of immune complexes. These soluble immune complexes were prepared with ^{131}I-labeled human serum albumin (HSA) and ^{125}I-labeled rabbit anti-HSA (IgG) at five times antigen excess, as determined by a precipitation curve. The size distribution of the complexes upon sucrose density gradient ultracentrifugation is shown. The micromoles of antigen and micromoles of antibody in each fraction are plotted against the percent gradient volume, with the top of the gradient being to the right. Starting from the right, the free excess antigen (Ag) is evident, and some unreactive or denatured antibody (Ab) is present. A small amount of Ag_1Ab_1 complexes is present, and a distinct peak of Ag_2Ab_2 complexes is evident with a sedimentation constant of 11 units. Ag_1Ab_1 and Ag_2Ab_2 complexes are collectively called *small-latticed immune complexes*. These complexes are inefficient in complement activation and interactions with FcγR and do not deposit in tissues. Beyond the peak of Ag_2Ab_2 complexes is a spectrum of larger lattices, ranging up to 22 units at the bottom of the tube. Discrete sizes of complexes cannot be distinguished, and therefore these complexes are collectively called *large-latticed immune complexes* (>Ag_2Ab_2). These complexes can activate complement, interact with FcγR, and deposit in tissues.

of equivalence. At this molar ratio of the interactants, free antigen and free antibody are not detectable in the supernatant. The addition of antigen beyond the point of equivalence leads to the formation of soluble immune complexes, and the amount of formed precipitate is decreased. At low degrees of antigen excess the soluble complexes have relatively large lattices (Fig. 1). With the addition of higher degrees of antigen excess, the formed soluble immune complexes become smaller. With very high degrees of antigen excess, only Ag_1Ab_1, Ag_2Ab_2, or Ag_2Ab_1 is formed, depending on the characteristics of the antigen. Furthermore, the absolute concentration of antigen and antibody influences lattice formation independent of the antigen–antibody molar ratio. Very low concentrations of antigens and antibodies tend to form more small-latticed complexes than are formed at higher antigen and antibody concentrations at the same antigen–antibody molar ratio. Finally, the association constant between the antigen and the antibody influences the lattice formed by these interactants. In general, low-affinity antibodies form smaller lattices than high-affinity antibodies when all other variables remain constant. With increasing lattice formation, biologic properties such as complement activation and interaction with cell receptors increase, as is discussed further in a subsequent section.

The initial interaction of an antigen and antibody depends on the antibody-combining site and the antigenic determinant of the antigen molecule. Interactions between other parts of antibody molecules, such as the Fc regions, are thought to contribute to nonspecific aggregation, to cryoprecipitability, and to formation of precipitates of the immune complexes. These events are slower than the initial antigen–antibody interaction.

Complement components have two significant influences on antigen–antibody complexes. First, when small amounts of immune complexes at equivalence are formed in the presence of fresh serum, then precipitation is prevented and only soluble complexes are generated (Fig. 2). When complement components are inactivated, then immune precipitates are formed under the same conditions. In this prevention of precipitation, the classical complement pathway plays a significant role [29]. Second, small quantities of already formed immune precipitates can be converted to soluble immune complexes by activation of the complement system. The alternative complement pathway is important in this complement-dependent solubilization of immune complexes [30]. The solubilized immune complexes contain covalently bound C3b and no longer are able to form immune precipitates. These observations, in conjunction with the observed increased prevalence of immune complex-mediated diseases in patients with deficiencies of the components of the classical pathway, have suggested an important role for complement components in retarding the deposition of immune complexes in tissues [31]. Thus, the possibility exists that the absence of complement components or the decrease of complement components due to the activation by immune complexes may contribute to the formation of immune complexes with increased pathogenic potential in tissues or in the circulation. However,

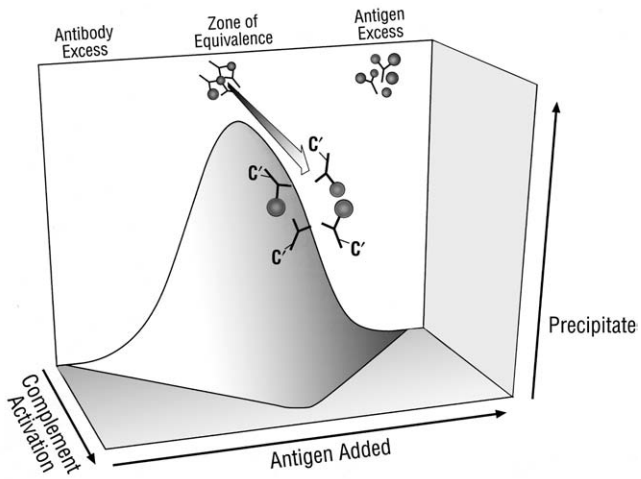

FIGURE 2 Schematic representation of immune precipitation and the effect of complement on this process. The classical precipitin curve demonstrates the effect of adding increasing amounts of antigen to a constant amount of antibody. With increasing amounts of antigen, the amount of precipitate increases until the zone of equivalence. Upon the addition of even more antigen, the amount of precipitate decreases due to the formation of soluble immune complexes. This relationship is shown by the two-dimensional precipitin curve shown as the "back" of this schematic. This three-dimensional schematic also illustrates the effect of complement on the amount of immune precipitate. Increasing amounts of added complement prevent the formation of immune precipitates and large immune complexes via the classical pathway, and the alternate pathway solubilizes preformed immune precipitates. The complement protein fragment C3b interferes with formation of the immune complex lattice or disrupts the lattice that has been formed. The large arrow represents solubilization of immune complexes by increasing amounts of added complement.

inflammatory cells may be recruited to the sites of immune deposits less efficiently in the presence of complement deficiency. These possibilities and the association between genetic abnormalities of the complement system and SLE are considered further in Chapters 5 and 6.

BIOLOGIC PROPERTIES OF IMMUNE COMPLEXES

Among the many properties of immune complexes, activation of the complement systems, interaction with cell receptors, and deposition in tissues are most relevant to the present discussion. Interactions with cells are mediated largely through Fc and complement receptors present on a variety of cell types. The degree of these biologic activities depends in part on the class or subclass of antibodies in the immune complexes and on the degree of lattice formation in the complexes.

Several biologic properties of immune complexes form the basis of tests that have been designed to detect and quantify immune complexes in serum or other body fluids. The use of these tests for clinical evaluation is discussed in the last section of this chapter.

Complement Activation by Immune Complexes

Activation of the complement systems by immune complexes may proceed through the classical or the alternative pathways. The interested reader should refer to standard texts or reviews of the complement system.

Antibodies of the IgG and IgM class activate the complement by the classical pathway, if sufficient lattice formation is present. The IgG1, IgG2, and IgG3 subclasses are effective in complement activation, and the IgG4 subclass is ineffective. As the initial step of complement activation through the classical pathway, globular regions of the C1q molecules bind to the Cγ2 domain of the IgG molecule in immune complexes. The exact site for binding C1q, however, remains controversial, and differences in the binding site may depend on the species and isotype of immunoglobulin studied [32–35]. Even monomeric IgG molecules bind weakly to isolated C1q, as revealed by analytic ultracentrifugation. Activation of the system, however, requires that the immune complexes containing IgG form a multivalent ligand for interaction with C1. In general, immune complexes become increasingly more effective in binding C1 and activation of the complement system with increasing numbers of IgG molecules [36]. The number of IgM molecules required in soluble immune complexes for complement activation has not been carefully defined, but on the cell surface, one IgM antibody suffices to activate the complement system. The other classes of antibody molecules in immune complexes do not activate complement. The alternative complement pathway is also activated by immune complexes that activate the classical pathway by generating C3b and thereby activating the C3b-dependent loop of the alternative pathway. Immune complexes containing IgA as antibodies activate the alternative pathway directly and efficiently [36].

Complement activation by immune complexes has several consequences in relation to disease processes. For example, the generation of chemotactic factors leads to an influx of phagocytic cells to tissues that contain deposits of immune complexes. The phagocytic cells ingest the immune deposits and, during this process, release enzymes and other factors that contribute to the damaging effects of inflammation. In

addition, the Fc receptor-mediated interaction of IgG-containing immune complexes with phagocytic cells is enhanced by the presence of complement components on immune complexes and complement receptors on these cells. The binding of complement components to immune deposits contributes to tissue damage and organ malfunction. For instance, complement components of the membrane-attack complex have been identified in skin and in glomeruli of patients with SLE [37, 38]. Studies in experimental animals have shown that the binding of complement components to the subepithelial deposits in glomeruli initiates the proteinuria associated with this lesion [39]. There is, however, a critical role of FcγRs in the mediation of experimental murine immune complex nephritis, as discussed later. The role of complement in the solubilization of immune precipitates was discussed in a preceding section and in Chapter 5.

The pivotal role of complement in causing immune complex disease has been challenged by experiments involving animals without functional complement, caused by induced defects in either complement proteins or complement receptors. In mice lacking complement proteins due to experimental manipulation, immune-mediated renal disease may be less severe, more severe, or essentially unchanged in comparison with mice with genetically normal complement proteins. The acute renal disease caused by administration of antibodies to glomerular basement membrane (GBM) antigens is less severe in mice deficient in C3 or C4 [40], whereas the chronic immune complex phase, mediated by antibodies to the administered anti-GBM, is little different or possibly slightly more severe in mice with complement deficiency. In MRL/lpr mice with C3 deficiency, a larger number of glomerular immune deposits were observed but the renal disease was no different histopathologically than found in MRL/lpr mice with normal C3 genes [41]. Together, these data indicate that an intact complement system is not necessary for many forms of immune complex tissue damage. Nevetheless, other evidence indicates that complement deficiency can ameliorate immune complex disease and decrease tissue damage (see Chapter 5 and 6).

Interaction of Immune Complexes with Cell Receptors: Binding and Functional Consequences

Specific receptors exist on cells that interact with the antibody molecules in immune complexes. Other receptors react specifically with complement components that have bound to immune complexes. Cellular receptors have important roles in the clearance of immune complexes from the circulation and from tissues, in recruitment of inflammatory cells into an area of immune deposits, and in regulation of cells function, as discussed later.

Fcγ receptors reacting with IgG molecules and not with other classes of immunoglobulins exist in three major forms, termed FcγRI, FcγRII, and FcγRIII [42–44]. Each of these major types has subtypes, with three genes encoding FcγRI, three genes encoding FcγRII, and two genes encoding FcγRIII; gene loci are on the long arm of chromosome 1 [1q21–23]. In addition, there are splice variants of several of the FcγRs (see Table 1). The FcγRI, FcγRII, and FcγRIII on Kupffer cells of the liver all may have a role in the removal of circulating IgG-containing immune complexes, and FcγRs on liver endothelial cells may also have a role in immune complex binding [45–47]. FcγRI have high affinity for monomeric IgG1 and IgG3 on cell surfaces and function in antibody-dependent cellular cytotoxicity [42, 47]. Genetic polymorphisms exist for FcγRII and FcγRIII and possess different functions. Most of the FcγRs are transmembrane protein, but FcγRIIIb, which is expressed only on neutrophils and activated eosinophils, is a phosphatidylinositol glycan-anchored form of the CD16 molecule. Several clinical studies have implicated allelic polymorphisms of FcγR II and FcγR III as risk factors for SLE. In addition, mice genetically engineered to delete FcγRI and FcγRIII have been shown to be protected from experimental immune complex disease, whereas FcγRII knockout mice have more severe immune complex disease [42–44].

The lattice of immune complexes significantly influences the interaction of complexes with FcγR. Monomeric IgG molecules have a weak interaction with FcγRII and FcγRIII and these interactions do not trigger interiorization of the attached molecules by the cells. The attachment of immune complexes with sufficient lattice, however, results in phagocytosis of the complexes. Small-latticed immune complexes are not efficiently phagocytized by neutrophils, monocytes, or Kupffer cells. Such small complexes could be formed with monovalent or divalent antigens or formed by high degrees of antigen excess with polyvalent antigenic molecules. In contrast, large-latticed immune complexes are attached to the FcγR and then phagocytized by the cell. Investigations have suggested that the interaction of large-latticed complexes with receptors results in an increased local concentration of immune complexes that leads to further condensation or rearrangement of the complexes to even larger lattices before interiorization [48].

The interaction of immune complexes with cell receptors provides the principal basis for their removal from circulation by the mononuclear phagocyte system. This topic is considered later. In addition, immune

TABLE 1 Characteristics of Fc gamma receptors

Receptor class, CD designation	Affinity for IgG (M^{-1})	Genes	Cell linkage	IgG form	Effect on cells	Cells bearing receptor	Clinically important allelic isoforms	IgG subclass specificity	Functional importance	Relevance to SLE
FcγRI, CD64	10^8–10^9 (high)	FcγRIA	TM	monomeric	Activation	Monocytes, macrophages, activated PMNs		1,3 >> 4 >> 2	Binds monomeric IgG as well as immune complexes	KO mice protected

complexes have a role in regulating lymphocytes and inflammatory cells.

Immune complexes can alter the immune response and lymphocyte functions. For example, immune complexes are 100 to 1000-fold more effective in inducing the proliferation of primed T-cells-than antigen alone [49]. FcγRs may have an important role in modulating T-cell-mediated responses by targeting immune complexes to antigen-presenting dendritic cells, leading to internalization of antigen, maturation of dendritic cells, activating or inhibiting dendritic cell function, and antigen presentation to T cells [50]. Polyclonal B-cell activation by immune complexes is of considerable interest in autoimmune diseases such as SLE. In experimental animals, immune complexes have been demonstrated to stimulate the proliferation of B cells and the synthesis of antibodies that are not related to the constituents of immune complexes [51]. Binding of immune complexes to Fc receptors leads to aggregation of those receptors and triggers intracellular signalling pathways [42]. Immune complexes binding via the FcγRIIB receptor have been shown to exert a downregulatory immunomodulatory effect, counterbalancing the activation induced by immune complexes binding to cells via the FcγRI and FcγRIII receptors [42]. Soluble and insoluble immune complexes appear to activate neutrophils by different mechanisms and via somewhat different FcγR involvment. Activation by soluble complexes is mediated by binding to both FcγRII and FcγRIIIb and leads to the release of secreted inflammatory mediators from cytokine-primed neutrophils, whereas insoluble complex activation was mediated by FcγRIIIb without FcγRII and led to the production of intracellular reactive oxygen species and the release of granule enzymes from both cytokine-primed and -unprimed neutrophils [52].

Information indicates that FcγR may have a more important role in mediating immune complex disease than had been appreciated previously. These data have been reported in a series of papers, largely using mice generated by Ravetch, that lack the transmembrane, signal-transducing γ chain that is found on IgG FcγRI and FcγRIII. In cutaneous Arthus reaction models in those mice, as well as experiments with autoimmune mice crossbred with the Fc receptor knock out mice, neutrophil infiltration and organ dysfunction required intact Fc receptors, despite the presence of immune complexes in tissues [53]. Furthermore, inflammation was not altered by complement deficiency. The susceptibility to murine lupus nephritis [54, 55] and to collagen-induced arthritis was also found to be altered in FcγR-deficient mice [56], indicating that similar mechanisms were important in these diseases. In a murine model of immune complex peritonitis, neutrophil migration was attenuated after complement depletion, but was totally abolished in mice lacking the FcR γ chain [57]. Additional data suggested that engagement of FcγRIII did not lead to neutrophil recruitment, but that engagement of FcγRI was most important in inducing inflammatory exudates [57]. It has been proposed that local microenvironments within different tissues could influence the expression of FcR on macrophages at different sites, thus modulating the local inflammation and other tissue effects of circulating or deposited immune complexes [58].

Investigations have explored the implications of polymorphisms in various Fcγ receptors with regard to their potential role in clearing immune complexes from the circulation and causing a predisposition to SLE. Lack of the H131 allele of the FcγRIIA, which is responsible for the efficient clearance of IgG_2-containing immune complexes, has been associated with lupus nephritis in American blacks [59]. While a large meta-analysis confirmed this association [60], studies in other populations have failed to find an association between SLE and this polymorphism [61]. A report has implicated a functionally important genetic polymorphism of FcγRIIIA as a risk factor for SLE in a genetically diverse group of patients [62]. FcγRIIIa-F176 is associated with SLE in some populations, particularly Caucasians [60].

As already pointed out, human erythrocytes possess receptors for C3b, termed *complement receptor type I* (CR1). The average number of CR1 molecules per erythrocyte varies considerably among normal persons and also among erythrocytes of an individual. CR1 molecules exist in clusters, rendering them highly effective in interacting with immune complexes that contain multiple molecules of C3b or C4b [63, 64]. Therefore, because of the red cell mass, these receptors effectively bind the very large, complement-containing immune complexes and thus prevent them from depositing in tissues. *In vitro* experiments have shown that immune complexes with complement components transfer effectively from erythrocytes to monocytes with FcγR and CR1 receptors. This reaction is much faster than the uptake of the same complexes from a fluid phase [65]. Experiments in monkeys suggest that binding of very large, complement-containing immune complexes to erythrocytes may diminish immune deposits in glomeruli [66]. It must be emphasized, however, that this system is applicable only to very large immune complexes that have bound complement components. In rodents and rabbits, CR1 does not exist on erythrocytes, but is present primarily on platelets. In patients with SLE, the number of CR1 molecules per erythrocyte is decreased [67].

Complement receptors have also been described in tissues. Of particular interest has been the presence of

C3b receptors in glomeruli. Several investigations have indicated that these receptors are present on the epithelial cells of glomeruli [68, 69]. These receptors have been found to be decreased in glomeruli of patients with proliferative lupus glomerulonephritis, but not with membranous lupus glomerulonephritis, in whom the deposits are adjacent to the epithelial cells [68]. The role of C3b receptors in the localization of immune complexes in glomeruli has not been established. In experimental animals, immune deposits form in the same location in species that do not have demonstrable C3b receptors in glomeruli. These observations suggest that the presence of C3b receptors in glomeruli do not play a significant role in the deposition of immune complexes.

Fate of Circulating Immune Complexes

Studies in experimental animals have indicated that with increasing loads of circulating immune complexes, deposition in tissues is enhanced. Protective mechanisms, however, exist to remove complexes from circulation, thereby decreasing the possibility of deposition in tissues. The principles involved in the removal of circulating immune complexes have been examined in experimental animals. Once immune complexes are formed in circulation or gain access to circulation, the removal by protective mechanisms is influenced by the lattice of immune complexes, the status of the mononuclear phagocyte system, the nature of antibodies in the complexes, and, to some degree, the nature of the antigen molecules in the complexes.

Studies in mice, rabbits, and rhesus monkeys showed that large-latticed immune complexes composed of lattices greater than Ag_2Ab_2 (ranging from 14 to 22 S units) and containing IgG molecules were removed from the circulation by the mononuclear phagocyte system. The interaction of complexes with the FcγR of Kupffer cells in the liver mediated this removal from circulation. In contrast, small-latticed complexes composed of Ag_2Ab_2 and Ag_1Ab_1 complexes persisted longer in circulation but were removed faster than antibodies alone. The spleen in these animals accounted for only a relatively small proportion of the large-latticed immune complexes removed from circulation [70]. Furthermore, complement components were not involved in this rapid uptake of these large-latticed immune complexes in mice and rabbits. The rapid removal of immune complexes by Kupffer cells is aided by the fact that these cells in hepatic sinusoids are not covered by endothelial cells and thus are directly exposed to circulating materials.

The mononuclear phagocyte system in the liver, previously termed the reticuloendothelial system, is involved in the removal of a variety of substances from the circulation independent of the FcγR. This nonspecific uptake is a saturable process. Also, the FcγR-specific uptake of large-latticed circulating immune complexes is saturable, as established by injecting increasing does of immune complexes. Saturation of the hepatic uptake of immune complexes caused prolonged circulation of the large-latticed immune complexes and increased deposition in glomeruli [70].

Several studies of soluble immune complex clearance have been conducted in humans. In the first study, immune complexes were formed with tetanus toxoid and antibodies to tetanus toxoid [71]. The injected complexes were quite large (45 S units or larger) and rapidly incorporated complement components. In normal persons, these complexes were cleared with a single exponential component, ranging from 9.9 to 18.7% of the injected complexes per minute. In 11 of 15 patients with SLE or other immune complex diseases, an initial very rapid component of removal was present. This was thought to result from trapping in tissues, but proof for this was not obtained. The second phase of clearance in patients ranged from 8.6 to 32.2% per minute. The binding of injected complexes to erythrocytes during the first minute correlated with the average number of CR1 molecules per erythrocyte. Furthermore, when immune complexes with complement components were bound to autologous erythrocytes and then injected, a large fraction of the complexes were dissociated from erythrocytes during the first minute. This release was inversely proportional to the average number of CR1 molecules per erythrocyte. Thus, these studies demonstrate that patients with SLE have neither excessive persistence of immune complexes in circulation nor a decreased hepatic uptake of immune complexes. This is in contrast to the previously described decreased splenic uptake and prolonged circulation of IgG-coated red blood cells in patients with SLE [72]. The splenic uptake of a probe, however, is highly dependent on splenic blood flow [73].

A second study examined the clearance from circulation and uptake by the liver and spleen of immune complexes, prepared with hepatitis B surface antigen (HBsAg) and antibodies to this protein, in normal persons ($n = 12$) and in patients with SLE ($n = 10$) [74]. The polymeric HBsAg had a molecular mass of about 3000 kDa and the formed immune complexes were quite large and fixed complement effectively. Upon intravenous injection, some of the very large but soluble immune complexes made in antibody excess bound to erythrocytes at a higher percentage in normal persons than in patients with SLE. The clearance from blood, however, was faster in patients with SLE than in normal persons. The median half-life in patients was 2.15 min (range 1.3 to 6.6) and in normal persons 5.15 min (range

3.6 to 14). Sucrose density gradient analysis showed that in patients with SLE the very largest immune complexes were not removed selectively from plasma. In contrast, the same analysis of plasma from normal persons showed that the very largest immune complexes had been selectively removed. External counting of the ^{123}I on HBsAg in immune complexes demonstrated that the radioactive probe was taken up more rapidly in the liver in SLE patients than in normal persons. The median time in minutes to 90% of maximal uptake was 9 min (range 4.05 to 18) in SLE patients and 16 min (range 13 to 23) in normal persons. In contrast, the splenic uptake at 60 min was decreased in patients with SLE; 9.03% of injected dose (range 4.05 to 23.7) as compared to normal persons with 23.9% of injected dose (range 17.9 to 30.7]. In the SLE patients a high correlation was found between the half-life of immune complexes and the C4 concentration. These findings clearly indicate the role of the complement system in the clearance from circulation of the very large immune complexes. Once complement components are bound to the complexes, they become attached to the erythrocytes via the CR1, are no longer in plasma, and are then delivered mainly to the spleen. The large complexes that are less effective in activating complement are mainly removed by the liver. In patients with SLE and with decreased complement levels the binding of the very large immune complexes to erythrocytes is decreased and these complexes are diverted to the liver. This accounts for the observed initial rapid removal from blood, increased hepatic uptake, and decreased splenic uptake. This interpretation is also consistent with the already discussed decreased hepatic uptake by the spleen of IgG-coated erythrocytes [72]. In addition, this interpretation was confirmed by a study in a patient with hereditary homozygous C2 deficiency [75]. The study was conducted with immune complexes prepared as described earlier. The initial clearance of the complexes was rapid without binding to erythrocytes, the hepatic uptake was rapid, and no uptake was observed in the spleen. After administration of fresh frozen plasma the initial rapid removal was decreased, immune complexes bound to erythrocytes, hepatic uptake was decreased, and splenic uptake was enhanced.

In another investigation, immune complexes were formed *in vivo* in humans during cancer immunotherapy [76]. The formed complexes consisted of monoclonal mouse IgG and purified human antibodies to mouse IgG. The formed complexes had sedimentation coefficients of 19–25 S units. These complexes were cleared by the liver independent of the CR1 on red blood cells, as only a small portion of the complexes bound to erythrocytes. Immune complexes of comparable size, formed between bovine serum albumin and rhesus monkey IgG antibodies to bovine serum albumin and with lattices similar to those illustrated in Fig. 1, were cleared by the liver and did not bind to rhesus erythrocytes *in vivo* or *in vitro* [77].

Radiolabeled, aggregated human IgG has been used in normal persons and small numbers of patients with SLE to determine its clearance from circulation and uptake by the liver. The material used, however, was a mixture of aggregated and monomeric IgG, thereby complicating the analysis of collected data. The study involved 22 patients with SLE, and the kinetics of the removal of the aggregates was analyzed by a model assuming homogeneity of the material and a distribution phase faster than the elimination phase. The authors concluded that the initial phase of removal of the IgG aggregates was faster in patients with SLE than in normals and that the amount of aggregates bound to red cells was higher in normals [78].

Studies in humans and nonhuman primates led to the following concepts on the removal of circulating immune complexes. The very large immune complexes in circulation that have already bound complement components bind effectively to erythrocytes. These complexes thus are no longer available for deposition in tissues and obviously are not detectable by assays for immune complexes in serum specimens. A significant proportion of the erythrocyte-bound immune complexes is delivered to the spleen. As pointed out earlier, in patients with SLE and decreased complement levels or in patients with absent early complement components, the delivery of immune complexes to the spleen is defective. This defect in patients with SLE was also detected by IgG-coated erythrocytes that are removed primarily by the spleen [72]. Small immune complexes that still contain several IgG molecules do not bind to erythrocytes and are cleared by the liver, mainly by Kupffer cells via FcγR. When the binding of very large immune complexes to erythrocytes is defective, these complexes are also cleared rapidly by the liver. Small immune complexes, containing one or two IgG molecules, persist in circulation and are not deposited in tissues (see Fig. 3). In C1q-deficient mice, the clearance of experimental immune complexes in the spleen was shown to be decreased, whereas the initial phase of immune complex clearance in the liver was enhanced [79]. Because mice lack CR1-dependent immune complex binding to erythrocytes, these experiments indicate that activation of the classical pathway of complement may have additional roles in the clearance of immune complexes, at least in mice.

In mice, immune complexes containing the IgA class of antibodies were taken up rapidly by the liver when eight or more IgA antibodies were present in the immune complexes. This critical number of eight or

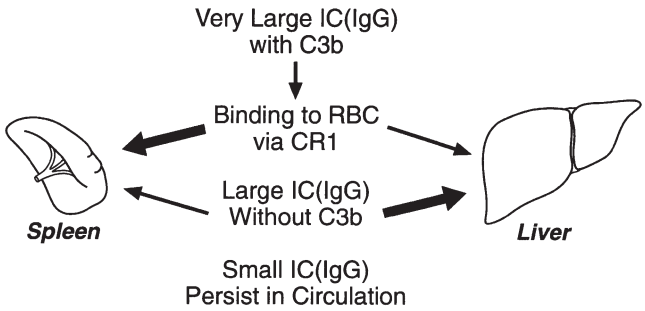

FIGURE 3 Schematic representation of the fate of circulating immune complexes (IC). Very large IC formed in antibody excess activate complement effectively, bind C3b, and become attached to red blood cells (RBC) via complement receptor 1 (CR1). IC bound to RBC do not deposit in tissues and are delivered principally to the spleen. The splenic uptake of IC bound to RBC is decreased in patients with SLE and hypocomplementemia, and IC with C3b are diverted to the liver. Large IC without bound C3b are taken up principally by the liver, both in normal persons and in patients with SLE. Small IC (e.g., Ag_1Ab_1, Ag_2Ab_1, or Ag_2Ab_2) are not removed rapidly and do not deposit in tissues.

more antibody molecules could be achieved either with eight monomeric IgA molecules or by four dimeric IgA molecules [80].

As pointed out under the discussion of antigens, the nature of antigens in the immune complexes can alter the fate of immune complexes. If the antigen alone is removed rapidly from circulation, then the presence of such antigens in the immune complexes can enhance the removal of complexes from circulation. It was demonstrated in experimental animals that the clearance of immune complexes containing glycosylated antigens was governed in part by specific carbohydrate receptors on hepatocytes [3]. A serum carbohydrate-binding protein, mannose-binding protein (MBP), may have an important role in clearing immune complexes containing antigens with selected carbohydrate residues [81]. A member of the collagen motif-containing collectin family of proteins, MBP binds terminal mannose, fucose, glucose, frutose, or *N*-acetylglucosamine residues, can serve as an opsonin, activate the classical or alternative pathways of complement [82], and activate macrophages via the C1q receptor [83]. It has been shown that genetic polymorphisms responsible for depressed function and serum levels of MBP are associated with SLE in African-Americans [84] and some other ethnic and national groups [85–88]. Furthermore, certain ribonucleoprotein autoantigens, including the U1-specific 68-kDa and A proteins and the U2-specific B″ protein, are glycoproteins, with mannose, glucose, and *N*-acetylglucosamine detected on the 68-kDa protein [89]. Thus, it is conceivable that the clearance of glycoprotein antigens or immune complexes containing such antigens, including the U1-RNP particle, could be influenced by MBP polymorphisms. These considerations suggest that MBP polymorphisms could participate in the pathogenesis of SLE by influencing immune complex clearance, analagous to the role of polymorphisms in complement components and FcR.

TISSUE DEPOSITION OF IMMUNE COMPLEXES

In patients with SLE, deposits of immune complexes have been identified in several organs, including glomeruli, renal peritubular capillaries, small and medium blood vessels in several organs, dermal–epidermal junction, and choroid plexus. In most of these sites the presence of immune complexes has been inferred from the presence of immunoglobulins and complement components. Only in the glomeruli and blood vessels have specific antibodies been identified. The presence of immune complexes at various sites may arise from the deposition of circulating immune complexes or from the local formation of antigen–antibody complexes at the site of their presence. The local formation of immune complexes can arise from selective deposition or presence of an antigen at a given location, followed by binding of specific antibodies to the localized antigens. At this time, information is not available to distinguish in human diseases and in patients with SLE the immune complexes that have arisen in the given location by deposition from circulation or by local formation. The presence of circulating immune complexes in association with tissue deposition should not be considered unequivocal evidence for deposits of circulating immune complexes. Studies in experimental animals have clarified the concepts of how immune deposits may arise in glomeruli. Less progress has occurred in the understanding of immune deposit formation in other organs. For this reason, emphasis is given to information concerning immune deposit formation in glomeruli.

Localization of Immune Complexes in Glomeruli

A number of studies in experimental animals have indicated that immune deposits in glomeruli may arise from the deposition of immune complexes from the circulation or immune deposits in glomeruli may develop by the local formation of antigen–antibody complexes. Several unique structural features of glomeruli may well contribute to these processes. First, large volumes of

plasma are filtered through the capillary wall with transient retention of macromolecules, including immune complexes. Second, the glomerular capillary wall contains a fenestrated endothelium. Third, fixed negative charges are present in the glomerular basement membrane in the lamina rara interna (subendothelial area) and in the lamina rara externa (subepithelial area).

In lupus nephritis, in other forms of glomerulonephritides, and in chronic serum sickness models in experimental animals, the renal lesions may contain mesangial, subendothelial, and subepithelial immune deposits (Fig. 4). Experiments with the injection of preformed immune complexes into unimmunized animals have indicated that the complexes in circulation deposit principally in the subendothelial and mesangial areas. In a number of studies of this nature, immune complexes injected into circulation caused no deposits in the subepithelial area [70, 90].

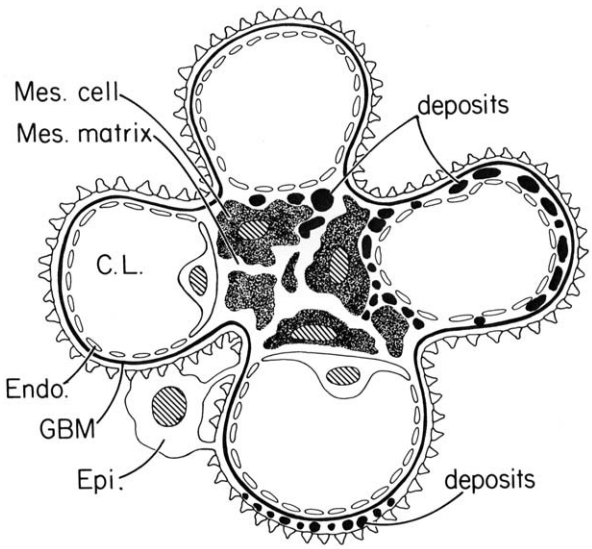

FIGURE 4 Schematic representation of the location of immune complexes in glomeruli. Glomerular capillaries cut in cross section are shown. The capillary lumen (CL) is lined with fenestrated endothelium (Endo). The glomerular basement membrane (GBM) is a size and charge barrier to circulating macromolecules. Negative charges are present in the subendothelial area (lamina rara interna) and in the subepithelial area (lamina rara externa). Beyond the GBM are the foot processes of the epithelial cells (Epi). The area between the capillary loops is the mesangium, consisting of mesangial matrix (Mes. matrix) and mesangial cells (Mes. cell). Immune complexes, recognized as electron-dense deposits by electron microscopy, may be only in the mesangium. Immune complexes may exist in the subendothelial area, but these are accompanied by immune complexes in the mesangium. Immune complexes may be present in the subepithelial area, as seen in membranous glomerulonephritis.

Several lines of evidence have indicated that the lattice of circulating immune complexes is highly important to their deposition in glomeruli. First, when mixtures of large-latticed and small-latticed immune complexes in antigen excess were injected into mice, the glomerular deposition of complexes progressed only while the large-latticed complexes remained in circulation [70]. Second, the injection of only small-latticed immune complexes into the circulation of mice caused no deposits in the glomeruli [91]. Third, when large-latticed immune complexes were deposited in glomeruli, the injection of a large excess of antigen resulted in the complete removal of the antigen–antibody deposits within hours, presumably by the conversion of immune deposits into small-latticed immune complexes [92]. All these studies have indicated that the lattice of immune complexes has a pivotal role in their deposition in the glomeruli.

Immune deposits in the subendothelial or mesangial area, as visualized by electron microscopy, are considerably larger than immune complexes that have been injected into experimental animals. This suggests that after the initial deposition in glomeruli, the immune complexes must undergo further condensation or rearrangement into even larger deposits. The need for further condensation or rearrangement of immune complexes to persist in glomeruli and to become visible as electron-dense deposits was demonstrated by the use of covalently cross-linked immune complexes. Covalent cross-linking established a fixed lattice in the immune complexes so that they could not rearrange into large lattices or precipitate. When such complexes were injected into mice, only transient deposits in glomeruli were identified by immmunofluoresence microscopy, and large electron-dense deposits did not evolve. In contrast, when similar complexes were prepared without covalent bonds and administered to mice, then deposits evolved that persisted and became visible as electron-dense deposits [93]. These studies suggest that large-latticed immune complexes containing more than two antibody molecules become locally concentrated in glomeruli, either as a result of filtration of plasma or because of interactions with glomerular structures. As a consequence of this increased local concentration, condensation occurs into larger lattices. Thus, nonprecipitating antigen–antibody systems would not form persisting immune deposits in glomeruli and would not lead to the formation of electron-dense deposits.

Electrostatic interactions constitute one possible mechanism for the attachment to glomeruli and to the local increase in concentration of immune complexes. When chemically cationized (positively charged) antibodies were used to prepare soluble immune complexes, the injection of these complexes caused

extensive subendothelial and mesangial deposits in glomeruli. In contrast to immune complexes prepared with unaltered antibodies, complexes with cationic antibodies caused extensive subendothelial deposits that persisted in this location for several days, even when injected in small doses. The lattice of the complexes was still highly important with the cationized antibodies. When only small-latticed immune complexes were prepared with these antibodies and injected into mice, the deposits persisted in glomeruli by immunofluorescence microscopy comparable to antibodies alone [94]. These results suggest that when large-latticed immune complexes with more than two antibody molecules attach to the fixed negative charges in the lamina rara interna, their local concentration is increased, leading to rearrangement and formation of larger deposits that become visible as electron-dense deposits in the subendothelial area. Small-latticed immune complexes would initially attach in a comparable manner, but they would not condense into larger deposits and therefore remained in glomeruli only for a few hours. The initial interaction of cationic immune complexes with the fixed negative sites on the glomerular basement membrane is a charge–charge interaction and was disrupted by unrelated polycationic molecules. Once the condensation to larger deposits occurred, then the unrelated polycationic molecules no longer displace the deposits [95]. The mechanism for the removal of immune complexes from the basement membrane and other organs is not well understood. The absence of C3 in experimental immune-mediated renal disease may lead to an alteration in the distribution of immune deposits within the glomerulus, suggesting that complement may play a role in immune complex rearrangement within the kidney [96]. The complement system, particularly C3, probably plays a role not only in the solublization of immune precipitates, but also in the removal and trafficking of immune deposits within the basement membrane of the kidney [97].

The formation of mesangial deposits must also involve other yet unknown factors. Mesangial deposits occurred with large-latticed immune complexes containing cationized antibodies. Similar deposits, however, also occurred with immune complexes prepared with anionic (negatively charged) antibodies and anionic antigens, suggesting that charge–charge interactions were not important in the formation of mesangial deposits [98]. It is of interest that FcγR were not expressed by unstimulated human mesangial cells in culture. Upon stimulation with IL-1 and lipopolysacharide, however, these cells contained mRNA of FcγRIII [99]. The expression of receptors on mesangial cells may enhance localization and retention of immune complexes in the glomerular mesangium.

Several experimental models exist for local immune complex formation in glomeruli due to antigens that become attached or planted in glomeruli [90]. Intravenously injected aggregated IgG or aggregated albumin becomes entrapped in the mesangial matrix. When this event is followed by the injection of specific antibodies, immune deposits form and cause an inflammatory response in the mesangial area of glomeruli, as reviewed by Michael *et al*. [100]. Concanavalin A binds to the endothelium and subendothelial area, and when antibodies to concanavalin A are administered, lumpy-bumpy immune deposits evolve on the glomerular basement membrane [101]. Considerable evidence indicates that subepithelial immune deposits, as seen in membranous lupus glomerulonephritis, are formed locally and are not deposited from the circulation as immune complexes. The initial evidence for local or *in situ* immune complex formation was obtained in rats with the model of passive Hayman nephritis. In this model the antigen is the so-called Fx1A antigen, which is derived from the brush border of proximal tubules but also exists on the epithelial cells of glomeruli. When antibodies to the Fx1A antigen were perfused into the renal artery in a nonrecirculating system, immune deposits formed within hours in the subepithelial area. In these experiments the possibility of immune complexes arising in circulation was excluded [102]. It is now recognized that the involved antigens are part of the epithelial cell surface, and upon interaction with antibodies the formed immune complexes are released into the subepithelial area [103]. The local formation of immune complexes was also achieved by the repeated perfusion of rat kidneys with an bovine serum albumin alternating with an infusion of antibodies to bovine serum albumin [104]. The high density of fixed negative charges in the lamina rara externa (subepithelial area) has served as a mechanism for planting positively charged antigens in glomeruli. The administration of cationized antigens followed by the administration of specific antibodies leads to persisting immune deposits in the subepithelial area and to the formation of electron-dense deposits [105]. Similar results have been achieved with the chronic administration of cationic antigens, leading to an endogenous immune response and to the development of extensive membranous glomerulonephritis with subepithelial deposits [106]. The formation of persisting immune deposits in the subepithelial area and the formation of electron-dense deposits also required precipitating antigen–antibody systems. With nonprecipitating antigen–antibody systems, only transient deposits formed in the subepithelial area as detected by immunofluorescence microscopy, and electron-dense deposits were not formed [107].

The described studies in experimental animals suggest that the formation of subepithelial immune deposits in human disorders, including SLE, should involve cationic antigens or cationic antibodies that become localized in this area due to electrostatic interactions. The subsequent access to this area of glomeruli by specific antibodies or antigens, respectively, would then lead to the formation of immune deposits. The sequence of events may be even more complicated. Studies in experimental animals have shown that cationic histones bind to glomeruli by charge–charge interactions, followed by DNA, and finally antibodies to histones and to DNA bind to these antigens in glomeruli [108]. In support of this concept was the identification of histone H3 and a complex of ubiquitin and histone H2A in the majority of glomeruli in renal biopsies of patients with SLE [109]. Whereas in the study of 70 biopsies from other forms of glomerular disease, these molecules were present only in two specimens.

In patients with lupus the presence of a number of serum autoantibodies has been associated with renal disease, reviewed by Lefkowith and Gilkeson [110]. Serum antibodies to dsDNA have a strong association with renal disease. In addition, antibodies to histones and to chromatin share this association. The extraction of antibodies from glomeruli of patients with SLE has demonstrated the presence of antibodies to dsDNA, ssDNA, and nucleoproteins [2, 111]. In a subsequent investigation, the presence of antibodies to SS-A(Ro) was identified in eluates of renal cortical tissue in two patients with SLE [112]. In patients with proliferative lupus glomerulonephritis (WHO class IV lesions), autoantibodies were identified in serum to the collagen-like region of C1q (anti-C1q-CLR) [113, 114]. Subsequent studies showed that the development of these antibodies in circulation served as a better predictor of developing proliferative glomerulonephritis than a rise in the level of antibodies to dsDNA [115]. Anti-C1q-CLR has been extracted from isolated glomerular basement membrane fragments from four of five patients with proliferative lupus glomerulonephritis [116]. Anti-C1q-CLR do not react with circulating C1 and do not bind well to C1q in the fluid phase. Anti-C1q-CLR, however, bind well to C1q attached to immune complexes *in vitro* or *in vivo* [117]. Therefore, it is likely that anti-C1q-CLR contribute to the glomerular inflammation by binding to already deposited immune complexes with bound C1q. Alternatively, these antibodies may bind to C1q attached to DNA because DNA in glomeruli may bind C1q directly without the presence of antibodies [118]. Further studies have shown that multiple autoantibody specificities, including anti-dsDNA, anti-C1q-CLR, anti-SSA, anti-Sm, anti-SSB, antihistone, and antichromatin, are frequently and concurrently present and enriched in the glomerular basement membranes from kidneys of patients with lupus [119]. In contrast, control antibodies such as antibodies to tetanus and to Epstein–Barr virus antigens are present in concentrations that reflected only the serum concentration of those antibodies and were not enriched in the kidneys. Furthermore, elution of the antibodies from lupus kidneys required strong denaturants and even disruption of covalent bonds, indicating that in chronic human immune complex disease the immune complexes form covalent bonds with components in the kidney.

The mechanisms, however, of how the various autoantibodies deposit in glomeruli of patients with SLE have not been established with certainty. Perhaps the main reason for the absence of this information is the fact that very little is known about the nature and the source of antigens that are present in the glomerular immune deposits of patients with lupus renal disease.

Localization of Immune Complexes in Other Organs

The localization of immune complexes in other organs has not been examined in the detail described for glomeruli. The existence of immunoglobulins and complement components at the dermal–epidermal junction of patients with SLE is well established. Antibodies to nuclear antigens and antibodies to DNA have been recovered from these deposits, suggesting that indeed the detected deposits exist as immune complexes at this location. Some evidence indicates that keratinocytes at the basal layer of skin contain the Ro (SS-A) antigen. As this antigen is extruded, immune complexes form at the dermal–epidermal junction with antibodies to Ro [120].

Studies with preformed immune complexes have suggested that charge–charge interactions contribute to the formation of immune complexes at this site. First, cationic antibodies alone bound to the dermal–epidermal junction of mice, as detected by immunofluorescence microscopy. This finding raises the possibility that *in situ* immune complex formation may occur with the initial deposition of, for example, cationic antibodies to DNA and subsequent immune complex formation with DNA. Second, large-latticed circulating immune complexes, prepared with cationic antibodies, deposited at this location in the skin. The deposited immune complexes persisted in this location longer than the cationic antibodies alone [121]. Third, the chronic injection of a cationized antigen caused immune deposits at the dermal–epidermal junction, whereas the injection of the

unaltered antigen according to the same schedule and dose did not cause these deposits [122].

In patients with SLE, immune complexes have been described in the choroid plexus, between the basement membrane and the base of the epithelial cells. Similar lesions have been observed in NZB/NZW mice and in patients with chronic serum sickness. The injection of very large doses of preformed immune complexes has resulted in some localization of the injected immune complexes in the choroid plexus [123]. The injection of cationic antigens has resulted in deposits of the antigen in the choroid plexus. When antibodies were injected later, immune complexes were formed in the choroid plexus and persisted in this area. Of interest was the observation that a cationic antigen persisted for many days in the choroid plexus, whereas the bulk of cationized antigens lasted in glomeruli for less than a day. These findings suggest differences in the nature or the turnover of the fixed negative charges in glomeruli compared with the choroid plexus [124].

The immune deposits in blood vessel walls clearly are associated with vasculitis in patients with SLE. The mechanisms for the formation of these deposits are not known. In experimental animals, serum sickness is associated with vascular deposits of immune complexes; increased permeability of the vessels facilitates the development of these deposits [125]. Injection of a single bolus of preformed immune complexes into mice also caused vascular deposits, as recognized by immunofluorescence microscopy. These deposits, however, tended to persist for a much shorter period in dermal, myocardial, and peritubular renal small vessels than in glomeruli [121].

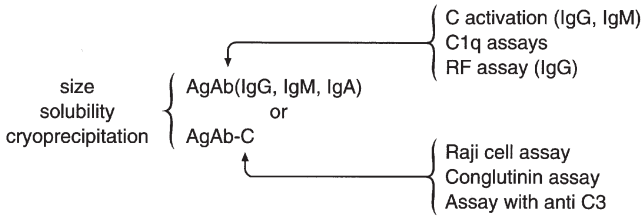

FIGURE 5 A diagrammatic representation of the tests used for the detection and measurement of immune complexes. Immune complexes (AgAb) may contain antibodies belonging to IgG, IgA, or IgM classes. Other immune complexes may have bound complement components *in vivo*. Physical methods for the detection of immune complexes can detect both categories of immune complexes by their size, decreased solubility, or cryoprecipitability. Some biologic assays for immune complexes, as depicted, distinguish immune complexes from free antibodies, as the antibodies in complexes have acquired new or more pronounced properties (i. e., complement activation, binding to C1q or to IgM rheumatoid factors). Other tests recognize immune complexes, as components of complement have bound to the immune complexes (e.g., Raji cell assay, conglutinin assay, or assays with antibodies to C3 components).

MEASUREMENT OF IMMUNE COMPLEXES AND USE OF THESE TESTS IN PATIENTS WITH SLE

Because the clinical manifestations of SLE and other systemic immune complex diseases are related at least in part to circulating immune complexes, it seems desirable to quantify these materials in serum. The principles involved in the tissue deposition of circulating immune complexes, as established in experimental animals, were reviewed previously. A number of methods have been developed to detect and to quantify immune complexes in the serum or other body fluids.

Methods for the detection of immune complexes rely on either the physical or the biologic properties of immune complexes. As already pointed out, both of these categories of properties of immune complexes are highly variable because of the variations in antigens, antibodies, and numbers of reactants that are present in a given complex. The physical methods rely largely on the fact that immune complexes differ from antibodies alone by size, solubility, or cryoprecipitability. Tests based on biologic properties recognize immune complexes because antibodies have acquired properties different from free antibodies or because complement components have been attached to the immune complexes. These principles are presented schematically in Fig. 5.

Physical Methods

Physical methods for the detection of immune complexes are based on the fact that complexes are larger than antibodies alone; the solubility of immune complexes is less than that of antibodies alone, and some immune complexes are precipitable by exposure to cold. Antibodies alone have defined size; therefore, if a serum specimen is submitted to ultracentrifugation or to gel filtration, the obtained fractions can be analyzed for the presence of various classes of immunoglobulins. Identification of immunoglobulins in fractions that normally do not contain antibodies suggests the presence of immune complexes. The normal distribution of antibody molecules upon size separation, however, is a function of the concentration of these molecules. Therefore, in SLE and other diseases in which hypergammaglobulinemia is common, the interpretation of data becomes difficult. Furthermore, small immune complexes are difficult to distinguish from the normal distribution of

antibodies. This type of analysis is time-consuming, and therefore these methods are not used by clinical laboratories but remain tools for research laboratories.

The addition to serum specimens of low concentrations of polyethylene glycol precipitates some immune complexes. At the same time, however some normal serum proteins are also precipitated, particularly large serum proteins. Therefore, the quantitation of precipitated protein alone is not reliable, and the immunologic quantitation of the precipitated proteins is fraught with additional problems. Small amounts of cryoglobulins have been identified in patients with SLE and other disorders with immune complexes. Not all immune complexes, however, are precipitated at a low temperature. Therefore, this approach has not provided a reliable and easy tool for the quantitation of circulating immune complexes.

Methods Based on Biologic Properties

Several assays for the measurement of immune complexes are based on recognizing antibody molecules that have acquired properties that distinguish them from free antibody molecules. This category of assays includes complement activation, C1q assays, and rheumatoid factor assays and assays that depend on the presence of complement components. Because the activation of complement depends on the lattice and on the class of immunoglobulin molecules in the complexes, only immune complexes with IgG and IgM are recognized, and they must have attained sufficient lattice to activate complement. Because the amount of complement activity present in the serum is variable, this activity must first be destroyed before activation of a known amount of added complement is quantified. These tests are not readily employed in clinical laboratories because of their complexity.

C1q assays depend on the ability of immune complexes to interact with the globular regions of C1q. IgG- and IgM-containing immune complexes are recognized by this test, provided sufficient lattice is present. Two major types of assays are used with C1q. In the C1q-binding assay, isolated radiolabeled C1q is added to the serum. Upon the addition of low concentrations of polyethylene glycol, the radiolabeled C1q bound to immune complexes is precipitated, whereas unbound radiolabeled C1q remains in the supernatant. This assay does not distinguish the binding of immune complexes to C1q from the binding of other serum proteins in C1q. The presence of polyanionic molecules in serum and the presence of fibrinogen will lead to positive results. In the solid-phase C1q assay, isolated C1q is absorbed to the walls of the test tubes or microtiter wells. Immune complexes in the specimen bind to the C1q, other serum proteins are removed by washing, and the IgG or IgM bound to the C1q is quantified immunochemically. When the sizes of immune complexes in patients with SLE were examined, those with proliferative lupus glomerulonephritis had IgG-containing complexes but also had monomeric IgG that bound to C1q in the solid-phase assay [113]. This reactivity was shown to result from the presence of autoantibodies to C1q, directed to the collagen-like region of these molecules [114]. Therefore, when the solid-phase C1q assay is used, the presence of immune complexes and autoantibodies to the collagen-like region of C1q must be distinguished. This can be achieved optimally by the use of purified collagen-like regions of C1q for identification of the autoantibodies [126]. Although some authors have measured binding of IgG to C1q in the presence of high salt concentrations as a surrogate for the measurement of autoantibodies to C1q, the two experimental approaches are not identical [127].

Assays using rheumatoid factors detect only immune complexes that contain IgG molecules as antibodies. The main principle of the test is that the IgM rheumatoid factor binds with a much higher affinity to polymeric IgG than to monomeric IgG. The technical conduct of these and other tests for immune complexes is beyond the scope of this discussion, and several reviews are available [128–131].

Some major problems exist in these categories of tests for immune complexes. First, as already pointed out, these biologic properties of immune complexes depend on the lattices of the complexes. Thus, C1q assays and rheumatoid factor assays detect large-latticed complexes more efficiently than small-latticed complexes. The same degree of positivity in a clinical specimen can arise from the presence of a relatively small amount of large-latticed immune complexes or a relatively large amount of small-latticed immune complexes. Furthermore, the presence of monomeric IgG can interfere with these tests to some degree. Second, no ideal standard exists for the detection of immune complexes with these test methods. Heat-aggregated IgG is the most commonly used standard. The degree and the size of the aggregates are usually not defined, and therefore large variations can exist from laboratory to laboratory, as documented by a World Health Organization study [132]. If a standardized method and preparation were adopted and defined, then at least this potential problem could be surmounted.

Other tests for immune complexes depend on the fact that complement components have bound to immune complexes *in vivo*. The prototypic assay in this category is the Raji cell assay [129]. Raji cells are lymphoblastoid B cells derived from a patient with Burkitt's lymphoma. These cells lack surface immunoglobulins

and have low-affinity receptors for IgG and high-affinity receptors for activated complement components. Accordingly, this assay detects immune complexes that have C3b and other complement components bound to them. When the serum specimen with immune complexes is incubated with these cells, the immune complexes with C3b or other components of complement bind to the cells, the cells are washed, and the amount of complexes bound to the cells are quantified by specific radiolabeled or enzyme-labeled antibodies to IgG or to other immunoglobulins. Aggregated IgG is used as a standard for this test. Because the amount of IgG on the cell is quantified, the presence of lymphocytotoxic antibodies to B cells can lead to false-positive results. Some evidence also indicates that even antibodies to nuclear antigens may give false-positive tests, as nuclear antigens either bind to cell surface molecules or are extruded by the cells [129].

The conglutinin assay detects only immune complexes that have activated complement and contain C3bi. If C3b is present before inactivation by the C3b inactivator, the complexes are not detected. Furthermore, once C3bi is cleaved into C3d and C3c, the immune complexes are no longer effectively detected by this method. Another method has been developed by taking advantage of specific antibodies to C3b or C3d that have been absorbed on the surface of plastic tubes. The binding of immune complexes with these complement components to the test tubes is then detected and quantified by antibodies to specific immunoglobulins, either radiolabeled or enzyme linked. Because the solubilization of immune complexes by complement leads to the formation of IgG–C3d complexes without the presence of antigen molecules, this assay also detects material in the size range of normal IgG that does not represent immune complexes.

Assays for the detection and quantification of immune complexes described earlier are not specific for any given antigen; therefore, these tests have no specificity to a given disease and provide no assistance in reaching a specific diagnosis. Research laboratories have shown that antigens can be recognized with appropriate antisera in the complexes detected by these assays. Therefore, it is possible that tests become available for specific disease, including SLE.

In experimental models the load of circulating immune complexes increase the likelihood of tissue deposition and induction of lesions; therefore one would expect that in patients with SLE the manifestations of SLE caused by circulating immune complexes would have a relationship to the measured level of immune complexes. If this were the case, then the measurement of circulating immune complexes should have a predictive value and assist in therapeutic decisions. At this time, however, conclusive data are not available to use these tests in therapeutic decisions, and the clinical utility of tests of circulating immune complexes is limited [133].

In experimental animals, as reviewed earlier, mesangial and subendothelial immune deposits are formed by circulating immune complexes. Using a C1q solid-phase assay for immune complexes in conjunction with size separation of the immune complexes by ultracentrifugation, large immune complexes were found in serum or plasma of patients with SLE who had subendothelial and mesangial immune deposits [113]. These patients also had autoantibodies to the collagen-like region of C1q molecules [114, 115, 126].

Tests for Immune Complexes and Clinical Activity of SLE

Relationships between the clinical activity of SLE and the concentrations of immune complexes by one or more tests have been examined by several laboratories [134]. Positive correlations have been found between the clinical activity of disease in patients with SLE and immune complexes detected by the fluid-phase C1q-binding assay, solid-phase C1q assay, Raji cell assay, and conglutinin assay. Other observers have, however, reached the conclusion that a definite relationship does not exist between disease activity or renal involvement with one form or another of lupus nephritis and the measured levels of immune complexes. One retrospective study concluded that the level of total hemolytic complement or complement components (C4) had a better relationship to disease activity than the fluid-phase C1q-binding assay for circulating immune complexes [135]. A clear and uniform definition of disease activity has not been used in all investigations that would permit critical comparisons of the study results. In addition, some of the differences in conclusions may stem from differences in the methods for the detection of immune complexes. Of course, the possibility exists that indeed the currently available tests for immune complexes do not relate to disease activity and thus would be of no predictive value. Ideally, the predictive value of assays for immune complexes should be determined in a prospective manner with defined criteria for disease activity. This type of information, however, is not on hand for tests for immune complexes or, for that matter, for many other tests used in clinical medicine. In one prospective study the solid-phase C1q assay, which also detects autoantibodies to C1q, was found to have predictive value for flare-ups of SLE or for improvements of SLE, but not the fluid-phase C1q-binding assay [136]. In this study the association with clinical improvement or flare-up was thought to exist if

the solid-phase C1q assay changed from positive to negative, or vice versa, within 2 months of the clinical event, an association that has not been validated. Furthermore, the degrees of clinical changes were not related to the quantity of immune complexes; only the change from a negative to a positive result, or vice versa, was related to a clinical event indicative of improvement or worsening of the disease.

For all these reasons the recommendation has been made that tests for immune complexes are not essential in any clinical condition, but that the detection of immune complexes may be helpful for the assessment and monitoring of disease activity in some disorders, including SLE [133]. Obviously more information and new developments are needed. Meanwhile, clinicians familiar with the interpretation of these tests may use the tests for the measurement of immune complexes as an adjunct with other tests or in place of other tests (e.g., total hemolytic complement or complement component levels) along with clinical information to make therapeutic decisions.

DEVELOPMENT OF THERAPIES BASED ON THE IMMUNE COMPLEX MODEL

The immune complex model for the cause of tissue damage in SLE has been the dominant paradigm for several decades, and it remains so. Therapeutic approaches based on this paradigm, however, have been relatively disappointing. For example, whereas plasmapheresis for the treatment of SLE was originally met with great enthusiasm, a controlled clinical trial of plasmapheresis in patients with lupus nephritis was unsuccessful [137].

Affinity columns containing silica-bound staphylococcal protein A (SPA) have been approved for use in patients with severe, refractory rheumatoid arthitis [138]. The rationale for the use of SPA immunoabsorbants arises from the observation that IgG within immune complexes binds preferentially to SPA, compared with mononeric noncomplexed IgG. It has been suggested that other mechanisms besides immune complex removal may play a role in the improvement [139]; nevertheless, this successful therapy was developed because of the immune complex disease model. C1q immunoadsorption has been employed in the treatment of patients with SLE [140, 141]. Further follow-up and evaluation of this investigational approach are needed to substantiate this therapy, however. As noted earlier, animal studies have shown the efficacy of administered heparin and heparinoids to prevent nephritis in MRL/lpr mice, presumably by preventing the binding of nucleosome-containing immune complexes to heparan sulfate in glomerular basement membranes [23]. Thus, therapeutic approaches targeting the antigens in immune complexes, as well as approaches that are not antigen specific, could prove helpful in the treatment of SLE. Immune complexes play a pivotal role in the pathogenesis of lupus nephritis, as well as other manifestations of SLE, and understanding the pathophysiology could provide an important basis for further therapeutic approaches.

ORIGINS OF ANTINUCLEAR ANTIBODIES

Westley H. Reeves
Minoru Satoh
Hanno B. Richards

The production of antinuclear antibodies (ANAs) is one of the defining features of systemic lupus erythematosus (SLE). Description of the LE cell phenomenon (phagocytosis of intact nuclear material by polymorphonuclear leukocytes) by Hargraves *et al*. in 1948 was the first evidence for the existence of these autoantibodies [1]. This was followed by the identification of antinuclear and anti-DNA antibodies in 1957 [2–4]. The landmark discovery of anti-Sm antibodies by Tan and Kunkel in 1966 provided definitive evidence that autoantibodies in lupus recognize nuclear structures other than nucleosomes [5], marking the beginning of a 30-year period during which the major autoantibody–autoantigen systems associated with systemic autoimmune diseases were identified and characterized. Despite significant progress in defining both autoantibodies and their molecular targets, an understanding of the ultimate causes of these abnormal antibodies remains elusive. This chapter reviews what has been learned about antinuclear antibodies, emphasizing recent progress in defining the mechanisms. Because certain antinuclear antibodies are highly specific markers for SLE, understanding their origins will be an important step toward determining the pathogenesis of lupus.

DIAGNOSTIC IMPORTANCE OF ANTINUCLEAR ANTIBODIES

The autoantibodies produced in SLE are directed primarily, although not exclusively, against nuclear antigens. This is the basis for the diagnostic utility of the fluorescent ANA assay, a highly sensitive screening test for SLE that is positive in >95% of patients [6, 7]. However, the specificity of a positive ANA is relatively low [8]. Early on, it was recognized that ANAs stained the nuclei of cells in a variety of different patterns (Fig. 1). It subsequently became clear that these patterns correspond to reactivity with different subsets of nuclear antigens. Some of the specificities are uniquely associated with SLE (reviewed in Tan [9, 10]).

The discovery that certain types of ANAs are specific for the diagnosis of SLE or for other systemic autoimmune diseases was a key advance in the immunodiagnosis of systemic autoimmunity. Autoantibodies specific for SLE, systemic sclerosis (SSc, scleroderma), and polymyositis/dermatomyositis (PM/DM) are of considerable use clinically (Table 1). Anti-dsDNA antibodies, for example, are found in ~70% of SLE patients at some point during their disease and are 95% specific for the diagnosis [7, 11]. Anti-Sm antibodies are found in ~10–25% of lupus patients' sera depending on ethnicity [12], and also are virtually pathognomonic of SLE [5, 13]. Antibodies to the ribosomal P0, P1, and P2 antigens [14] and proliferating cell nuclear antigen (PCNA) [15] are highly specific, but less sensitive, markers of the disease (Table 1). These "marker" autoantibodies are highly unusual in drug-induced lupus. In contrast, other types of autoantibodies, such as antisingle-stranded (ss) DNA, nRNP, Ku, and Su [12, 16], are associated with SLE, but are seen in other systemic autoimmune diseases as well. However, they usually are not found in healthy individuals. Anti-ssDNA and antihistone antibodies are associated with SLE as well as drug-induced

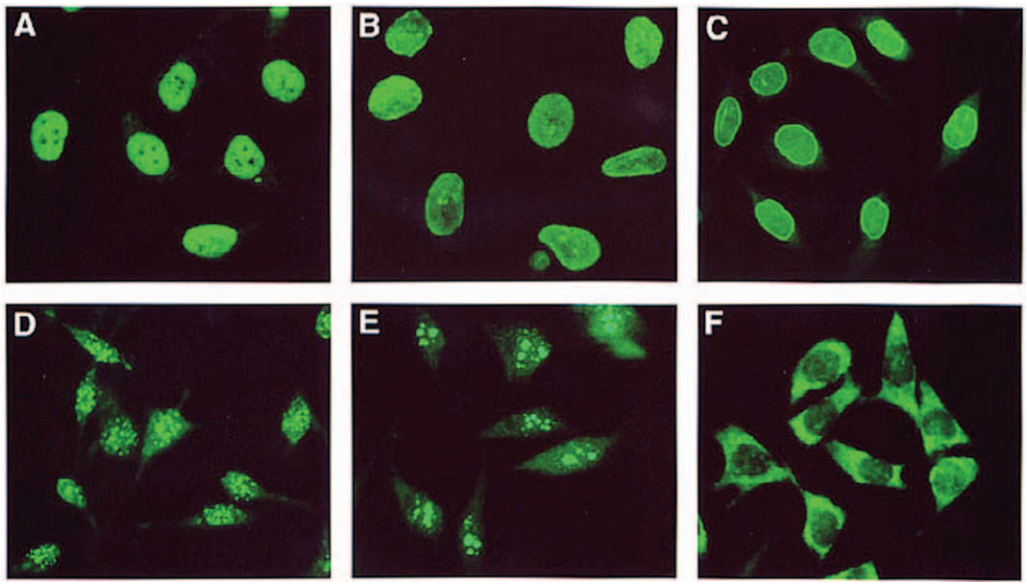

FIGURE 1 ***Prototype fluorescent antinuclear antibody patterns.*** HeLa cells (human cervical carcinoma cell line) were fixed with methanol and stained with human autoimmune serum at a dilution of 1:40. The binding of antinuclear antibodies to fixed and permeabilized cells was detected with fluorescein isothiocyanate (FITC)-conjugated goat antihuman IgG antibodies. (**A**) Fine speckled pattern sparing the nucleolus produced by anti-nRNP antibodies. (**B**) Diffuse (homogeneous) pattern produced by anti-dsDNA antibodies. (**C**) Rim (peripheral) pattern produced by antilamin B antibodies. (**D**) Centromere staining exhibited by serum from a patient with CREST syndrome producing anti-CENP-B autoantibodies. (**E**) Nucleolar pattern produced by antifibrillarin (U3 ribonucleoprotein) autoantibodies from a patient with scleroderma. (**F**) Cytoplasmic pattern produced by serum containing antiribosomal P autoantibodies.

lupus, and anti-Ro60 (SS-A), Ro52, and La are associated with primary Sjogren's syndrome, but also with sicca syndrome complicating SLE, scleroderma, or polymyositis (Table 1).

In view of the high specificity of anti-Sm and anti-dsDNA antibodies, it can be argued that serological criteria should be weighted more heavily in the diagnosis of SLE [6] than clinical features, which individually are less specific for SLE [7]. Remarkably, most of the same antibodies are associated with murine lupus: anti-dsDNA antibodies are produced by (NZB × NZW)F1 mice [17], anti-dsDNA, Sm, and ribosomal P by MRL mice [17, 18], and anti-Sm, dsDNA, and ribosomal P by mice with pristane-induced lupus [19–21] (Table 2).

There are several possible explanations for why certain autoantibodies [anti-dsDNA, Sm, proliferating cell nuclear antigen (PCNA), and ribosomal P] are specific for lupus, whereas others are specific for SSc (anti-topoisomerase I, fibrillarin, RNA polymerases I/III) or PM/DM (anti-tRNA synthetase). Autoantibodies could contribute directly to the disease process. For instance, the injection of certain anti-DNA antibodies causes glomerulonephritis [22–24]. Alternatively, the production of autoantibodies specific for SLE could reflect autoimmune mechanisms unique to the pathogenesis of SLE. For example, molecular mimicry between the U1 snRNP 70K protein (U1-70K) and a retroviral gag protein may lead to the production of anti-nRNP and Sm autoantibodies [25]. The question of whether disease marker autoantibodies, such as anti-Sm, cause disease or reflect a unique aspect of the disease process is key to understanding the pathogenesis of SLE. Intensive study of the antigens recognized by autoantibodies in SLE has provided some tantalizing clues.

AUTOANTIGENS ARE USUALLY MACROMOLECULAR COMPLEXES

Although the nuclei of cells contain thousands of proteins, only a small number (less than 50 or so) are autoantigens in systemic autoimmune diseases. Most of the antigens recognized by autoantibodies in SLE, PM/DM, SSc, and overlap syndromes are multiprotein or nucleoprotein complexes (Table 3). Many play key roles in cell regulation, including the organization of chromatin into transcriptionally active and inactive domains or RNA splicing [9, 10].

TABLE 1 Frequencies of Some Autoantibodies Associated with Human Systemic Autoimmune Disease (University of Florida Autoimmune Disease Center)[a]

		Frequency of autoantibody (%)		
Autoantibody	**Marker for**	**SLE (*n* = 317)**	**SSC (*n* = 46)**	**PM/DM (*n* = 25)**
dsDNA[b]	SLE	49	0	9
PCNA	SLE	0.6	0	0
Ribosomal P0, P1, P2	SLE	3	0	0
Sm	SLE	15[c]	0	0
nRNP	—	40[c]	4	4
Ku	—	6[c]	2	4
Ro60 (SS-A)	(Sicca)	36	7	40
La (SS-B)	(Sicca)	10	0	13
Scl-70 (topoisomerase I)	SSC	0.6[d]	17	0
RNA polymerase I and III	SSC	0.6[d]	20	0
Threonyl tRNA synthetase (PL7)	PM/DM	0	0	0[e]
Alanyl tRNA synthetase (PL12)	PM/DM	0	0	4
Glycyl tRNA synthetase (EJ)	PM/DM	0	0	4
Multienzyme complex (OJ)	PM/DM	0	0	4

[a] With the exception of anti-dsDNA, autoantibody specificities were determined by protein immunoprecipitation using sera from patients meeting ACR criteria for the classification of SLE [6] or scleroderma (SSC) [290] or with a primary clinical diagnosis of polymyositis or dermatomyositis (PM/DM). Demographics were as follows: SLE (91% female, 50% black, 43% white, 7% other); SSC (74% female; 32% black, 66% white, 2% other), and PM/DM (75% female, 46% black, 46% white, 8% other).

[b] *Crithidia luciliae* kinetoplast staining assay. Note that anti-dsDNA antibodies often are present only transiently, but data are from single serum samples. Estimates in the literature suggest that about 70% of SLE patients will produce anti-dsDNA at some time during their disease.

[c] There are marked racial/ethnic differences in frequency of certain autoantibodies (12).

[d] SSC criteria not available (*n* = 3, 2 topo I and 1 RNA polymerase I/III).

[e] Estimate from the literature is ~3%.

TABLE 2 Prevalence of Autoantibodies in Murine Lupus

	Spontaneous lupus (%)			Pristane-induced lupus (%)

TABLE 3 Some Examples of RNA–Protein and DNA–Protein Autoantigens

Antigen	Autoantibodies	Protein component	Nucleic acid component
U1 snRNP	α-Sm, α-nRNP, α-U1RNA	A, B′/B, C, D1/2/3, E, F, G, 70K	U1 small nuclear RNA
Y5 RNP	α-Ro (SS-A), α-La (SS-B), α-Y5RNA	60K Ro, 45K La	Y5 small RNA
Nucleosome	α-DNA, α-histone	H2A/H2B, H3, H4	DNA
DNA-PK	α-Ku, α-DNAPK$_{cs}$	Ku70, Ku80, DNA-PK$_{cs}$	DNA

The nucleosome, which consists of DNA packaged in a complex of histones H2A/H2B, H3, and H4 [26], was the first DNA–protein autoantigen to be identified [27]. Other DNA–protein autoantigens include the transcription factor NOR-90 [28, 29], centromeres [30], PCNA, a component of DNA polymerase δ [31], and Ku antigen, a component of the DNA-dependent protein kinase (DNA-PK) [32].

RNA–protein complexes, especially small nuclear ribonucleoprotein particles (snRNPs), also are important autoantigens (reviewed in Tan [9, 10]). U snRNPs (U1, U2, U4–6, U5), which carry Sm and nRNP antigenic determinants, were the first small ribonucleoprotein autoantigens recognized [33]. Others include the Y1-5 small ribonucleoproteins recognized by anti-Ro/SS-A antibodies, RNA polymerase III precursor RNA particles recognized by anti-La/SS-B antibodies, the 7-2 and 8-2 small nucleolar ribonucleoproteins recognized by anti-To/Th antibodies, U3 small nucleolar ribonucleoproteins recognized by antifibrillarin antibodies, tRNA synthetases, and the signal recognition particle [9, 10].

It may be significant that the macromolecular complexes recognized by autoantibodies in different disease states tend to be localized in different subcellular compartments. Many of the major lupus autoantigens are nucleoplasmic structures, such as spliceosomes (macromolecular arrays containing U1, U2, U4–6, and U5 snRNP particles) or nucleosomes. In contrast, antigens recognized by scleroderma-specific autoantibodies tend to be nucleolar structures involved in the transcription of ribosomal RNA, whereas those recognized by myositis-specific autoantibodies are cytoplasmic complexes involved in protein synthesis. The disease-specific targeting of particular subcellular compartments remains unexplained.

Characterization of Autoimmune Responses to Multicomponent Antigens

Many techniques have been used to study autoantibody specificities, including gel diffusion techniques (double immunodiffusion and counterimmunoelectrophoresis), enzyme-linked immunosorbent assays (ELISA), and Western blot (immunoblot) analysis. However, none of these approaches is adequate for evaluating immune responses to multicomponent antigens. While gel diffusion and ELISA permit detection of autoantibodies to native antigenic determinants, the composition of the antigenic particles and fine specificities of the autoantibodies cannot be investigated. Conversely, autoantibody fine specificities can be discerned by immunoblot analysis, but not the interrelationships between various components of a particle because the test is performed after dissociating the antigen. In addition, the harsh detergents used for this assay destroy many determinants dependent on the tertiary or quaternary structure of the antigen. For these reasons, immunoprecipitation of radiolabeled cell extracts has become an important tool for identifying autoantibody specificities in the research setting.

Immunoprecipitation is performed as illustrated in Fig. 2A. Tissue culture cells are grown in the presence of a radioactive amino acid, usually [^{35}S]methionine, and an extract containing radiolabeled cell proteins is incubated with protein A–Sepharose beads to which human autoantibodies are attached via the Fc region (Fig. 2A). The beads are washed extensively to remove unbound material, and then the bound proteins are eluted using heat and the detergent sodium dodecyl sulfate (SDS) before SDS–polyacrylamide gel electrophoresis. The radioactive proteins are visualized by exposing the gel to X-ray film. Figure 2B shows a typical immunoprecipitation experiment. Antiribosomal P antibodies (lane 1) immunoprecipitate three proteins of relative mobilities ~38, 19, and 17 kDa (P0, P1, and P2), whereas anti-nRNP (lane 2) and anti-Sm (lane 3) antibodies immunoprecipitate the same set of eight proteins ranging from 31 to 9 kDa (A, B′/B, C, D, E/F, and G, see also later). Another protein of ~70 kDa is not visualized because it is methionine deficient. Anti-PCNA (lane 4), anti-Ki (lane 5), anti-Ro (SS-A, lane 6), anti-La (SS-B, lane 7), and anti-Ku (lane 8) autoantibodies are associated with distinctive patterns, easily distinguished on the autoradiograph. Different types of autoantibodies may immunoprecipitate the same set (e.g., anti-nRNP and Sm, lanes 2 and 3) or partially overlapping sets (e.g., anti-Ro and La, lanes 6 and 7) of proteins. The association of several proteins with one another in a particle is responsible for the overlapping patterns. Similar tech-

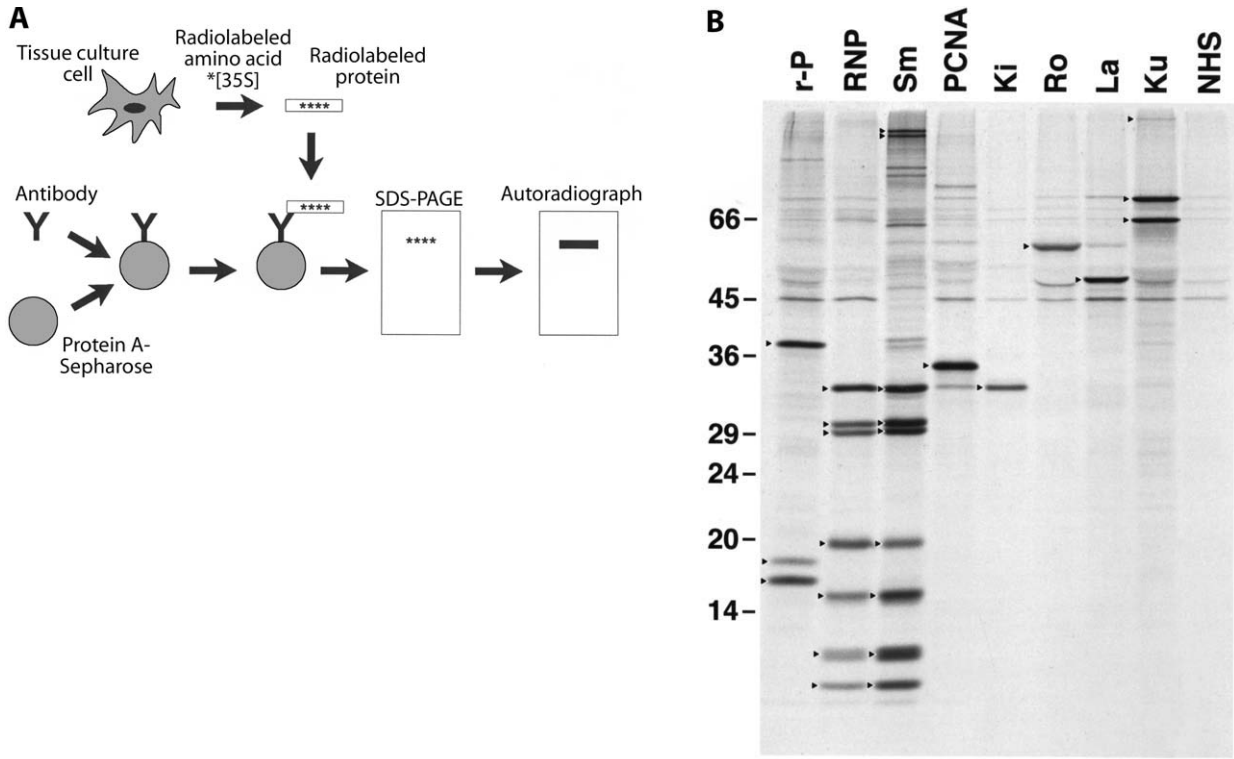

FIGURE 2 ***Immunoprecipitation assay.*** (**A**) Diagrammatic representation of technique. Tissue culture cells are labeled *in vitro* with a radioactive amino acid, usually [^{35}S]methionine. An extract containing the metabolically labeled proteins is added to protein A–Sepharose beads that have been preincubated with human autoimmune serum containing IgG autoantibodies. Autoantibodies attached to the beads via their Fc region recognize the radiolabeled proteins in the extract and bind them. The beads are washed, and the radioactive proteins are eluted from the beads by boiling in SDS sample buffer. The proteins can then be analyzed by SDS–polyacrylamide gel electrophoresis, which separates them on the basis of size. The gel is then exposed to X-ray film to visualize the bands on the gel. (**B**) Typical autoradiograph showing various autoantibody specificities. Immunoprecipitation was performed as diagrammed in A using prototype sera containing anti-ribosomal P (r-P), nRNP (RNP), Sm, proliferating cell nuclear antigen (PCNA), Ki, Ro (SS-A), La (SS-B), or Ku autoantibodies. Immunoprecipitation with normal human serum (NHS) is shown as a control. Positions of the protein bands characteristic of each specificity are indicated with arrowheads. Positions of molecular mass standards in kilodaltons are indicated on the left.

niques are used to analyze the nucleic acid components of small ribonucleoprotein particles [33, 34]. In this case, cells are labeled metabolically with [^{32}P]orthophosphate, and the immunoprecipitates are extracted with phenol–chloroform before analyzing the immunoprecipitated nucleic acids by gel electrophoresis.

Anti-Sm and nRNP Autoantibodies Recognize the U1 snRNP

The U1 snRNP, an RNA–protein autoantigen, is a typical multicomponent autoantigen illustrative of the general principles applying to many other autoantigen/autoantibody systems (Fig. 3). It is a macromolecular complex consisting of a group of proteins designated U1-70K, A, B′/B, C, D1/2/3, E, F, and G, which are associated with U1 small nuclear RNA [33]. The proteins B′/B, D, E, F, and G assemble into a stable 6S particle (the Sm core particle) reactive with anti-Sm, but not anti-nRNP, antibodies [35]. Autoantibodies to the Sm core particle are unique to SLE [5, 13]. In contrast, antibodies to the proteins A, C, and 70K, which carry nRNP antigenic determinants, may be found in SSc, PM/DM, and other subsets of systemic autoimmune disease, as well as SLE [13, 36]. High levels of anti-nRNP antibodies, without anti-Sm, are seen in mixed connective tissue disease (MCTD) [37]. The A and 70K proteins interact directly with U1 RNA via RNA recognition motifs [38], whereas the association of U1-C with the U1 snRNP, although RNA dependent, is mediated through interactions with the B′/B components of the Sm core particle [39]. In addition to the U1 snRNP,

TABLE 4 Protein and RNA Components of Abundant U snRNPs[a]

snRNP particle	RNA	Shared proteins	Unique proteins	Antibody binding
U1 snRNP	U1	B′/B,D,E,F,G[b]	70K, A, C	Sm, nRNP
U2 snRNP	U2	B′/B,D,E,F,G[b]	A′, B″	Sm, A′, B″
U5 snRNP	U5	B′/B,D,E,F,G[b]	8 proteins	Sm, 100, 102, 200K (doublet)
U4/U6 snRNP	U4 and U6	B′/B,D,E,F,G[b]	150K	Sm, 150K

[a] Data from Refs. 33,291–294.
[b] *Proteins B′/B, D, E, F, and G form the 6S Sm core particle, which is shared by all of the U snRNPs listed.*

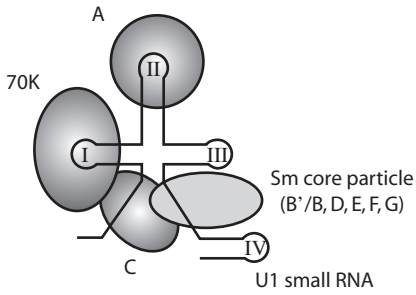

FIGURE 3 ***Structure of the U1 snRNP particle.*** The U1 snRNP is a complex of several proteins (designated 70K, A, B′/B, C, D, E, F, and G) bound to a single molecule of U1 small nuclear RNA. The 70K, A, and C proteins (dark shading) are recognized by anti-nRNP antibodies. The B′/B, D, E, F, and G proteins form a 6S particle termed the Sm core particle. This particle contains the major antigenic determinants recognized by anti-Sm antibodies. Base pairing within the U1 RNA molecule results in the formation of four stem-loop structures (I–IV). Two of these (stem-loops II and IV) are recognized by autoantibodies.

other small ribonucleoprotein complexes, each with a unique uridine-rich (U) RNA species, carry the Sm core particle. These include the U2, U4/U6, and U5 snRNPs, as well as a number of other less abundant U snRNPs [40]. U1, U2, U5, and U4/6 snRNPs are present at levels ranging from 10^6 copies (U1 and U2) to 2×10^5 copies (U5 and U4/U6) per mammalian cell [40]. The Sm core particle [35] is a component of each of these snRNP particles. In addition, each of these major snRNP particles carries unique protein components (Table 4).
