Resistance is acquired in a variety of ways. Mutation of any gene occurs at a rate of one cell in 10^7 and, if this cell is then presented with antibiotics that it can survive, it will become a dominant cell, reproducing at a rate of 10^9 overnight.

Enzymes, such as the β-lactamases, inactivate a large array of antibiotics. Class 1 β-lactamase is effective against some β-lactam-containing antibiotics but extended-spectrum β-lactamases (ESBLs), which incorporate enzymes such as TEM-24, will produce

cross-resistance to multiple classes of antibiotics, including fluoroquinolones and aminoglycosides.[9–12]

The Ambler classification categorised all β-lactamases into four classes A–D, based upon molecular structure, and ESBLs are Class A enzymes. The major ESBL types are TEM, SHV and CTX-M – the latter being the predominant genotype globally.

AMPc enzymes are Class C, and differ chiefly in the fact they are not inhibited by clavulanate in vitro. *Enterobacter*, *Serratia* and *Citrobacter* can all produce AMPc β-lactamases. This fact is mainly of use in the diagnostic laboratory, where different markers aid in helping define potential therapeutic options. For example, β-lactam/β-lactamase inhibitor drug combinations, such as co-amoxiclav (amoxicillin and clavulanic acid) and piperacillin-tazobactam, may be considered in ESBL producers with mild infection, but not in AMPc producers. However, this is rarely appropriate in the ICU setting.

Resistance may be produced by a combination of mechanisms, such as in *P. aeruginosa* where the resistance is due to a combination of protein efflux systems, cephalosporinases and derepression of AmpC enzyme.

Carbapenemases were first described in the 1980s but have become prominent over the last 10 years, especially with the rise of Class B metallo β-lactamases (MBLs). In particular the New Delhi MBL (NDM-1), which was characterised in 2008, is of growing concern as the plasmid carrying the enzyme also carries other resistance mechanisms, rendering such infections extremely drug resistant.[13] Other carbapenemase enzymes exist (such as KPC and OXA enzymes), and the degree to which they inhibit the action of the drug varies. This has implications for both the detection and management of these infections

The big problem particularly with carbapenemases and ESBLs is that they can spread by plasmid transmission, which is very rapid. The enzyme production is encoded chromosomally within an organism, and can then be transferred between bacteria by plasmids. Transposons transfer genes between plasmids.

The phenomenon of induction is the process whereby the presence of an antibiotic appears to 'induce' or switch on the production of the relevant enzyme so that the organism becomes resistant. For example, staphylococcal resistance to methicillin occurs due to an altered penicillin-binding protein that has low affinity for all β-lactam agents. It is linked to a *MecA* gene, which is usually expressed only when stressed by antibiotic pressure. This gene does not develop readily and the spread of methicillin resistance is by vector transmission, not de novo production of resistance (Table 71.2).[9]

PROBLEM ORGANISMS

See Box 71.3 for organisms responsible for the majority of nosocomial infections.

Table 71.2 The influence of extended-spectrum β-lactamases (ESBL) on resistance in *Klebsiella*

ANTIBIOTICS	ESBL-NEGATIVE (% RESISTANT)	ESBL-POSITIVE (% RESISTANT)
Gentamicin	8	76
Amikacin	3	52
Ciprofloxacin	3	31
All the above	0	5

Reproduced from Livermore DM, Yuan M. Antibiotic resistance and production of extended-spectrum beta-lactamases amongst *Klebsiella* spp. from intensive care units in Europe. *J Antimicrob Chemother*. 1996;38:409–424.

These infections are likely to be associated with an increase in morbidity and mortality, primarily due to delayed recognition, an association with other resistant mechanisms (ESBLs are often aminoglycoside and quinolone resistant too) and a lack of therapeutic options.[11]

An indication of their perceived importance is that in 2016 the United Nations General Assembly passed a resolution on antimicrobial resistance (AMR), aimed at improving country action plans. In the United Kingdom the government published a 5-year AMR strategy and as a result AMR was placed on the UK government risk register in 2015.[14] The World Health Organization released their Global Action Plan in 2015 stating 'antimicrobial resistance threatens the very core of modern medicine'.[15] The epidemiological evidence shows that the prevalence of such infections is increasing worldwide.[12]

EXTENDED-SPECTRUM β-LACTAMASE-PRODUCING ENTEROBACTERIACEAE

Enterobactericeae encompass a large family of enteric, oxidase-negative, Gram-negative bacilli. In terms of nosocomial infection, *Escherichia coli* and *Klebsiella* spp. are the most frequently seen but *Enterobacter* spp., *Citrobacter* spp., *Serratia* spp. and *Proteus* spp. (amongst others) are also implicated.

Of these, *E. coli* and *Klebsiella* are particularly able to produce ESBLs, which may be defined as transferable plasmid-mediated enzymes that hydrolyse third-generation cephalosporins (ceftriaxone) but are inhibited in vitro by clavulanate.[10]

CARBAPENEMASE-PRODUCING ENTEROBACTERIACEAE (CPE)

Of major public health concern over the last decade has been the rise of CPEs. Enterobacteriaceae implicated tend to be *E. coli* and *Klebsiella pneumoniae*, but the range of organisms capable of producing these enzymes is expanding. The organisms are resistant

to carbapenems, and frequently the majority of other antibiotic classes, rendering treating patients extremely difficult, with colistin as the only reliable therapeutic option. As such these organisms are associated with increased morbidity and mortality and have the capacity to cause outbreaks. International guidance recommends combination antibiotic therapy in treating these infections, with strict adherence to infection control practice.[13,16,17]

PSEUDOMONAS AERUGINOSA

P. aeruginosa is one of the commonest pathogens associated with hospital-acquired pneumonia (HAP). Due to a large genome, it is inherently resistant to a significant number of commonly used antibiotics, rendering therapy challenging. It is of particular importance in patients suffering from chronic lung disease (such as cystic fibrosis, chronic obstructive pulmonary disease [COPD] or bronchiectasis), where colonisation within the respiratory tract leads to recurrent infections, and subsequently worse morbidity and mortality. Resistance is able to develop in a range of ways and produces a very broad spectrum of resistance, making combination antibiotic therapy a popular option.[18] It is associated with an adverse outcome in the critically ill[19] and, like the ESBL producers, multidrug-resistant pseudomonal strains are growing in number.[20]

STENOTROPHOMONAS MALTOPHILIA

This is an increasingly common and troublesome environmental organism. It is often resistant to β-lactam antibiotics, quinolones and aminoglycosides. Co-trimoxazole is the only reliably effective antibiotic agent. It also produces a carbapenemase, which makes it intrinsically resistant to carbapenems, and prolonged treatment with carbapenems predisposes to *S. maltophilia* colonisation and subsequent infection.

ACINETOBACTER BAUMANII

A. baumanii is an increasing and major problem. It survives even in dry environments and, despite its name, spreads and cross-infects readily (*a cineto*: without movement). It is multiresistant and, although generally sensitive to carbapenems, it is increasingly resistant even to these agents. It becomes rapidly resistant and the profile of resistance is unpredictable but can be extremely broad, with some organisms sensitive only to colistin.[21]

COAGULASE-NEGATIVE STAPHYLOCOCCI (CoNS)

CoNS are low-virulence organisms and common skin commensals, but are increasingly causing nosocomial infection. Their resilience may be in part due to the production of biofilm, when associated with catheter-related or bone and joint infections. They are resistant to multiple classes of antibiotics, but are usually sensitive to glycopeptides. As glycopeptide resistance patterns alter, agents such as linezolid and tigecycline have a therapeutic role.

METHICILLIN-RESISTANT STAPHYLOCOCCUS AUREUS

S. aureus is a virulent pathogen causing a wide range of infections. It has a plethora of virulence factors but endogenous toxins produce most of the clinical syndromes such as invasive skin and soft tissue infections, food poisoning and necrotising pneumonia.

Methicillin resistance was first noted in the early 1960s and, although rates between countries and ICUs vary considerably, there has been an inexorable rise in its prevalence in most countries. Glycopeptides are currently commonly used to treat invasive MRSA infections but, as ever, source control is of paramount importance. Newer anti-MRSA agents include linezolid, tigecycline and daptomycin. Anti-MRSA cephalosporins have also been developed (ceftaroline, ceftobiprole). MRSA has been a model of the failure of some infection control methods and is a well-publicised marker of quality in a health care setting.

CLOSTRIDIUM DIFFICILE

This originally emerged as an organism considered a problem after administration of certain antibiotics, including clindamycin. It is now clear that in the critically ill it often emerges after using almost any broad-spectrum antibiotics. The organism produces toxins that can cause pseudomembranous colitis, a potentially catastrophic disease leading to toxic megacolon. Although it usually settles on metronidazole or vancomycin orally, recurrence is common and it can ultimately lead to radical surgery, such as a colectomy.[22] Fidaxomicin shows promise against recurrent disease.[23] Faecal microbiota transplant has developed a good evidence base and use for recurrent disease is increasing.[24] Surgery carries a high mortality rate, quoted at 11% for total colectomy, and very high mortality for less aggressive surgery, such as hemicolectomy in the presence of toxic megacolon.[25]

CANDIDA *SEPSIS*

Candida sepsis is the fourth commonest bloodstream infection in the United States and the sixth commonest in Europe.[26]

The prevalence of species is defined by each unit, but *Candida albicans* is most common. There is some evidence to suggest that the widespread use of azoles may have influenced the relative increase in *C. glabrata* and *C. krusei* species. *C. auris* has recently emerged as a difficult pathogen in the ICU with multidrug resistance and persistence in the environment.[27] Definitive diagnosis is by blood culture, but presumptive diagnosis is suggested by the triad of clinical infection, a high-risk patient and *Candida* at more than two sites (Fig. 71.1). Antifungal treatment should depend on the sensitivity of the species involved.

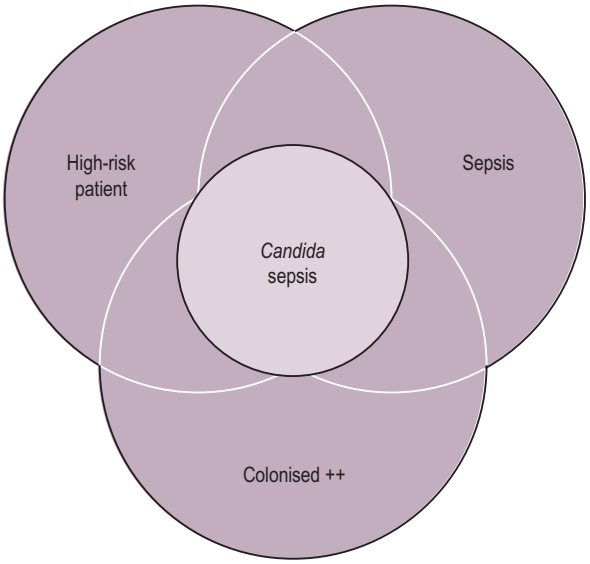

Figure 71.1 Diagnostic triad of *Candida* sepsis.

Box 71.4 Principles for the diagnosis of nosocomial pneumonia

Crackles on auscultation or dullness to percussion on physical examination of the chest and any of the following:

- New onset of purulent sputum
- Organism isolated from blood cultures
- Isolation of pathogen from specimen obtained by transtracheal aspirate, bronchial brushing or biopsy
- Chest radiography examination shows new or progressive infiltration, consolidation, cavitation or pleural effusion
- Isolation of virus or detection of virus antigen in respiratory secretions
- Diagnostic single antibody titre immunoglobulin (Ig)M or fourfold increase in paired serum samples (IgG) for pathogen
- Histopathological evidence of pneumonia

SITES OF INFECTION

The main sites of nosocomial infection are the respiratory system, surgical site wounds and intravenous lines. Urinary tract infection appears to be relatively uncommon compared with non-critical care environments, with only 14% point prevalence in the EPIC II study compared with 64% of respiratory-related infections.

NOSOCOMIAL PNEUMONIA

Nosocomial pneumonia is a common problem in the critically ill, particularly in ventilated patients with an attributable mortality of 13%.[28]

AETIOLOGY

There are several possible mechanisms, including aspiration from the nasopharynx, local spread and haematogenous spread of infection. Some 45% of healthy adults aspirate in their sleep. In the sick the nasopharynx colonises rapidly with a wide range of organisms, usually Gram negatives, and aspiration is encouraged by the unconscious state, the presence of a nasogastric tube or endotracheal intubation. Pneumonia will develop in up to 25% of colonised patients, compared with a 3% incidence in non-colonised patients.

Patient factors predisposing to nosocomial pneumonia include acute severity of illness, chronic illness, especially chronic lung disease, diabetes, immunosuppression, advanced age, recent surgery to thorax or abdomen, intubation and bronchoscopy. Environmental factors include broad-spectrum and prolonged use of antibiotics, potential pathogens in the vicinity, bacterial properties such as the ability to adhere to surfaces, cross-infection, 24-hour ventilator tubing changes and foreign bodies such as nasogastric tubes. Intubated and ventilated patients have a higher rate of nosocomial infection than patients receiving non-invasive ventilation. However, this may be due to different patient populations with different underlying problems and background morbidity.[29] The role of neutralisation by H_2 antagonists and proton pump inhibitors is still debated.[30–32]

DIAGNOSIS

The general criteria for diagnosis are clinical signs of a chest infection, purulent sputum, rising inflammatory markers, radiological evidence and positive cultures from sputum or blood.[28] These criteria are non-specific, and obtaining deep respiratory samples with quantitative analysis remains the stated gold standard method of diagnosis. This can be achieved with protected brush specimens bronchoalveolar lavage (BAL) and protected BAL. These are difficult and time consuming, and it appears that non-bronchoscopic techniques, such as blind tracheal aspirates through the endotracheal tube, are both practical and reasonably effective from a clinical – if not a research – viewpoint.[28] A Cochrane review showed there was no evidence that quantitative cultures (compared with qualitative analysis) reduced mortality, length of stay, time on mechanical ventilation or antibiotic change (Box 71.4).[33]

THE ORGANISMS

The majority of VAP is due to aerobic Gram-negative organisms such as *Klebsiella* spp., *E. coli* and *Pseudomonas* spp., but early-onset VAP, between 48 hours and 5 days, may be due to community pathogens, such as methicillin-sensitive *S. aureus*, *Streptococcus pneumoniae* and *Haemophilus influenzae*. This has been described as early endogenous infection.

In late-onset VAP (after 5–7 days), multidrug-resistant organisms, such as MRSA, *P. aeruginosa*, *Acinetobacter baumannii* and *S. maltophilia*, occur more commonly than in non-ICU patients.[28,34]

PREVENTION

Prevention is by methods that reduce aspiration, cross-infection and contamination of respiratory devices.[30] Recommended methods include:

- hand washing
- limiting antibiotic use
- changing ventilator circuits at longer intervals – 1 week
- orotracheal, rather than nasotracheal intubation
- removing nasogastric tubes
- semi-recumbent position – this reduces aspiration
- avoiding muscle relaxants
- avoiding re-intubation
- using non-invasive ventilation, where possible.

TREATMENT

The use of inappropriate antibiotics leads to an increased mortality, so current trends are towards initial broad-spectrum antibiotics followed by reassessment and de-escalation.[35,36] As the spectrum of resistance grows, it is highly likely that it will be increasingly difficult to apply this broad-spectrum empirical treatment, especially with late-onset VAP. Surveillance of current colonisation, awareness of an individual ICU's ecology and targeted treatment will replace empiric regimens. Most international guidance advocate the empirical use of combination therapy to cover *S. aureus*, *P. aeruginosa* and other Gram-negative bacilli, in patients with suspected VAP.[28,35,37–39] The evidence is not conclusive, however, and many studies have shown good results with monotherapy.[40,41]

Duration of treatment has always been widely debated. Shorter courses are increasingly being advocated, with a 7-day course shown to be effective.[28,42] Pseudomonal or MRSA pneumonia may require longer courses, of 14 and 21 days, respectively, depending on severity.[43] Linezolid and vancomycin have similar efficacy for HAP.[44]

SURGICAL SITE INFECTIONS

Surgical site infections remain the second most common HCAI in Europe and the United States affecting up to one-third of surgical procedures. The organisms involved may be those introduced at the time of surgery or from later contamination.[45]

RISK FACTORS

- The procedure itself and the level of contamination prior to or during surgery. Highest cumulative incidence (9.5%) was for colon surgery compared to 1.0% and less in orthopaedic prosthetic surgery in Europe.[46]
- Poor surgical technique and low volume of surgery[47]
- Host factors: see Box 71.2
- Inappropriate use of antibiotic prophylaxis
- Prolongation of stay in the ICU.

PREVENTION

Clean theatres, good operating technique and thorough asepsis, both in the theatre and postoperatively, are important.

ANTIBIOTIC PROPHYLAXIS

Efficacy of antibiotic prophylaxis has clearly been demonstrated. If there is no risk of infection with a clean procedure, there is no place for antibiotics. If contamination is either seen or likely to occur, the use of antibiotics is to provide cover for the spillage. Effective prophylaxis requires an antibiotic:

- that covers the most likely organisms
- to be given prior to contamination (0–2 hours pre-operatively)[48]
- at peak dosage at the time of contamination.

A single dose should suffice, although a second dose is recommended if the procedure extends beyond 4 hours or a significant amount of blood loss occurs. Prolonged administration:

- increases the chance of antibiotic resistance
- unnecessarily exposes the patient to adverse effects from the drugs
- encourages colonisation and late infections with resistant organisms.

In many circumstances the evidence supporting prophylaxis is minimal, and frequently the antibiotics used are inappropriate to the perceived risk. Most hospitals will have specific guidance on appropriate antibiotic prophylaxis tailored to the procedure, taking into account local microbial resistance data. With grafts, mesh or prostheses the morbidity from infection is so great as to justify using prophylaxis even if the evidence is marginal (Table 71.3).

LINE SEPSIS

The use of intravascular devices in hospital practice is ubiquitous. There is a significant morbidity associated with line sepsis with 64% of bloodstream infections occurring in patients with a vascular access device.[49] The catheter type influences the rate of infection. A systematic review[50] showed the following rates per 1000 catheter days:

- peripheral intravenous catheters – 0.5 (95% confidence interval [CI] 0.2–0.7)
- non-cuffed central venous catheters (CVCs)
  - non-medicated and non-tunnelled – 2.7 (95% CI 2.6–2.9)
  - non-medicated and tunnelled – 1.7 (95% CI 1.2–2.3)

Table 71.3 Surgical prophylaxis

TYPE OF SURGERY	
Abdominal wall	Insertion of mesh. Staphylococcal or streptococcal cover. In the groin, Gram-negative cover may be needed
Cardiac	Protection of valves and grafts. Staphylococci may be resistant
Vascular	Protection of grafts. Staphylococci are a major consideration. If the groin is involved, it may require Gram-negative cover
Orthopaedic	Prostheses. Staphylococci are an increasing problem
Biliary upper GI	Usually Gram-negative and anaerobic cover, with an awareness of resistant enterococci
Colorectal	Protection against faecal flora. Cephalosporins and metronidazole have been popular but predispose to developing enterococci, such as *Enterococcus faecalis* or *E. faecium*, which may be multiresistant
Gynaecological	Conventionally broad-spectrum involving cephalosporins or, currently, co-amoxiclav. Metronidazole is also favoured
Urological	Protection from instrumentation of the urinary tract, Gram-negative cover. Awareness of any existing infection

GI, Gastrointestinal.

- cuffed and tunnelled CVCs – 1.6 (95% CI 1.5–1.7)
- arterial catheters for haemodynamic monitoring – 1.7 (95% CI 1.2–2.3)
- pulmonary artery catheters – 3.7 (95% CI 2.4–5.0)
- peripherally inserted central catheters
  - inpatient – 2.1 (95% CI 1.0–3.2)
  - outpatient – 1.0 (95% CI 0.8–1.2)
- peripherally inserted midline catheters – 0.2 (0.0–0.5).

Many other factors influence the development of infection, such as conditions of insertion, catheter care and duration of catheter. Peripheral catheters should be inspected daily and removed when complications occur or when they are no longer required. CVCs should not be routinely replaced to prevent infection (Box 71.5).[49]

CENTRAL VENOUS CATHETERS

Colonisation of catheters is common and it is likely that this is a precursor of infection. Colonisation rates are in the order of 5%–40%, determined in part by the risk factors involved (see below). Infection rates are approximately 10% of the colonised catheters.[51]

Box 71.5 Risk factors for catheter infection

Host risk factors
Site: subclavian is a lower risk than internal jugular and femoral
Catheter material: antibacterial catheters recommended for central catheters >5 days
Number of lumens: multilumen catheters increase the infection risk[30]
Number of administrations through the lines
Dressing type: frequency of changes
Skin preparation
Experience of technique of personnel
Occurrence of bacteraemia
Tunnelling: often used for long-term access but the data are contentious[31]

DEFINITIONS

1. *Colonised catheter:* growth of greater than 15 colony-forming units (semi-quantitative) or 10^3 (quantitative) from a proximal or distal catheter segment in the absence of accompanying clinical symptoms and signs.
2. *CR-BSI:* isolation of the same organism from the catheter segment (see above) as from a peripheral blood culture in a patient with signs of infection and in the absence of another source.

THE ORGANISMS

The organisms involved in catheter sepsis are influenced predominantly by the patient's endogenous flora. There is a 25% incidence of CoNS, which are increasingly recognised as pathogens due to their ability to form biofilms on prosthetic material. A biofilm is a three-dimensional matrix of extracellular polymeric material (slime) that allows bacteria to live in communities. These are important owing to the increased resistance to antimicrobials and strong adherence to prosthetic material.[52] *S. aureus* and *Candida* spp. can cause significant bacteraemia, and seeding to other organs, such as the eyes and heart valves, must be ruled out. Gram-negative pathogens predominate in patients with haematological malignancies, and *Pseudomonas* is frequent in burns patients.

TREATMENT OF CATHETER INFECTION

The most important aspect of treatment is a high index of suspicion that leads to removal of the device if infection is present either locally or systemically.[49] Antimicrobials after line removal are recommended and duration is dependent upon the organism. CoNS need up to 5 days, but *Candida* spp. and S. *aureus* require a minimum of 14 days. Guidewire-assisted

catheter exchange is not recommended if bacteraemia are present, and a period of central line free days prior to re-insertion is optimum. Salvage therapy for infected lines is not routinely recommended, especially if the organism is highly virulent, but 14 days of antibiotics via the line would be the minimum.

PREVENTION

Important issues include insertion under aseptic conditions, an intravenous team to insert and manage lines, the anchoring of lines to prevent excessive movement, closed systems with limited interruptions to the lines, the application of sterile dressings to the insertion site, and daily inspection of the catheter site. Administration sets in continuous use do not need to be replaced more than every 96 hours unless they are used for blood or total parenteral nutrition (TPN). Daily chlorhexidine cleansing at the line site and use of transparent semipermeable dressings should be considered.[49,53,54]

Techniques of unproven benefit include antiseptic cream at the insertion site, antibiotic lock therapy, occlusive antimicrobial dressings, in-line filters, tunnelling of CVCs and routine flushing of long-term CVCs.

METHODS OF INFECTION CONTROL

Each hospital has an infection control team that can employ techniques to reduce infection (Box 71.6). Prevention of nosocomial infection, thus reducing length of stay, will decrease antibiotic utilisation and therefore the generation of multidrug resistance.

The most important aspects of preventing nosocomial infection and facilitating infection control are simple hygiene, such as hand washing, and being aware that the problem exists. There are several ways in which the issue of nosocomial infection can be addressed. These include surveillance, screening, isolation and strategic planning.[55]

SURVEILLANCE AND SCREENING

Routine culture surveillance of both patients and environment provides information on the organisms currently prevalent, and is a useful tool in guiding management when infection occurs. Molecular typing of specific pathogens allows the identification of cross-infection, and gives the clinician the ability to track the organism during an outbreak.

Screening of patients allows the identification of multidrug-resistant organisms and therefore barrier precautions to be implemented. MRSA, carbapenem-resistant Enterobacteriaceae (CRE), vancomycin-resistant Enterococci (VRE) and *Acinetobacter baumanii* are organisms often targeted during screening.

Box 71.6 Roles of infection control teams

- Surveillance and investigation of infection outbreaks
- Education of staff
- Review of antibiotic utilisation
- Review of antibiotic resistance patterns
- Review of infection control procedures and policies

ISOLATION

Although physical barriers undoubtedly reduce cross-contamination, isolation may be hazardous as it often indicates lower-intensity care. The relative risks need to be addressed.

STRATEGIC PLANNING

There are two elements. One is enforcing hygienic practice, which is simple, cheap and very effective. The other is looking towards means of reducing both nosocomial infection and the emergence of resistance by good antimicrobial stewardship.

On an individual basis the approach to management must change. In the past, empirical treatment on the basis of likely organisms led to the use of very-broad-spectrum antibiotics. Narrow-spectrum targeted treatment will cease to be an option and will become a necessity. Prolonged broad-spectrum antibiotic management aimed at dealing with any eventuality will be replaced by short-duration specific and effective regimens.

SELECTIVE DIGESTIVE DECONTAMINATION OR OROPHARYNGEAL DECONTAMINATION

Selective digestive decontamination (SDD) and selective oropharyngeal decontamination (SOD) are based on the idea that elimination of colonising organisms in the gastrointestinal tract will reduce nosocomial infection as the majority of infections arise from endogenous flora. SDD administers oral non-absorbable antibiotics, such as polymyxin and nystatin, in conjunction with a parenteral cephalosporin. SOD limits therapy to oral antiseptics such as chlorhexidine. The uptake of this technique has been limited owing to concerns over antibiotic resistance generation, but it is associated with a higher survival at day 28, a lower incidence of bacteraemia and reduced VAP.[34,56–58] It is likely that SDD would be most effective in ICUs with low levels of antibiotic resistance, and SOD should be considered in ICUs with concerns of higher levels of resistant organisms.[59]

Severe soft-tissue infections

Mohamed Abbas, Ilker Uçkay, Tristan Ferry, Elif Hakko, Didier Pittet

PATHOGENESIS

The skin is the largest organ and acts as an excellent barrier against infection. Microorganisms cause skin and soft-tissue infections (SSTIs) (1) if there is a break in the skin because of a traumatic lesion or maceration; (2) if the soft tissues are ischaemic; (3) if virulent bacteria is present, such as community-acquired methicillin-resistant *S. aureus* (CA-MRSA)[1]; (4) if there are surgical site infections[2]; or (5) if the patient is severely immunocompromised.[2,3] Skin lesions can on occasion be manifestations of systemic infection; examples are bacteraemia with meningococci or endocarditis.

In this chapter, we do not address secondary infections; fungal, parasitic or mycobacterial infections; dressings; surgical techniques; wound care; or the epidemiology and prevention of healthcare-associated SSTIs.

EPIDEMIOLOGY

SSTIs are a diverse group of clinical syndromes that have varying severity and are associated with a wide range of pathogens. There has been a steady increase in the incidence of SSTIs,[4,5] and rates of emergency department visits increased between 2000 and 2010, from 6.4 to 13.5 per 1000 persons.[6] Also, SSTIs frequently cause severe sepsis and can be responsible for 6.5% of cases of septic shock.[7] The burden of SSTIs was shown in a European study where adult patients had a median length of hospital stay of 12 days; 6.5% required admission to the ICU, and 37% required surgical intervention.[8] Necrotising fasciitis (NF) and myositis are the most feared SSTIs that can affect even the healthiest young individual with very rapid onset and rapid progression to death.[9–11] Mortality rates historically range between 20% and 30%.[12–16] More recently, a study of death certificates showed a crude mortality rate of 4.8 deaths/1,000,000 person-years, with no significant time trend in the number of fatal NF during the study period.[17] Another study showed that, despite increasing co-morbidities, there has been a decrease in mortality from 9.0% to 4.9%.[18]

MICROBIOLOGY

The microbiota of the human skin is highly diverse; different body sites represent different ecological niches and have different compositions.[19,20] In healthy adults it remains stable for up to 2 years,[21] and is probably independently of gender, race, or age. Its alterations are associated with disease or colonisation status (e.g. up to 30% of healthy adults are colonised with *S. aureus*); specifically, it has been suggested that microbe–microbe interactions may help prevent colonisation by pathogenic bacteria.[22] Transient colonisation by Gram-negative bacteria occurs in hospitalised patients, particularly in the ICU.[23] A high proportion of Gram-negative pathogens may be encountered in the clinic. For example, in Southern China, 41% of SSTIs in an inpatient population were reported to be due to Gram-negative bacteria, of which one-third were due to *Escherichia coli*.[24] Severe cellulitis with haemorrhagic bullous lesions can be caused by marine trauma, such as with *Vibrio* spp.[25]

Significant SSTIs due to human skin flora in absence of implants, lymphatic disease or trauma are exceptions. The classical pathogens of deep layer SSTIs are beta-haemolytic streptococci, notably *S. pyogenes*, and *S. aureus*.[26]

This microbiological pattern has not changed significantly over the last decades[27] with three main exceptions: CA-MRSA, often producing a necrotic cytotoxin (Panton-Valentine Leukocidin), is an emerging burden of severe SSTIs worldwide[1,28]; severe *Acinetobacter* infections following war trauma and natural disasters in arid regions[25,29]; and earthquakes (with associated tsunamis) highlight the potential for atypical microorganisms (*Aeromonas* spp., *Vibrio* spp., *Pseudomonas* spp.) causing soft tissue infections.[25,30,31]

DIAGNOSIS

Diagnosis of SSTIs can be difficult, and is essentially based on clinical presentation (e.g. rapid-onset redness, pain, and discomfort that spreads over time, which may be accompanied by fever, shivering or hypotension;

ABSTRACT

Skin and soft-tissue infections are a heterogeneous group of infections, which are mostly caused by bacteria, and may be severe, such as cellulitis/erysipelas, necrotising fasciitis and myositis. The most frequent causative bacteria are *Staphylococcus aureus* and beta-haemolytic streptococci (especially *Streptococcus pyogenes*), although Gram-negative bacteria may also play an important role in specific circumstances (e.g. *Acinetobacter* infections after trauma in arid regions, *Vibrio* spp. infections after marine trauma). Antibiotic therapy is the mainstay of treatment, and should be adapted according to local epidemiology (e.g. coverage of community-acquired methicillin-resistant *S. aureus*), the immune status of the host, and whether the infection is nosocomial or community-acquired. In severe and/or necrotising infections, surgery for source control is paramount. The jury is still out regarding the role of adjunctive therapy (toxin production inhibition, intravenous immunoglobulins, hyperbaric oxygen therapy) as well as that of newly marketed and approved antibiotics.

myositis

or the presence of an abscess with pus). Misdiagnosis is common,[32] and has important consequences for patients.[33] Although microbiological confirmation is necessary for targeted antibiotic therapy, it is only rarely obtained.[34,35] Growth of microorganisms *per se* in swabs is not proof of infection, since some differential diagnoses of SSTIs (ischaemia, necrosis, allergy, pyoderma gangrenosum, venous thrombosis or stasis dermatitis) may equally be associated with a breach of the cutaneous barrier with consequent bacterial colonisation.[36] The classification of SSTIs can be confusing because almost every pathogen can be associated with a wide range of clinical presentations; for example, *S. pyogenes* can be responsible for erysipelas, but can spread into deeper tissues and cause fasciitis with or without associated myositis. It is not known why some infections remain superficial, while others become bacteraemic, and others still penetrate deeper structures.

Of note, colonisation with healthcare-associated MRSA poorly correlates with the pathogen of the SSTIs,[37] and patients receiving antibiotics before hospital admission may present negative culture results. The only useful serology is the antistreptolysin-O-antibody that may help diagnose infection by beta-haemolytic streptococci groups A, C and G.[38] Histology may confirm clinical suspicion, especially for NF,[39] whereas radiology detects abscesses or confirms fasciitis,[40] eventually guiding the surgeon for appropriate debridement.[35]

CLINICAL PRESENTATIONS

Cellulitis and erysipelas are skin infections that differ from each other based on the depth of involvement in the skin layers: erysipelas involves the dermis and lymphatics, whereas cellulitis is defined as a deep dermal and subcutaneous infection.[35] Both can lead to bacteraemia in roughly 2% of cases.[3,41,42] In erysipelas, prominent lymphatic blockade results in a painful bright red patch with a raised sharp border, delineating infection from the surrounding skin. In cellulitis, less lymphatic involvement causes less-well-defined borders. Differentiation between cellulitis and erysipelas is sometimes difficult; because of this, and the lack of standardised definitions, many authors prefer classifying cellulitis and erysipelas together to form one clinical entity.[9,41,43] In cases of unsatisfactory evolution, abscesses requiring drainage should be excluded. Patients with lymphedema, chronic venous insufficiency, ipsilateral deep vein thrombosis and peripheral vascular disease are at risk of recurrence.[44] In selected patients with recurrent erysipelas, secondary prophylaxis with (benzathyl)-penicillin may be useful.[9,45]

TOXIN DISEASE

Some bacteria may cause sepsis not only through local inflammatory damage but also by the production of superantigens and toxins, aptly named staphylococcal or streptococcal 'toxic shock syndromes' (TSSs). Streptococcal TSSs is often associated with NF, whereas staphylococcal TSSs is not imperatively associated with locally spreading infection. A fine macular rash on the patient's skin, with palmar and plantar distribution, and ultimately desquamation, may be subtle clues to the presence of toxin.[46]

Figure 72.1 Necrosis on the calf due to progressive underlying necrotising fasciitis.

NECROTISING FASCIITIS AND MYOSITIS

Initially, NF presents as cellulitis/erysipelas that eventually fails to improve on antibiotics and quickly spreads along fascial planes; it is associated with the production of destructive bacterial enzymes and toxins that cause necrosis and liquefaction of the surrounding tissue[47] (Fig. 72.1). The intensity of the pain is often disproportionate with the extent of visible erythema or injury. Fever and crepitus may be rare and are not required for diagnosis.[48] Microthrombi[39] and impaired local blood supply lead to deep gangrene. Spontaneous drainage of debris and pus does not occur, and bullae may form. Late lesions may resemble deep burns, which may become pain-free because of nerve fibre necrosis.

Involvement of genitalia is called Fournier's gangrene.[14] Immunosuppression (e.g. diabetes mellitus) is a risk factor for NF.[47] Formally, there are two types: type I infections are mixed (in immunosuppressed patients), while type II infections are *per definition* caused by *S. pyogenes* and are very rapidly progressive (in otherwise healthy patients).[11] However, this distinction is academic because, apart from the choice of a targeted antimicrobial agent, the morbidity, mortality or management approach between the two types of infection are similar.

Often, the fasciitis also involves muscle, therefore, anatomically speaking, most NF cases are musculofascitiis, or fasciomyositis. The bacterial infection of muscles by *Clostridium perfringens* or *C. septicum*, named 'gas gangrene' (due to the presence of crepitus), is rare nowadays (Fig. 72.2). Largely contaminated

Figure 72.2 Gaseous cellulitis in a standard X-ray.

anaerobic wounds (e.g. in war or septic abortions) are predisposing conditions for gas gangrene *sensu strictu*. Of note, many bacteria, such as *E. coli*, may produce gas in soft-tissue infection.

TREATMENT

Superficial SSTIs, erysipelas and cellulitis, can be treated by antibiotics alone,[12,49] whereas abscesses, fasciitis or myositis require combined surgical and medical treatment (Table 72.1).[50] Many authors groups advocate that a successfully drained superficial abscess, up to 5 cm in diameter and without accompanying erysipelas, does not need systemic or local antibiotics (unless antibiotics are used for systemic decolonisation of CA-MRSA body carriage).

SURGICAL TREATMENT

Timely surgery for source control in the management of severe SSTIs is paramount, as highlighted in guidelines,[51,52] and demonstrated in a cohort study of ICU patients with sepsis, where 45.7% of SSTI patients required source control.[53] Early consultation by a surgeon experienced in treating fasciitis, even if no immediate surgery is performed, is important. Often, experienced surgeons may delay or avoid surgery if the patient remains stable at close follow-up intervals, and if clinical diagnosis is unclear; yet this is not without risk. In a cohort study of patients with *V. vulnificus* necrotising SSTI, mortality was improved when

Table 72.1 Pathogens and presumptive antibiotic therapy in severe soft-tissue infections

DISEASE	MAIN PATHOGENS	ANTIBIOTIC CHOICE*	REMARKS†
Cellulitis/erysipelas	*Streptococcus pyogenes, Staphylococcus aureus*; rarely, various other organisms	First-generation cephalosporin, amoxicillin/clavulanate clindamycin (for severe penicillin allergy)	Clindamycin resistance in *S. pyogenes* and *S. aureus* exists. Vancomycin when high suspicion of MRSA
Necrotising fasciitis	Type I: mixed. Anaerobic species together streptococci and *Enterobacteriaceae* Type II: *S. pyogenes* or *S. aureus*	Empirically, high-dose amoxicillin/clavulanate IV, plus clindamycin IV	Surgical debridement essential. Add vancomycin if MRSA very likely Immunoglobulins in case of severe life-threatening sepsis
Gas gangrene	*Clostridium spp., C. perfringens, C. septicum*	Empirically, high-dose amoxicillin/clavulanate IV, plus clindamycin IV	Surgical debridement essential
Myositis	*S. aureus*, beta-haemolytic streptococci, rarely *C. perfringens*	Empirically, high-dose amoxicillin/clavulanate IV, plus clindamycin IV	Surgical debridement essential Add vancomycin if MRSA likely. Immunoglobulins in case of severe life-threatening sepsis

*Once causative pathogens have been identified, antibiotic choice can be modified and its spectrum narrowed.

†Be aware of local endemicity of community- or hospital-acquired MRSA. Co-trimoxazole or clindamycin are the choice in most community-acquired low-grade infections; for all other cases vancomycin is used.

IV, Intravenous; *MRSA*, methicillin-resistant *Staphylococcus aureus.*

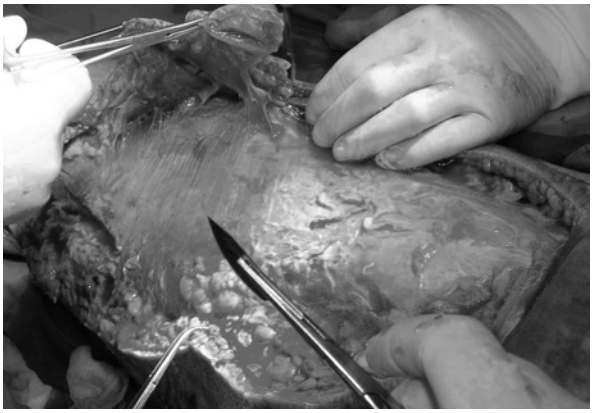

Figure 72.3 Debridement of fascia. All infected tissue is elevated off.

surgical debridement was performed within 12 hours of admission, even after controlling for the severity of infection.[54] When surgery is decided, the removal of damaged tissues is essential[55,56] without compromising viable tissue, which is ultimately needed for wound coverage. During surgery, greyish necrotic fascia, a lack of resistance of normally adherent muscular fascia to blunt finger dissection, a lack of bleeding from the fascia or dishwater pus may be observed. All involved tissue that can be easily elevated off the fascia with gentle pressure or finger spreading, is debrided (Fig. 72.3).[47] The extent of the debridement area is determined clinically and intraoperatively, and it is unnecessary to perform intraoperative histological assessment of multiple sites for this purpose. A planned second look at a 24- to 48-hour interval is recommended.[51,52] In extreme cases, amputation may be life saving. When infection is treated and necrotic tissues debrided, wound closure may become a major problem. Besides healing by secondary intention or mesh, musculocutaneous flaps or vacuum-assisted closure therapy[57] are modern approaches of reconstructive surgery.

MEDICAL TREATMENT

Besides supportive care, discussed elsewhere, the armamentarium against NF, myositis, cellulitis/erysipelas, is antimicrobial therapy. The role of intravenous immunoglobulins (IVIG) or hyperbaric oxygen therapy (HBOT) is considered as supportive at best.

Despite the variety of possible microorganisms involved, with different resistance patterns, the choice of empirical antibiotic treatment lies in the severity of the infection, the host's immune status, and whether it is nosocomial.[51] It is important to regard local epidemiology of multidrug-resistant bacteria, such as CA-MRSA, extended spectrum beta-lactamase- or carbapenemase-producing *Enterobacteriaceae*, and resistant *Pseudomonas aeruginosa*.[58]

Patients with community-acquired septic shock,[51,59] or who are immune-suppressed, often receive empirical antibiotic therapy that includes broad-spectrum antibiotics (plus vancomycin), while awaiting culture results. However, this is more due to fear of a potentially lethal evolution than to microbiological data. Indeed, most causal pathogens are susceptible to narrow-spectrum antibiotics. Apart from contraindication (e.g. allergy) or nosocomial infection, there is no need to increase coverage, and in the majority of instances, initial broad-spectrum coverage retrospectively reveals itself to be too broad, and could have been restricted to penicillins.[11,35,43] Major exceptions are CA-MRSA (which depends on local epidemiology) or fasciitis after trauma.

Evidence is lacking regarding the optimal duration of antibiotic therapy for non-bacteraemic severe SSTI. Often, the clinical course, the presence of undrained abscesses and the experience of the physician determine the duration.[60] It is unclear whether antibiotics should be administered until skin lesions disappear, or can be stopped when systemic infection improves despite the persistence of redness. A randomised study with 121 cellulitis patients suggested that 5 days of levofloxacin therapy were equivalent to 10 days.[61] A large multicentre randomised controlled trial (RCT) is ongoing (ClinicalTrials.gov NCT02032654) comparing 6–12 days of antibiotic therapy.[62]

For TSS, there is a case for using antibiotics that target protein synthesis, such as clindamycin, combined with systemic beta-lactam antibiotic therapy during the first 3–5 days.[63] The rationale lies in the inhibition of toxin production, which is mostly supported by in vitro data.[63] In vivo, to the best of our knowledge, only one observational study investigated this strategy and found a positive result – albeit with a large confidence interval (univariate analysis, non-adjusted odds ratio 4.7; 95% confidence interval [CI] 1.0–25).[64] Likewise, the duration of clindamycin administration for 3–5 days lies on expert opinion or that of the treating physician.[65]

NEWER ANTIBIOTICS

New antibiotics targeting Gram-positive bacteria with MRSA coverage have been developed and approved by regulatory agencies in recent years.[66,67] Some are long-acting, and allow out-patient treatment.[68] Three new US Food and Drug Administration-approved lipoglycopeptides completed phase III trials showing non-inferiority to vancomycin for the treatment of SSTI: oritavancin, dalbavancin and telavancin.[67,69] The European Medicines Agency also approved oritavancin and dalbavancin. In the family of oxazolidinones, there is linezolid and tedizolid. These lipoglycopeptides and oxazolidinone molecules include MRSA coverage, but are strictly limited to Gram-positive pathogens.

Ceftaroline and ceftobiprole conserve anti-Gram-negative activity, but are also active against MRSA.[67] A new fluoroquinolone, delafloxacine, which also has anti-Gram-negative and anti-MRSA activity, has completed phase III trials showing that it is non-inferior to vancomycin and aztreonam for the treatment of SSTI.[70]

Lastly, a phase IIa trial of an innovative drug targeting a T-lymphocyte receptor, CD28, whose aim is the reduction of the inflammatory response to superantigen toxins, suggested that it could be a useful agent, while demonstrating that it was safe for ICU patients.[71]

IVIG are regularly debated as supportive therapy, and the rationale behind their use is the activation of complement, the promotion of antibody-dependent cytotoxicity, the reduction of interleukin-6 and TNF-alpha production[64] and the inhibition of superantigens.[72] Several in vitro and in vivo articles published in one scientific journal[49,63,64,72–74] by the same group of researchers. They published the best available evidence in a multicentre, European, randomised, double-blind, placebo-controlled trial among patients with TSS, which was prematurely terminated. For the primary endpoint, there was a non-significant trend to decreased 28-day mortality in the IVIG group compared to placebo (2/10 vs. 4/11).[73] Adjustment for case-mix could not be performed due to the small study population of only 21 patients. The authors concluded that IVIG are very probably beneficial. Two more recent observational studies, with small sample sizes, showed that adjunctive IVIG, in addition to clindamycin, are associated with decreased mortality, although the association was statistically significant in only one of these studies.[75,76] This uncertainty leads to differing positions by professional societies: the Infectious Diseases Society of America (IDSA) states that the paucity of studies precludes the formulation of a recommendation,[51] whereas the World Society of Emergency Surgery (WSES) states that IVIG may be considered in all patients with necrotising soft tissue infection (weak recommendation, low to very-low quality of evidence).[52]

HBOT is costly, labour-intensive and not risk-free, but it can nonetheless be safely delivered to critically ill patients.[77] There is conflicting evidence on the effect of HBOT on mortality in necrotising SSTI, with some studies suggesting no effect, and others describing decreased mortality.[18,78] HBOT is not recommended by the IDSA guidelines, as 'it has not been proven as a benefit to the patient and may delay resuscitation and surgical debridement' (strong recommendation, low level of evidence).[51] However, the WSES guidelines suggest that it may be considered when available.[52] Importantly, HBOT should never delay surgery.[47] Another role of HBOT may lie in enhanced cicatrisation of ischaemic and/or infected scars, which is another question that requires confirmation in prospective trials.

FUTURE ASPECTS

The future will hopefully show robust prospective RCTs on the optimal management of severe SSTIs. Due to the heterogeneous case-mix of these infections, multidisciplinary and multicentre trials are needed regarding all aspects of care, from the post-debridement surgical approach to the role and dosing of clindamycin and immunoglobulins in the early management of these infections. Future developments also should include additive strategies to inhibit toxins and determine the minimal duration of antibiotic administration. Finally, the benefit of vaccines against *S. pyogenes* or invasive *S. aureus* must be further elucidated.[13,79,80]

Fungal infection

Alaistair Craig Carr

The incidence of fungal sepsis has increased steadily over the last 30 years. The use of broad-spectrum antibiotics and the treatment of increasingly debilitated patients are likely contributors to this trend. *Candida* species were the fourth commonest isolates from blood cultures in a recent US study[1] and the sixth commonest in a European one.[2] Global incidences of candidaemia in blood culture samples have been recorded between 0.2 and 34/1000 intensive care unit (ICU) patients in different locations. Primary and opportunistic fungal infections are associated with high mortality when systemic infection occurs.

Late diagnosis and treatment worsens outcomes. Unfortunately, the diagnosis of invasive fungal infections (IFI) may be extremely challenging; cultures may take weeks to isolate certain fungi, serological testing often proves insensitive or nonspecific and radiological changes become evident late in the disease process. While newer rapid, sensitive, specific diagnostic analyses, such as polymerase chain reaction (PCR) and matrix-assisted laser desorption/ionisation - time of flight (MALDI-TOF) spectrometry exist to amplify and identify specific fungal DNA, they are not widely available. An understanding of fungal infections, their clinical characteristics and predisposing factors remains critical to early diagnosis, appropriate management and improvement in outcomes.

Classical markers for infection are less reliable in fungal than bacterial infections. Meta-analysis suggests an elevated but low procalcitonin (PCT) (>0.5 but <2 ng/mL) in the presence of clinical sepsis may have diagnostic merit in indicating IFI.[3,4] The value of C-reactive protein (CRP) is less clear with a spectrum of values (including normal) being reported in instances of proven IFI.

Almost all IFI (Fig. 73.1) can cause cutaneous lesions and these readily lend themselves to biopsy if recognised.

BACKGROUND MYCOLOGY

Fungi are complex eukaryotic organisms. Whilst a few exist in unicellular states (yeasts), most exist in multicellular states (mould) and expand through multicellular hyphal growth. Rarer, dimorphic species exist in either unicellular yeast or multicellular mould states. Controversy exists around precise classifications with certain fungi considered yeasts by some and moulds by others; *Candida albicans* exists in yeast, pseudo-hyphal and true hyphal forms.

A network of interdigitating hyphae is termed a mycelium. The multicellular mould with its mycelium is described as a 'colony' but is a single microorganism rather than a collection of discrete microorganisms.

Moulds reproduce through the production of mononuclear or multinuclear, unicellular or multicellular spores along their hyphae. The spores break off and form new colonies distinct from their point of origin. Hyphae secrete lytic enzymes that digest complex organic structures into simpler nutrients, and mycotoxins that inhibit the growth of competitor microorganisms.

Certain mycotoxins may benefit humans; penicillin antibiotic production. Others are harmful: carcinogenic, neurotoxic and hepatotoxic aflatoxins produced by aspergillus in improperly stored foodstuffs; neurotoxic ergot alkaloids from *Claviceps purpurea* in ergotism. Even devoid of toxins or angioinvasion, moulds may lead to harmful inflammatory, allergic and progressive respiratory diseases.

The Centers for Disease Prevention and Control estimates 1.5 million fungal species exist, with around 600 recognised as human pathogens. This chapter will largely restrict itself to the diagnosis and management of respiratory and systemic IFIs.

INVASIVE FUNGAL INFECTIONS

There are two main categories of IFI:

(i) **Primary Mycoses** occur in immunocompetent patients. These are endemic in geographical locations where the spores are abundant. The infecting agent has innate virulence that overcomes normal host defences.

(ii) **Secondary or Opportunistic Mycoses** have less innate virulence than primary mycoses but occur in patients with increased susceptibility or impaired immunity. General debility, cancer, malnutrition, immunosuppressive drugs, burns, HIV, broad-spectrum antibiotics and diabetes all increase susceptibility.

ABSTRACT

Invasive fungal infections (IFI) present an increasing challenge in intensive care medicine as we care for increasingly debilitated and immunocompromised patients. The use of broad-spectrum antibiotics in sepsis and prophylactic antifungal agents in certain 'at-risk' patient populations is associated with both a rising incidence of IFI generally and previously rare multiresistant fungal infections specifically. Mortality from IFI remains very high and a significant obstacle to early initiation of appropriate management and subsequent improved outcomes is the lack of widely available sensitive, specific and rapid diagnostic testing. Without a high index of suspicion and understanding of the limitations of the standard diagnostic testing and antifungal therapies available, this is unlikely to improve.

This chapter outlines the five main primary mycoses and six secondary mycoses associated with IFI, together with current diagnostic techniques and treatment recommendations for each group.

KEYWORDS

Invasive fungal infection
primary mycoses
secondary mycoses
β-D-glucan

TREATMENT OPTIONS

Treatment of most IFI is largely limited to four classes of agent:

(i) Polyenes, effectively amphotericin B presentations, bind to ergosterol in the fungal wall causing damage and cell death.

(ii) Azoles (imidazoles and triazoles) inhibit ergosterol synthesis in the fungal wall. They are usually fungistatic but can exhibit organism-dependent fungicidal activity too (e.g. voriconazole in aspergillus).

(iii) Echinocandins inhibit β-glucan synthesis leading to cell wall instability. These are fungicidal for many yeasts and fungistatic for aspergillus.

(iv) Flucytosine is converted to 5-fluorouracil within yeasts and incorporated into RNA there. Efficacy is much better in yeasts than moulds.

Certain IFIs have alternative or additional therapeutic options. Folic acid inhibition is employed in managing pneumocystosis. Adjuvant interferon-γ is being investigated for invasive candidiasis and aspergillosis management.[5] Adoptive T-cell therapy is being assessed for prevention of invasive aspergillosis in stem-cell transplant recipients.[6,7]

The site of infection is important when selecting appropriate antifungal therapy. For example, caspofungin has minimal renal excretion and poor efficacy in treating renal tract infection, whereas amphotericin and fluconazole enjoy good efficacy.

Surgical excision of primary and secondary lesions is often required for disease control or eradication.

PRIMARY MYCOSES

There are five main primary mycoses. Four (not cryptococcus) are dimorphic pathogens.

(i) Blastomycosis (Gilchrist disease) is caused by blastomycoses dermatitidis found largely in soil in North America.[8] While not transmitted directly from dogs to humans, dogs are susceptible and often exhibit symptoms ahead of their owners during outbreaks.

Primary infection is usually pulmonary. However, wound inoculation is also described. Initial infection may be asymptomatic or cause myalgia, malaise, fever and arthralgia. Later, cough, pleurisy, haemoptysis and acute respiratory distress syndrome (ARDS) may develop. Granulomas form at the initial site then spread haematogenously in 50% of patients. Skin, bone, prostatic, epididymal and testicular infections are common. Central nervous system (CNS) infection occurs in around 10% of disseminated cases.

Untreated, disseminated blastomycosis mortality exceeds 80%. Early recognition is difficult as symptoms are non-specific. Even in established disease, symptoms of night sweats, weight loss, cough and respiratory failure may be mistaken for malignancy or tuberculosis. Similarly, skin and oropharyngeal lesions (see Fig. 73.1) can be mistaken for carcinomas. The detection of fungi in skin lesions or sputum requires specific staining; the thick capsule evades routine stains. Culture is more reliable than microscopy but commonly takes 4–6 weeks to yield positive results.

Treatment with amphotericin is preferred in severe disease and immunocompromised patients. Courses of 12 months may be required for cure. Itraconzaole has proven efficacy in moderate disease and as step-down therapy from amphotericin. Case reports suggest reasonable efficacy for voriconazole and posaconazole but not fluconazole. Echinocandins have poor efficacy in-vitro and are not recommended.

(ii) Coccidiodomycosis is caused by *Coccidioides immitis* and *Coccidioides posadasii*, endemic in regions of North America. Infection results from inhalation of spores or, less frequently, wound inoculation. Sixty-five per cent of primary infections are asymptomatic; the rest develop fever, headache and symptoms of respiratory tract infection. Immunological sequelae distant from the primary site may present as erythema multiforme or nodosum and arthralgia (originally called Jaoquin Valley Fever). Chest X-ray (CXR) may show patchy infiltration, lobar pneumonia or effusions. ARDS can occur. Around 5% of patients develop chronic pulmonary infection with cavitation.

One per cent of patients develop disseminated coccidiodomycosis with granulomatous lesions of skin, bone, joints and meninges being commonest. Disseminated disease has high associated mortality and is often diagnosed late in non-endemic areas where suspicion is low. Travel to North America and occupational, agricultural exposure should be sought in the history.

Amphotericin B is recommended to treat disseminated disease. Localised disease can be managed with triazoles or imidazoles but not echinocandins.

(iii) Cryptococcosis as a primary infection is usually associated with the encapsulated yeast *Cryptococcus gattii* rather than *Cryptococcus neoformans*. Both are covered later under opportunistic infections.

(iv) Histoplasmosis is caused by *Histoplasma capsulatum* found throughout Africa, Indonesia, Australasia, the North American mid-west and Central and South America.[9] Some adult populations evidence almost ubiquitous prior exposure on serological testing. Spores from soil and bird droppings are inhaled and invade pulmonary macrophages, divide and result in granuloma formation.

Pulmonary disease may remain contained running a self-limiting course or disseminate, particularly in the immunocompromised, via the bloodstream and reticuloendothelial systems causing lymphadenopathies often with hepatic, splenic, gastrointestinal and even CNS involvement; 90% of cases are asymptomatic not requiring treatment. Symptomatic patients experience non-specific malaise, headaches, fever, myalgia and occasionally arthralgia. Immune-related erythema nodosum or multiforme may be seen during initial pulmonary infections whilst infected papules and mucosal ulceration (see Fig. 73.1) develop only in disseminated disease. Dyspnoea, chest pain and haemoptysis may occur. Chronic pulmonary infection is not uncommon in those with pre-existing respiratory disease.

Amphotericin B is the agent of first-choice, azoles can be used in less severe disease. Untreated, mortality is around 50%.

(v) Paracoccidiodomycosis (South American Blastomycosis) is caused by *Paracoccidioides brasiliensis* and *lutzii*. It is largely confined to South and Central America and southern Mexico.[10] Invasion occurs via the lungs where it may cause (usually lobar) pneumonia, pleurisy or remain asymptomatic before spreading to involve skin, mucous membranes, lymphatics, bone and meninges.

Acute and subacute forms are both associated with lymphadenopathy, fever, malaise and anorexia. These are normally self-limiting and resolve over time. Respiratory symptoms, skin and mucous membrane lesions are rare in acute cases but are common in chronic disease.

Mortality is high without treatment; 50% of chronic disease progresses to pulmonary fibrosis and 5% develop pulmonary hypertension and cor pulmonale.

Where affordable, itraconazole is the treatment of choice for moderate disease and amphotericin B for severe and refractory cases.[11] Sulphonamides were once the mainstay of therapy being inexpensive compared to azoles and amphotericin B in endemic areas. Maintenance azole therapy lasting several years is required to achieve eradication, and relapse is common. Echinocandins are not recommended.

OPPORTUNISTIC MYCOSES

There are six main classes of opportunistic mycoses. Generic predispositions include: central venous cannulation, recent cavity surgery, neutropenia greater than 10 days, steroids greater than 7 days, immunosuppressive therapies or diseases (e.g. HIV, disseminated malignancy), ICU stay greater than 7 days, total parenteral nutrition (TPN), malnutrition, organ transplantation and burns.

Antifungal prophylactic therapy has become a norm in certain high-risk patient groups (e.g. haematopoietic stem-cell transplant patients). This has shifted the characteristic fungal infections seen with increases in previously rare, highly resistant IFI by *Candida parapsilosis*, zygomycoses[12] and fusarium.[13]

Rarely, opportunistic mycoses develop in immunocompetent patients; IFI should not be excluded solely because of lack of obvious predisposition. Diagnosing IFI with certainty is difficult, requiring isolation of fungal material from a normally sterile site. While positive identification on culture or microscopy may be diagnostic, negative microscopy and cultures cannot exclude fungal infection. Up to 50% of blood cultures are negative in patients with proven, disseminated IFI and/or deep-seated infection. More usually, diagnostic probability is achieved through the amalgamation of recognised risk factors, clinical picture, serological, microbiological, radiological and DNA-amplification

techniques. Sequential rather than isolated data points are more informative in both diagnostic and treatment response assessments.

ASPERGILLOSIS

Aspergillosis is caused by the ubiquitous Aspergillus genus of moulds. In humans, *A. fumigatus*, *flavus* and *niger* are frequent invasive species. In addition, *A. clavatus* is a significant cause of allergic respiratory disease.

While aspergillus infection is usually evidenced in immunosuppressed patients (chemotherapy, HIV, steroids, transplant recipients), it also occurs in apparently immunocompetent patients with intercurrent illnesses, such as pancreatitis, liver disease and diabetes. Additionally, patients with chronic lung disease, especially when on regular low-dose steroids and otherwise well patients exposed to high spore loads are at increased risk of aspergillosis.

The usual route of entry is inhalation of spores into the lungs or sinuses. The signs of disease are non-specific: dyspnoea, cough, fever, haemoptysis, malaise and discomfort in the chest. Pneumothorax is a well-recognised but rare complication. Resting hypoxaemia is common at presentation.

Pulmonary aspergillosis describes a spectrum of disorders from localised simple aspergilloma (this may still result in haemorrhage or bronchopleural fistula by tissue erosion) through allergic bronchopulmonary aspergillosis in asthmatic and cystic fibrosis patients, to progressive multisite pulmonary disease with extensive, cavitating, tissue destruction. Invasive disease can lead to systemic infection with lesions in the brain and solid organs.

Even when identified and treated with amphotericin, overall mortality of 50%–66% is cited from invasive aspergillosis with maxima around 88% in disseminated disease to minima of 24% in localised sinus or pulmonary disease managed by surgical resection and amphotericin.[14] Haemopoietic stem-cell transplant recipients (especially from matched unrelated donors) have poorer outcomes regardless of the infective magnitude, although mortality has fallen from greater than 95% in the 1990s to between 80% and 90% since 2002.[15]

DIAGNOSIS

(a) Greatest certainty requires positive cultures or microscopic identification from pathology samples.

(b) Focal lesions may be found on chest, liver or brain computed tomography (CT) or magnetic resonance imaging (MRI) scans with or without the characteristic halo sign (Fig. 73.2). Changes may be subtle and easily overlooked even in established disease.

(c) Positive PCR of body or bronchoalveolar lavage (BAL) fluids is a useful diagnostic test facilitating faster diagnosis than culture and microscopy with sensitivities and specificities up to 90% being reported.

(d) Galactomannan identification in BAL-fluid, urine, serum or cerebrospinal fluid (CSF) is relatively specific for aspergillus although cross-reactivity can occur with Penicillium species. Beta-lactam antibiotics and dietary ingestion of galactomannan (dairy and cereal products) can also cause false positives. Sensitivities of 80% have been achieved in patients not receiving prophylactic therapy. Prophylactic therapy may reduce fungal load, and sensitivity is reported to fall to around 20%

(e) β-D-Glucan detection in BAL-fluid or serum is useful but shows cross-reactivity with other fungal pathogens (e.g. candida) and false positives with beta-lactam antibiotics, albumin and immunoglobulin administration and during renal replacement therapies using cellulose membranes.

(f) The combination of positive galactomannan and β-D-glucan tests may improve specificity reducing the likelihood of a false-positive result.[16]

TREATMENT

First-line therapy of invasive aspergillosis is usually with systemic voriconazole.[17] Liposomal amphotericin B and isavuconazole are alternatives.[18] Echinocandins should not be used as first-line agents. Combination therapies with echinocandins and azoles or amphotericin have been described; some small studies suggest superiority to single-agent regimens.[19] The outcomes of larger studies are awaited and routine combination therapy remains unusual.

Treatment duration is determined by clinical and radiological response rather than serological marker determination. Conversion to oral therapy with voriconazole or itraconazole may be considered once significant improvement is secured.

Resection of pulmonary lesions, pulmonary-vascular therapeutic embolisation for pulmonary haemorrhage, granulocyte transfusions,[20] and the use of interferon-gamma[21]/antifungal agent combination therapy (in refractory disease) are described in the medical literature.

CANDIDIASIS

Candidiasis remains the commonest IFI diagnosed globally, accounting for greater than 60% of ICU IFIs. Mortality exceeding 50% is commonly reported. Late diagnosis and suboptimal treatment lead to poorer outcomes.

Candida albicans' predominance has gradually been overtaken by *tropicalis*, *glabrata*, *parapsilosis* and *krusei* in some locations, particularly following prophylactic therapy with fluconazole. Where broader spectrum prophylactic agents (voriconazole and posaconazole) are used, the overall incidence of opportunistic candidiasis is falling but infections with resistant fungi (e.g. zygomycoses and fusarium) are rising.

Early symptoms of invasive candidiasis are non-specific; fever, chills, malaise and dyspnoea. Sites of

secondary infection may offer more localised signs and symptoms (e.g. joint pain, visual impairment with loss of red reflex on ophthalmoscopy and neurological disturbances).

DIAGNOSIS

(a) Greatest certainty requires positive cultures or microscopic identification in samples from normally sterile sites.

(b) Focal lesions may be found on chest, liver or brain CT or MRI scans (see Fig. 73.2) but frequently lag behind serological testing for fungal DNA or cell wall components. During neutropenia, radiological appearances of abscess can almost entirely disappear from CT with reappearance when counts recover, misleading the unwary.[22]

(c) Positive PCR in is increasingly showing promise with test sensitivities and specificities of greater than 90% being achieved.

(d) Mannan Ag/Antimannan antibodies, when measured concurrently, may offer sensitivity and specificity of testing of above 80%.[23]

Data extracted from multiple sources. Recommended reading as overview: Matthaiou DK, Christodoulopoulou T, Dimopoulos G. How to treat fungal infections in ICU patients. *BMC Infect Dis.* 2015;15:205.

(e) β-D-Glucan detection in BAL fluid or serum with the same caveats as outlined for use in aspergillus diagnosis.

(f) Scoring systems (Table 73.1), such as Paphitou's, Ostrosky-Zeichner's and Nebraska Clinic's, all offer high (>95%) negative predictive values but low positive predictive values (<50%). They better advise who should probably not receive antifungal therapy than who should.

(g) Limited-availability PCR, nanoparticle hybridisation techniques are being developed and reportedly show excellent sensitivity and specificity.

(h) ELISA for serum enolase, an enzyme secreted by many candida species, and immunoglobulin G (IgG) to enolase are being investigated but are not yet widely available.

(i) Early clinical investigations suggest detection of D-arabinitol, a metabolite of most candida species, in serum or BAL fluid, appears to predict invasive candida infection significantly ahead of culture positivity, and normalisation appears to correlate with successful therapy. The utility of this assay remains under investigation.

TREATMENT

Pharmacological treatment of candidiasis is dependent upon the species and local sensitivity pattern. A typical sensitivity chart is offered (Table 73.2) but local knowledge and antibiograms should guide therapy. When CNS involvement or endophthalmitis is present, combination therapy with flucytosine, which enjoys excellent CNS penetration, has evidence of improved efficacy. Some experts also recommend combining the primary agent with flucytosine when candida endocarditis is being managed.[24] Regular therapeutic drug monitoring is required and peak flucytosine levels should be maintained below 100 mg/L to avoid toxicity (target 2-h post-dose peak = 70-80 mg/L).

CRYPTOCOCCOSIS

Cryptococcosis – *C. neoformans*, an encapsulated yeast found in soil and bird excrement, enters the body via inhalation. Initial infection may cause non-specific inflammatory symptoms of fever, cough and dyspnea or may be asymptomatic. In immunocompromised hosts – especially those with HIV, solid organ transplants or concomitant cytomegalovirus (CMV) infection – it then spreads haematogenously, causing disseminated disease with particular affinity for the CNS. CNS infection classically results in meningoencephalitis with hydrocephalus, seizures, a reduced Glasgow Coma Scale and neurological deficits. Permanent cranial nerve palsies, visual and hearing impairment are common.

Cryptococcus can exert immunomodulatory effects including inhibition of phagocytosis and stimulation of peripheral blood monocyte interleukin-10 secretion with consequent pro-inflammatory cytokine production suppression.[25] Following the eradication of Cryptococcus from the CNS, paradoxical inflammation may occur[26] as the immunosuppressive, anti-inflammatory effects of the pathogen diminish; Cryptococcus-immune reconstitution syndrome (c-IRS). A similar syndrome occurs when highly active anti-retroviral therapy (HAART) is commenced too soon after antifungal therapy in Cryptococcus presenting as AIDS, and immunity is restored before fungal load in the CNS reduces sufficiently.[27] In addition, autoimmune damage may occur during active infection.[28]

C. gattii is also an encapsulated yeast found in soil, trees and animal faeces. Previously largely confined to northern Australia and Papua New Guinea, more

recently it emerged in America and India. Unlike *C. neoformans*, *C. gattii*, readily causes infections in immunocompetent hosts and can multiply within white blood cells. CNS infection remains common but is more rapidly progressive with high fatality rates in previously healthy individuals.

DIAGNOSIS

A high index of suspicion is required to facilitate early diagnosis and treatment. Diagnosis typically occurs around 2 weeks sooner from the onset of symptoms in HIV or post-transplantation patients than in other groups owing to the well-recognised association. This has been suggested as the cause of the better outcomes for cryptococcosis in HIV patients compared with other groups.

Diagnostic steps include:

(a) Positive serum cryptococcal antigen.
(b) MRI scanning may demonstrate dilated perivascular spaces and basal ganglia pseudocysts. Cryptococcomas demonstrate high signal in T2/flair (see Fig. 73.2) and low signal in T1 (without Gd). CT brain scans are not recommended to exclude diagnosis: 40% are normal, 40% reveal non-specific abnormalities and 10%–20% offer suggestive features such as abnormal masses and hydrocephalus.
(c) Tissue biopsy and microscopy with India Ink, Alcian Blue or Fontana-Masson staining.
(d) CSF sampling, microscopy, biochemistry, cytology and testing for cryptococcal antigen.
(e) CSF cultures for at least 5 days on Saboraud Agar if CSF analysis reveals increased leucocytes or low glucose.

TREATMENT

In severe cryptococcal or CSF antigen-positive infection, prolonged, high-dose, intravenous (IV), antifungal therapy is indicated.

(a) Efficacy is best proven for liposomal amphotericin B in combination with IV flucytosine therapy.
(b) Fluconazole 400 mg/day may be required for 1–2 years in those with residual irresectible

cryptococcomas. Posaconazole crosses the blood–brain barrier well and has been shown to be efficacious against cryptococcal CNS infection in small case series – doses of 800 mg/day in divided doses are recommended. Randomised controlled trials comparing posaconazole, voriconazole and fluconazole are required. Itraconazole does not cross the blood–brain barrier and should be avoided.

(c) Management of raised intracranial pressure (ICP) using shunts or drains is required if obstructive hydrocephalus develops.

(d) Dexamethasone may offer benefits to some patients with persistent neurological abnormalities despite normal ICP and culture-negative CSF following successful antifungal therapy for *C. gattii*[29] and in treatment of confirmed immune reconstitution syndrome (IRS) following anti-retroviral therapy (ART) in AIDS; however, routine co-prescription with anti-cryptococcal therapy worsens outcomes.[30]

(e) c-IRS may benefit from corticosteroids, thalidomide or other immunomodulators.[31]

In disseminated disease without CNS involvement, fluconazole, itraconazole or posaconazole may be used. Treatment should continue from 6 to 24 months depending upon the immunocompetence of the patient.

PENICILLINOSIS

Most commonly found in patients with HIV and CD4 counts less than 100/μL, who have lived or travelled in China and Southeast Asia, penicillinosis is caused by inhalation of spores of the dimorphic fungus *Penicillium marneffei*. Presentation usually occurs at the stage of disseminated rather than pulmonary infection with fever, weight loss, dyspnea, cough, anaemia, lymphadenopathy and hepatomegaly. Papular and follicular skin lesions (see Fig. 73.1), sometimes with central necrosis, and oropharyngeal lesions are common.

Diagnosis is by microscopy and culture of biopsied lesions. A PCR assay is under development. With prompt treatment, mortality falls to around 20%. Amphotericin B enjoys the greatest success in case series to date. Two weeks of IV amphotericin followed by 6 weeks of IV itraconazole and then on-going maintenance prophylactic oral itraconazole is recommended.

PNEUMOCYSTOSIS

Pneumocystis jirovecii pneumonia (PJP) was once considered a protozoan rather than fungal infection. Modern gene sequencing techniques resulted in its reclassification. Nonetheless, it differs from most fungi by the substitution of cholesterol for ergosterol in the cell wall; the rarity of extrapulmonary invasion or infection is often attributed to this. This substitution renders the standard antifungal polyenes (amphotericin B), and azoles impotent. In animal models, echinocandins reduce the number of cystic forms[32] (the third of three stages in *Pneumocystis jirovecii* [PJ] life cycle) seen, but not the number of trophic forms (the first stage) that constitute >90% of all PJ fungal forms in infected lungs. Only the cyst walls express B-glucans, the target of echinocandin activity. Whilst disease progression slowed or even halted, cessation of echinocandins was associated with immediate relapse.

Evidence derived from measurement of IgE and IgG informs that asymptomatic childhood infections with PJP are common. For PJP to cause symptomatic pathology normally requires impaired host immunity, especially that associated with CD4 cell counts less than 200/mm3 in HIV. Non–HIV-related PJP infections are usually associated with immunosuppression secondary to haematological malignancy or immunosuppressive therapies used in transplant, cancer or rheumatological disease management. Previous or current CMV infection also predisposes to PJP infection through its effect on reducing helper T-cell function. PJP infections are often more severe and are diagnosed later in the non-HIV patient population – this is likely related to the widespread use of prophylactic therapy and a higher awareness of PJP amongst HIV+ patients.

Symptoms of PJP are often non-specific early in the disease course. They include malaise, dyspnoea and a non-productive cough. As the disease progresses, pyrexia, weight-loss, worsening cough, dyspnoea and exertion induced hypoxia are also characteristic. Pneumothorax arises in a minority of patients. Although CXR appearances are classically of widespread infiltration arising from the hila, occasionally more localised, infiltrative patterns and cavitating lesions are seen. CXR may appear normal in early disease, whereas high resolution computed tomography (HRCT) normally demonstrates ground-glass opacification.

DIAGNOSIS

Clinically suspected PJP on the basis of history, characteristic radiological findings and a known predisposition should be taken as sufficient grounds to initiate treatment. Up to 40% of patients have a normal CXR at presentation. Delays in treatment initiation, even by one day, are associated with significant increases in mortality. As soon as practicable thereafter, confirmation or exclusion of the diagnosis should be undertaken by:

(a) demonstration of PJP using immunofluorescence or silver staining of induced sputum or BAL samples

(b) demonstration of PJP DNA on PCR of BAL and/or peripheral serum samples.

TREATMENT

Co-trimoxazole, inhibits folic acid synthesis in *P. jirovecii* via two separate pathways. It is the agent of first choice. Administered intravenously in high dose (120 mg/kg per day in divided doses) for 21 days, drug intolerance results in around 50% of patients

requiring a change of agent. Co-administration of IV steroids has been shown to reduce mortality in HIV patients. Their use is recommended in severe disease where the A-a gradient is less than 35 mm Hg (4.6 kPa) and may reduce the inflammatory response and worsening respiratory failure associated with treatment-induced fungal lysis. Different studies have used different dose regimens with most in the range 1–2 mg/kg methylprednisolone for the first 10 days of antifungal therapy.[33] Some regimens recommend reduced dosing for subsequent days whilst receiving IV cotrimoxazole.

Alternative therapeutic regimens for those intolerant of cotrimoxazole include:

(a) pentamidine IV 4 mg/kg o.d. (1× daily), or
(b) clindamycin 450 mg q.i.d. (4× daily) and primaquine 30 mg o.d., or
(c) dapsone 100 mg o.d. and trimethoprim 5 mg/kg q.i.d., and
(d) atavaquone 750 mg b.d. (2× daily)

In addition, combination therapy with clindamycin and caspofungin has been described as providing successful treatment of severe PJP in isolated case reports.[34]

ZYGOMYCOSES

Zygomycoses[35] consists of two orders of fungi; Mucorales and Entomophthorales. Sometimes the term is used interchangeably with muromycosis as the majority of infection seen is secondary to Mucorales, a ubiquitous, angioinvasive mould that causes tissue necrosis and characteristic cutaneous, sinus, cerebral, pulmonary, gastrointestinal and disseminated infections. The main species causing human infection are *M. Rhizopus*, *M. Lichtheimia* and *M. Mucor*. Fungal spores may be inhaled, ingested or cause direct infection via damaged membranes.

Disseminated disease is usually fatal in immunocompromised hosts. Muromycosis is the third commonest invasive fungal disease (IFD) in patients receiving haematopoietic stem-cell transplants, causing 1%–2% of IFI in this group. The incidence is rising secondary to the widespread use of broad-spectrum, prophylactic anti-fungal agents such as voriconazole in a bid to reduce aspergillus and candida infections.[36] In addition, infections are associated with poorly controlled diabetes, haematological malignancy (especially acute myeloid leukaemia [AML]), trauma, iron overload, acidosis (especially ketoacidosis), malnutrition and steroids.

Symptoms are often non-specific initially and reflect inflammation at the site of initial inoculation (e.g. sinusitis). After a period of malaise, fever (only in 50% of patients) and symptoms of site-specific local inflammation, evidence of invasion may become more apparent with progression of a cough and dyspnea to haemoptysis or a sinusitis to cellulitis of the skin over the paranasal sinuses. Unmanaged, further invasion will lead to massive pulmonary haemorrhage, bronchial occlusion and mediastinitis in the pulmonary cases and orbital, ocular and cerebral invasion, cranial nerve palsies, and skin necrosis in sinus ones. Where skin invasion occurs, a black eschar is often seen.

DIAGNOSIS

Early diagnosis and treatment of muromycosis before angioinvasion and dissemination is essential to improve survival. Diagnostic steps include:

(a) a high degree of suspicion based on clinical risk profile
(b) early recognition of characteristic skin lesions
(c) CT findings (e.g. nodules, halo signs, reverse halo signs and wedge infiltrates on lung CT), and MRI findings with low intensity on T1 and high intensity on T2 with leptomeningeal disease
(e) microscopy of samples from sinus drainage, abscess drainage, BAL or tissue biopsy using wet mount slides with calcofluor staining and periodic acid-Schiff (PAS) or Grocott's methenamine silver (GMS) dry-mount staining
(f) culture – usually positive in 3–5 days unless receiving appropriate antifungal therapy at the time of sample collection
(g) PCR and molecular diagnostic techniques are currently in evolution but are not yet widely commercially available.

TREATMENT

Amphotericin B (preferably as a lipid formulation) is the mainstay of treatment with proven efficacy in vitro and in vivo. A dose of 5 mg/kg lipid formulation per day has been suggested. Retrospective human studies and prospective animal studies suggest improved survival utilising combination therapy of a lipid formulated polyene and an echinocandin.[37] Azoles are not recommended in the treatment of human mucormycosis, although very high-dose posaconazole has seen some success in animals.

Entomophthorales infection is usually restricted to skin and subcutaneous infections in tropical areas and largely occurs as a primary rather than opportunistic infection. It is not normally angioinvasive and disseminated disease is largely confined to immunocompromised individuals.

OTHERS

A large and growing variety of opportunistic fungal infections is increasingly recognised and it is beyond the scope of this chapter to cover all of those that may be encountered. In addition to the commonest infections outlined above, the possibilities of rarer infections with fusarosis, hyalophomycoses, phaeohyphomycoses and scedosporium merit consideration in immune-compromised patients with infection of unknown aetiology, especially haematopoietic transplant recipients.[38]

CONCLUSION AND GENERAL CONSIDERATIONS

The definitive diagnosis of IFI is one of the great challenges of modern medicine. Identification of fungi in samples from normally sterile sites allows definitive diagnosis, but certain species take up to 6 weeks to grow even in ideal media; tissue samples are rarely obtained early during a patient's ICU stay and even then, certain fungi require specific, non-routine staining to identify them. Antibody/antigen testing of fungal components and PCRs of fungal DNA are improving rapidly and certainty of diagnosis for certain species but are far from perfect across the range of pathogenic fungi.

In 2008, a revised consensus definition of IFD was published by the European Organisation for Research and Treatment of Cancer/IFI Cooperative Group and the National Institute of Allergy and Infectious Diseases Mycoses Study Group.[39] This classified secondary IFI as definite, probable or possible. The consensus definitions' utility lies in categorising patient groups during research and epidemiological studies facilitating comparisons between different studies using a common definition. They should not be used to determine a tipping point as to whether to treat a patient for 'probable' IFI or not, and are deliberately omitted here. A retrospective re-analysis of neutropenic patients treated for IFI based on the 2002 criteria demonstrated a significant shift of treated patients from 'probable' (2002) to 'possible' (2008), and an increased survival in the group now re-classified as 'possible'. As all had received treatment, the authors suggested this may indicate that treatment earlier in the course of infection, before diagnostic certainty increased, resulted in better outcomes.[40]

Until the advent and widespread availability of high sensitivity and specificity test(s) covering the spectrum of recognised fungal infections seen in the ICU, a high awareness of the possibility of primary and secondary mycoses, an understanding of the available diagnostic tests and algorithms together with knowledge of their limitations, offers the best chances of early diagnosis and the instigation of appropriate treatment. Even with appropriate treatment, the mortality of IFD in the ICU remains over 50% for many fungi. Poorer outcomes are seen when diagnosis and treatment are delayed.

Principles of antibiotic use in the ICU

Jeffrey Lipman

The intensive care unit (ICU) is always the area of any hospital associated with the greatest use of antibiotics. Much of this high usage is unavoidable, but the clinician working in the ICU must realise that there is an essential consequence of this use. Antibiotic use, which should eliminate susceptible bacteria, promotes (over) growth of other non-susceptible organisms, especially fungi. As far as bacteria are concerned, antibiotics confer enormous selective advantage to resistant strains, and therefore these strains will congregate where their advantage is greatest – in the ICU. Resistance (and fungal overgrowth) is a direct consequence of usage, and every course of inappropriate antibiotics should be avoided to help reduce the burden of resistance.

Antibiotic stewardship[1,2] has been suggested as a new strategy to help limit resistance. This involves selecting an appropriate drug and optimising its dose and duration to cure an infection while minimising toxicity and conditions for the selection of resistant bacterial strains. Inadequate doses of even the 'correct' antibiotic may lead to the survival of initially susceptible organisms.[3,4] For the optimal use of antibiotics not only should antibiotic pharmacokinetics be understood but also there should be clear and rational principles on which each specific antibiotic prescription in the ICU is based. In addition, it is probably better to have portions of the ICU population receive different classes of antibiotics at the same time.[5]

Although this chapter will provide basic principles for most of the antibiotic classes commonly used in ICUs, some important antimicrobial agents will not be specifically addressed here, namely macrolides, clindamycin and the antifungal agents.

GENERAL PRINCIPLES[6,7]

1. All appropriate microbiological specimens, including blood cultures, should be obtained before commencing antibiotic therapy. An immediate Gram-stained report may indicate the appropriate antibiotic to use, otherwise a 'best guess' choice is made depending on the clinical situation. This important and common clinical phenomenon involves trying to predict the infecting organism(s).
2. Blood cultures should be taken from a venepuncture site, after adequate skin antisepsis, and not from an intravenous or arterial catheter. Two *separate* sets of 20 mL (for adults) should be taken, the timing of which is less important.[8] Depending on what system is used, probably 10 mL should be placed into two different blood culture bottles.
3. Once a decision is made to administer antibiotics, they should be administered *without delay*, as delay to antibiotic therapy **in shock** increases morbidity and mortality.[9]
4. The decision for empirical therapy (i.e. cover for the most 'likely' organisms causing any specific infection) must include various factors such as: the site of the infecting organism (respiratory tract pathogens differ from those of abdominal infections), community- versus hospital-associated infection, recent previous antibiotic prescription, ward- versus ICU-acquired infection, travel history and knowledge of the organisms commonly grown in patients in any specific area. This latter point is where ward/unit surveillance becomes important.[10,11]
5. Although there should be an attempt to use a narrow-spectrum antibiotic whenever practicable, appropriate therapy, particularly for empirical choice for nosocomial sepsis, often requires starting off with broad-spectrum antibiotics, even a combination, until culture results are back[12,13] – at which time de-escalation should be embarked upon (see below).[7] Inappropriate[14] and/or delayed correct[9] antibiotic use in the ICU has been shown to impact on morbidity and mortality (Table 74.1).[7]
6. Monotherapy with a single agent effective against the expected organisms aims to decrease the risk of drug antagonism, reaction or toxicity.[15] Monotherapy often costs less than multiple antibiotic usage and limits co-lateral damage.
7. The clinical response to treatment already given should always be considered when bacteriological results suggest reduced susceptibility.
8. A standard 2-week course of antibiotics is unnecessary[16–18] and probably harmful (see Table 74.1). After a single day of imipenem a French study demonstrated some patients will grow imipenem-resistant bacteria in their faeces.[19] The overgrowth

ABSTRACT

Antibacterial agents kill bacteria, but allow growth of other organisms, including resistant bacteria. Critically ill patients need different doses to those in the wards. Often critically ill patients have augmented renal clearance predisposing them to underdosing and the development of resistance. It is therefore prudent to use high-dose, short courses and as narrow a spectrum as possible. Therapeutic drug monitoring not only for toxicity but also for efficacy (including for beta-lactams) can help with dosing requirements. Delay in the initiation of antibiotics in septic shock is harmful, but cultures need to be taken prior to initiation of the antibiotic. Evidence suggests double Gram-negative cover is unnecessary. Prophylactic antibiotics should be administered just prior to surgery and continued for any length of time. Infection control is just as important, if not more so, in treating infected patients.

Table 74.1 New paradigm of treatment for nosocomial sepsis

OLD	NEW
Start with penicillin	Get it right 1st time (broad spectrum)
Cost-efficient low dose	Hit hard up front
Low doses = fewer side effects	Low dose → resistance
Long courses ≥2 weeks	Seldom longer than 7 days

From Lipman J, Boots R. A new paradigm for treating infections: 'go hard and go home'. *Crit Care Resusc.* 2009;11:276–281.

of resistant organisms, a 'natural' consequence of broad-spectrum antibiotic use, is termed 'co-lateral damage'.

9. In consultation with infectious disease specialists, additional tests, such as antibiotic minimum inhibitory concentration (MIC), antibiotic assay, serum bactericidal activity and synergy tests of antibiotic combinations, may be useful in serious infections (e.g. endocarditis and infections in immunocompromised patients). Susceptibility tests should be interpreted carefully. In vitro sensitivity does not equate with clinical effectiveness; in vitro resistance is a better negative predictor.
10. Consultations with the laboratory staff, infectious diseases/clinical microbiology specialists and clinical pharmacists are always useful and should be mandatory in serious infections (e.g. meningococcal sepsis, methicillin-resistant staphylococci and multiresistant Enterobacteriaceae).
11. The pharmacokinetics and pharmacodynamics (e.g. penetration into relevant tissues) as well as the spectrum of activity of the antibiotic must be considered. Antibiotic pharmacokinetic principles should determine the dosage and frequency of antibiotic regimens (see below).[20,21]
12. Adequate drug doses should be given. Underdosing leads to overgrowth of resistant organisms.[3,4] The intravenous route is preferable in critically ill patients, but other routes should be considered when appropriate.
13. Serum levels of potentially toxic antibiotics should be monitored not only for toxicity but also for efficacy (prevention of underdosing).[22,23] Recent data suggest that many patients are underdosed in ICUs.[24]
14. Prophylactic use of antibiotics should be limited to certain situations, should cover organisms that potentially can cause infections in that specific group of patients (e.g. organisms causing skin and soft-tissue infections differ from those implicated in intra-abdominal infections) and should be given at the appropriate timing (see below).
15. General signs of infection are signs of systemic inflammation. Although bacterial infection is likely, non-bacterial infection and non-infective causes should also be considered. High procalcitonin and C-reactive protein levels may be discriminatory for infection but are often too non-specific and have significant limitations.[25,26]
16. Antibiotic guidelines are only one aspect of infection control.[27–29] Hand washing and hand hygiene in general are vital and the fundamental aspect of infection control.[27] Identification and elimination of reservoirs of infection,[28,29] blocking transmission of infection,[29] barrier nursing as well as terminal cleaning of high-touch areas are imperative controls that need to be in place in every ICU.[28,29]

COMMON ERRORS WHEN USING ANTIBIOTICS

1. Administration of antibiotics before microbiological specimens are obtained.
2. Quantity and quality of blood cultures.
3. Extended use of antibiotics after eradication of infection (e.g. a 2-week course for ventilation-associated pneumonia).[16–18] With adequate source control, even intra-abdominal sepsis can be treated with a short course of antibiotics.[18]
4. Antibiotic 'surfing' (i.e. switching from one combination to another) when the patient is not improving without delving into the cause of persistent inflammatory response.
5. Inadequate and delayed therapy and/or incorrect dosing of antibiotics, the latter is increasingly more commonly recognised.
6. Failure to recognise patients with high creatinine clearances (augmented renal clearance). These patients have high clearance of renally excreted drugs (beta-lactams, glycopeptides, aminoglycosides) and therefore are predisposed to underdosing of these drugs.[20–24,30]
7. Failure to adequately predict 'resident' microbial flora and therefore the inability to correctly choose empiric antibiotics for nosocomial infections (i.e. no adequate surveillance data).
8. Failure to recognise toxic effects of antibiotics, particularly when polypharmacy is used.
9. Use of combination therapy, irrespective of infection.

SPECIFIC ISSUES

PHARMACOKINETIC PRINCIPLES

The goal of antimicrobial prescription is to achieve effective active drug concentrations (a combination of dose and duration) at the site of infection whilst avoiding, or at least minimising, toxicity.

The various antibiotic classes have different 'kill characteristics' and therefore should be dosed differently (Table 74.2).[20,31]

Table 74.2 Pharmacodynamic properties of selected antibiotics

Antibiotics	Aminoglycosides	Fluoroquinolones Glycopeptides	β-lactams Carbapenems Glycopeptides
PD kill characteristics	Concentration dependent	Concentration dependent with time dependence	Time dependent
Optimal PK parameter	C_{max}:MIC	AUC:MIC	$T > MIC$

AUC, Area under concentration time curve; C_{max}, peak serum concentration; *MIC*, minimum inhibitory concentration; *PD*, pharmacodynamics; *PK*, pharmacokinetic; $T > MIC$, time above MIC.

From Roberts JA, Lipman J. Pharmacokinetic issues for antibiotics in the critically ill patient. *Crit Care Med*. 2009;37:840–851.

β-LACTAMS (ALL PENICILLINS AND CEPHALOSPORINS, MONOBACTAMS)[20,31]

1. Studies of β-lactam antibiotics on Gram-negative bacilli show a bactericidal activity that is relatively slow, time-dependent and maximal at relatively low concentrations. Bacterial killing is almost entirely related to the time that levels in tissue and plasma exceed a certain threshold. The maximum time that plasma β-lactam levels should be allowed to fall below MIC is 40% of the dosing interval.
2. β-lactam antibiotics lack a significant post-antibiotic effect (PAE) particularly against Gram-negative organisms, and it is not necessary to achieve very high peak plasma concentrations. PAE is the continued suppression of bacterial growth despite zero serum concentration of the antibiotic. It is suggested that concentrations of any β-lactam should be maintained at about four to five times MIC for long periods, as maximum killing of bacteria in vitro occurs at this level. If antibiotic concentrations fall below this threshold in the in vitro models, bacterial growth is immediately resumed.[3,4,20,31]
3. Thus, it is important for the efficacy of β-lactams that the dosing regimen maintains adequate plasma levels for as long as possible during the dosing interval. Although a recent double blind, randomised, controlled trial of 420 patients could not demonstrate benefit of continuous infusions,[32] it may be that in the sicker patients continuous infusions may be beneficial.[33] A 7000-patient, randomised, controlled trial is currently planned, which formally addresses the place of continuous infusions of β-lactams.[34]

CARBAPENEMS

1. Similar to β-lactams, the carbapenems also have time-dependent kill characteristics but have some PAE.
2. Prolonged infusions (over 3 hours) have been utilised to improve time above MIC.[35]
3. In vitro data suggest that low concentrations may predispose to development of resistant organisms.[4]

AMINOGLYCOSIDES[20,31]

1. The agents above contrast with the kill characteristic of the aminoglycosides, which is concentration-dependent. Experimentally, a high peak concentration of an aminoglycoside antibiotic provides a better, faster killing effect on standard bacterial inocula.
2. All aminoglycosides exhibit a significant PAE. The duration of this effect is variable, but the higher the previous peak the longer the PAE. This phenomenon allows drug concentration to fall significantly below MIC of the pathogen without allowing regrowth of bacteria.
3. These principles allow for single daily doses of aminoglycosides (also termed extended interval dosing). Combining various meta-analyses involving thousands of patients, once-daily administration was found to be more efficacious with reduced toxicity, higher peak/MIC ratios, further prolonged PAE and reduced administration costs.
4. With renal dysfunction there should be the same loading dose but then the dose should be altered according to creatinine clearance.[21] If ≥60 mL/min give 5–7 mg/kg per day; if 59–40 mL/min, give the same dose at an interval of 36 hours; 39–20 mL/min increases the dosing interval to 48 hours.[36]

QUINOLONES[20,31]

1. Ciprofloxacin, in contrast, has a combination of both of the above characteristics (i.e. concentration-dependent and time-dependent effects), as well as some PAE.
2. Although one suggested 'target' parameter for a good clinical bactericidal effect is a high peak, the most validated parameter is the area under the inhibitor curve (AUIC) – that is, AUC/MIC > 125.
3. There is general concern about the emergence of resistance related to inappropriately low doses of ciprofloxacin (see Table 74.1).

GLYCOPEPTIDES[20,37]

1. Vancomycin induces a PAE and a post-antibiotic sub-MIC effect. These combined effects suggest that bacterial regrowth will not occur for prolonged periods following a fall in drug concentrations to levels below the MIC.
2. Continuous infusions of vancomycin may have some advantages.

Aminoglycosides and glycopeptides distribute well into fluids of the extravascular, extracellular space, and less well into tissues. This has two important implications. First, these agents should not be first-line agents, or monotherapy, for solid organ infections (lung, kidney, liver, etc.). Second, in situations where extravascular fluid shifts are significant (e.g. in situations of 'third-space losses' of abdominal sepsis, in severe burns, etc.), the volume of distribution of these drugs is significantly affected. Hence for any serum level required a larger than usual dose may have to be administered.[37] The volume of distribution of the quinolones (very large) suggests penetration is excellent into most tissues and hence these drugs are good for solid organ infections. Similarly, β-lactams as a group (including carbapenems) all have reasonable tissue penetration.

ANTIBIOTIC PROPHYLAXIS[6,38]

The main indications for prophylaxis are:

- when surgery involves incision through an area of colonisation or normal commensal flora and a resultant potential infection has morbidity or mortality
- when a procedure (e.g. catheterisation, instrumentation, intubation, dental work) potentially produces a bacteraemia in the presence of an immunocompromised patient, or when the potential bacteraemia occurs in the presence of an abnormal heart valve or a prosthesis.

Basic principles of choice of prophylactic regimen should include the following:

1. The organisms colonising the area through which the incision is made should be covered (Gram positives if skin is breached, Gram negatives and anaerobes if bowel is opened).
2. A similar case should be made for colonising organisms through the area breached by catheterisation or instrumentation, etc. (Gram negatives for bladder catheterisation, Gram positives and anaerobes for dental procedures).
3. If prevalence of a resistant organism in a specific area is high (e.g. *Pseudomonas* in burns units) then those organisms should be covered by the prophylactic regimen.

TIMING AND DURATION OF PROPHYLAXIS

1. Optimal blood levels of antibiotic(s) are needed when the occurrence of the potential bacteraemia occurs (i.e. for surgery the optimal timing of the antibiotic should be at, or just prior to, induction of anaesthesia and skin incision).[38]
2. For prolonged procedures where bacteraemias are still a potential occurrence, a second dose of antibiotic(s) may be considered.
3. There is no extra benefit to postoperative antibiotic prophylaxis.

DOSES[20–25,31,37]

Comments on dosing regimens are provided below. Doses suggested below are intravenous, for a 70-kg adult with *normal* renal function. All these drugs accumulate with renal dysfunction and modified doses should be used accordingly. It should be noted that some patients with 'normal' renal function may have increased renal clearance of antibiotics and hence need a higher than usual dose.[20,21,31]

1. Doses for β-lactams vary with each different drug, *but* recent emphasis supports lower boluses with more frequent administration (i.e. 4-hourly versus 8-hourly, or b.d. versus daily).[31] Continuous infusions (or possibly prolonged infusions) may become standard practice.[33,34,35]
2. *Aminoglycosides:* give tobramycin and gentamicin at 7 mg/kg as a loading dose on the first day, followed by 5 mg/kg per day. Amikacin 25 mg/kg as the loading dose followed by 15 mg/kg per day. These doses are the same for adults and children, neonates excluded.
3. *Quinolones:* the ciprofloxacin dose is *at least* 400 mg b.d. (up to t.d.s.).
4. *Glycopeptides:* the vancomycin[37] dose is at least 30 mg/kg loading and similar/day either as continuous infusion or in divided doses (40 mg/kg per day for children).
5. *Carbapenems:* give meropenem or imipenem at 3 g/day in at least three divided doses.

SURVEILLANCE

Some type of simple laboratory-oriented surveillance, which primarily collects data and resistance patterns of microbiological isolates, is important. Each unit should have access to its own such data as there is an increasing prevalence of resistant organisms in intensive care units. This is complicated even further by different units having differing resistance patterns.[10] Empirical antibiotic therapy must take these factors into account. Some form of surveillance that provides units with their own microbiological data, updateable quarterly or biannually, is therefore beneficial in helping to choose empirical and prophylactic regimens that are applicable to any specific unit.[10]

MULTIRESISTANT ORGANISMS

Although this chapter is on antibiotics, the point must be made that without good, efficient and effective infection control policies in all areas treating critically ill patients the spread of multiresistant organisms would be rampant and their control useless.[27–29] Part of these policies should involve attention to good hand hygiene and the use of antiseptic soaps and alcohol-based hand rubs.[27] Hands are still the most documented and incriminated mode of transmission of infection. In

this regard a decrement in nursing numbers has also been incriminated in outbreaks of infections possibly due to the time it takes to adequately wash between procedures.[27] High-touch areas are important areas to address with terminal cleaning procedures.[28,29]

1. Multiresistant streptococci and vancomycin-resistant enterococci, although not common in all countries, are an increasing worldwide problem, as is community-acquired MRSA.
2. New agents are available for the treatment of resistant Gram-positive infections.[39]
3. Antibiotic resistance is agent-specific. Often resistance is claimed to be against third-generation cephalosporins, but this is largely to ceftazidime (particularly the extended-spectrum β-lactamases of *Klebsiella pneumoniae, E. coli* and some Enterobacteriaceae).
4. Worrying Gram-negative organisms are *K. pneumoniae, Pseudomonas aeruginosa, Acinetobacter baumanii* spp. and *Stenotrophomonas maltophilia* (the latter specifically, for which trimethoprim may need to be used). A common feature of these organisms is intrinsic resistance to multiple antibiotics. *P. aeruginosa* and *Acinetobacter* complex (also named *A. baumanii*) have become particular problems. Sulbactam and polymyxin B or colistin have been used for these problem organisms.
5. Although the antibiotic pipeline is drying up, there are some new agents on the horizon.[40]
6. Finally, the most worrying of all organisms from an infection control point of view is *Acinetobacter baumanii* spp. It has intrinsic abilities to rapidly, and often, swap genetic material and hence it develops resistance very quickly.[41] It is also able to survive on inanimate object for months. These features allow it not only to become highly resistant, but also to become endemic in ICUs.[42] Isolation of patients infected, or even colonised with, multiresitant *Acinetobacter* spp. is therefore important, as is terminal cleaning of the environment.

MONO VERSUS COMBINATION THERAPY[12,13,15]

1. Much of the work in this area was performed before the clinical introduction of the carbapenems, penicillin/β-lactamase combinations and fourth-generation cephalosporins. It seems that newer single agents are adequate, apart possibly from resistant pseudomonal infections.[15]
2. There is no clear evidence supporting the claim that combination antimicrobial therapy prevents the emergence of resistance.[15]
3. However, combination therapy is often suggested for endocarditis and some pseudomonal infections.[13] When combination therapy is used, preference should be given to the combination therapy of two different classes of antibiotics that act synergistically. The combination of two β-lactam antibiotics should not be used.

BROAD-SPECTRUM INITIAL COVER WITH DE-ESCALATION[7,13,14]

In view of the morbidity and mortality of delayed appropriate therapy for nosocomial sepsis,[9,14] patients with risk factors for infection with resistant pathogens should initially receive broad-spectrum antibiotics, possibly even combination therapy,[7,13,14] then, as soon as the pathogen and the susceptibilities are available, treatment should be simplified to a more targeted one – so-called 'de-escalation' therapy (see Table 74.1).[7] In the limited studies to date, de-escalation has led to less antibiotic usage, shorter durations of therapy, fewer episodes of secondary pneumonia and reduced mortality, without increasing the frequency of antibiotic resistance.

Tropical diseases

Vivekanandan M Pillai, Ramachandran Sivakumar

Once an exotic and esoteric topic, modern travel and the quest for unusual holidays has the potential to bring tropical diseases to every intensive care unit (ICU). This chapter covers some important diseases, which are common in the tropical belt.

MALARIA

EPIDEMIOLOGY AND PATHOGENESIS

It is estimated that four species of *Plasmodium* (*vivax, malariae, ovale* and *falciparum*) cause 200 million infections per year with about 300,000–600,000 deaths. Most of the deaths are caused by *Plasmodium falciparum* and the majority of deaths are in children under 5 years in Sub-Saharan Africa. Malaria is also widely prevalent in the Indian subcontinent and Southeast Asia. It is transmitted from human to human by the bite of infected female Anopheles mosquitoes. After development in the liver, there is invasion of red cells by parasites, which is followed by their multiplication and the rupture of the red cells. The cycle is then repeated in red cells. In *vivax* and *ovale* infections, development to dormant forms can occur in the liver, which may lead to relapse. A fifth species, *Plasmodium knowlesi*, is a parasite of the macaque monkeys. It has been identified across almost all Southeast Asian countries and in travellers returning from these areas.[1]

CLINICAL FEATURES

UNCOMPLICATED MALARIA

Uncomplicated malaria typically presents as an undifferentiated febrile illness and resembles a viral illness. Classic symptoms of fever, body ache, and headache are usually, but not always, present. Other features such as diarrhoea, vomiting, cough and abdominal pain, may confuse the unwary. Unusual presentations are more common in children and may be missed. Initially the fever is irregular. Later on a pattern of cyclic paroxysms of chills and rigors, fever and drenching sweats may develop. Classically, these paroxysms last for a few hours only, and repeat every 24, 48 or 72 hours depending upon the species. The spleen becomes palpable in non-immune individuals only after several days. Mild hepatomegaly may occur. Rash is not a feature. Very rarely, petechiae may occur in severe *falciparum* malaria. Lymphadenopathy is very rare. Neck stiffness and photophobia do not occur.

SEVERE MALARIA

Severe malaria is usually seen with *falciparum* infection but also occurs with *vivax* and *knowlesi* infections.

Risk factors for severe malaria

- Children under 5 years in high transmission areas
- People of any age in areas of low transmission
- Non-immune travellers to endemic areas
- Pregnancy, human immunodeficiency virus (HIV) infection, people who have undergone splenectomy[2]

Definition

Clinical features:

- impaired consciousness: Glasgow Coma Score less than 11 or Blantyre Coma Score less than 3 in children
- prostration (i.e. generalised weakness) so that the patient is unable to sit stand or walk without assistance
- failure to feed
- multiple convulsions – more than two episodes in 24 hours
- deep breathing, respiratory distress (acidotic breathing)
- shock: compensated shock is defined as capillary refill 3 or more seconds but no hypotension; decompensated shock is defined as systolic blood pressure less than 80 mm Hg in adults and less than 70 mm Hg in children, with evidence of impaired perfusion (cool peripheries or prolonged capillary refill)
- clinical jaundice plus evidence of other vital organ dysfunction
- haemoglobinuria
- abnormal spontaneous bleeding
- pulmonary oedema (radiological)

Laboratory findings:

- hypoglycaemia (blood glucose <2.2 mmol/L or <40 mg/dL)

ABSTRACT

Tropical diseases are no longer unique or limited to tropical and subtropical regions alone. Increasing globalisation and ease of travel mean that tropical diseases can present as emergencies to intensive care units (ICUs) anywhere in the world. Malaria, typhoid, leptospirosis, rickettsial infections and dengue fever and other viral haemorrhagic fevers are some of the important infections that may be seen in the ICU. Emergencies related to tuberculosis, though not strictly a tropical disease, may also pose a diagnostic challenge to the ICU physician. These diseases may present with severe sepsis, multiorgan dysfunction, renal failure, acute respiratory distress syndrome, jaundice, liver failure, meningoencephalitis or bleeding manifestations, singly or in combination. There is considerable overlap in the clinical presentation of various tropical infections. In addition, these exotic illnesses must also be differentiated from locally prevalent illnesses. Detailed travel history, including details such as exposure to animals and vectors, terrains visited, recreational activities indulged in, food habits, details of vaccinations and drug prophylaxis, are some of the important factors in narrowing down the diagnosis. Incubation period of various illnesses should be kept in mind. Findings such as rash, eschar, hepatomegaly, splenomegaly and lymphadenopathy can help in the differential diagnosis. Adequate knowledge of the available laboratory tests and their limitations is very important. Empirical therapy may be justified in the critically ill while awaiting laboratory results.

KEYWORDS

Malaria
typhoid
leptospirosis
rickettsial infections
dengue fever
viral haemorrhagic fever tuberculosis

- metabolic acidosis (plasma bicarbonate <15 mmol/L)
- severe normocytic anaemia (Hb <5 g/dL, packed cell volume [PCV] <15%)
- haemoglobinuria
- hyperparasitaemia (>10%)
- hyperlactataemia (lactate >5 mmol/L)
- renal impairment serum creatinine greater than 265 µmol/L or urea more than 20 mmol/L.

The incubation period is 7 days (usual range 9–14 days) but this may be prolonged. Several of the above co-exist or may develop in rapid succession. Cough, convulsions and hypoglycaemia are more common in children. Jaundice is common, but hepatic failure is uncommon. The acidosis of malaria is multifactorial and probably very similar to other forms of sepsis involving tissue hypoxia, liver dysfunction and impaired renal handling of bicarbonate.

The differential diagnosis of malaria includes

- Meningitis, typhoid fever, septicaemia
- Severe influenza, dengue and other arboviral infections
- Haemorrhagic fevers
- Hepatitis, leptospirosis
- Rickettsial diseases (e.g. scrub typhus)
- Relapsing fever (*Borrelia recurrentis*)
- Febrile convulsions in children.

Pregnancy increases the risk of developing severe malaria. During pregnancy both maternal and foetal morbidity and mortality are increased.

Poor prognostic indicators include age under 3 years, cerebral malaria, circulatory collapse and organ dysfunction. Laboratory evidence of poor prognosis includes hyperparasitaemia (>250,000/µL or >5%), peripheral schizontaemia, severe anaemia (PCV <15% or Hb <50 g/L), raised blood urea greater than 60 mg/dL and serum creatinine greater than 265 µmol/L (>3.0 mg/dL), raised venous lactate (>5 mmol/L), raised cerebrospinal fluid (CSF) lactate (>6 mmol/L), low CSF glucose and a very high concentration of tumor necrosis factor α.

Cerebral malaria

Cerebral malaria[3] may be the most common non-traumatic encephalopathy worldwide. The term is restricted to the syndrome in which altered consciousness due to malaria could not be attributed to convulsions, sedatives, hypoglycaemia or a non-malarial cause.

Clinical, histopathological and laboratory studies have suggested two potential mechanisms:

- mechanical hypothesis – cytoadherence of parasitised erythrocytes
- cytotoxic hypothesis – neuronal injury by malarial toxin and excessive cytokine production.

Cerebral malaria has few specific features, but there are differences in clinical presentation between African children and non-immune adults.[3]

Clinical findings include:

- coma
- convulsions
- raised intracranial pressure
- hypoglycaemia
- acidosis
- abnormalities of tone and posture (the commonest being symmetrical pyramidal signs)
- retinopathy – patchy macular whitening sparing foveola, white-centred retinal haemorrhages orange or whitish discoloration of retinal vessels, capillary whitening.

DIAGNOSIS

- Microscopy of thick and thin films remains the gold standard for both the diagnosis and to follow the efficacy of treatment. In the non-immune patient there is a close association between parasite levels and complications; however, severe complications can occur in patients with low counts.
- Rapid diagnostic tests (RDT), which detect specific antigens (proteins) produced by malaria parasites, are useful in diagnosis. Current tests are based on the detection of histidine-rich protein 2 (HRP2), (which is specific for *P. falciparum*) pan-specific or species-specific parasite lactate dehydrogenase (pLDH) or other pan-specific antigens such as aldolase. Many commercial assays are available. Some tests detect only one species (*P. falciparum*), while others detect one or more of the other three species. RDTs do not give information about the parasite load, and their sensitivity drops at low parasite densities, making them less useful for the diagnosis of malaria in non-immune travellers who may experience symptoms of malaria even at low parasite densities. It is important to seek microbiological advice regarding the RDT tests used locally.
- In one study of returned travellers in France, a US Food and Drug Administration (FDA)-approved rapid test, based on HRP2 for *P. falciparum*, had a sensitivity of 96% and specificity of 99%.[4] In another study of returned travellers in the United States, the sensitivity of rapid test was 100% for facliparum compared to only 88% for blood smear, using polymerase chain reaction (PCR) as the reference standard.[5] HRP2-based tests may be persistently positive up to 28 days after treatment. RDTs for *Plasmodium vivax* are less sensitive. *P. knowlesi* cannot be specifically identified by microscopy. It will be reported as *Plasmodium malariae* or less commonly as *P. falciparum*. There are no specific rapid tests for *P. knowlesi*. Pan-specific tests have low sensitivity. Species-specific rapid tests for *P. vivax* or *P. falciparum* may be positive in *P. knowlesi* infection. *P. knowlesi* infection can only be confirmed through PCR.

- PCR tests based on detecting malarial DNA are more sensitive than microscopy but are expensive and do not give estimates of parasite load.

TREATMENT OF MALARIA

The World Health Organization (WHO) has recently issued new guidelines for the treatment of malaria.[6]

FALCIPARUM MALARIA

To counter the threat of resistance of *P. falciparum* to monotherapies, and to improve treatment outcome, combinations of antimalarials are now recommended by the WHO for the treatment of *falciparum* malaria. Antimalarial combination therapy is the simultaneous use of two or more blood schizontocidal drugs with independent modes of action. Artemisin-based combination therapy (ACT) is the recommended treatment for uncomplicated *falciparum* malaria (Box 75.1). The choice of ACT in a country or region will be based on the level of resistance of the partner medicine in the combination.

Box 75.1 World health organization recommendations for treatment of uncomplicated *falciparum* malaria

Artesunate + amodiaquine

4 mg/kg of artesunate and 10 mg base/kg of amodiaquine given once a day for 3 days.

Artesunate + sulfadoxine–pyrimethamine

4 mg/kg of artesunate given once a day for 3 days and a single administration of sulfadoxine–pyrimethamine (25/1.25 mg base/kg BW) on day 1.

Artesunate + mefloquine

4 mg/kg of artesunate given once a day for 3 days and 25 mg base/kg of mefloquine usually split over 2 or 3 days.

Artemether–lumefantrine

Available as co-formulated tablets containing 20 mg of artemether and 120 mg of lumefantrine. The recommended treatment for persons weighing more than 34 kg is four tablets twice a day for 3 days.

Dihydroartemisinin + piperaquine

4 mg/kg per day of dihydroartemisinin and 18 mg/kg per day of piperaquine once a day for 3 days. The piperaquine dose in children weighing <25 kg should be at least 20 mg/kg per day

During the first trimester of pregnancy, quinine with clindamycin should be used. During the second and third trimesters ACT should be used. Tetracycline should be avoided in breast-feeding women. In HIV-infected patients, avoid artesunate + sulfadoxine–pyrimethamine if they are receiving co-trimoxazole, and avoid artesunate + amodiaquine if they are receiving efavirenz or zidovudine

Second-line antimalarial treatment (as per older WHO recommendation made in 2010)

Artesunate (2 mg/kg once a day) plus doxycycline (3.5 mg/kg once a day) or clindamycin (10 mg/kg twice a day) for 7 days.

Quinine plus tetracycline or doxycycline or clindamycin for 7 days.

ACT, Artemisin-based combination therapy; *BW*, body weight; *HIV*, human immunodeficiency virus.

Severe falciparum malaria

Two classes of drugs are currently available for the parenteral treatment of severe malaria: the cinchona alkaloids (quinine and quinidine) and the artemisinin derivatives (artesunate, artemether and artemotil). A recent Cochrane review showed that treatment with artesunate significantly reduced the risk of death both in adults (relative risk 0.61) and children (relative risk 0.76) as compared to quinine.[7] The dosage of artemisinin derivatives does not need adjustment in vital organ dysfunction. The WHO recommended regimens for severe *falciparum* malaria are listed below (Box 75.2).

In patients with features of severe malaria, a mixed infection with *falciparum* should be assumed even if only a benign species is identified in the film. If the clinical suspicion is high, a therapeutic trial of antimalarial treatment is justified even if the film is negative.

Severe malaria may lead to septic shock, and the principles of management are the same including resuscitation and provision of supportive treatment. These patients are at risk of acute lung injury but do need adequate fluid resuscitation. A major trial in children showed convincingly that bolus fluids lead to increased mortality. The relevance of this study for adults is not clear.[8] Patients with malaria and shock should also receive empirical antibiotic therapy after the collection of samples for cultures, as bacterial sepsis may co-exist, particularly so in

Box 75.2 World health organization recommendations for treatment of severe *falciparum* malaria

Artesunate

2.4 mg/kg IV or IM given on admission (time = 0), then at 12 h and 24 h, then once a day. Children weighing less than 20 kg should receive 3 mg/kg per dose. Artesunate is recommended in pregnant women in any of the trimesters, and in lactating women and infants.

Artemether or, less preferably, quinine, should be used if parenteral artesunate is not available: artemether 3.2 mg/kg BW IM given on admission then 1.6 mg/kg BW per day; or quinine 20 mg salt/kg BW on admission (IV infusion or divided IM injection), then 10 mg/kg BW every 8 h; infusion rate should not exceed 5 mg salt/kg BW per hour.

Give parenteral antimalarials in the treatment of severe malaria for a minimum of 24 h, once started (irrespective of the patient's ability to tolerate oral medication earlier), and, thereafter, once oral therapy is tolerated, complete treatment by giving a complete course of one of the regimens listed in Box 75.1.

BW, body weight; *IM*, intramuscularly; *IV*, intravenously.

children. Shock may also be due to complications such as severe metabolic acidosis, gastrointestinal (GI) bleed or splenic rupture. Convulsions must be actively treated. Complications should be managed as they present. The threshold for dialysis should be low.

Exchange transfusion has been used in severe malaria. It has been advocated for use in patients with high parasitaemia (>10%) in the presence of severe disease. It helps by removing infected red cells which may lead to organ dysfunction by sequestration in organs. Red cells with mature parasite forms are more likely to lead to sequestration. Quinine kills primarily mature parasites so immature parasites may still mature despite ongoing treatment leading to further sequestration; artesunate kills young parasite forms as well and it more rapidly lowers parasitaemia. Hence exchange transfusion is less likely to add to artesunate therapy. In fact, a recent meta-analysis did not find an association between exchange transfusion and survival outcome (odds ratio 0.84; 95% confidence interval [CI], 0.44–1.60).[9] Nevertheless, exchange transfusion may be considered as an adjunctive therapy in patients with persistent acidosis and/or multiorgan impairment unresponsive to first-line treatment. It may also be considered in children with sickle cell anaemia and severe malaria. Such use should be considered experimental.[10]

OTHER FORMS OF MALARIA (Box 75.3)

Box 75.3 World health organization recommendations for treatment of *vivax*, *ovale*, *malariae* and *knowlesi* malaria

Uncomplicated *vivax*, *ovale*, *malariae* and *knowlesi* malaria:

For chloroquine sensitive malaria, use ACT or chloroquine.

For chloroquine resistant malaria use ACT.

ACTs containing piperaquine, mefloquine or lumefantrine are recommended as sulfadoxine–pyrimethamine and amodiaquine are not effective against *Plasmodium vivax* in many places.

Chloroquine is safe during pregnancy. For chloroquine-resistant malaria during the first trimester of pregnancy, quinine should be used in place of ACT.

To prevent relapse in case of *vivax* or *ovale* malaria, primaquine should also be given in addition to ACT or chloroquine except in pregnant women, infants younger than 6 months, women breast-feeding children younger than 6 months and those with G6PD deficiency. The dose of primaquine is 0.25 mg base/kg, taken with food once daily for 14 days. In Oceania and Southeast Asia, the dose of primaquine should be 0.5 mg/kg.

The dose of chloroquine is 25 mg base/kg divided over 3 days.

Severe *vivax* or *knowlesi* malaria

Treat as for severe *falciparum* malaria.

ACT, Artemisin-based combination therapy.

PROGNOSIS

Data are largely derived from endemic areas where presentation with convulsions, acidosis or hypoglycaemia is associated with a poorer outcome. The mortality of severe malaria even with artesunate therapy is still high (24% in adults and 11% in children).[7] In cerebral malaria, mortality is around 20%. The prognosis of cerebral malaria frequently is determined by the management of other complications, such as renal failure and acidosis, but neurological sequelae are increasingly recognised.

TUBERCULOSIS

EPIDEMIOLOGY

Tuberculosis (TB) continues to be a devastating disease worldwide. *Mycobacterium tuberculosis* infects one-third of the world's population; each year about 10 million individuals develop active disease and 1.4 million die from the disease. Medical conditions that predispose to TB include HIV infection, silicosis, diabetes, chronic renal failure/haemodialysis, malnutrition, solid organ transplant, gastrectomy, jejunoileal bypass, injection and inhalational drug abuse, alcoholism, chronic pulmonary disease and prolonged steroid use. Social factors such as institutional living conditions (nursing homes, homeless shelters, prisons), urban dwelling and poverty are associated with an increased risk of TB.

PATHOGENESIS

TB is usually caused by *M. tuberculosis* and four others (*M. bovis, M. africanum, M. microti* and *M. canetti*) grouped in the *Mycobacterium* complex. The genus *Mycobacterium* consists of many different species all of which appear similar on acid-fast staining.

Inhalation of tubercle bacilli leads to one of four possible outcomes: immediate clearance of the organism, primary or progressive primary disease, chronic or latent infection, and reactivation disease. Latent infection refers to the presence of tuberculous infection (positive tuberculin reaction) without the disease.

The primary focus of infection is in the lungs which usually heal spontaneously. The primary infection is symptomatic in only 5%–10% of adults with a higher incidence in children and those with HIV infection. It may present with hilar lymphadenopathy or with progressive pneumonic consolidation. Limited lymphohaematogenous dissemination commonly occurs during primary infection and leads to silent seeding of multiple organs. These sites remain dormant (latent infection) but may become reactivated after a period of months to years. This is called secondary or reactivation TB. This is responsible for 90% of TB in patients not infected with HIV. Occasionally,

lymphohaematogenous seeding may lead directly to disseminated miliary and meningeal disease.

CLINICAL SPECTRUM

The manifestations of TB are protean, and TB should be considered in the differential diagnosis of all patients with fever of unknown origin, night sweats or unexplained weight loss. Besides the lungs, it can also involve central nervous system (CNS), peritoneum, pericardium, GI and genitourinary tract, bone and joints, lymph nodes and skin. Occasionally it can be disseminated in the form of miliary TB.

PULMONARY TUBERCULOSIS

Secondary pulmonary TB is usually seen in adults; it is usually due to reactivation but may be due to re-infection. It typically starts in the apex of one or both lungs as a small infiltrate that spreads progressively. Later caseation necrosis leads to cavitation surrounded by fibrosis. The caseous material liquefies and drains into the bronchus. Coughing generates infectious aerosol leading to spread within the lung via bronchial tree as well as to close contacts. Progressive spread can lead to severe disease with extensive bilateral lung involvement characterised by infiltration, cavitation and fibrosis. Rupture of a lesion into the pleura may lead to spontaneous pneumothorax. Clinically, the patient presents with insidious onset of non-specific symptoms such as fever, night sweats, anorexia, weight loss and malaise. A cough develops and haemoptysis may occur. Dyspnoea is seen with more extensive disease.

Sputum, induced sputum, bronchial washings and transbronchial biopsy of infiltrates should be performed to isolate the organism. Computed tomography (CT) is more sensitive than chest radiography for detection of infiltrates, cavities, lymphadenopathy, miliary disease, bronchiectasis, bronchial stenosis, bronchopleural fistula and pleural effusion.

Tuberculous pleural effusion

Pleural TB may result in pleural effusion, or pleural empyema with or without bronchopleural fistula. Thoracentesis should be performed. The pleural fluid should be examined for total protein and glucose content, white blood cell count and differential count, and fluid pH. Positive fluid cultures are found in less than 25% of cases. Pleural fluid adenosine deaminase (ADA) levels more than 70/L strongly favour tuberculous aetiology, and levels less than 40 U/L make it less likely. In populations with a high prevalence of TB and clinical suspicion, an elevated ADA level might be considered as a confirmatory test justifying treatment initiation.[11] If the ADA level is more than 70 U/L and the lymphocyte percentage in the fluid is more than 75%, the diagnosis is virtually certain and pleural biopsy may not be needed.[12] In low prevalence countries, pleural biopsy may be required if diagnosis is doubtful. Pleural biopsy shows granulomatous inflammation in approximately 60% of patients, and culture may be positive even in those without granulomas. When culture of three biopsy specimens is combined with histologic examination, the diagnosis can be made in up to 90% of cases. Pleuroscopy-guided biopsies increase the yield in pleural sampling. Nucleic acid amplification tests have high specificity but low and variable sensitivity.

TUBERCULOUS MENINGITIS

Tuberculous meningitis[13] remains the most serious manifestation of TB for the intensive care physician. It results from haematogenous spread. Pathologically there is a thick gelatinous exudate around the sylvian fissures, basal cisterns, brainstem and cerebellum. Classically it presents as a subacute meningitic illness. The majority of patients with TB meningitis have had recent contact with infectious TB particularly during the preceding 12 months. A prodrome of vague ill-health lasting 2–8 weeks is commonly seen followed by signs and symptoms of meningeal irritation. Occasionally TB meningitis may present acutely without a prodromal period. Neck stiffness is usually absent during early disease.

Cranial nerve palsies occur in 20%–25% of patients, and papilledema may be present. Choroidal tubercles are rare but almost pathognomonic. Visual loss due to optic nerve involvement may occasionally be the presenting feature. There may be focal neurological deficit such as hemiplegia; extrapyramidal movements and seizures are other manifestations. As the disease progresses, cerebral dysfunction sets in and the mortality approaches 50%.

Both a diagnostic algorithm[14] and consensus case definition[15] have been published. The key is a high degree of clinical suspicion especially in the critically ill.

Definitive diagnosis of TB meningitis depends upon the detection of the organism in the CSF, either by smear examination or by bacterial culture. The yield from smear is variable, but generally low. The sensitivity of CSF culture is 60%–70% in adults and is considerably lower in children.[16] The sensitivity of smear and culture may be increased by using the centrifuged deposit from relatively large volume of CSF. Given the need for urgent diagnosis, Xpert MTB/RIF should be used in preference to conventional microscopy and culture as the initial diagnostic test for CSF specimens. This test is discussed in a later section.

CT or magnetic resonance imaging of the brain, which are sensitive but not specific, may reveal thickening and intense enhancement of meninges, especially in basilar regions. Hydrocephalus and tuberculomas may also be present. Infarcts due to either vasculitis or mechanical strangulation of the vessels by the surrounding exudates are detected in up to 40%. The radiological differential diagnosis includes cryptococcal

meningitis, cytomegalovirus encephalitis, sarcoidosis, meningeal metastases and lymphoma.

TUBERCULOUS EMERGENCIES

- Massive haemoptysis
- Respiratory failure
- Pericardial tamponade
- Small intestinal obstruction
- Tuberculous meningitis
- Status epilepsy due to tuberculomas

DIAGNOSIS OF TUBERCULOSIS

Once considered, isolate the patient and sample all potential sites for acid-fast staining and culture. Pleural, peritoneal, pericardial and other fluids must be cultured and analysed for differential cell count, protein, glucose and ADA.

Histological examination for granulomatous infection is useful in bronchial tissue, pleural, peritoneal and skeletal tissues. Peritoneal biopsies are best obtained via laparoscopy. Newer culture media have reduced the time for culture to 2 weeks.

Nucleic acid amplification (NAA) tests amplify target nucleic acid regions that uniquely identify the *M. tuberculosis* complex, and are available as commercial kits or in-house assays. A sensitive and specific fully automated and commercially available NAA Xpert MTB/RIF assay (Cepheid, Sunnyvale, California) can produce results in less than 2 hours permitting a specific TB diagnosis and rapidly detect rifampicin resistance. However, NAA tests cannot entirely replace conventional diagnostic approaches using microscopy and culture.

For Xpert MTB/RIF as an initial test replacing smear microscopy, a Cochrane review reported a pooled sensitivity of 89% and pooled specificity of 99%. In sputum smear negative specimens, the pooled sensitivity was lower at 67%; for people with HIV infection, the pooled sensitivity was 79%.[17]

Its performance in extrapulmonary TB is inferior and varies with sample type.[18] In CSF, Xpert's pooled sensitivity was 80.5% (95% CI, 59.0%–92.2%) against culture and 62.8% (95% CI, 47.7%–75.8%) against a composite reference standard (CRS). The pooled sensitivities were somewhat better with lymph node tissue or aspirate and significantly lower with pleural fluid. The pooled specificity was consistently over 98.7% against CRS across different sample types.

The current status of NAA tests is summarised below:

- NAA tests, in general, have high specificity and positive predictive value; they are useful in ruling in rather than ruling out TB. Resources permitting, the WHO recommends usage of Xpert MTB/RIF as the initial diagnostic test in sputum, CSF, lymph nodes and other tissues but not for blood, urine or stool.[19]
- A positive NAA test in smear-positive patients can differentiate *M. tuberculosis* from non-tuberculous mycobacteria (NTM); treatment can then be started.
- The interpretation of smear-positive but negative NAA test is controversial.
- In smear-negative and NAA-positive patients with a high clinical suspicion treatment can be started, particularly when prompt treatment is imperative.
- If clinical suspicion is high, TB is not excluded by both a negative smear and NAA.
- NAA results may remain positive for months. This method should be used only for initial diagnosis and not follow-up.

Serological tests are not recommended for the diagnosis of TB but highly specific tests are currently under development. The tuberculin skin test (TST) and interferon gamma release assays (IGRAs) assess cell-mediated immune response to tubercle bacillus. IGRAs are at least as sensitive as and more specific than TST as the latter test is also positive in those infected with NTM and those who have been vaccinated with BCG (Bacillus Calmette-Guerin). They indicate infection with tubercle bacillus but cannot differentiate between active disease and latent infection. They are primarily used in the diagnosis of latent infection as sensitivities and specificities are not high enough to confirm or rule out active disease.

Drug susceptibility tests should be performed on initial isolates from all patients in order to identify an effective antituberculous regimen, and may have to be repeated if the patient remains culture positive after 3 months.

TREATMENT OF TUBERCULOSIS

Local guidelines are of paramount importance and advice should be sought.[20] The commonest regimen used is isoniazid (5 mg/kg), rifampicin (10 mg/kg) pyrazinamide (1000–2000 mg daily depending upon body weight) and ethambutol (800–1600 mg depending upon the body weight) for the first 2 months and isoniazid and rifampicin for the next 4 months. Steroids are generally recommended in tuberculous meningitis and pericardial TB.

DRUG RESISTANT TUBERCULOSIS

This is an increasing problem. Multidrug-resistant TB (defined as resistance to two or more of the first-line antituberculous drugs, usually isoniazid and rifampicin) can be primary (no prior antituberculous therapy) or secondary (development of resistance during or after chemotherapy). Extensively drug-resistant (XDR) TB, defined by additional resistance to one of the fluoroquinolones and one of the injectable drugs, is more difficult to treat and may be incurable.

Diagnosis depends upon the collection of adequate specimens for culture prior to the initiation of antituberculous therapy. In critically ill patients, rapid

diagnosis of drug resistance is of paramount importance. With the improvements in the culture methods and the availability of newer techniques, rapid identification of resistance is possible. When resistance is present to two or more first-line agents, multiple drugs including parenteral aminoglycoside (streptomycin, amikacin, etc.) and fluoroquinolones are generally added.[21] Specialist microbiological advice should be sought.

TYPHOID FEVER

Typhoid fever is caused by *Salmonella typhi* and less commonly by paratyphi A, B and C. Even non-typhoidal salmonellae have occasionally been isolated.[22] Typhoid fever, common in South and Southeast Asia, is almost exclusively caused by faecal-oral spread. In the developed world, cases either are seen in international travellers or are occasionally caused by infected food.

CLINICAL FEATURES

The incubation period is 5–21 days. Typhoid presents non-specifically with fever, chills, abdominal pain and constitutional symptoms. Constipation may be more frequent than diarrhoea. Hepatosplenomegaly, erythematous macular rash (30%) and relative bradycardia, which is a non-specific but useful clue,[23] may be present.

COMPLICATIONS

- Shock
- Intestinal perforation
- GI haemorrhage
- Jaundice and encephalopathy[24]
- Neuropsychiatric manifestations
- Septic arthritis, pericarditis
- Obstetric complications in pregnant women.

DIAGNOSIS

Anaemia, leukopenia and deranged liver function are common.[25] Leukocytosis may occur and is more common in children. Blood cultures are positive in up to 60% of cases,[26] and are the investigation of choice; 10–15 mL yields higher success than smaller volumes.[27] Though culturing urine, stool, rose spots and duodenal contents are useful, bone marrow culture is the most sensitive, and its yield remains unchanged up to 5 days after commencement of treatment.

Serodiagnosis using Widal tests has limited clinical value. Commercial serological tests, such as Typhidot-M, and Tubex, which detect immunoglobulin (Ig)M antibodies against different *S. typhi* antigens, have a higher sensitivity and specificity.[28] Nested PCR is very promising in the diagnosis of typhoid fever.

TREATMENT

For uncomplicated typhoid fever, fluoroquinolones are the drug of choice.[29] There is some concern in using fluoroquinolones in children as they have been shown to cause cartilage toxicity in immature animals, but this appears largely unfounded in clinical trials.[30] Azithromycin, cefixime or ceftriaxone should be used for infections acquired in South Asia or other areas with a high risk of reduced susceptibility to fluoroquinolones. For severe typhoid fever, ceftriaxone is the drug of choice. A parenteral fluoroquinolone is also an appropriate alternative if infection has been acquired in regions where reduced susceptibility to quinolones is not a concern. The duration of therapy is 7 days for azithromycin, 7–14 days for fluoroquinolones and 10–14 days for cephalosporins.

Dexamethasone reduces mortality in severe typhoid fever: delirium, obtundation, stupor, coma or shock.[31] Intestinal, especially ileal, perforation – which may occur classically in the third week of febrile illness – requires prompt surgical intervention.[32]

CHOLERA

Cholera is caused by enterotoxin producing *Vibrio cholera*.[33] The incubation period varies from 12 hours to several days. The clinical case: infection ratio is about 1:10. It starts abruptly with painless watery diarrhoea associated with vomiting and painful muscle cramps. Vomiting may be the first symptom before diarrhoea. Stool output can reach as high as 1 L/h in the most severe cases. Typically, fever is absent.

Stool examination shows neither leukocytes nor erythrocytes. Dark field microscopy examination may reveal rapidly motile comma-shaped bacilli in fresh stool. Commercial assays detecting O antigen in stool samples, which take less than 5 minutes, are now available and are as sensitive and specific as stool culture. Aggressive rehydration is the mainstay of treatment; very large quantities of fluid may be needed. Adjunctive antimicrobial therapy is effective in shortening the duration of diarrhoea. A recent Cochrane review concluded azithromycin and tetracycline may have some advantages over other antibiotics.[34]

LEPTOSPIROSIS

This is caused by *Leptospira interrogans*. It occurs due to exposure to contaminated water. The disease has an incubation period of 7–10 days with a range of 2–20 days. It has two phases: a septicaemic phase and an immune phase. Clinical features include conjunctival suffusion or haemorrhages (useful diagnostic clue), uveitis, severe muscle tenderness, non-oliguric renal failure, hypokalaemia, hepatic dysfunction, pulmonary haemorrhage, acute respiratory distress syndrome

(ARDS), myocarditis, rhabdomyolysis, thrombocytopenia, disseminated intravascular coagulation (DIC), haemorrhage into the skin and internal organs, and digital gangrene. Weil syndrome is characterised by hepatorenal dysfunction, bleeding diathesis and pulmonary involvement.

Diagnosis is made with isolation of the organism by culture (blood, urine, CSF) or serology using the gold standard microscopic agglutination test (MAT). Alternative serology tests including enzyme-linked immunosorbent assay (ELISA) tests are available. Both culture and serology should be attempted if available, and local microbiological advice should be sought. Treatment is with penicillin G or ceftriaxone. In penicillin-allergic patients, doxycycline can be used.

DENGUE FEVER

EPIDEMIOLOGY AND PATHOGENESIS

It is estimated that 50 million cases of dengue fever (DF) occur worldwide annually and half a million people suffering from dengue haemorrhagic fever (DHF) require hospitalisation each year, a very large proportion of whom (approximately 90%) are children younger than 5 years old.[35] The causative agent is a flavivirus with four distinct serogroups, which is transmitted by the bite of Aedes mosquitoes. Two patterns of transmission have been recognised: (1) epidemic due to isolated introduction of dengue to a region, usually due to a single serotype; and (2) hyperendemic referring to the continuous circulation of multiple dengue virus serotypes.

Following a mosquito bite, viremia begins and usually lasts up to 7 days. Infection with one of the four serotypes (primary infection) provides life-long immunity against that serotype but not against the other serotypes (secondary infection). Epidemiological studies have suggested that the risk of severe disease (DHF/dengue shock syndrome [DSS]) is significantly higher in secondary infection than primary infection.

CLINICAL FEATURES

Dengue virus infection may be asymptomatic or may cause undifferentiated febrile illness (viral syndrome), DF or DHF, including DSS.[36]

DF has an incubation period of 3–14 days and is characterised by the sudden onset of fever, severe headache, retro-orbital pain on moving the eyes, and fatigue. The fever usually lasts for 2–7 days. It is often associated with severe myalgia and arthralgia (breakbone fever). Maculopapular rash, flushed facies and injected conjunctiva are common. Haemorrhagic manifestations can occur in DF and do not necessarily mean DHF.

DHF occurs primarily in children younger than 10 years old and is characterised by plasma leakage syndrome as evidenced by haemoconcentration (20% or greater rise in haematocrit), pleural effusion or ascites. The diagnosis is made if all of the following symptoms and signs are present: bleeding or positive tourniquet test, a platelet count of less than 100,000 per cubic millimetre, and plasma leakage. Haemorrhagic manifestations without evidence of plasma leakage do not constitute DHF. The mechanism underlying the profound capillary leak in DHF but not in DF is poorly understood. It is important to watch for the onset of DHF, which typically occurs 4–7 days after the onset of the disease, approximately at the time of defervescence. A decrease in the platelet count and a rise in haematocrit are useful clues.[36]

DSS is characterised by profound hypotension and shock.

Due to the limitations of the 1997 WHO classification, a new classification was adopted by them in 2009[37]:

- Dengue without warning signs
- Dengue with warning signs
- Severe dengue

Warning signs include any one of abdominal pain or tenderness, persistent vomiting, clinical fluid accumulation, mucosal bleed, lethargy; restlessness, liver enlargement greater than 2 cm, laboratory: an increase in haematocrit, concurrent with a rapid decrease in platelet count.

Criteria for severe dengue include any one of:

1. Severe plasma leakage leading to shock (DSS) or fluid accumulation with respiratory distress
2. Severe bleeding as evaluated by the clinician
3. Severe organ involvement (any) such as liver (aspartate aminotransferase [AST] or alanine aminotransferase ≥ 1000), CNS (impaired consciousness), heart and other organs referred to as expanded dengue syndrome.

DIAGNOSIS

Dengue should be suspected in all febrile patients who live in, or have returned from, endemic areas in the preceding 2 weeks. Leukopenia, thrombocytopenia with a positive tourniquet test, and raised AST are frequently seen; the former two tests have the highest sensitivity (about 90%) for the diagnosis of early dengue.[36] A positive tourniquet test alone cannot differentiate DHF from DF.

IgM immunoassay allows rapid confirmation of the diagnosis. If it is negative, particularly in the first 6 days of the illness, the diagnosis should not be ruled out. Acute and convalescent sera should be analysed by immunoassay or haemagglutination assay to demonstrate seroconversion or a fourfold rise in titre.

Virus isolation, viral nucleic acid detection by techniques such as reverse transcriptase PCR and viral antigen detection are the other diagnostic tests available. The dengue NS1 antigen test has a high specificity (93%–100%). It is very useful for early diagnosis before

the antibodies become positive. Sensitivity is highest on day 1 of the illness and declines gradually over time, and is 45%–57% at the time of hospital admission.[38]

TREATMENT

Supportive therapy for shock, especially appropriate and prompt fluid replacement, can reduce mortality. Fluid management is complex and WHO guidelines are available.[39] In DSS, steroids have not been shown to be useful. Once capillary leakage abates, fluid overload and pulmonary oedema can become problematic.

HANTAVIRUS

Hantaviruses[40] are rodent viruses distributed worldwide, with over 150,000 cases being registered annually. There are two major clinical syndromes: haemorrhagic fever with renal syndrome (HFRS) and hantavirus cardiopulmonary syndrome (HCPS). Both are typically acquired by exposure to aerosols of rodent excreta.

HANTAVIRUS CARDIOPULMONARY SYNDROME

The incubation period is about 3 weeks. There are two phases: (1) the prodromal phase is characterised by a relatively mild febrile illness, typically lasting 3–5 days; and (2) the cardiopulmonary phase, which is characterised by severe, rapidly progressive respiratory failure. In the latter phase, acute pulmonary oedema due to increased capillary permeability occurs. The progress from the prodromal phase to the cardiopulmonary phase is dramatic. In severe cases, significant myocardial depression also occurs, resulting in low cardiac output and hypotension. Acute renal failure can occur. The combination of thrombocytopenia, myelocytosis, haemoconcentration, lack of significant toxic granulation in neutrophils and immunoblastic morphology of more than 10% of the lymphocytes is highly sensitive and specific. ELISA for IgM and IgG antibodies is useful in the diagnosis. The hantavirus infection can also be confirmed by detection of hantavirus genome in blood or serum samples by reverse transcription (RT)-PCR. Treatment is mainly supportive with mechanical ventilation, early use of vasopressors, and careful administration of intravenous fluids and blood products. Because shock in HCPS is cardiogenic rather than distributive in nature, the lack of improvement in response to a fluid challenge is characteristic of HCPS. Mortality rates are estimated to be as high as 60% in HCPS and 12% in HFRS and extracorporeal membrane oxygenation may be effective.[41]

HAEMORRHAGIC FEVER WITH RENAL SYNDROME

This is characterised by fever, renal failure and haemorrhagic manifestations. The disease has five progressive stages: febrile, hypotensive, oliguric, diuretic and convalescent. Non-specific constitutional symptoms are followed by shock, oliguria, DIC and haemorrhagic manifestations. Diagnosis is made using ELISA for IgG and IgM antibodies. Treatment is supportive including renal support. Ribavirin has been found to be useful.

ARBOVIRAL ENCEPHALITIS

Viruses transmitted to human beings by the bites of arthropods (especially mosquitoes and ticks) are major causes of encephalitis worldwide. Although different viruses can cause encephalitis, an antigenically related group of flaviviruses[42] accounts for a major proportion of cases worldwide. These include mosquito-borne diseases such as Japanese encephalitis, West Nile virus encephalitis, St. Louis encephalitis, Murray Valley encephalitis[43] and tick-borne encephalitis.[44] Viral encephalitis is characterised by a triad of fever, headache and an altered level of consciousness. Other common clinical findings include disorientation, behavioural and speech disturbances, and focal or diffuse neurological signs such as hemiparesis or seizures. The incubation period is usually 5–15 days. Other manifestations include recurrent seizures, including status epilepticus, a flaccid paralysis resembling that of poliomyelitis, and Parkinsonian-type movement disorders. Flavivirus encephalitis is diagnosed usually by the IgM capture ELISA. Treatment is supportive. Interferon-α, ribavirin and intravenous Ig have all been tried with mixed success.

VIRAL HAEMORRHAGIC FEVERS (VHFs)

VHF is a general term for a severe illness, sometimes associated with bleeding, caused by a number of viruses.

EPIDEMIOLOGY

Lassa virus, Rift Valley fever, Crimean-Congo haemorrhagic fever (CCHF), HFRS, Marburg and Ebola virus disease, yellow fever and DHF are some of the most important VHFs. An Ebola epidemic started in 2014 in West Africa. Haemorrhagic fever viruses have an affinity for the vascular system and increased vascular permeability is the primary defect. Petechial haemorrhages are usually associated with fever and myalgias. Later, frank mucous membrane haemorrhage may occur, with accompanying hypotension, shock and circulatory collapse. Multisystem organ failure can occur. There is a wide variation in the relative severity of the clinical presentation.

The source of infection is rodent for the Lassa virus and the hantavirus, mosquito for Rift Valley fever,

yellow fever and DHF, and tick for the CCHF virus. At least four of the haemorrhagic fevers, Lassa fever (LF), Ebola virus, Marburg virus and CCHF are capable of person-to-person transmission through close contact with infected blood and other body secretions. Epidemiological studies of VHF in humans indicate that although possible, the airborne route does not readily transmit infection from person to person.

CLINICAL FEATURES

The patient will have either been in an endemic area or been in contact with someone from an endemic area.

VHFs generally have an abrupt onset with an incubation period less than 10 days. The incubation period can be up to 21 days. They present as acute febrile illnesses with a prodrome that often includes severe headache, dizziness, flushing, conjunctival injection, myalgia, lumbar pain and prostration. GI symptoms with nausea, vomiting, abdominal pain and diarrhoea may occur.

Leukopenia or leukocytosis, thrombocytopenia and elevated serum aminotransferases may be evident early in the disease; a petechial rash may appear on days 3–10. Coagulation profiles become progressively more abnormal, and overt haemorrhagic features of the disease (ecchymoses, epistaxis, gingival bleeding, malaena, and haematuria) may supervene from day 5 onward, or sometimes even earlier. Multiple organ failure supervenes and death may ensue. Clinical improvement becomes apparent toward the end of the second week of illness in patients who survive.

DIAGNOSIS

A high index of suspicion is needed and VHF should be suspected in the following circumstances:

- Unexplained fever in patients who have visited areas where VHF is endemic within 3 weeks of becoming ill. The likelihood is greater if they have camped in the bush, slept on the ground or in rural farms, or had any bites or contact with sick animals.
- Febrile medical and nursing staff in the endemic areas and laboratory workers who handle VHF viruses.
- Febrile contacts.

Tests on samples present an extreme biohazard risk. Diagnosis is mainly based on direct detection of viral antigens or viral RNA in blood or other body fluids through immunoassays or RT-PCR.[45] Serological tests have several limitations and are not very useful for diagnosing VHF in the acute phase

TREATMENT

Therapy is essentially supportive for a severe shock state. Haemorrhage is managed by replacement of blood, platelets and clotting factors as indicated. Ribavirin is useful in treating LF, and in CCHF. Ribavirin may reduce mortality by 10-fold if treatment is begun within 6 days of onset. Other treatment options are post-exposure vaccination.

PRECAUTIONS

These diseases must be notified immediately. In addition to universal blood and body fluid precautions, airborne isolation – including the use of goggles, high-efficiency masks, a negative-pressure room with no air circulation and positive-pressure filtered air respirators – has been recommended, as is surveillance of contacts. If applicable, to prevent further mosquito transmission, patients should be isolated in well-screened rooms sprayed with residual insecticides. Guidelines on infection control in the management of highly pathogenic infectious diseases have been published.[46]

RICKETTSIAL INFECTIONS

Rickettsial infections require early diagnosis and treatment to prevent severe outcomes. Scrub typhus, murine typhus, and to an uncertain extent spotted fever rickettsiosis (*Rickettsia conorii, Rickettsia africae*, etc.) are important treatable causes of undifferentiated febrile illness in the tropics and among travellers.[47] Scrub typhus is widespread in the Indian subcontinent and Southeast Asia. Murine typhus has a worldwide distribution: Africa, Southeast Asia and South Asia are the common sites of disease acquisition in the returning traveller. *R. conorii* causes Mediterranean spotted fever or boutonneuse fever. It also occurs in the Indian subcontinent. *R. africae* causes African tick typhus or African tick bite fever seen in Sub-Saharan Africa. Rickettsial infections present with fever, headache and myalgia. Rash is common and is usually maculopapular. An inoculation site eschar is characteristic. Eschar is absent in murine typhus but may be multiple in African tick typhus. GI and respiratory symptoms, meningoencephalitis, hepatomegaly and splenomegaly, and localised or generalised lymphadenopathy may occur. Multiorgan dysfunction, including ARDS, may develop in severe cases especially if treatment is delayed. Leukopenia or leucocytosis may occur, while thrombocytopenia and elevated transaminase levels are common. CSF may show lymphocytic pleocytosis and elevated protein. Diagnosis is suspected on clinical grounds and a dramatic response to doxycycline or azithromycin is a strong pointer. Beta-lactams and quinolones are ineffective in rickettsial infections. Diagnosis may be confirmed by antibody detection or PCR in specialised laboratories.

Part Eleven

Severe and Multiple Trauma

This page intentionally left blank

76

Severe and multiple injuries

Li C Hsee

Trauma can be defined as physical injury from mechanical energy. It is usually categorised as blunt or penetrating. In Western countries, severe blunt trauma is common, caused by road crashes, falls and, less frequently, blows and assaults. Severe penetrating trauma, usually from stabbings and gunshots, is less common except in larger cities of the United States,[1,2] South Africa and war zones. Blunt injuries are frequently internal, multiple and not obvious initially. The severity of penetrating injury depends on its trajectory and the force of energy involved. The risk of missing serious injuries can only be lessened by a systematic approach and repeated assessments.[3–5]

ASSESSMENT AND PRIORITIES

TRIAGE

An important first step is triage – sorting patients with acute life-threatening injuries and complications from those whose lives are not in danger. Depending on the complexity of injury, it is important to ensure resources are available for treatment. If institutional capacity is lacking, consider transferring the patient to an advanced trauma unit. The severity of total body injury is related to the number of separate injuries present, and to the severity of individual injuries. Assessment can be made either at the scene of injury or on arrival at hospital. As in any emergency, assessment, diagnosis and treatment need to be concurrent. There is limited time for detailed histories, examinations, investigations or well-considered diagnoses before starting emergency care.

RECOGNITION OF SEVERITY

Most patients with severe injury can be distinguished early by the following:

- *Signs of shock:* shock is almost always hypovolaemic from blood loss, but other types of shock occasionally occur in trauma.
- *Depressed consciousness:* in the trauma patient, depressed consciousness can be related to brain injury, hypoxaemia, shock, alcohol or other ingested drugs, or precipitating neurological or cardiac events. Frequently, a combination of factors is present, and the precise extent of physical brain injury is not initially known. Initial treatment is, in any case, determined by the level of consciousness rather than its exact cause.
- *Breathing difficulty:* this is common in patients with trauma to the head, face, neck and chest. If rapid or distressed breathing is present then airway obstruction, laryngeal injury, pulmonary aspiration and lung or chest wall injury (especially pneumothorax and lung contusion) must be considered.

PRIORITIES

A trauma patient often has multiple problems requiring attention. Determining priorities is not always easy. In general, the priorities are to:

- *support life:* the patient is kept alive with resuscitative techniques, while the various injuries and complications are attended to
- *locate and control bleeding*, which may be varied
- *prevent brainstem compression* and spinal cord damage
- *diagnose and treat* all other injuries and complications.

BASIC TREATMENT PRINCIPLES

A systematic approach to managing severe and multiple trauma is important. Effective programmes developed by the American College of Surgeons are now well established.[6] A number of basic treatment principles apply to all severe trauma patients.

EMERGENCY ASSESSMENT (PRIMARY SURVEY)

While airway, breathing, circulation (ABC) management is traditionally followed, battlefield trauma is managed using a <C>ABC approach, where <C> refers to the management of catastrophic external bleeding. The treatment priorities are as follows:

- <C> – *Catastrophic bleeding:* life-threatening external haemorrhage should be dealt with rapidly using the

ABSTRACT

The management of severe and multiple trauma requires a team approach. These patients are often critical with life-threatening injuries. In order to optimise outcomes, the patient must be evaluated in a systematic manner. This chapter highlights the key systems required for evaluation. They include assessment and priorities, primary and secondary surveys and resuscitation principles. The use of radiological evaluation in trauma is described. In this chapter, topics such as damage control resuscitation and massive transfusion protocols have been updated and emphasised. The severity and morbidity of trauma measurement tools such as Injury Severity Scores (ISS) and Abbreviated Injury Scales (AIS) are presented. Finally, emphasis is given to the organisation of trauma care to reduce the morbidity and mortality.

KEYWORDS

Initial assessment
triage
priorities
damage control resuscitation
massive transfusion protocol

field-dressing, tourniquet and topical haemostatic agents. Following management, or in the absence of catastrophic external bleeding, the ABC approach should be followed.

- *A – Airway obstruction:* is suggested by noisy (or silent) breathing, with paradoxical chest movements and breathing distress, and inadequate airway protection from impaired gag reflexes in patients with depressed consciousness. Airway obstruction should be managed with cervical spine protection.
- *B – Breathing difficulty:* is suggested by tachypnoea, abnormal pattern of breathing, cyanosis or mental confusion.
- *C – Circulatory shock:* is manifested by cold peripheries with delayed capillary refill, rapid weak pulse or low blood pressure (see below).
- *D – Disability:* neurological status needs to be evaluated by checking the pupils and Glasgow Coma Scale (GCS). A decreased level of consciousness can be caused by poor cerebral perfusion, direct cerebral injuries, alcohol, recreational drugs and opiates.[6]
- *E – Exposure:* the patient needs to be exposed for examination, but at the same time hypothermia must be prevented and dignity preserved.[6]

OXYGEN AND VENTILATORY THERAPY

High-flow oxygen by mask is given to all trauma patients. Patients with severe trauma frequently require ventilatory support. A restless uncooperative patient should be anaesthetised and intubated under a rapid sequence induction to facilitate resuscitation.

BLOOD CROSS-MATCH AND TESTS

Blood is concurrently sent for baseline haematological and biochemical tests, including blood ethanol level. Blood ethanol level is clinically useful in assessing individual patients with depressed consciousness, quite apart from epidemiological and preventive medicine,[7] and for legal considerations. Six units of red cells should be cross-matched urgently, but it is impossible to predict the amount of blood that will be required. Most institutions have policies on transfusion in the unstable patient.

FLUID RESUSCITATION

Resuscitation fluids are given (see below). If necessary, two or three large 14- or 16-gauge intravenous (IV) cannulae are inserted in upper limb, external jugular or femoral veins. Intraosseous cannulation can be useful initially if intravenous access is not obtainable.

ANALGESIA

Analgesia is easily overlooked. Opioid agents should be titrated IV, and not given intramuscularly or subcutaneously as the latter routes give unpredictable absorption in shock states. Large doses may be needed.

URINE OUTPUT

A urinary catheter is inserted unless a ruptured urethra is suspected (because of blood at the urinary meatus, severe fractured pelvis or abnormal prostate position on rectal examination), in which case a urethrogram is indicated before catheterisation. Urine output monitoring is an important guide to resuscitation.

CLINICAL EVALUATION OF INJURIES (SECONDARY SURVEY)

Injuries are easily missed in an emergency, especially when one injury is obvious. A secondary, and even a tertiary, survey should be performed.[5] The back and the front of the patient should be examined. Special attention is paid to regions with external lacerations, contusions and abrasions. All body regions are examined systematically.

HEAD

Neurological observations are made. The ears and nose are inspected for cerebrospinal fluid and blood, and the scalp is examined thoroughly.

FACE

Bleeding into the airway should be excluded, and the face and jaws tested for abnormal mobility.

SPINE

A cervical spine fracture or dislocation is assumed in all patients with depressed consciousness until proved otherwise. Signs of spinal cord injury should be sought (e.g. warm dilated peripheries from loss of vasomotor tone, diaphragmatic breathing, paralysis, priapism and loss of anal tone). The thoracic and lumbar spine should be inspected and palpated.

THORAX

Fractured ribs in themselves are not usually life threatening, but haemothorax, pneumothorax, lung contusion and chest wall instability (flail chest) will require attention if present. Tension pneumothorax is a life-threatening emergency that needs to be detected and treated early. Less common but very serious injuries can occur to the heart and great vessels (see Chapter 79).

ABDOMEN

The spleen, liver and mesenteries are often damaged. Retroperitoneal haemorrhage is common. Injuries to

the pancreas, duodenum and other hollow viscera are less frequent, and may be missed until signs of peritonitis occur. Renal injury with retroperitoneal haemorrhage is suggested by haematuria and loin pain (see Chapter 81).

PELVIS

Pelvic fractures may be difficult to detect clinically, especially in the unconscious patient. Blood loss may be massive, particularly with posterior fractures involving sacroiliac dislocation. Consideration of a pelvic binder may be useful in the initial stages of resuscitation. Ruptured bladder and ruptured urethra may occur with anterior fractures.

EXTREMITIES

A litre or more of blood may be lost into a fractured femur. Long-bone fractures are more serious when they are open, comminuted or displaced, or if associated with nerve or arterial damage.

EXTERNAL

Contusions may be extensive and serious, especially in falls from heights, and may be overlooked if the victim's back is not examined. Road crash victims may sustain serious burns or abrasions.

SHOCK IN THE TRAUMA PATIENT

The earliest, most constant and reliable signs of shock are seen in the peripheral circulation. A patient with cold, pale peripheries has shock until proved otherwise. Tachycardia is not always present and hypotension is a late sign of shock. The commonest form of shock in trauma is hypovolaemic shock.

HYPOVOLAEMIC SHOCK

If the neck veins are empty, hypovolaemic shock should be inferred. Possible sites of blood loss causing shock are:

- *external loss*, which is obvious clinically from blood-soaked clothing and pooled blood
- *major fractures*, which are obvious clinically by deformity, swelling, crepitus, pain and tenderness (e.g. femurs) or seen on a plain X-ray (e.g. pelvis)
- *pleural cavity*, detected on urgent chest X-ray. Intrapleural drains will reveal the amount and rate of blood loss
- *peritoneal cavity*, detected by laparotomy, diagnostic peritoneal lavage (DPL), computed tomography (CT) scan or ultrasound. Clinical examination of the abdomen can be misleading when the patient is intoxicated, has depressed consciousness or has multiple injuries. A single clinical examination is of limited value; changes over time are more important
- *retroperitoneum*, detected at laparotomy or by CT scan, or inferred when all the above are negative, especially in the presence of pelvic or lumbar spine fracture.

CARDIOGENIC SHOCK

If the trauma patient with shock has distended neck veins, possible causes are tension pneumothorax, concurrent myocardial infarction, cardiac tamponade or myocardial contusion.

NEUROLOGICAL SHOCK

Patients with paraplegia or tetraplegia from spinal cord injury may have low blood pressure with warm dilated peripheries accompanied by lax anal tone and by priapism in the male (see Chapter 80). This is a diagnosis of exclusion and all causes of hypovolaemic shock (see above) must be sought.

SEPTIC SHOCK

Occasionally, patients with pulmonary aspiration may develop septic shock. This is unlikely to confuse the initial trauma assessment soon after injury, but may require consideration some hours or a day or two later.

ABDOMINAL ULTRASOUND

The non-invasive nature and increasing availability of FAST (focused assessment with sonography for trauma) scanning in emergency departments has made this modality attractive in trauma to detect haemoperitoneum and haemopericardium.

However[8]:

- it is operator dependent and needs to be performed by trained personnel
- it may have an unacceptably high false-negative rate
- there is a small but important false-positive rate for intra-abdominal bleeding
- it is unable to diagnose ruptured bowel
- it is not good for bleeding in the pelvis.

Its main usefulness is in the shocked patient, where a positive FAST indicates the need for immediate laparotomy without further investigation.[6,9,10]

DIAGNOSTIC PERITONEAL LAVAGE

DPL is now less commonly performed and is largely replaced by FAST. However, it may still be used to diagnose intra-abdominal bleeding and bowel injury in some circumstances.

This is an invasive procedure that may make subsequent clinical abdominal examination difficult.[6,11]

Caution is needed with pregnancy, previous abdominal surgery or massive pelvic injury. Isotonic saline

1 L (or 10 mL/kg) is instilled into the peritoneal cavity, after drainage of the stomach and bladder. The presence of more than 10 mL frank blood on catheter aspiration necessitates immediate laparotomy; otherwise a lavage fluid specimen should be examined for red and white cell counts and amylase concentration. A red cell count over 100,000 per mm^3, white cell count over 500 per mm^3 or an increased amylase concentration suggests bleeding or viscus injury, and laparotomy should be undertaken immediately. These absolute figures are debatable, however, and lower values are accepted in penetrating trauma.[6,12,13]

COMPUTED TOMOGRAPHY ABDOMEN

Improved availability, reduced scanning times and better definition increasingly favour CT abdomen over DPL in patients who are sufficiently stable to tolerate the procedure safely. It needs to be performed quickly and safely, with gastric and IV contrast, and interpreted by radiologists experienced in trauma. Visualisation of abdominal and pelvic organs and haemorrhage is excellent.[14,15] Diaphragm, pancreas and hollow viscus injuries may be difficult to visualise on CT, but the presence of free fluid in the absence of solid organ injury raises suspicion of hollow viscus injury.[16]

FLUID RESUSCITATION

TYPES OF FLUIDS

Almost all patients who are hypotensive or noticeably vasoconstricted will need a blood transfusion but, in general, early control of bleeding is the key. Isotonic saline or a balanced salt solution should be the first fluid infused. Shocked patients will need to be resuscitated early with blood and blood products. One-litre bags or bottles and giving sets with in-line pumps should be used on all IV lines. If fluid resuscitation is likely to be extensive, warmed fluids and rapid infusion devices should be used. Albumin solutions (and probably other colloid resuscitation fluids) are contraindicated in trauma patients as the SAFE study, comparing albumin and saline for fluid resuscitation, conducted in intensive care unit (ICU) patients showed higher mortality in patients given albumin, in the predetermined trauma subgroup, particularly in those with traumatic brain injury.[17] Initiation of massive transfusion protocol (MTP) can be life saving in the exsanguinating patient.

All resuscitation fluids have a high sodium concentration, similar to that of extracellular fluid. Glucose 5% and glucose–saline solutions are not effective resuscitation fluids. Few trauma patients actually require them in the first day.

THE EXSANGUINATING PATIENT

With exsanguination secondary to penetrating thoracic injury, there is a place for emergency room thoracotomy, but this approach has little place in blunt trauma.[18] The exsanguinating blunt trauma patient needs rapid intubation, volume resuscitation, bilateral intrapleural drains, chest and pelvic X-rays, and a rapid trip to the operating room if it seems likely that the bleeding is in the thorax or abdomen.

MASSIVE TRANSFUSION PROTOCOL

Coagulopathy is common in patients with haemorrhagic shock and can be made worse by fluid resuscitation. Many institutions will have a MTP for exsanguinating patients. The principle of MTP is to increase plasma to platelet to red blood cell (RBC) ratios during the resuscitation phase.[19] MTP is shown to improve outcome. Haemostatic agents such as tranexamic acid[20,21] and other novel adjunct therapies are now available. Prothrombin complex concentrate and fibrinogen concentrate do not have any known infectious complications and are increasingly used in trauma management.[22]

PERMISSIVE HYPOTENSION

In penetrating trauma, there is some evidence that extensive fluid resuscitation prior to haemostasis may be detrimental, presumably because of higher blood pressure, the displacement of a blood clot and dilution of the coagulation factors.[23,24]

Permissive hypotension is the limited use of crystalloid during the initial phase of resuscitation. The aim is to prevent bleeding and haemodilution secondary to fluid resuscitation causing a loss of coagulation factors and platelets. With such fluid restriction, the goal is to allow enough end-organ perfusion and maintenance of systolic blood pressure (SBP) to 90 mm Hg before surgical correction. The use of hypotensive resuscitation has demonstrated early intraoperative survival benefit in penetrating torso trauma.[25]

Traumatic brain injury is often present in blunt trauma, which frequently involves several body regions. Hypotension is disastrous to an already injured brain, and must not be prolonged by underresuscitation (see Chapter 77, section on traumatic brain injury – emergency treatment).[26–28]

DAMAGE CONTROL RESUSCITATION

Damage control surgery was described some years ago as abbreviated surgery to stop bleeding and contamination, followed by a period of ICU care before further surgery, to try to arrest the lethal triad of acidosis, hypothermia and coagulopathy.[29] US military experience with combat patients is extending this concept to fluid resuscitation as well, with a tendency to give no (or only small amounts of) resuscitation fluids before haemostatic surgery.

Following the evolution of the damage control surgery concept, trauma resuscitation is often widely referred to as ‘damage control resuscitation’ (DCR), which is defined as a systematic approach to major

exsanguinating trauma incorporating strategies of haemostatic resuscitation, permissive hypotension and damage control surgery.[30,31]

Haemostatic resuscitation is the early use of combined blood components and, in some situations whole blood, as primary resuscitation fluids. The aim is to provide the same ratio of each blood component (RBC, fresh frozen plasma and platelets) to treat intrinsic coagulopathy. Recent studies have shown that higher ratios of component therapy have increased patient survival. Other factors that need to be considered in the haemostatic resuscitation are fibrinogen and calcium levels.

Regular assessments of the efficacy of replacement therapy are required to guide and monitor coagulation parameters. Thrombelastography (TEG) and thromboelastometry (ROTEM) are frequently used to guide the real-time coagulation therapy.[32]

Some enthusiasts are now injudiciously extending DCR to other types of trauma.[33] As mentioned above under permissive hypotension, great caution should be exercised before extending this concept to non-exsanguinating blunt trauma, particularly if a traumatic brain injury is present,[28] or if the patient is remote from a trauma centre.

URINE OUTPUT

Hourly urine output is a useful guide to resuscitation from shock. Minimal acceptable urine output is 0.5 mL/kg per hour, but 1–2 mL/kg per hour is more adequate. Furosemide has no place in initial resuscitation. Apart from adequate resuscitation, diuresis can be due to ethanol, mannitol, dopamine, nephrogenic or neurogenic diabetes insipidus, or non-oliguric renal failure. Polyuria may mask early recognition of acute renal failure.

INADEQUATE RESUSCITATION

Patients in shock have depleted interstitial fluid as well as circulating blood volume, and need trauma resuscitation fluid volumes greater than the actual volume of blood lost. With blunt injury, volume losses often continue for 24–48 hours. Prolonged shock from delayed and inadequate resuscitation leads to renal failure, acute respiratory distress syndrome (ARDS), sepsis, disseminated intravascular coagulation (DIC) and multiple organ dysfunction.[34,35]

PULMONARY OEDEMA

Pulmonary oedema during resuscitation may be related to fluid overload, direct lung trauma, aspiration of gastric contents, pulmonary responses to non-thoracic trauma and reactions to resuscitation fluids. They can all cause leaky capillaries and produce non-cardiogenic pulmonary oedema.

RADIOLOGY FOR TRAUMA PATIENTS

Patients with depressed consciousness, breathing difficulties or unstable circulation should be X-rayed in the emergency department, and not sent to a radiology department remote from skilled resuscitation facilities. Conversely, extensive imaging examinations of shocked patients in the emergency department are unacceptable. Only a maximum of three examinations should ever be requested in the emergency department.

CHEST

A supine film is usually sufficient in the major trauma setting. An erect film is better for showing intrapleural air or fluid, ruptured diaphragm, free abdominal gas and for defining an abnormal mediastinum, but it is often impractical in shock or suspected spinal injury. Tension pneumothorax is a clinical diagnosis and does not require a chest X-ray before insertion of an intercostal drain.

LATERAL CERVICAL SPINE

Lateral cervical spine X-ray in the severely injured patient is now largely replaced by CT. It is no longer routinely done in the resuscitation room in major trauma. With head or facial injuries, a cervical fracture should be initially assumed and a cervical collar applied.

PELVIS

Unexplained blood loss can be due to a missed pelvic fracture. A dislocated hip can be missed in multiple injuries. Pelvic X-ray is an important adjunct of primary survey in an unstable trauma patient.

OTHER RADIOLOGICAL INVESTIGATIONS

Other X-rays should be performed after adequate resuscitation in the radiology department, operating room or ICU:

- *Skull*: plain skull X-rays are not useful and do not guide immediate treatment. An urgent CT scan of the brain is a more useful investigation.
- *Extremities*: X-rays of the extremities to assess bony injuries are not urgent unless there is vascular injury. Therefore these films should not be taken in the emergency department, unless the patient is going directly to the operating room for fracture fixation.
- *Spine*: X-rays of thoracic or lumbosacral spine are seldom indicated in the emergency department.
- *Abdomen*: a plain abdominal X-ray is of limited value in the initial evaluation of trauma. It may be helpful in high-velocity penetrating injuries, such as gunshot wounds, to help determine trajectory.
- *CT abdomen*: this can be valuable to evaluate a patient who is haemodynamically sufficiently stable to tolerate the procedure safely (see above).

- *CT head*: this is vital in the treatment of traumatic brain injuries.
- *CT neck*: the most reliable way to exclude or delineate cervical spine injuries is by a CT neck scan,[4,36] which can conveniently be done when the patient is going to the CT scanner for other examinations.
- *CT thorax*: apart from diagnosis of aortic injury, CT thorax is of limited value in the trauma patient. Visualisation of thoracic structures is excellent, but it seldom discovers important undiagnosed injuries that affect patient treatment.[37] If aortic injury is suspected, multislice CT is the current definitive diagnostic test. The use of aortic stent grafts for this injury, in locations where this technology is available, means that CT not only is the best diagnostic test but also is necessary for preoperative planning.[38] Aortography is no longer the definitive diagnostic test for traumatic aortic rupture.
- *Urethrography*: this is used when urethral injury is suspected. Properly done CT abdomen may well demonstrate bladder injury; otherwise *cystography* is used.
- *Interventional radiology*: percutaneous transcatheter embolisation is therapeutic rather than diagnostic. It can provide life-saving haemostasis in massive retroperitoneal haemorrhage associated with pelvic fracture.[39] The logistics of managing such haemodynamically unstable patients in the radiology department are formidable.

TRAUMATIC BRAIN INJURY (SEE CHAPTER 77)

Injuries to the head region are common, but those requiring urgent cranial operations are less so. Traumatic brain injury may initially be obvious amongst multiple injuries, but may not be the most important injury. Conversely, traumatic brain injury may seem initially unimportant. Traumatic brain injury is a major determinant of outcome in critically injured patients.

EMERGENCY TREATMENT

Resuscitation measures, as in the emergency assessment (primary survey) section above, are undertaken. Victims with one or both dilated unreactive pupils, or a rapidly deteriorating level of consciousness not due to hypoxia or shock, should be given mannitol 1 g/kg IV to relieve brainstem compression until definitive diagnosis and treatment can be arranged. However, mannitol should be given only if the patient has been adequately volume-resuscitated as it may add to hypovolaemia. In the ICU, concentrated salt is often preferred to mannitol because it is readily available and does not produce hypovolaemia.[40,41]

Shocked trauma patients with or without traumatic brain injuries require the same crystalloid resuscitation fluids. Treatment of shock and maintenance of cerebral perfusion are vital, as hypotension is disastrous to an already damaged brain.[26–28] Contrary to common belief, sodium-containing fluids are not inherently dangerous in traumatic brain injury. However, after adequate resuscitation, further sodium administration is usually not indicated. Excessive (free) water is potentially dangerous, however, as it can lead to hypo-osmolar brain swelling.[42]

NEUROLOGICAL EVALUATION

Factors such as hypoxaemia, shock, alcohol, analgesics, anaesthetic agents, muscle relaxants and other drugs confound neurological signs. Clinical neurological evaluation includes the GCS[43,44] and a search for lateralising signs.

CT scanning is indicated in all patients who will not obey verbal commands, especially if they are rendered neurologically inaccessible by sedative and relaxant agents. Lateralising motor or pupillary signs with a deteriorating level of consciousness are indications for immediate CT scanning (or, if unavailable, emergency burr holes). In an unstable patient, a laparotomy for intra-abdominal haemorrhage should take priority over a head CT scan.[45]

SEVERITY AND MORBIDITY OF TRAUMA

Severity of injury is measured by the Abbreviated Injury Scale (AIS), updated over the years, most recently in 2008.[46–48] AIS divides the body into six regions: head and neck, face, thorax, abdomen, pelvis and extremities, and external. Specific injuries in each body region are coded on a scale of 1 (minor), 2 (moderate), 3 (serious, not life threatening), 4 (severe, life threatening, survival probable), 5 (critical, survival uncertain) and 6 (unsurvivable). The AIS was designed for motor vehicle injuries, but has been validated for blunt and penetrating trauma. It can provide a basis for research, education, audit and allocation of resources.

Severity of trauma is related not just to the severity of individual injuries, but also to the combined effects of multiple injuries. Multiple injuries are graded by the Injury Severity Score (ISS), which is an empirical system based on the AIS grades for the three worst body regions.[49,50] ISS gives a score between 0 and 75 for total body injury; 16 or more indicates major trauma. Death with an ISS below 24 should be rare. Above an ISS of 25, there is a stepwise increase in mortality, with very high rates over 50.[51,52]

The AIS and ISS study mostly the anatomy of injury. Other factors influence trauma mortality and morbidity, including age, pre-existing health, degree of physiological derangement, standard of prehospital and early hospital care, and complications. Degree of physiological derangement can be measured by the Revised Trauma Score (RTS),[53] which is computed from the coded values of the GCS, systolic blood pressure and respiratory rate, usually at admission to the

emergency department. The Trauma Score – Injury Severity Score (TRISS) is based on the RTS, ISS and patient age.[54] It correlates well with outcome, and has been used to compile survival norms for blunt and penetrating trauma.[51,52] Physiological scoring systems such as APACHE (Acute Physiology and Chronic Health Evaluation) do not work well for trauma patients (see Chapter 3).[55,56] Preinjury illness (co-morbidity) has a profound effect on trauma outcome.[57]

Shock influences trauma mortality and morbidity. Complications of shock include renal failure, ARDS, sepsis, liver failure and multiorgan dysfunction.[34,35,58] Acute oliguric renal failure on the first day after trauma is now rare, but non-oliguric renal failure is often seen 2–4 days later, caused by the shock and delayed or inadequate resuscitation. It is often heralded by polyuria, which is misinterpreted as a sign of adequate resuscitation.

EPIDEMIOLOGY OF INJURIES

Only a minority of victims of severe trauma reach hospital alive.[59,60] The majority of deaths are immediate (within minutes) at the scene of injury. Some deaths are early (within hours) in the emergency department or the operating room, and a few are late (after days or weeks) and occur in the ICU or ward.[61] Those in the ICU are mostly from severe head injury within a few days and, less commonly, multiorgan dysfunction later.

Of trauma admissions to hospital, only a minority have severe or multiple trauma.[62] In order of frequency, life-threatening injuries involve the head, abdomen and chest (Table 76.1), and are often multiple. The hospital services that this small number of severely injured patients use out of proportion to their numbers are major surgery, intensive care, radiography and CT scanning.[62] Major trauma outcome studies in the United States,[51] the United Kingdom[52] and Australasia[63,64] offer valuable epidemiological data. The US study found that the mortality of direct admissions is strongly related to serious head injury.

Table 76.1 Percentage of intensive care unit trauma patients with grades of injury in different body regions

	AIS ≥4	AIS 3	AIS 1 or 2	AIS 0
Head and neck	63	9	9	19
Face	2	11	8	79
Thorax	10	17	7	66
Abdomen	17	6	2	75
Extremities	1	31	11	57
External	0	<1	63	37

Data on 5031 trauma patients (excluding burns) in the Department of Critical Care Medicine, Auckland City Hospital, 1988–2011. AIS-80 codes: 0 = no injury; 1 = minor; 2 = moderate; 3 = serious, not life threatening; 4 = severe, life threatening, survival probable; 5 = critical, survival uncertain; 6 = unsurvivable. In tertiary referral centres (like Auckland City Hospital) these figures will vary with the mix of local and referred patients.[63]

AIS, Abbreviated Injury Scale.

ORGANISATION OF TRAUMA CARE

Many of the problems of trauma care are organisational. Problems faced by health authorities are the provision of advanced care at the scene of injury, rapid transportation to hospital, policies on which hospitals should receive trauma patients, systems for rapid evaluation and decision making in hospitals, and rapid, safe patient transfer between hospitals. If survival from major trauma is to be maximised then prehospital and hospital care must be coordinated.

Regionalisation of trauma care has become an accepted concept.[2,65] Trauma centres are designated hospitals that meet certain requirements. The main prerequisites are rapidly available experienced surgeons, anaesthetists and neurosurgeons, and a minimum number of patients seen annually for staff expertise. Regionalisation involves the concept of ambulances bypassing non-designated hospitals.[2] Helicopters are used increasingly to speed patient transportation.[66] Trauma teams are teams of surgeons and intensivists or anaesthetists who immediately attend the trauma victim on arrival at hospital.[2–4,58]

Trauma registries and databases are important tools in organising and improving trauma care. The UK major trauma outcome study[52] showed that the doctors in charge of resuscitation were often junior, delays in performing urgent operations were common and the number of preventable deaths was significant. A hospital may not see enough trauma patients to justify a trauma team or supply adequate experience for its staff, and may not have all the facilities required by trauma patients. Transfer to a trauma hospital may be desirable, but geography and limited transport facilities may make such transfers hazardous.

In Western countries, trauma is a leading cause of death and disability under the age of 38 years.[51] Reduction of mortality and morbidity depends on public education, new legislations, on-site advanced care, rapid evacuation (see Chapter 4), hospital trauma expertise and coordination of services.[67,68]

Severe head injuries

Manoj K Saxena, John A Myburgh

EPIDEMIOLOGY

Head injury is a heterogeneous disease entity that can be defined as either an alteration in brain function, or evidence of structural brain pathology, which is caused by an external force.[1] Traumatic head injury is the leading cause of death in those under 45 years of age, affecting males disproportionately.[2] Data from the Global Burden of Disease suggest that traumatic head injury contributes to between 8% and 15% of years lost due to disability as a proportion of the total global injury burden.[3] Overall, the incidence of the disease is probably increasing, driven primarily by an increase in low- and middle-income countries.[4]

In addition to high mortality, the cost to survivors in emotional, social and financial terms is substantial as the effects of the original injury may persist for many years.

AETIOLOGY

Traumatic head injury may be due to transport accidents, unintentional falls, assaults due to interpersonal violence or exposure to external forces and other causes. Increasingly, traumatic head injury related to military conflict and sports or recreational activity is being recognised. In high-income countries the incidence of head injury due to vehicular trauma has significantly decreased due to technical improvements in vehicle design and safety, and in public health initiatives.[1] However, the ageing demography of the population are now influencing the presentation of the disease in this setting.[4]

DEMOGRAPHICS

The numbers of patients with traumatic head injury presenting to hospitals vary widely in accordance with hospital admission policies and capabilities. The incidence of hospitalisation for traumatic brain injury has been reported to be between 69.7 cases per 100,000 population in America[5] and 101 cases per 100,000 in Europe.[6] A recent population-based study of moderate and severe traumatic head injury reported a rate of 40 (95% confidence interval 32–51) cases per 100,000 in New Zealand.[7] Age- and gender-specific data typically show two peaks: one in the second and third decades, with a male:female ratio of 2:1, and the latter in the seventh to ninth decades with a more equal gender ratio.

PATTERNS OF INJURY

Traumatic head injury represents a range of injury from mild head injury that may fully recover to severe injury associated with high mortality or high levels of disability. Injury may be either blunt or penetrating, with the latter associated with a higher mortality.

Although most head injuries (70%–80%) are minor, a significant proportion of these patients have poor functional outcomes due to secondary brain insults and co-morbidities. Of the 20%–30% who constitute moderate to severe head injury, approximately 10% of these are dead on admission, whereas the remainder will usually require admission to the intensive care unit (ICU) for management in the first 7–10 days.

PATHOPHYSIOLOGY

Head injury is a heterogeneous pathophysiological process.[8] It encompasses a spectrum of injury that includes the degree of brain damage at the time of injury (primary injury) in addition to insults that occur during the post-injury phase (secondary injury). These processes are depicted in Fig. 77.1.

PRIMARY BRAIN INJURY

The severity of primary injury is determined by the degree of neuronal damage or death at the time of impact. This is the major determinant of outcome from traumatic brain injury.

Primary brain injuries include all types of injury to the brain parenchyma and vasculature. Primary injuries that are associated with adverse outcome include traumatic subarachnoid haemorrhage and non-evacuable mass lesions, particularly in critical parts of the brain, such as the posterior fossa.

ABSTRACT

Traumatic head injury is a global public health problem, with a high mortality and survivors affected by appreciable disability. The epidemiology, aetiology and demography of the disease is changing in high-income as well as low- and middle-income settings. Despite improvements in resuscitation and vital organ support, the management of patients with traumatic head injury in the intensive care unit remains a challenge to all members of the critical care team. Following initial resuscitation, good intensive care management forms the basis of management. This takes priority over brain-specific therapies, which to date remain inconclusive in their efficacy. There is no standard or uniform method of managing traumatic head injury, and practices are determined by local factors (preferences, experience, caseload and resources) and local interpretation of evidence. A debate is emerging about disability in survivors from the varied perspectives of clinicians, families and society; the generation of high-quality evidence remains challenging.

SECONDARY BRAIN INJURY

Secondary brain insults are characterised by a reduction in cerebral substrate availability and use (Box 77.1). Of these, hypotension (defined as a systolic blood pressure of <90 mm Hg [11.97 kPa]), hypoxia (oxygen saturation <90% or PaO_2 <50 mm Hg [6.65 kPa]), hypoglycaemia, hypothermia (temperature <35°C), hyperpyrexia (temperature >39°C) and prolonged hypocapnia ($PaCO_2$ <30 mm Hg [3.99 kPa]) have been associated with worse survival following traumatic brain injury.

Secondary insults may occur during initial resuscitation, transport both between and within hospitals, during anaesthesia and surgery, and in the ICU. These insults may initiate or propagate pathophysiological processes that may damage neurons already rendered susceptible by the primary injury.

INTRACRANIAL INFLAMMATION

As the brain is enclosed within the rigid skull and dura, small increases in intracranial volume result in sharp increases in intracranial pressure (ICP; Monroe–Kelly doctrine). Consequently, the brain is a poorly elastant organ with a limited capacity to accommodate pathological increases in ICP.

Traumatic head injury invokes an inflammatory response characterised by the release of pro- and anti-inflammatory mediators. The consequence of this response is disruption and alteration in the permeability of the blood–brain barrier, glial swelling and alterations in regional and global cerebral blood flow. The extent of this inflammatory process is an important determinant of ICP that may persist for some time following injury. Furthermore, alteration in blood–brain permeability may change the normal physiology of the cerebral circulation and alter the response to intravenous fluids, osmotic diuretics and vasoactive drugs.

CEREBRAL BLOOD FLOW AND AUTOREGULATION

Normally, cerebral blood flow is maintained at a constant rate in the presence of changing perfusion pressures by regional myogenic and metabolic autoregulation. These homeostatic mechanisms are impaired following head injury due to neuronal damage and intracranial inflammation. Research techniques that measure cerebral blood flow have described phases of cerebral blood flow following head injury that include an early hypoperfusive phase, and in a proportion of patients, subsequent hyperaemic followed by vasospastic phases.[9] The clinical significance of these described changes in blood flow and cerebral autoregulation is uncertain but these described changes may be used to provide a rationale for justifying haemodynamic targets during the evolution of the brain injury.

RESUSCITATION

INITIAL ASSESSMENT

The resuscitation of head-injured patients should follow the principles outlined in the Advanced Trauma Life Support (ATLS) guidelines for the early management of severe trauma.[10]

The initial emphasis is directed at assessing and controlling the airway, ensuring adequate oxygenation and ventilation, establishing adequate intravenous access and correcting hypotension. Neurological assessment and brain-specific treatment should follow only after cardiorespiratory stability has been established.

AIRWAY

All patients with severe head injury (traumatic coma), marked agitation or significant extracranial trauma require early oral endotracheal intubation.

Depending on the skill of the operator and available facilities, this should be performed using a rapid sequence induction of anaesthesia with cricoid pressure and in-line immobilisation of the cervical spine.

All head-injured patients should be assumed to have a potential cervical spine injury, and should be immobilised in a rigid collar until that possibility has been appropriately evaluated.

BREATHING (= VENTILATION)

Patients should be ventilated with 100% oxygen using 6–10 mL/kg tidal volumes until blood gas analysis is available.

Oxygenation should be maintained at 80–100 mm Hg (13 kPa) and the ventilator adjusted to achieve a normal arterial carbon dioxide tension (35–40 mm Hg; 4.5–5.0 kPa).

Non-depolarising muscle relaxants and narcotics, such as fentanyl, may facilitate ventilation in the immediate post-intubation period in combative patients.

Empirical hyperventilation during initial resuscitation is not indicated.

CIRCULATION (= CONTROL OF SHOCK)

Prompt restoration of circulating blood volume and restoration of euvolaemia is critical.

Early arterial monitoring for accurate measurement of mean arterial pressure and central venous catheter placement and the administration of blood and drugs is essential. The placement of these lines must not delay volume resuscitation.

Blood transfusion should be commenced as soon as possible in actively bleeding patients with early administration of coagulation factors where appropriate.

Crystalloid, specifically 0.9% saline, is recommended for fluid resuscitation of patients with traumatic brain injury.[11] Hypertonic saline may have a role as a small-volume resuscitation fluid in patients with traumatic brain injury, although there is no evidence of reduced mortality when used in the pre-hospital period.[12]

Vasoactive drugs, such as epinephrine (adrenaline) or norepinephrine (noradrenaline), may be used to defend blood pressure once correction of hypovolaemia is under way. This may be necessary if sedatives or narcotics are co-administered.

DISABILITY (= NEUROLOGICAL ASSESSMENT)

Assessment of neurological function following injury is important to quantify the severity of traumatic brain injury and to provide prognostic information. This may be influenced by associated injuries, hypoxia, hypotension and/or drug or alcohol intoxication.

Recording the mechanism of injury is important, as high-velocity injuries are associated with more neuronal damage. It is important to review ambulance and emergency personnel and records to obtain the most accurate information.

Level of consciousness

A rapid and practical initial assessment of consciousness during initial resuscitation is based on the

Table 77.1 The Glasgow Coma Score – the best response following non-surgical resuscitation is scored

BEST EYES OPEN SCORE		BEST VERBAL RESPONSE		BEST MOTOR RESPONSE	
Spontaneously	4	Orientated, adequate	5	Obeys spoken command	6
On spoken command	3	Disorientated, confused	4	Localised pain	5
To pain	2	Inappropriate words	3	Flexion withdrawal	4
No response	1	Incomprehensible	2	Abnormal flexion	3
		No response	1	Extension	2
		INTUBATED PATIENTS:	5	No response	1
		Appears able to converse	3		
		Questionable ability to converse	1		
		Unresponsive			

Adapted from Teasdale G, Jennett B. Assessment of coma and impaired consciousness. A practical scale. *Lancet*. 1974;2:81–84.

response to incremental stimulation, and the response may be graded as Awake, responsive to Verbal stimulation, responsive to Painful stimulation only or Unresponsive (AVPU).

The Glasgow Coma Scale (GCS) has an established place in the management of traumatic head injury and is the most widely accepted and understood scale.[8] Although originally described as a prognostic index, it provides an overall assessment of neurological function, derived from three parameters: eye opening, verbal response and motor response (Table 77.1).

The best responses in the GCS components should be recorded following cardiorespiratory resuscitation and prior to sedation or anaesthesia. A GCS of 14–15 indicates a mild injury, 9–13 a moderate injury and 3–8 is classified as severe injury (traumatic coma). In severely injured patients or those who are intubated or with ocular or facial trauma, the motor response is the most reliable and reproducible of the three GCS components.

Pupillary responses

Pupil size and reactivity are important when consciousness is impaired. Whilst not part of the GCS, pupillary function should always be assessed and recorded at the same time as the GCS, particularly prior to the administration of narcotics, sedatives or muscle relaxants.

In the absence of traumatic mydriasis, abnormalities of pupil size and reactivity may indicate compression of the third cranial nerve, suggesting raised ICP or impending herniation, particularly when associated with lateralising motor signs and depressed consciousness.

Papilloedema is uncommon in the acute phase of head injuries.

Global peripheral motor function

In addition to the motor response of the GCS, decerebrate or decorticate posturing, hemiparesis or lateralising signs, paraparesis and quadriparesis (given the high association with spinal injuries with traumatic brain injury) should be documented concurrently with the GCS and pupillary responses.

SECONDARY SURVEY

Once the initial assessment is complete and resuscitation under way, a thorough secondary survey, as outlined in the ATLS, is mandatory.

The principles outlined in the initial assessment form the basis for prioritising interventions in the secondary survey. Extracranial causes of hypoxia, such as haemo/pneumothorax, must be excluded and promptly treated. Haemorrhage – both externally from fractures or lacerations and internally from major vascular disruption or visceral injuries – must be aggressively treated until circulatory stability is achieved. There is no place for 'permissive hypotension' in head-injured patients as has been advocated in selected cases of penetrating trauma.

Target mean arterial pressure should be estimated in the context of the patient's premorbid blood pressure. Higher pressures may be necessary in hypertensive or elderly patients. The early use of vasoactive drugs, such as epinephrine or norepinephrine, may be necessary to achieve this.

An approach of 'damage-control surgery' is recommended in patients with traumatic brain injury to minimise secondary insults.[13] In the initial 24–48 hours following injury, only life- or limb-threatening injuries should be addressed, following which patients should be transferred to the ICU for stabilisation and monitoring. Thereafter, semi-urgent surgery, such as fixation of closed fractures or delayed plastic repairs, may be done.[14] Patients with severe traumatic head injury undergoing prolonged emergency surgery should have ICP monitoring placed as soon as possible.

BRAIN-SPECIFIC RESUSCITATION

The place of interventions and therapies specifically directed at reducing ICP has been extensively reviewed

in evidence-based guidelines for the management of severe head injury.[15,16]

HYPERVENTILATION

Ventilation-induced reductions in $PaCO_2$ result in marked reductions in cerebral blood flow and consequently in ICP. However, as cerebral blood flow may be reduced during the initial period following injury, further reductions in cerebral perfusion will result if hyperventilation is used during this phase. Consequently, empirical hyperventilation is not indicated during initial resuscitation.[17]

In the resuscitated head-injured patient with unequivocal clinical signs of raised ICP or impending tentorial herniation (new pupillary dilatation or lateralising signs or a witnessed neurological deterioration), temporary hyperventilation is an option. Reductions of $PaCO_2$ to levels ≤30 mm Hg (4 kPa) may be considered prior to urgent imaging or surgery for evacuation of a mass lesion.

OSMOTHERAPY

Osmotically active agents, such as mannitol, are administered to increase plasma osmolality to cause net efflux of fluid from areas of oedematous brain, with resultant reduction in ICP. An intact blood–brain barrier is necessary for this to occur. Following intravenous administration of mannitol, an immediate plasma-expanding effect that reduces haematocrit and viscosity ensues, which temporarily increases cerebral blood flow. Subsequent reductions in ICP may result from restoration in cerebral perfusion pressure (CPP) and rheological changes in cerebral blood flow rather than specific cerebral dehydration.

Osmotherapy is associated with several potential adverse effects. Mannitol exerts an osmotic effect over a narrow range of plasma osmolality (290–330 mOsm/L), above which theoretically beneficial effects may be negated, and induces an osmolal gap between measured and calculated osmolality. This gap may be increased by alcohol, which is frequently present in the acute period. Mannitol will enter the brain where the blood–brain barrier is damaged, thereby potentially increasing cerebral oedema by increasing brain osmolality. It is a potent osmotic diuretic that may compromise haemodynamic stability by inducing an inappropriate diuresis in a hypovolaemic patient.

Given the high risk with minimal benefit during resuscitation, the routine use of mannitol is not recommended in the absence of raised ICP.[15]

Similarly to hyperventilation, mannitol can be considered in resuscitated patients with unequivocal signs of raised ICP prior to imaging or evacuation of a mass lesion. Although doses are frequently quoted as 0.25–1.0 g/kg, lower doses are equally as effective as higher doses in terms of improving cerebral perfusion and are associated with a lower incidence of side effects.

Hypertonic saline (3% solution) exerts similar osmotic plasma-expanding effects to mannitol. These solutions do not exert an osmolal gap so serum sodium reflects serum osmolality allowing easier titration.[14]

EMERGENCY SURGICAL DECOMPRESSION ('BURR HOLES')

The advent of advanced in-field resuscitation, medical retrieval, imaging, teleradiology and telemedicine in high-income countries has largely superseded the need to perform urgent, undirected craniotomy in patients with traumatic head injury. In most instances, patients are resuscitated, stabilised and imaged with computed tomography (CT) scans prior to any surgical intervention. This usually involves transfer to a specialised trauma centre.

In remote communities or in low- and middle-income countries without immediate access to CT scanning, surgical evacuation may be life saving in selected patients with a strong clinical probability of an expanding mass lesion, such as an extradural or subdural haematoma. These include patients with low-velocity injuries to the temporal region with an associated skull fracture and evolving lateralising neurological signs.

IMAGING

X-RAYS

Routine 'trauma series' of X-rays, namely chest, pelvis, skull and cervical spine, have been superseded by high-resolution, multislice CT. In areas without immediate access to CT, X-rays should focus on identifying injuries or confirmation of placement of lines and tubes post resuscitation.

COMPUTED TOMOGRAPHY SCAN

CT scanning is now standard in all patients following traumatic head injury. As CT scanning requires moving the patient to a radiological suite, this must be done only when initial assessment and resuscitation are complete and the patient is stable enough to be transported by appropriately trained and equipped personnel.

The following patients should undergo CT head scan following traumatic head injury:

- all patients with a history of loss of consciousness or traumatic coma (GCS <8)
- combative patients where clinical assessment is masked by associated alcohol, drugs or extracranial injuries; these patients may require endotracheal intubation, sedation and ventilation to facilitate completion of CT scanning
- to exclude a cervical spine injury.[18]

The most important role of CT scanning is prompt detection of intracranial mass lesions such as extradural

Table 77.2 Classification of computed tomography scan appearance following traumatic brain injury*

CATEGORY	DEFINITION
DI I (diffuse injury)	No visible intracranial pathology seen on CT scan
DI II (diffuse injury)	Cisterns are present with midline shift 0–5 mm and/or: Lesion densities present No high- or mixed-density lesion >25 mm May include bony fragments and foreign bodies
DI III (swelling)	Cisterns are compressed or absent with midline shift 0–5 mm No high- or mixed-density lesion >25 mm
DI IV (shift)	Midline shift >5 mm No high- or mixed-density lesion >25 mm
Evacuated mass lesion	Any lesion surgically evacuated
Non-evacuated mass lesion	High- or mixed-density lesion >25 mm, not surgically evacuated

*An example is shown in Fig. 77.2A.

CT, Computed tomography.

Adapted from Marshall L, Marshall SB, Klauber M, et al. The diagnosis of head injury requires a classification based on computed axial tomography. *J Neurotrauma*. 1992;9:S287–S292.

or subdural haematomas. Thereafter, the degree of brain injury may be quantified by radiological criteria (Table 77.2 and Fig. 77.2A).[19]

These criteria are important for providing an index of injury severity, providing criteria for ICP monitoring, comparing the progression of injuries with subsequent scans and providing an index for prognosis. Examples of typical injuries appear in Fig. 77.2A and B.

The presence of traumatic subarachnoid haemorrhage should be recorded. This is an important index of severity of injury and is relevant for prognostication.[20]

MAGNETIC RESONANCE IMAGING

Magnetic resonance imaging (MRI) provides accurate details of parenchymal damage, specifically small collections and non-haemorrhagic contusions. The information provided is not significantly better than that obtained from CT scanning to warrant routine use of MRI in the acute phase of injury.

In patients when a major intracranial vascular injury is suspected, such as carotid artery dissection where the patient's clinical condition is not consistent with the CT findings (e.g. a dense hemiparesis in the absence of a mass lesion), magnetic resonance angiography or direct cerebral angiography is indicated.

MRI has an emerging role in prognostication at a later stage in management.[21]

INTERHOSPITAL TRANSFER

All severely head-injured patients should be managed at a specialised neurotrauma centre in close collaboration with intensive care physicians and neurosurgeons. This may involve intra- or interhospital transportation. Appropriately skilled and equipped personnel should do this only once resuscitation, stabilisation and initial imaging are completed.

A full primary and secondary survey and review of all documentation and investigation is required following transfer to a secondary or tertiary centre.

INTENSIVE CARE MANAGEMENT

The Brain Trauma Foundation of the American Association of Neurological Surgeons has published iterative evidence-based recommendations for the management of severe brain injury for treatment and monitoring for areas where sufficient evidence is available for synthesis.[15] The stated intention is that the recommendations are used by clinicians to develop protocols, incorporating local consensus and clinical judgment, for the many areas where currently high-quality evidence is lacking or insufficient. There is therefore no standard or uniform method of managing traumatic head injury in the ICU. Most practices are determined by local preferences and experience, caseload and resources.

Following initial resuscitation, good intensive care management forms the basis of head injury management and is regarded as a continuum of care. This takes priority over brain-specific therapies, which to date remain inconclusive in their efficacy.

HAEMODYNAMIC MANAGEMENT

Monitoring

Accurate measurement of systemic blood pressure is essential and should be measured via an arterial catheter referenced to the aortic root. A large artery, such as the femoral artery, should be considered in haemodynamically unstable patients as radial or dorsalis pedis arterial catheters may underestimate systemic pressure in shocked patients. Given the importance of maintaining adequate systemic blood pressure, non-invasive measurement of blood pressure is not recommended during the acute phase of monitoring.

Maintaining systolic blood pressure (SBP) at ≥100 mm Hg for patients 50–69 years old or at ≥110 mm Hg or above for patients 15–49 or over 70 years old is recommended.[15]

Volume status should be assessed using clinical criteria including an estimate of fluid and blood losses from the available history, pulse rate, mean arterial

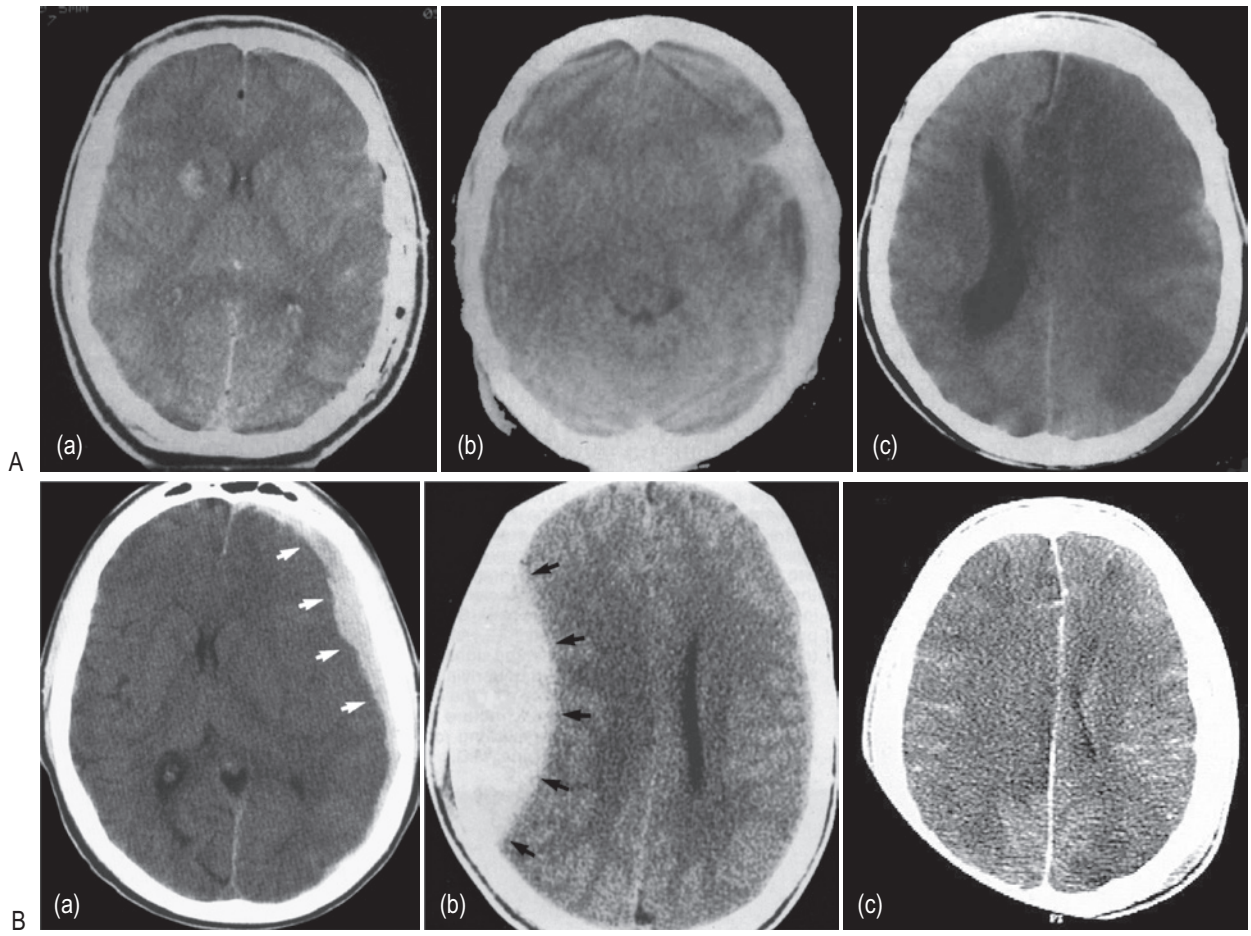

Figure 77.2 (A) Computerised tomographic classification of diffuse axonal injury (see Table 77.2): panel *(a)* diffuse injury II; panel *(b)* diffuse injury III; panel *(c)* diffuse injury IV. pressure, urine output, serum sodium and osmolality, urea and creatinine.

Pulmonary artery catheterisation and other advanced haemodynamic monitoring techniques for the measurement of cardiac output and pulmonary artery pressures are rarely indicated in head-injured patients and are not recommended.

Fluid management

The attainment of euvolaemia is essential throughout intensive care management; both dehydration and fluid overload should be avoided.

0.9% saline is the resuscitation fluid of choice for patients with traumatic brain injury. The use of albumin is associated with increased ICP and mortality; whether this applies to other colloids is unknown but, on current evidence, resuscitation with colloids should probably be avoided.[11] Equally, hypotonic crystalloids, such as compounded sodium lactate (Ringer's lactate or Hartmann's solution), should be avoided.

Maintenance fluids should be restricted to a minimum and directed at maintaining normal serum sodium (140–145 mmol/L) and osmolality (290–310 mOsmol/L). As a general principle, glucose-containing solutions are not recommended; however, these may be required if patients become hyperosmolal (>320 mOsm/L).

Vasoactive therapy

Catecholamines such as epinephrine, norepinephrine or dopamine are frequently used to augment mean arterial pressure to attain an adequate CPP. These should be commenced once volume resuscitation is actively under way. The early use of vasoactive drugs is increasingly being advocated during resuscitation as an important strategy during the hypoperfusion phase.[22]

There are no conclusive trials to recommend one vasoactive drug over another or a combination of drugs. Epinephrine, norepinephrine and dopamine are equally effective in augmenting CPP.[23] The degree by

which these agents directly affect the cerebral circulation following head injury is unknown, although there is some evidence suggesting that dopamine has both direct cerebrovascular and adverse neuroendocrine effects.

Norepinephrine is currently regarded as the initial agent of choice for patients with traumatic brain injury in doses titrated to achieve a target mean arterial or CPP. Epinephrine is widely used, particularly in low-income countries, but may be associated with transient metabolic side effects such as hyperlactataemia and hyperglycaemia, which may confound assessment of the adequacy of circulatory and metabolic resuscitation.[24]

Doses may range widely between and within patients to attain a target CPP. However, excessive doses of catecholamines (i.e. >40 µg/min) should be avoided, particularly after 72 hours after injury when lower CPP targets (i.e. 40–60 mm Hg) may be appropriate.[9] At all times, other causes of hypotension, such as dehydration, sedatives, bleeding and sepsis, must be excluded.

Vasopressin is commonly used as a catecholamine-sparing agent or as a primary vasopressor in septic and distributive shock, but its role in traumatic brain injury has not been established and is not recommended.

Neurogenic hypertension

Neurogenic hypertension is common in the latter phases following injury (>5 days) and is usually centrally mediated. It may be associated with electrocardiography changes and/or supraventricular arrhythmias. It is usually self-limiting and correlates with the severity of injury, although a small proportion may require long-term therapy. Treatment depends on the severity of the problem: beta blockers or centrally acting agents, such as clonidine, are usually effective in the short- to medium-term; vasodilators are contraindicated.

RESPIRATORY THERAPY

Monitoring

Continuous measurement of arterial oxygen saturation is essential.

Continuous measurement of end-tidal carbon dioxide is frequently performed in ventilated patients, although the reliability is questionable and should be intermittently checked with arterial blood gases to maintain normocapnia.

The monitoring of ventilatory parameters should be consistent with standard approaches and includes measurement of tidal volumes, respiratory rates, and inspiratory and expiratory airway pressures.

Ventilation

Most patients with severe head injury will require mechanical ventilation to ensure adequate oxygenation and to maintain normocapnia (36–40 mm Hg; 4.8–5.3 kPa).

The principles of optimal ventilation, humidification and weaning are addressed elsewhere. Strategies such as 'permissive hypercapnia' that are advocated for selected patients with acute lung injury or acute respiratory distress syndrome do not have a role in head-injured patients owing to the requirement to maintain normocapnia.

Positive end-expiratory pressure (PEEP) is recommended at low levels (5–10 cm H_2O) to maintain functional residual capacity and oxygenation. Higher levels may compromise systemic blood pressure, particularly in hypovolaemic patients, and should be used with caution. High levels of PEEP (>15 cm H_2O) may compromise cerebral venous return but adverse effects on ICP are uncommon.

Weaning from ventilation should commence once intracranial pathology has stabilised – that is, the resolution of cerebral oedema on CT scan and the control of intracranial hypertension.

Extubation should be carefully considered so that subsequent hypoxic episodes do not occur, as these are potent secondary insults.

Patients with slow recovery of adequate consciousness should be considered for early tracheostomy, either percutaneously or surgically.

Neurogenic pulmonary oedema

This is a dramatic clinical syndrome that occurs in some patients with severe head injury and correlates with the severity of injury. The underlying pathophysiological process is complex, but is primarily related to centrally mediated sympathetic overactivity. It is characterised by the sudden onset of clinical pulmonary oedema, hypoxia, low filling pressures, poor lung compliance and bilateral lung infiltrates, usually within 2–8 hours following injury.

The process is usually self-limiting and treatment is primarily supportive, aimed at ensuring adequate oxygenation and ventilation. This usually requires endotracheal intubation and mechanical ventilation with the administration of PEEP. Ablation of sympathetic overactivity is effectively done with adequate sedation; beta blockade is usually unnecessary. Diuretics are effective, particularly if patients have received substantive fluid resuscitation, and must be titrated against the volume status of the patient.

The development of pulmonary oedema in patients with cardiac disease should be regarded as cardiogenic until proven otherwise.

Nosocomial pneumonia

Head-injured patients who require prolonged ventilation are at increased risk of nosocomial pneumonia. Risk factors include the severity of the head injury, barbiturate use and hypothermia therapy. Diagnosis and treatment are discussed elsewhere.

SEDATION, ANALGESIA AND MUSCLE RELAXANTS

There are no standards for sedation and analgesia in head-injured patients – protocols will depend on

local preferences and resources. The level of sedation and analgesia required for head-injured patients depends on the degree of traumatic coma, haemodynamic stability, ICP and systemic effects of the head injury itself.[15]

During the initial resuscitation phase, sedation should be titrated to cause the least effect on systemic blood pressure. During this period, short-acting narcotics, such as fentanyl, are useful, particularly if patients have associated extracranial injuries. These agents have relatively little adverse effect on haemodynamics and have the additional benefit of tempering the systemic sympathetic surges that frequently occur after injury. As narcotics affect pupillary responses, these must be documented before administration. Short-term muscle relaxants, such as vecuronium, are useful to control combative patients following intubation, ventilation and sedation.

During the intensive care phase, the requirements for sedation are different. Sedation should be titrated to have the patient sedated as lightly as possible to allow clinical assessment of neurological function and to facilitate mechanical ventilation. The level of sedation will depend on haemodynamic stability and ICP. Infusions of narcotics and benzodiazepines (e.g. morphine and midazolam) are useful in providing moderate to deep levels of sedation and are effective in controlling surges of ICP. However, these agents may accumulate, resulting in a delay in the return of consciousness or may be associated with an emergent delirium state or other nosocomial complications related to increased length of stay.

The use of propofol as a sole sedating agent has become popular. It provides deep levels of sedation, which is effective in controlling systemic sympathetic swings and rises in ICP. It is rapidly reversible on cessation allowing prompt assessment of neurological status and does not accumulate. In addition, pupillary responses are not directly affected. Propofol should be used with caution in haemodynamically unstable patients, however, as it is a potent vasodilator and negative inotrope. The prolonged use of propofol is associated with tachyphylaxis and significant caloric loading from the lipid vector. Concerns have been raised about myocardial depression and sudden cardiac death, particularly if large doses are administered.[25]

The routine use of muscle relaxants is not recommended either to facilitate sedation or to control raised ICP.

BODY POSITION AND PHYSIOTHERAPY

Patients should be nursed at 30–45 degrees head elevation to facilitate ventilation, improve oxygenation and reduce the risk of aspiration. The head should be kept in a neutral position.

Physiotherapy has an important role in the removal of lung secretions and the prevention of contractures and venous thrombosis. Patients with raised ICP may require boluses of sedation before chest physiotherapy to prevent acute rises in ICP.

METABOLIC MANAGEMENT

Routine measurement of biochemistry is essential.

Hyperglycaemia is common following severe head injury and is usually centrally mediated and transient. Blood sugar levels should be maintained with insulin infusions if necessary, between 6.0 and 10.0 mmol/L; hypoglycaemia should be avoided and is less likely with this strategy, compared to strategies that target normoglycaemia (4.4–6.1 mmol/L).[26]

Core temperature should be routinely monitored, as both hypothermia (<35°C) and hyperthermia (>39°C) have been associated with adverse outcomes and may contribute to secondary injury.[27,28]

NUTRITION

The caloric needs of head-injured patients must be addressed following resuscitation. Early enteral feeding is recommended.[15]

Placement of a nasogastric and/or enteral feeding tube in head-injured patients is usually via the oral route until an anterior cranial fossa (fractured cribriform plate) is excluded.

STRESS ULCER PROPHYLAXIS

The incidence of gastric erosions and 'stress ulceration' has markedly decreased with better resuscitation and early enteral feeding. Head-injured patients are at no more risk than other critically ill patients for developing stress ulceration.

H_2 antagonists or proton pump inhibitors should be used in ventilated patients until enteral feeding is established, following which they may be ceased.

Patients with a history of recent peptic ulceration should remain on proton pump inhibitors for the duration of the intensive care stay.

THROMBOPROPHYLAXIS

Head-injured patients, particularly those requiring prolonged ventilation and sedation or with extracranial injuries, are at increased risk for developing thromboembolism.

The use of anticoagulants, such as fractionated or low-molecular-weight heparins, is contraindicated in patients with clinically significant intracranial haemorrhage. Consequently, the role of pharmacological thromboprophylactic agents in head injury is difficult and there are no standards for their use.[15]

Generally, anticoagulants should not be used in head-injured patients with any evidence of destructive intracranial pathology or haemorrhage unless there is resolution or stabilisation of these processes on CT scan.

Non-pharmacological methods of thromboprophylaxis, such as elastic stockings or pneumatic calf compressors, are of unproven effectiveness but are a

reasonable first approach. Surveillance using Doppler ultrasound of the iliofemoral veins in high-risk patients, such as those with pelvic fractures, should be considered.

Pharmacological prophylaxis may be considered after the period of ICP guided management has been completed, and stabilisation or resolution of intracranial pathology, as indicated on serial cranial CT scans, has occurred.

Patients who develop deep-vein thromboses and who cannot be anticoagulated should be considered for inferior vena caval filters. The use of anticoagulants in head-injured patients with proven pulmonary embolism will depend on the relative risk to the patient's life.

ANTIBIOTICS

These should be used sparingly and in accordance with accepted microbiological principles. Prophylactic antibiotics should be prescribed only to cover insertion of ICP monitors and are not recommended for basal skull fractures. Frequent cultures of leaking or draining cerebrospinal fluid should be taken and infection specifically treated.[15]

BRAIN-SPECIFIC MONITORING

The most accurate assessment of brain function following traumatic brain injury is a full clinical neurological examination in the absence of drugs or sedatives. However, this is often not possible for most head-injured patients managed in the ICU.

Ideally, neuromonitoring should provide accurate and integrated information about ICP, patterns and adequacy of cerebral perfusion, and an assessment of cerebral function. No such monitor exists, although each of these parameters may be monitored in various ways with variable levels of accuracy and clinical utility.

CLINICAL ASSESSMENT

Regular assessments of GCS, pupillary signs and motor responses should be made and recorded in the ICU flow chart. Concomitant sedation may influence the level of consciousness and this should be recorded. Initially, these assessments are recorded hourly, but this may change as patients become more stable.

A witnessed deterioration in GCS, especially the motor response, or the development of new lateralising signs should be regarded as life-threatening intracranial hypertension or tentorial herniation until proven otherwise.

INTRACRANIAL PRESSURE MONITORING[15]

The recognition that raised ICP is associated with adverse outcome led to the measurement of this parameter to quantify the degree of injury and to assess the response to treatments directed at reducing ICP.

Indications

The Brain Trauma Foundation guidelines recommend the ICP monitoring of all salvageable patients with:

- Traumatic coma (GCS 3–8 after resuscitation) and an abnormal CT scan defined by the presence of hematomas, contusions, swelling, herniation or compressed basal cisterns.
- Traumatic coma (GCS 3–8 after resuscitation) with a normal CT scan if ≥2 of the following features are noted at admission: age greater than 40 years, unilateral or bilateral motor posturing or SBP less than 90 mm Hg.

Coagulopathy is a relative contraindication to ICP monitoring.

Methods

The measurement of ICP with an intraventricular catheter is the most accurate and clinically useful method. It has the advantages of zero calibration and drainage of cerebrospinal fluid drainage. Disadvantages include technical difficulty with insertion, particularly in patients with cerebral oedema and compression of the lateral ventricles, and an increased incidence of infection.

Solid-state systems, such as fibre optic (e.g. Camino) or strain gauge tipped catheters (e.g. Codman), may be placed intraparenchymally or intraventricularly. These systems transduce ICP to provide high-fidelity waveforms. They are small calibre and, although requiring a small craniotomy (burr hole) for insertion, may be inserted at the bedside. Disadvantages include the inability to perform zero calibration after insertion and baseline drift, which may be significant after 5 days.

Fluid-filled subdural catheters have been used for many years. However, these are no longer recommended owing to the development of more accurate solid-state systems. Subdural pressures do not accurately reflect global ICP, particularly in the presence of a craniectomy. Pressure readings may also be affected by local clot formation within the catheter.

Thresholds

Measurements are used to calculate CPP: mean arterial pressure minus ICP. For this calculation, both measurements should be referenced to the external auditory meatus (equivalent to the circle of Willis).

ICP monitoring should be continued until the patient can be assessed clinically and ICP has stabilised (<20 to 25 cm H_2O). This occurs in the majority of patients within 7 days. Patients with refractory intracranial hypertension may require monitoring for longer periods, although this may be complicated by drift (with solid-state systems), infection (with intraventricular catheters) or occlusion (subdural catheters). In this situation, ICP monitors may need to be replaced or removed and patients assessed by serial CT scan or clinically.

CEREBRAL BLOOD FLOW MONITORING

Currently, there is no method of routinely measuring cerebral blood flow at the bedside. Technological advances, such as mapping with labelled xenon under CT and laser Doppler flowmetry, provide useful imaging of regional and cerebral blood flow. However, these techniques are intermittent, labour-intensive and limited to research-based units.

Several qualitative measurement techniques are available that provide an indirect assessment of cerebral blood flow and have a limited and undefined role in routine management.

Jugular bulb oximetry

The measurement of oxygen saturation in the jugular bulb by the retrograde placement of a fibre optic catheter provides an indirect assessment of cerebral perfusion. Low jugular venous saturations (<55%) may be indicative of cerebral hypoperfusion, whereas high levels of jugular venous saturation (>85%) may be indicative of cerebral hyperaemia or inadequate neuronal metabolism, such as occurs during the hyperaemic phase or during the evolution of brain death. Both low and high jugular venous saturations are associated with adverse outcomes.[29]

There are insufficient data to provide evidence-based indications for the routine use of jugular bulb oximetry. Its use is limited to experienced units when an index of cerebral blood flow may be required during adjunctive therapies in patients with intracranial hypertension, for example augmentation with catecholamines, barbiturate coma, hyperventilation or induced cooling.

Transcranial Doppler

Transcranial Doppler ultrasonography with a 2-MHz pulsed Doppler probe allows non-invasive, intermittent or continuous assessment of the velocity of blood flow through large cerebral vessels. Directing the probe through a naturally occurring acoustic window, such as the transtemporal approach, allows insonation of the anterior, middle and posterior cerebral arteries, the terminal internal carotid artery and the anterior and posterior communicating arteries. However, the technique is operator-dependent and there may be significant variations in velocity patterns during the course of the injury. Measured indices of flow include systolic, mean and diastolic flow velocities.

Distinct patterns associated with normal, hyperaemic, vasospastic and absent flow are recognised. Derived indices, such as the Gosling pulsatility index (systolic/diastolic difference divided by the mean velocity) and the Lindegaard ratio (between middle cerebral artery to extracranial internal carotid artery), may assist in differentiating these flow patterns.

Despite the increasing use of transcranial Doppler to diagnose post-traumatic hyperaemia and vasospasm, there are insufficient data to provide evidence-based indications for its routine use.

CEREBRAL FUNCTION AND METABOLISM

Electroencephalography

Electroencephalography has been used for many years to assess seizure activity that may be masked by sedatives or muscle relaxants and to provide an objective estimate of the degree of electrical neuronal depression with barbiturate therapy. Although seizures may not be clinically apparent in a proportion of patients, and may constitute an important secondary insult, the accuracy and reliability of electroencephalography in ICU is questionable owing to outside electrical interference from monitors and ventilators.[30]

The development of bispectral index (BIS monitoring) as a measurement of depth of anaesthesia has led to the suggestion that this may be an alternative to the use of electroencephalography with barbiturate or sedative therapy in traumatic head injury. Nevertheless, BIS has not been validated in this context and cannot be recommended as a titration end-point.[31]

Evoked potentials

Measurement of evoked potentials, assessing the integrity of sensory and motor pathways, may provide diagnostic and prognostic information; however, because of the complexity of the technique it is not recommended for general use. The reliance on one variable, such as evoked potentials, to predict the outcome from a traumatic head injury is not recommended.[32]

Neuronal function

Research developments in microprobe technology have resulted in specific electrodes that may be placed into the brain parenchyma to measure tissue brain oxygen tension, brain temperature, pH, lactate and carbon dioxide tensions. These may be individual electrodes or combined with other sensors, such as pressure monitors, to form multimodal tissue monitors.[15]

Cerebral microdialysis is a technique that measures brain extracellular fluid metabolites. Dialysate is obtained through a microdialysis catheter inserted through the same burr hole as an ICP monitor to measure time-dependent changes in markers of neuronal health (e.g. glucose, lactate, pyruvate and other indices of inflammation and metabolism).

Although these systems provide highly specific information about the biochemical milieu of focal areas of brain tissue, their clinical utility is limited to research centres.

BRAIN INJURY SURVEILLANCE

Serial assessment of the anatomical injury is an important part of monitoring head injury. This is done by serial CT scanning at frequent intervals depending on the neurological status of the patient.

Any patient who develops an unexplained neurological deterioration or significant validated deviation of monitored parameters should have a CT scan so that new or delayed intracranial mass lesions are identified.

CT scans should be assessed and scored according to the classification outlined in Table 77.2. The progression or resolution of axonal injury, cerebral oedema, contusion and haemorrhages should be recorded. However, as CT scanning requires transport of the patient to a radiology suite, this should be done only by experienced personnel, when the patient is stable.

BRAIN-SPECIFIC THERAPY

Treatment options directed at ameliorating brain injury are limited. Despite intensive research into defining the pathobiological processes in primary injury, studies analysing therapies designed to modulate intracranial inflammation have not been successful. These include aminosteroids, calcium channel blockade, *N*-methyl-D-aspartic acid antagonists and erythropoietin.

Brain-specific or 'targeted' therapy is directed at maintaining CPP and minimising ICP. Although there is an inherent relationship between these two principles, priorities are different depending on the time course of the underlying injury. This is important as strategies directed at one may have adverse effects on the other.

DEFENCE OF CEREBRAL PERFUSION PRESSURE

The Brain Trauma Foundation guidelines recommend a range of CPP of between 60 and 70 mm Hg.[15] The guidelines also state that the minimum optimal CPP threshold is unclear and may depend upon the autoregulatory status of the patient and varies with time after injury. CPP targets maybe prescribed based on an early hypoperfusive phase and a subsequent hyperaemic phase that have been described in literature.

Early hypoperfusion phase

Soon after injury, cerebral hypoperfusion is present in many patients with severe head injury (GCS ≤8). During this phase, there is an imperative to maintain CPP by supporting systemic haemodynamic function. CPP of at least 60 mm Hg is recommended.

In addition to reduced cerebral blood flow, ICP may be increased by mass lesions or 'cytotoxic' cerebral oedema. During this phase, medical therapies directed at raised ICP, such as osmotherapy or hyperventilation, should be used only if CPP is maintained at an appropriate level and the patient is adequately monitored.

Assessment of adequacy of the response to augmentation of CPP is made by ICP trends, CT scan appearance and, where possible, neurological assessment. If patients appear to have stabilised, sedation may be reduced with the aim of extubation.

Hyperaemic phase

Approximately 25%–30% of patients will develop clinical signs of cerebral hyperaemia, characterised by increased ICP and persistent cerebral oedema on CT scan from 3 to 7 days after brain injury. This may occur due to vasogenic cerebral oedema caused by intracranial inflammation or be associated with increased catecholamines requirements (e.g. >40 μg/min of epinephrine or norepinephrine) to maintain a CPP of 60–70 mm Hg.

In this context, lowering the target CPP target can be considered.

If patients continue to have raised ICP, strategies directed at reducing ICP should be considered.

REDUCTION OF INTRACRANIAL PRESSURE[15]

In the absence of intracranial mass lesions, raised ICP is usually an indicator of severity of the underlying injury and represents exhausted intracranial elastance.

The most effective methods of reducing raised ICP are mechanical interventions such as the removal of mass lesions, the drainage of cerebrospinal fluid or a decompressive craniectomy.

Several medical strategies directed at reducing ICP have been used for many years. Despite widespread use and firmly held beliefs, there is little evidence to support the routine use of these therapies.

ICP should be maintained at less than 20–25 cm H_2O. Trends of ICP are equally as important and should be assessed within the context of CPP and the methods used to defend it.

Surgical evacuation of mass lesions

The prompt detection and evacuation of mass lesions causing raised ICP is the most effective method of relieving intracranial hypertension. Although many of these lesions will be present immediately after injury and will be treated during the resuscitative phase, approximately 10% of patients will develop delayed intracranial haematomas. These are detected by acute unexplained rises in ICP or by CT scan surveillance.

Cerebrospinal fluid drainage

Drainage of cerebrospinal fluid through an intraventricular catheter is an effective method of reducing ICP. If present, these catheters should be placed 5–10 cm above the head and opened for drainage every 1–4 hours.

Decompressive craniectomy

Unilateral or bilateral, frontoparietal craniectomies are highly effective in reducing elevated ICP after traumatic coma.

However, two large, randomised, controlled trials of early and late decompressive craniectomy in patients with traumatic intracranial hypertension have provided important information for understanding the role of surgery. Early decompressive craniectomy did not improve mortality or clinical outcomes of survivors[33] and later decompressive craniectomy, performed because of a raised ICP that was refractory to medical management, not only reduced mortality, but also was associated with an overall increase in disability in

survivors.[34] The role of decompressive craniectomy is now questioned in these patients.

Osmotherapy

The rationale and role of osmotherapy using mannitol or hypertonic solution are addressed above (in the section 'Brain-specific resuscitation'). These same principles also apply during intensive care management.

Mannitol or hypertonic saline should be used only in patients with validated intracranial hypertension who are euvolaemic, haemodynamically stable, with a serum osmolality less than 320 mOsm/L.

There is no evidence that osmotherapy or induced dehydration improves outcome or is more effective in cytotoxic than vasogenic cerebral oedema.[15]

Hyperventilation

The role of hyperventilation during intensive care management is limited to the indications outlined in the section 'Brain-specific resuscitation'.

The routine prolonged use of hyperventilation in head-injured patients is associated with a worse outcome than patients ventilated to normocapnia. This is probably due to the reduction of cerebral blood flow and secondary brain ischaemia.

Current evidence-based guidelines do not recommend the use of routine hyperventilation.[15,17]

Hypothermia

Induced physical cooling reduces cerebral metabolism and tissue oedema, modifies inflammation and reduces ICP.

Induced hypothermia has been used early after injury for prophylactic cerebral protection and later after brain injury to control intracranial hypertension.

However, experimentally demonstrated benefits have not been translated in clinical trials.[35,36]

Active cooling often requires the use of sedatives, neuromuscular blockade and additional antishivering strategies, and the intervention may be associated with hypotension and reduced cerebral blood flow, altered vital organ function, delayed drug metabolism, prolonged length of stay and associated nosocomial complications.

Induced hypothermia for prophylactic early cerebral protection or for raised ICP cannot be recommended.

Avoiding pyrexia ('normothermia')

Pyrexia is common after traumatic brain injury as core temperature gradually increases with time after brain injury.

Experimental models and clinical cohort studies report an association between pyrexia and adverse outcome,[27,28] but the effect of avoiding pyrexia on patient-centred outcomes has not been evaluated. Avoiding pyrexia is challenging as pharmacological agents have modest effects (reducing the temperature by <0.5°C),[37] and the use of induced cooling may be associated with adverse effects as outlined earlier.

The Brain Trauma Foundation does not make a recommendation on avoiding pyrexia, reflecting an absence of appropriate evidence. Avoiding pyrexia cannot be recommended, but remains a common goal in clinical practice (<39°C).

Barbiturate coma

The role of barbiturates in traumatic head injury is similar to hypothermia. Despite experimental evidence that barbiturates reduce cerebral metabolism and reduce ICP, no definitive studies have shown a benefit in clinical trials. Barbiturates have invariably been used in patients with refractory intracranial hypertension where a positive outcome was unlikely, making interpretation of these trials difficult.

Barbiturates may cause hypotension and reduce cerebral blood flow, potentially exacerbating secondary insults in patients with cerebral oligaemia. Prolonged use of barbiturates will delay awakening and predispose the patient to nosocomial complications.

Barbiturates are not recommended on current evidence.[15]

Steroids

Steroids have been advocated for many years to ameliorate intracranial inflammation, thereby reducing ICP. A large international study has provided conclusive evidence that high doses of steroids are associated with adverse outcomes in traumatic head injury, and therefore have no place in management.[15,38]

SEIZURE PROPHYLAXIS

Seizures are infrequent following traumatic head injury and usually present at the time of injury. These should be treated with anticonvulsants (e.g. diazepam, midazolam) when they occur. Subsequent prophylaxis with phenytoin or valproate may be considered for patients with destructive parenchymal lesions on CT scan to prevent early post-traumatic seizures (within 7 days). Short-term seizure prophylaxis does not prevent late-onset post-traumatic epilepsy.[15]

OUTCOME AND PROGNOSIS

Patient factors that determine outcome from traumatic head injury include severity of primary and secondary injuries, traumatic coma (GCS <8), age greater than 60 years, cranial CT scan findings and co-morbidities. Prediction of outcome is difficult as significant functional improvements, particularly in young patients, may occur over time.

There are patients in whom the prognosis is clearly very poor or hopeless. A proportion of these patients will become brain dead and may be considered for organ donation. In other patients, it may be

appropriate to withdraw active treatment. This increasingly complex process requires time, careful consideration and consensus with all members of the health care team and the patient's relatives.

Outcomes from traumatic head injury are difficult to quantify. Although mortality is an easy end-point to measure, functional outcome is an equally important measurement as the effects of traumatic brain injury on psychosocial recovery and duration of rehabilitation often take extended periods of time. In an inception cohort study of patients hospitalised with traumatic head injury in Australia and New Zealand, at 12 months after injury 26.9% of the population had died, and a further 42.7% had moderate or severe disability, or were in a vegetative state.[39] Importantly, even in the group classified as having good recovery (30.4%), over half had impairment of relationships with families or friends, or restriction of social and leisure activities. There is an important debate emerging about the interpretation of disability after brain injury from the varied perspectives of clinicians, families and health care service providers.[40]

CONCLUSION

Severe traumatic head injury is an important and heterogeneous global health problem, with evolving demography and disease patterns. The intensive care management of the condition is challenging and the cornerstone of management remains general intensive care, with brain-specific therapies of unproven efficacy beyond improvements in short-term physiology. There is no standard or uniform method of managing traumatic head injury, and practices are determined by local factors (preferences, experience, caseload and resources) and local interpretation of evidence. Generating high-quality evidence in this context remains a challenging endeavour.[41]

Maxillofacial and upper-airway injuries

Cyrus Edibam, Hayley Robinson

MAXILLOFACIAL INJURIES

Blunt or penetrating maxillofacial injuries may be isolated or part of multisystem trauma. Life-threatening associated injuries occur in 6.2% of patients with facial injuries and commonly include head, cervical spine and chest injury.[1] Life-threatening airway haemorrhage and airway obstruction are challenging issues and require skilled airway management to prevent adverse outcomes. This chapter outlines the basic anatomy, pathology, complications and common pitfalls in the emergency management of maxillofacial and upper-airway trauma.

EPIDEMIOLOGY

Maxillofacial trauma occurs most frequently in the 15- to 25-year age group and occurs three to five times more often in males than in females.[1–3] Blunt injury mechanisms account for nearly 98% of all maxillofacial injuries.[4] Motor vehicle trauma and physical assault account for the majority of injuries, with the remainder being due to falls, contact sports and industrial accidents.[2,3] The distribution of mechanisms is dependent on demographics and socioeconomic status. Preceding use of alcohol is widely variable and particularly dependent on age group.[3] In multiple trauma patients with an Injury Severity Score >15, maxillofacial injury occurs in up to 16%, with a corresponding mortality rate of 10.5%.[4]

ANATOMICAL ASPECTS

Fractures, haemorrhage, soft-tissue damage and oedema are the commonest manifestations of blunt facial trauma. The severity of facial injury is directly related to the velocity of force applied. Common maxillofacial fractures involve the midface (including orbital) (71.5%), mandible (24.3%) and frontal bone (4.2%).[5]

MANDIBULAR FRACTURES

The mandible is a unique horseshoe-shaped bone that is tubular and weakest where the cortices are thinnest. Most fractures occur at vulnerable points, regardless of the point of impact.[6] Common sites of weakness include the condylar area, followed by the symphyseal and parasymphyseal area and then the angle. Multiple fractures are common (64%),[6] with the body of mandible fractures often being accompanied by fractures of the opposite angle or neck due to transmitted forces. Mandibular fragments are often distracted owing to the action of the lower jaw muscles. Respiratory obstruction may occur after bilateral mandibular angle or body fractures due to the posterior displacement of the tongue – the 'Andy Gump' fracture.[7]

MIDFACIAL FRACTURES

The bones of the middle third of the face are relatively thin and poorly reinforced. Fracture dislocations occur through the bones and suture lines and the facial skeleton acts as a compressible energy-absorbing mass that gives on impact. The series of compartments (nasal cavity, paranasal sinuses and orbits) within the bony framework collapse progressively, absorbing energy and protecting the brain, spinal cord and other vital structures.[8] Multiple complex facial fractures usually result and isolated facial bone fractures are rare. Le Fort described three great lines of weakness in the facial skeleton and subsequently derived the Le Fort fracture classification (Fig. 78.1).[9] Le Fort fractures are perpendicular to the three main vertical buttresses of the facial skeleton – the nasomaxillary, zygomaticomaxillary and pterygomaxillary 'pillars'. Such fractures usually occur with mixed patterns as impact to the face is rarely centred (e.g. right hemifacial Le Fort I and left hemifacial Le Fort II). Airway obstruction may occur from posterior movement of the soft palate against the tongue and the posterior pharyngeal wall.

LE FORT I (ALSO KNOWN AS GUERIN'S FRACTURE)

This fracture involves only the maxilla at the level of the nasal fossa. It follows a horizontal plane at the level of the nose. The fracture separates the palate from the remainder of the facial skeleton (i.e. palate–facial disjunction) and is usually caused by direct low-maxillary blows or by a lateral blow to the maxilla.

ABSTRACT

Maxillofacial injuries may be isolated or part of multisystem trauma. The priorities of management are airway and control of haemorrhage. Elective intubation is the ideal but facilities to preform a surgical airway must be available. Haemorrhage is extremely common but life-threatening bleeding is rare. Urgent surgical opinion should be sought to determine if angiographic or surgical intervention is appropriate. Definitive surgical management is usually delayed 4–10 days to allow swelling to subside. Laryngeal trauma is rare due to protection provided by the sternum and mandible or death at the scene. The degree of injury is not easily assessable based on clinical symptoms, and airway obstruction can be insidious. Up to three-quarters of patients require intubation, and the safest mode is tracheostomy under local anaesthetic.

KEYWORDS

Maxillofacial trauma
facial fracture
laryngeal trauma
airway trauma

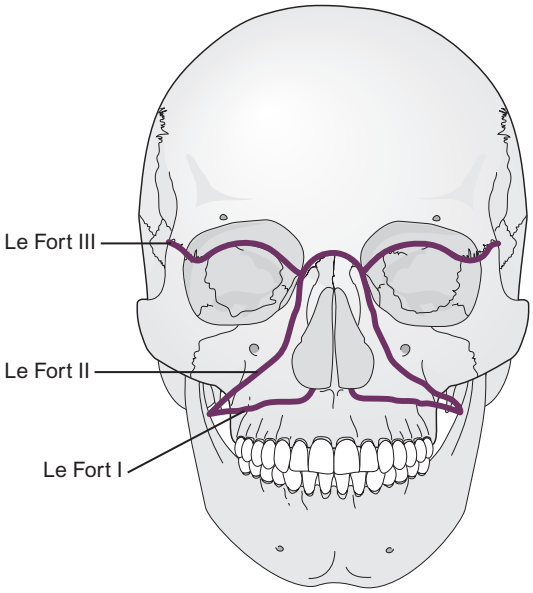

Figure 78.1 Le Fort classification of facial fractures.

LE FORT II

This is the most common midface fracture. The maxilla, nasal bones and medial aspect of the orbit are involved, which results in a freely mobile, pyramidal-shaped portion of the maxilla (i.e. pyramidal disjunction). The fracture line extends from the lower nasal bridge through the medial wall of the orbit, and crosses the zygomaticomaxillary process. It is caused by direct blows to the mid-alveolar area, or by lateral impacts and inferior blows to the mandible when the mouth is closed.

LE FORT III

This is known as craniofacial disjunction because the fracture line runs parallel to the base of the skull, separating the midfacial skeleton from the cranium. The fracture extends through the upper nasal bridge and most of the orbit and across the zygomatic arch. It involves the ethmoid bone, and thus may transect the cribriform plate at the base of the skull.[10] These fractures result from superiorly directed blows to the nasal bones.[10]

TEMPOROMANDIBULAR JOINT

Mechanical temporomandibular joint impairment may result from condylar or zygomatic arch fractures and can prevent jaw opening even after muscle relaxants have been administered.

ZYGOMATIC, ORBITAL AND NASAL FRACTURES

Zygomatic fractures account for approximately 30% of all facial bone fractures.[2,3] Its attachments to the maxilla, frontal and temporal bones are vulnerable and may be disrupted. Orbital injury is commonly associated with midface trauma. The severity of injury in the orbital region varies from oedema and ecchymosis of the periosteal soft tissue to subconjunctival haemorrhage,[11] and loss of visual acuity or ocular rupture. Facial fractures are associated with visual loss and blinding in 0.8% of patients.[12] The blinding mechanism is usually associated with globe perforation rather than optic nerve injury. Orbital blowout fractures occur when pressure that is directly applied to the eye is hydraulically transmitted via the globe to the interior bony structures. The weaker inferior orbital wall usually fractures, causing enophthalmos, diplopia, impaired eye movement and infraorbital hypoaesthesia. Ocular injuries are frequently missed and warrant further examination after primary survey and resuscitation have been completed. Nasal fractures are common, with epistaxis and septal haematoma being the prime concerns.

SOFT-TISSUE INJURIES

Abrasions, contusions and lacerations to the tongue, palate, pharynx, cheek, eyelids, nasolacrimal duct, ear, parotid gland and facial nerve can occur. Oedema evolving over 24–48 hours can be massive and cause gross distortion of soft-tissue structures. Patency of an initially unobstructed airway may become compromised during this period.

ASSOCIATED INJURIES

More than half of all patients with maxillofacial injuries will have other injuries and these are listed below.

BASILAR SKULL FRACTURE

The anterior cranial fossa is often involved in craniofacial injuries. Fractures involving the frontal bone, frontal sinus, nasoethmoid complex or fronto-orbital complex result in bone defects in the skull base and can cause dural tears with resultant leakage of cerebrospinal fluid (CSF). CSF fistulae occur in 10%–30% of basilar skull fractures.[13] The clinical finding of CSF rhinorrhoea represents only the site of exiting CSF and is not diagnostic for anterior cranial fossa lesions. The origin may be from a temporal bone fracture because CSF from the middle ear discharges into the nose via the Eustachian tube. A middle cranial fossa defect can produce rhinorrhoea through the sphenoid sinus. The vast majority of fistulae present within 1 week of injury. Meningitis in patients with midface fractures is uncommon, despite the fact that approximately 25% develop CSF leaks.[14]

Pulsating exophthalmos and the presence of an orbital bruit may lead to the diagnosis of a carotido-cavernous fistula, which may develop following fractures involving the skull base and orbit.

HEAD AND CERVICAL SPINE INJURY

The incidence of head injury in those with maxillofacial trauma has been variably reported to be from 15% for severe head injury, increasing to 80% if all grades of head injuries are included,[15,16] with around 8% requiring neurosurgical intervention.[17] Cervical spine injury has been reported in up to 11% of patients. The prevalence of cervical spine fracture with mandibular injury is 6.5%[18] and is attributed to forces exerted directly or indirectly from the facial skeleton to the neck. C1/C2 and C5-C7 are at particular risk.

The association between maxillofacial and cervical spine injury depends on the mechanism of injury. Falls and motor vehicle accident victims are more likely to have cervical injury than are sporting or personal assault victims.

OTHER INJURIES

In patients with severe maxillofacial trauma; thoracic trauma (~40%), abdominal trauma (~30%) and limb fractures (~40%) are other common co-existent injuries.[15] Dental injuries are present in 15%–20% of patients with maxillofacial fractures.[19,20]

ASSESSMENT OF INJURY

The obvious priorities are airway management and control of haemorrhage and identification of other life-threatening injuries. These are discussed later in detail. Once the patient is stable, formal assessment of the facial injuries can proceed.

HISTORY

Evaluation of facial fractures begins with a history of the injury. The mechanism of injury is important in order to assess the likelihood of other injuries.

EXAMINATION

Physical examination includes inspection for deformity, the presence of enophthalmos, asymmetry, dental malocclusion, nasal septal deviation or haematoma, CSF rhinorrhoea and the extent of jaw opening. Other signs associated with basal skull fracture also should be noted (haemotympanum, Battle's sign, raccoon eyes). Tenderness and mobility on bimanual palpation of the alveolar process and the infraorbital rim or frontozygomatic suture indicates the presence of a complex midfacial fracture. Naso-orbito-ethmoid instability also can be established by bimanual palpation. Visual acuity (in the conscious patient), corneal integrity and pupillary reflexes as well as eye movements (failure of upward movements in orbital blowout fracture) should be assessed early and thoroughly. Facial nerve function also should be assessed if possible. The presence of a bruit over the orbit may indicate a carotido-cavernous fistula.

INVESTIGATION

Computed tomography (CT) scanning, especially with three-dimensional reconstruction, is the preferred and most accurate method of imaging.[21] In addition to bony distortion, fluid in the paranasal sinuses, optic nerve integrity and soft-tissue distortion, the brain, upper cervical spine and other body areas can be visualised concurrently. Other investigations, such as colour Doppler ultrasound studies, CT angiography or standard angiography of the great vessels in the neck, may be required in cases of possible carotid dissection or carotid-cavernous fistulae. Nasal discharge should be tested for β_2-transferrin to confirm the presence of a CSF fistula.[22]

AIRWAY MANAGEMENT

Airway management in maxillofacial injury is potentially complex owing to multiple concurrent compromising factors (Table 78.1).

IMMEDIATE PRIORITIES

- Assess and monitor for signs of airway obstruction whilst maintaining cervical spine precautions
- Clear airway, assist respiration
- Provide high flow oxygen
- Definitive airway intervention.

An initially unobstructed airway may become compromised as swelling and oedema can progress in the initial hours after injury. Careful close monitoring in an intensive care unit or high-dependency unit is essential. Maintaining the head-up position and the use of humidified oxygen may lessen the likelihood of later airway compromise. Sudden obstruction may occur with clot dislodgement and inhalation. Signs of partial obstruction include noisy breathing, stridor, intercostal or supraclavicular recession and restlessness.

Occasionally, patients may assume positions that lessen airway obstruction (e.g. sitting forward or even prone). Simple measures, such as suction and clearing the airway and insertion of an oropharyngeal airway, may suffice.

In midfacial injuries, anterior digital traction on the mobile midsegment may relieve obstruction. In bilateral mandibular fractures of the angle or body, a towel clip or suture through the tongue may allow anterior traction on the unsupported tongue and relieve obstruction.

Bag and mask ventilation may be difficult owing to distorted anatomy, and this should be borne in mind when a decision to intubate is made. Failure of these simple manoeuvres necessitates definitive airway management.

TECHNIQUES (Fig. 78.2)

Facilities to perform a surgical airway must be available prior to elective intubation. The chosen technique

Table 78.1 Airway problems in maxillofacial trauma

GENERAL PROBLEMS	MANAGEMENT
Haemorrhage/debris Impaired laryngoscopy Aspiration risk from blood swallowing Clot inhalation/obstruction Teeth, bone fragments	Suction, volume replacement Head down Definitive control of haemorrhage (see text)
Oedema soft-tissue haematomas Increases over 48 h Mask fit can be poor	Monitor airway closely Head up 30° Maintain spontaneous ventilation during airway Manipulation; laryngeal mask ventilation
SPECIFIC PROBLEMS	
Bilateral mandibular body/angle fractures Posterior displacement of tongue	Anterior traction on tongue or jaw, towel clip or suture through tongue and elevate
TMJ impairment from mandibular condyle and or zygomatic arch fracture Mouth opening limited	Nasotracheal intubation (blind/fibre optic) or surgical airway may be required
Midfacial fracture Mask seal poor Soft palate collapses against pharynx	Anterior traction on mobile segment
Basilar skull Nasotracheal intubation contraindicated Pneumocephalus from mask ventilation	Avoid nasal intubation
Cervical spine injury	Orotracheal intubation with in-line stabilisation; fibre optic intubation; surgical airway

TMJ, Temporomandibular joint.

for securing the airway depends on the presence of airway obstruction and the likelihood of difficult direct laryngoscopy (extent of jaw opening, gross anatomical distortion and swelling, bleeding, operator experience). In a combative patient, or if urgent intubation is necessary, a rapid sequence induction can be used if difficulty in direct laryngoscopy is not anticipated. If direct laryngoscopy is likely to be difficult or impossible, spontaneous respiration must be maintained and intubation carried out under local anaesthesia.

Analgesia can be achieved with a combination of sprayed or nebulised local anaesthetic to the posterior pharynx as well as a transcricoid injection. The orotracheal route for intubation is the route of choice in the presence of a basal skull fracture.

If cervical spine injury is present or suspected, in-line stabilisation is mandatory. A variety of intubation techniques can be used, for example direct laryngoscopy, awake fibre-optic-guided laryngoscopy, video laryngoscopy and retrograde intubation techniques.[23] The operator should use the technique with which he/she is most comfortable. Excessive bleeding or debris may render fibre optic techniques difficult.

Failure to intubate and ventilate in the presence of airway obstruction necessitates the passage of an appropriate-sized laryngeal mask. If ventilation is not possible with a laryngeal mask in situ then emergency cricothyroidotomy should be performed. Formal tracheostomy may be required in those likely to need prolonged ventilatory support (e.g. multiple facial fractures combined with a head injury) and is best performed as a semi-elective procedure in the operating room.[24]

HAEMORRHAGE

Haemorrhage following blunt maxillofacial injury is extremely common. Life-threatening bleeding is rare with an approximate incidence of 1%.[25] Most severe haemorrhage is associated with midfacial fractures, although soft-tissue lacerations alone can cause significant blood loss. Swallowing of large quantities of blood may conceal haemorrhage and predispose to vomiting and aspiration.[26]

The origin of bleeding in facial trauma is complicated as the vascular supply is derived from both the internal and external carotid arteries, with anastomoses occurring between them as well as between both halves of the face. The internal maxillary artery, especially the intraosseous branches, is the main source of bleeding in facial injury because the artery passes within the common Le Fort fracture borders.[24,25] The

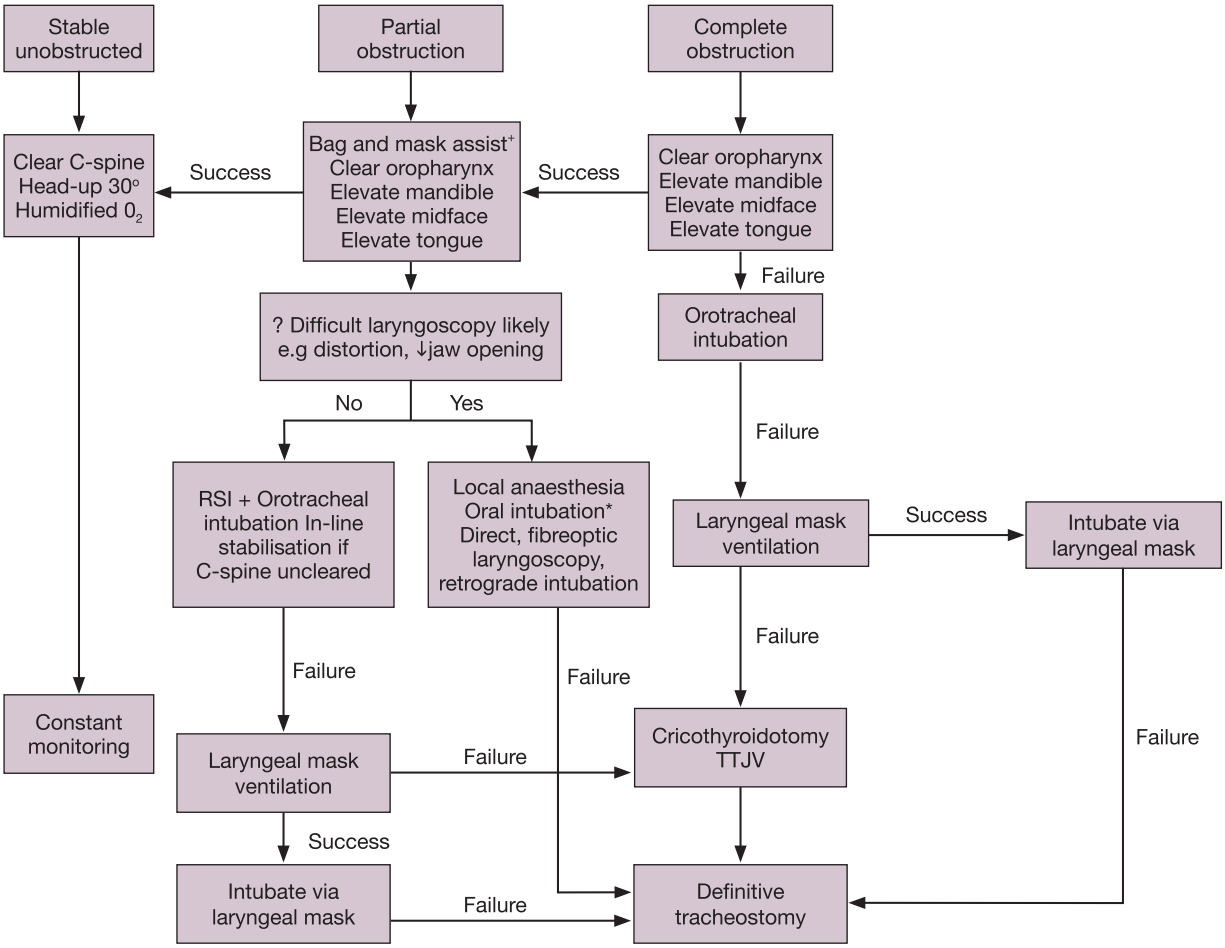

Figure 78.2 An airway management algorithm for maxillofacial trauma. *C-spine*, Cervical spine; *RSI*, rapid sequence induction; *TTJV*, transtracheal jet ventilation. +Mask seal may be poor. *Nasotracheal route contraindicated in basilar skull fracture.

comminuted nature of maxillary fractures makes the detection of an exact site of vessel damage nearly impossible.[24] Branches of the internal carotid artery, such as the lacrimal and zygomatic branches as well as the anterior and posterior ethmoidal arteries, may contribute to bleeding.

The priority is to secure the airway as required. Direct pressure and aggressive packing to open bleeding wounds, nasal cavities and oropharyngeal cavities is then required.[27] Topical vasoconstrictors may not be effective with ongoing nasal haemorrhage. Anterior or posterior nasopharyngeal packs are often an effective at reducing blood loss. Foley catheters passed into the posterior nasopharynx with the balloons filled with air may stem blood loss. These can be used as a second-line option but may displace fractures further. Permissive hypotension in these patients is controversial due to the high rate of concomitant head injuries.[27] Plastic or maxillofacial surgical opinion should always be sought early on regarding the appropriateness of angiographic versus operative intervention for persistent haemorrhage. Angiographic embolisation has an increasing role as a first-line approach for life-threatening intractable bleeding for blunt and penetrating trauma, with a success rate of greater than 85%.[25,28] Operative intervention includes reduction and stabilisation of fractures and direct ligation of bleeding vessels.

DEFINITIVE MANAGEMENT

Definitive surgery is generally delayed 4–10 days to allow swelling to subside. The timing of surgery may be further delayed if a severe head injury co-exists. Early surgery may be warranted if orbital injury with optic nerve compromise is present. The use of high-dose steroids in optic nerve compression is controversial, and no good data exist regarding its efficacy.[24]

Irrigation and debridement of open wounds, closure of facial lacerations and removal of foreign bodies must be undertaken as soon as is practicable, preferably within 24 hours.

The use of prophylactic antibiotics for a CSF leak is debateable, and local protocols should be followed. The timing of operative intervention is still under discussion but the recent trend is for conservative management due to the high rate of spontaneous closure, with lumbar drain insertion for leakage lasting longer than 5–7 days and endoscopic or surgical closure for those that persist.[29] Appropriate tetanus prophylaxis must be given.

The use of modern internal fixation techniques has reduced the need for intermaxillary fixation following elective facial fracture repair, with only unstable comminuted fractures requiring this form of fixation. Submental intubation during fracture repair is being used as an alternative to tracheostomy in some centres.[30]

INJURIES TO THE LARYNX AND TRACHEA

Direct trauma to the airway is rare, accounting for less than 1% of traumatic injury seen in most major centres.[31,32] The bony protection afforded to the airway by the sternum and mandible and death from asphyxia at the accident scene account for the rarity of the injury. Common associations with laryngotracheal injury include thoracic spine injury (15.5%), cervical spine injury (9%), closed head injury (8.5%), facial fractures (20.2%) and vascular injuries (11.3%); exact values vary depending on case series.[31,33]

Laryngotracheal injury can be classified as blunt or penetrating. Failure to recognise these injuries, their complications and specific pitfalls in airway management can lead to death.[34]

MECHANISM OF INJURY

BLUNT INJURY

Common causes include motor vehicle accidents where the extended neck impacts with the steering wheel or dashboard. The 'clothes-line injury' occurs when a cyclist or horse rider collides with a cable or wire causing direct injury to the upper airway. Assaults and strangulation account for the remainder of blunt injuries. Direct blows are more likely to injure the cartilages of the larynx, whereas flexion/extension injuries are most commonly associated with tracheal tears and laryngotracheal transection.[35] The larynx above the cricoid cartilage is injured in 35%, manifesting as oedema, contusions, haematomas, lacerations, avulsion and fracture dislocation, most commonly of the thyroid and arytenoid cartilages.

When the cricoid cartilage itself is injured this may cause recurrent laryngeal nerve dysfunction. The cervical trachea is injured in 45%.[36] Tracheal transection most often occurs at the junction between the cricoid cartilage and trachea. Oedema fluid and air dissecting within submucosal layers of the larynx and trachea may cause airway obstruction. Air in the soft tissues can cause epiglottic emphysema and narrowing of the supraglottic airway. Straining, talking and coughing may worsen the oedema.

PENETRATING INJURY

Penetrating injuries usually result from stab or gunshot wounds. The anterior triangle of the neck is the most common site of entry. The cervical trachea is most commonly involved in stab wounds. Of patients with penetrating laryngotracheal trauma, 19% also had cervicothoracic vascular injury, 15% had oesophageal injury and 34% had chest trauma.[31]

ASSESSMENT OF INJURY

Definitive investigation and management depend on the airway status and presence of associated injury. The degree of injury is not readily assessable on the basis of any one clinical symptom or sign (Box 78.1) and delayed diagnosis is common. Up to 14% of patients may have no presenting sign or symptom suggesting

Box 78.1 Clinical features in laryngotracheal injury

Symptoms
Respiratory distress, stridor, noisy breathing
Neck tenderness or oedema
Hoarseness
Dysphonia
Cough
Dysphagia
Signs
Abnormal laryngeal contour
Subcutaneous emphysema
Cervical ecchymosis
Haemoptysis
Investigations
Plain radiography
- Air in soft tissues
- Pneumomediastinum
- Pneumothorax
- Cervical spine fracture

CT scan
- Cartilage and soft-tissue injury
- Altered airway patency

Laryngoscopy
- Vocal paralysis
- Mucosal or cartilage disruption
- Haematoma
- Laceration

CT, Computed tomography.

Table 78.2 Summary of Schaefer's classification of laryngeal trauma and management

GROUP	SIGNS	SYMPTOMS	MANAGEMENT
1	Minor endolaryngeal haematomas or laceration without detectable fractures	No airway compromise	Humidified oxygen. Consider ICU/HDA admission for observation. Consider steroids
2	More severe oedema, haematoma, minor mucosal disruption without exposed cartilage or non-displaced fractures	Varying degrees of airway compromise	Direct laryngoscopy with oesophagoscopy, possible tracheostomy. Fractures treated expectantly. Likely ICU admission. Consider steroids
3	Massive oedema, large mucosal lacerations, exposed cartilage, displaced fractures or vocal cord immobility	Airway compromise	Tracheostomy, direct laryngoscopy with oesophagoscopy. Admit to ICU as required. Early exploration, reduce fractures and repair. No stent necessary
4	Same as group 3, but more severe with disruption of anterior larynx, unstable fractures, two or more fracture lines, or severe mucosal injuries	Airway compromise	Tracheostomy, direct laryngoscopy. Admit to ICU as required. Early exploration, reduce fractures and repair. May require the use of a stent

HDA, High dependency area; *ICU*, intensive care unit.

laryngotracheal injury.[33] Airway obstruction can be delayed and insidious, therefore frequent reassessment is required. The emphasis has moved towards CT scanning in the first instance in stable patients with laryngeal tenderness, endolaryngeal oedema and small haematomas. CT demonstrates fractures of cartilages, haematomas and other injuries. Further investigation with fibreoptic laryngotracheoscopy under local anaesthesia can be used to demonstrate vocal cord dysfunction, integrity of the cartilaginous framework and laryngeal mucosa. Rigid laryngoscopy can be used when adequate visualisation is not achieved with the former. Pharyngo-oesophagoscopy, contrast studies, open exploration and angiography may be required to exclude aerodigestive tract and major vascular injuries (Table 78.2).

AIRWAY MANAGEMENT

Up to three-quarters of patients with laryngotracheal injury require intubation.[32] The safest mode of intubation is via tracheostomy under local anaesthesia (Fig. 78.3).[37] Blind intubation can lead to complete airway obstruction owing to mucosal disruption and the creation of false passages.[34] Cricoid pressure can lead to laryngotracheal separation and is contraindicated. Positive-pressure ventilation can rapidly worsen air leaks and wherever possible the patient should maintain spontaneous respiration until a tube has been placed distal to the site of injury. Cricothyroidotomy is not recommended as it may compound laryngeal injury. In an emergency, gaping airway wounds (e.g. with tracheal transection) can be intubated under direct vision pending subsequent surgery.

SURGICAL MANAGEMENT

In many case series early fixation leads to fewer complications.[38,39] It is indicated in laryngeal injuries when there is unstable fractures, significant mucosal injuries, haematomas, uncontrolled bleeding or damaged vocal cords. Delays in repair may lead to granulation and scar tissue formation, which can lead to laryngeal stenosis.[34] Laryngeal stenting is still controversial and the risks versus benefits of skeletal stability versus mucosal lining harm must be weighed up.

Chest injuries

Ubbo F Wiersema

Chest injuries account for a quarter of all trauma deaths. Blunt trauma accounts for more than 90% of chest injuries in most civilian environments. Immediate death from severe blunt trauma is usually due to blunt rupture of the thoracic aorta, heart or major vessel. Patients who survive to hospital presentation may still have life-threatening chest injuries that require immediate intervention. The majority of chest injuries can be managed with simple measures such as intercostal tube thoracostomy, oxygen therapy, analgesia and mechanical ventilation.[1-3] Tension pneumothorax, open pneumothorax or massive haemothorax require immediate intercostal tube drainage. Urgent thoracotomy is indicated for pericardial tamponade, diaphragmatic rupture and massive haemothorax with ongoing bleeding.[2] Following the resuscitation phase, extensive pulmonary contusions with respiratory failure may require prolonged ventilatory support. Chest injuries that are initially missed may also significantly prolong intensive care stay.

IMMEDIATE MANAGEMENT

Identification of chest injuries forms a core component of the initial assessment of a patient with major trauma – both because immediate intervention can be lifesaving, and because restoration of respiratory and circulatory stability minimises secondary injury to extrathoracic organs, particularly traumatic brain injury.[1] A history of the mechanism and force of injury should be sought as this will guide the likelihood of different injuries and determine the need for more extensive investigation.

During the primary survey the airway patency is ensured, oxygen is administered by face mask and ventilation is assessed. The degree of circulatory compromise is determined and obvious external bleeding is controlled. Two large-bore intravenous cannulae are sited, blood samples taken and intravenous fluids commenced. Intravenous opioid analgesia is given as repeated small boluses, titrated to effect. Complete exposure of the patient is important to facilitate examination of the chest and facilitate intercostal tube insertion, if required. With penetrating trauma all surface wounds must be located so that the pathway of potential injuries can be determined.[2] There are four life-threatening chest injuries that require immediate intervention:

- tension pneumothorax
- open (sucking) pneumothorax
- massive haemothorax
- pericardial tamponade.

In addition, the clinical features of flail chest should be sought, as these will no longer be apparent if positive-pressure ventilation is instituted. Interventions required during initial management are outlined in Box 79.1. A chest radiograph is integral to the initial assessment and should be performed promptly. However, the severity of physiological derangement will dictate the time available for confirmatory imaging, and a patient with clinical signs of tension pneumothorax should undergo immediate intercostal tube thoracostomy before the chest radiograph. If there is no physiological improvement after unilateral tube thoracostomy, a second intercostal tube should be inserted in the contralateral chest.

Lung ultrasound can be completed faster than a chest radiograph, and has significantly higher diagnostic accuracy for pneumothorax and haemothorax when performed by experienced operators.[4] However, clinicians not experienced with lung ultrasound should avoid decision making based on this technique. Subcostal ultrasonography of the heart to look for pericardial fluid forms part of the focused assessment with sonography for trauma (FAST) and should be performed with penetrating chest trauma, or if there is haemodynamic instability with blunt trauma.[2,4,5] An electrocardiogram (ECG) is important in the assessment for blunt cardiac injury.[2,6]

Endotracheal intubation and mechanical ventilation are indicated for the patient with a compromised airway, severe head injury, or gross hypoventilation and/or hypoxaemia not attributable to pneumothorax. Haemodynamic instability should be anticipated (Box 79.2). Rarely, emergency cricothyroidotomy or tracheostomy is required when an airway obstruction cannot be bypassed by translaryngeal intubation. A nasogastric or orogastric tube (if facial injuries are suspected)

ABSTRACT

Chest injuries account for a quarter of all trauma deaths, usually from rupture of the thoracic aorta. On presentation to hospital, life-threatening chest injuries that require immediate identification and management include tension pneumothorax, open pneumothorax, massive haemothorax and pericardial tamponade. Most chest injuries can be managed with simple measures including intercostal tube insertion, oxygen therapy, analgesia and mechanical ventilation. Urgent thoracotomy is indicated for pericardial tamponade, diaphragmatic rupture and massive haemothorax with ongoing bleeding. Emergency thoracotomy is indicated after penetrating chest trauma with witnessed loss of vital signs. Significant blunt aortic injury requires good blood pressure control and endovascular or operative repair. Tracheobronchial and oesophageal injuries are uncommon, but require prompt treatment to avoid significant morbidity. Delayed identification of injuries and severe chest wall injuries may require prolonged intensive care stay.

- Hypovolaemia
- Oesophageal intubation with hypoxaemia
- Tension pneumothorax
- Pericardial tamponade
- Anaphylaxis
- Systemic air embolism
- Severe blunt cardiac injury

should be inserted to decompress the stomach after endotracheal intubation.

PNEUMOTHORAX

Pneumothorax visible on the initial chest radiograph should be treated with insertion of an intercostal tube connected to an underwater seal drainage system (Fig. 79.1). A single bottle drainage system without suction is usually adequate. Low-pressure suction (20 cm H_2O) is applied if the pneumothorax fails to fully resolve, or if there is associated haemothorax (Fig. 79.2). A three-bottle system (or a commercially available three-in-one system) allows more accurate control of suction (Fig. 79.3). Use of antibiotics (to prevent empyema or pneumonia) is controversial, but contamination during intercostal tube insertion is common and a 24-hour course of a first-generation cephalosporin may be appropriate.[7,8]

Tension pneumothorax results from progressive accumulation of air in the pleural space, positive intrapleural pressure and cardiorespiratory decompensation.[9] In awake patients, slow development of positive intrapleural pressure leads to progressive hypoxaemia and respiratory distress. Tachycardia is common, but preserved venous return maintains cardiac function

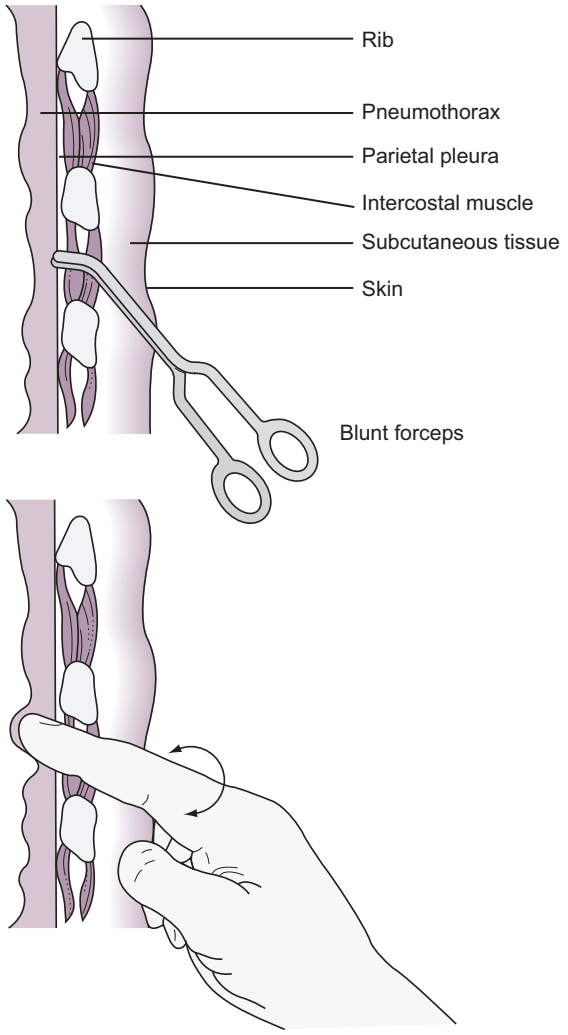

Figure 79.1 Intercostal tube insertion. After sterile preparation and drape, 1% lidocaine is infiltrated in the midaxillary line at the level of the nipple. A 2–3 cm transverse skin incision is made. Dissection is performed by blunt forceps down to the pleura passing just superior to the rib surface to avoid injury to neurovascular structures. A gloved finger is used to confirm separation of lung from chest wall. A large-bore (28–32 Fr) intercostal tube is inserted without a trocar and advanced in a postero-superior direction. Curved forceps clamped to the distal side hole of the tube can be used to guide the tube through the chest wall. The tube is immediately connected to an underwater seal drainage system (see Figs 79.2 and 79.3) and checked for satisfactory drainage and tidal rise and fall in the fluid level with respiration. Non-absorbable sutures are used to seal the skin incision around the tube and secure the tube. The intrathoracic position of the tube is checked with a chest radiograph.

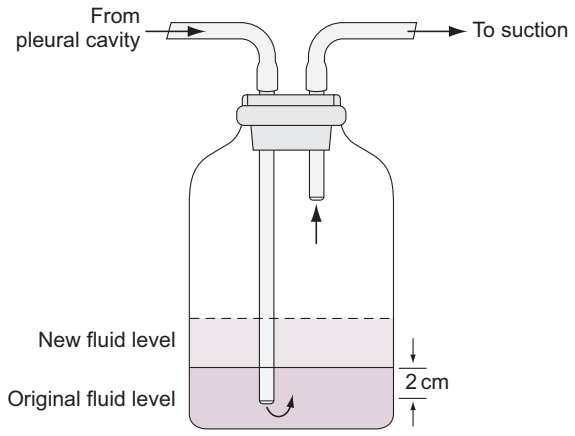

Figure 79.2 Single-bottle drainage system for haemopneumothorax. Air drainage will become more difficult if there is also fluid drainage, raising the fluid level in the bottle *(dashed line)* and increasing the depth of immersion of the hollow rod. This can be overcome by applying low-pressure suction (20 cm H_2O). *Arrows* indicate direction of air flow.

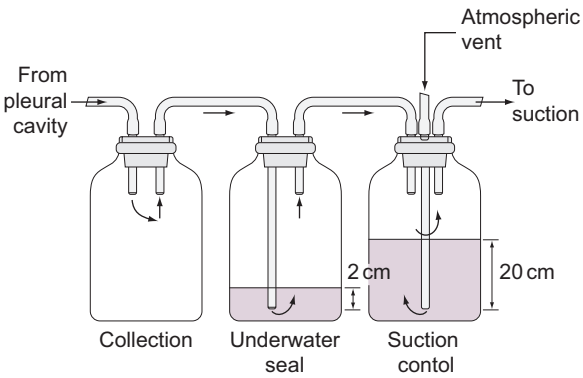

Figure 79.3 Three-bottle chest drainage system. The first bottle (connected to the intercostal tube) is a fluid collection chamber, the second functions as a one-way valve (underwater seal), and the third (connected to wall suction) limits the amount of suction applied. The level of suction is set by adjusting the depth of the atmospheric vent whilst ensuring that it bubbles continuously. Commercially available drainage systems function on the same principles as the three-bottle system. *Arrows* indicate direction of air flow.

and blood pressure. In sedated patients on positive-pressure ventilation, the positive intrapleural pressure throughout the respiratory cycle can lead to the rapid development of hypoxaemia. Cardiac output is compromised by obstructed venous return; hypotension is prominent and may progress to cardiac arrest. In both awake and ventilated patients, chest signs (hyperexpansion, decreased breath sounds and tracheal deviation) are not reliably present.[9]

If tension pneumothorax is suspected clinically, an intercostal tube should be inserted immediately, prior to the chest radiograph. Blunt dissection and insertion of a gloved finger into the pleural space allow rapid decompression of tension, prior to intercostal tube insertion.[7] Needle thoracostomy with a large-bore cannula inserted into the second intercostal space in the midclavicular line may be used to drain air more rapidly for patients in extremis. However, this is rarely necessary and may puncture the lung or a blood vessel, fail to reach the pleural space or kink when the needle is removed from within the cannula.[7] Furthermore, the landmarks for needle thoracostomy are often identified incorrectly, increasing the risk of adverse outcome. Whether successful or not, needle thoracostomy must be followed by intercostal tube drainage.

Open pneumothorax occurs when a chest wall defect allows direct communication of a pneumothorax with the exterior, usually after penetrating trauma. Tension can develop if air can enter but not exit through the defect. Treatment involves the application of an occlusive, non-adherent, square dressing sealed along three edges over the wound after sterile skin preparation. This allows air to escape but not enter through the wound, but should be followed by intercostal tube insertion at a site not immediately adjacent to the wound.

Simple pneumothorax may develop tension at any stage, especially with positive-pressure ventilation (see Box 79.2). A small pneumothorax may be missed on the initial chest radiograph. In the supine position pleural air collects anteroinferiorly and is demonstrated radiologically by a deep sulcus sign or increased radiolucency of one side of the chest compared with the other (Fig. 79.4).[10]

Occult pneumothorax is defined as visible on chest computed tomography (CT), or upper slices of an abdominal CT, but not plain radiograph. Drainage is not usually required, but should be considered if prolonged surgery is anticipated, there is significant cardiorespiratory compromise or interhospital transport is necessary. With a conservative approach the patient should be carefully monitored for deterioration from expansion of the pneumothorax.[11,12]

Subcutaneous emphysema over the chest wall in a patient with blunt chest trauma is almost always associated with pneumothorax, but should raise suspicion of other injuries (Box 79.3). The pneumothorax may not be visible on chest radiograph, either because it is obscured by the emphysema, or because it has largely decompressed into subcutaneous tissues. An intercostal tube should be inserted.

If there is no associated fluid collection, the intercostal tube can be removed once the pneumothorax is no longer visible on chest radiograph and there has been no air drained for at least 24 hours. Persistent air leak and incomplete drainage of a pneumothorax after

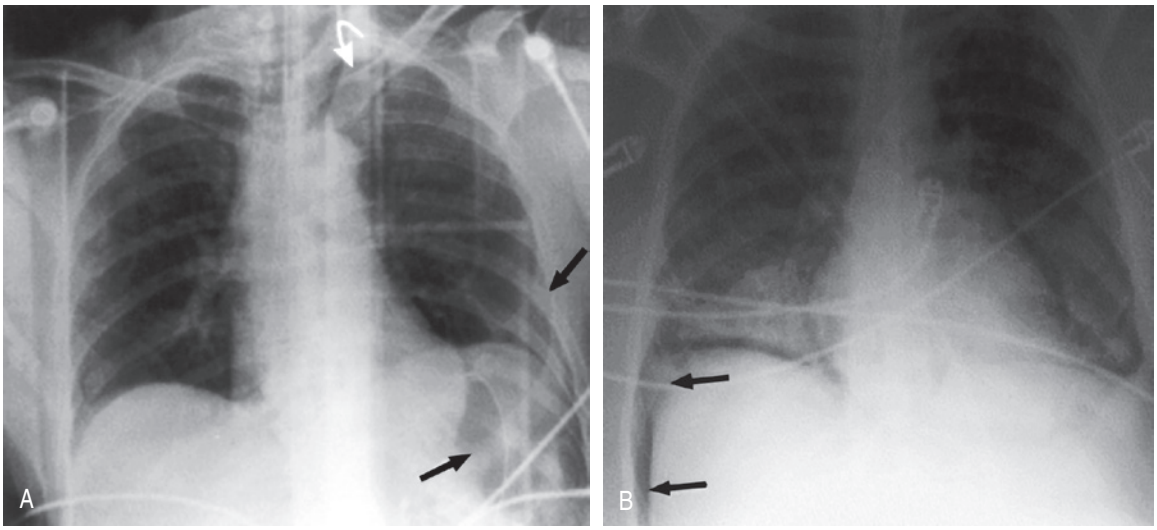

Figure 79.4 (A) Moderate-sized left pneumothorax on supine chest radiograph. The visceral pleura is visible at the lung apex *(curved arrow)*. intercostal tube insertion should prompt investigation for tracheobronchial or oesophageal injury. However, the depth of the tube within the pleural space and tubing connections should be checked to ensure that air is not being inadvertently entrained from outside the chest. Incomplete drainage with no air leak is usually due to tube malplacement.

HAEMOTHORAX

Haemothorax visible on chest radiograph should be drained as completely as possible (see Fig. 79.1). The tube can be removed once radiographic clearance is achieved, with <100 mL per 24 hours drainage. A small haemothorax (<300 mL) (visible on ultrasound or CT) may initially be managed conservatively, but should be drained if it enlarges. Persistent opacity on chest radiograph after tube placement should be investigated with CT or ultrasound to determine whether there is significant undrained fluid (see section "RETAINED HAEMOTHORAX AND EMPYEMA" later).

Massive haemothorax, defined as >1500 mL, causes life-threatening circulatory compromise from hypovolaemia and vena caval compression, as well as hypoxaemia. This requires immediate tube drainage and consideration of surgical exploration.[12] If the amount of ongoing bleeding following initial drainage is low, and if the patient remains haemodynamically stable after initial resuscitation and the blood is venous in appearance, the patient can be managed with close observation. Ongoing bleeding of >200 mL per hour, or >600 mL over 6 hours (massive haemothorax equivalent), is an indication for thoracotomy.

PERICARDIAL TAMPONADE

Pericardial tamponade should be suspected in any patient with a gunshot wound to the chest, or stab wound to the precordium. It occurs rarely with blunt trauma, but should be suspected if there is hypotension out of proportion to blood loss, and distended neck veins. Pulsus paradoxus may be detected in the spontaneously breathing patient. The differential diagnosis includes tension pneumothorax (most likely), cardiogenic shock from severe blunt cardiac injury, or inadequate resuscitation. Pericardial fluid can be detected with ultrasound via a subcostal view (as part of the FAST scan).[4] Echocardiography, or an operative subxiphoid window, can be used if diagnostic uncertainty remains.

Haemodynamically unstable patients should undergo thoracotomy.[13,14] Subxiphoid pericardiotomy can be performed in selected stable patients, but may

require conversion to open thoracotomy. Needle pericardiocentesis is rarely effective in the acute setting, but may have a role in the drainage of delayed pericardial effusions following stab wounds.[13]

CARDIAC ARREST AND EMERGENCY THORACOTOMY

External cardiac massage is invariably unsuccessful in the trauma setting; it may cause further injury to intrathoracic structures and obstruct access to the patient for more potentially useful interventions such as bilateral pleural decompression. For patients with witnessed loss of vital signs after penetrating chest trauma, emergency thoracotomy should be considered if suitably experienced medical personnel are available.[13–16] This is rarely successful for blunt trauma. The standard approach is a left-sided anterolateral thoracotomy. Access to the thoracic cavity facilitates specific interventions[13–15]:

- release of pericardial tamponade and control of cardiac bleeding
- control of intrathoracic bleeding
- control of massive bronchovenous air embolism
- control of bronchopleural fistula with pulmonary hilar cross-clamping
- temporary cross-clamping of the descending aorta, to redistribute blood volume to the brain, improve coronary perfusion and control intra-abdominal blood loss
- internal cardiac massage.

These temporising (damage control) measures are followed by transfer to the operating room for completion of surgery[14,15,17]:

- definitive repair of cardiac injury
- pulmonary tractotomy, wedge resection, or lobectomy/pneumonectomy for lung injury
- repair or grafting of vascular injury.

Postoperatively, the patient is admitted to the intensive care unit (ICU) for rewarming, correction of coagulopathy and resuscitation.

SPECIFIC INJURIES

After addressing initial management issues, a secondary survey and further imaging are performed to identify all injuries. Extrathoracic injuries causing haemodynamic instability should be addressed (e.g. laparotomy) before completion of thoracic imaging; unstable patients should not be transferred to an imaging department away from resuscitation facilities. With the widespread availability of multislice helical CT, chest CT angiography has become the primary imaging modality for the diagnosis of specific chest injuries. This is usually performed as part of a whole body 'pan scan' (CT head, neck, chest, abdomen and pelvis) with injection of intravenous contrast timed to provide aortic angiography. Endotracheal intubation and mechanical ventilation may be required to facilitate CT (e.g. the combative trauma patient with ethanol intoxication). Exposure to high doses of radiation has raised concern about the liberal use of the pan scan.[18] Chest CT is unlikely to identify additional significant injuries if the chest radiograph is normal and the mechanism of injury was low risk.[19]

BLUNT AORTIC INJURY

Blunt aortic injury usually occurs as a result of severe deceleration injury causing a tear at the junction between the fixed descending aorta and the mobile aortic arch, just distal to the origin of the left subclavian artery.[5] Less frequently the ascending aorta (or arch vessels) is injured by direct trauma. Most patients with blunt aortic injury die at the scene from complete aortic wall transection, or associated injuries. Of those that reach hospital, 90% will have a significant aortic injury and 50% of these will die with 24 hours.[5,20] Blunt aortic injuries may be divided into[21–23]:

- *significant aortic injury*, with disruption of the intima and full thickness of the media; there is a high risk of rupture
- *minimal aortic injury*, with laceration limited to the intima and inner media – radiologically this manifests as an intimal flap or pseudoaneurysm <1 cm in length, with minimal or no periaortic haematoma; there is a low risk of rupture.

Aortic injury should be suspected if the mechanism of injury is suggestive of rapid deceleration, such as high-speed (greater than 50 km/h) motor vehicle or motorcycle crash, pedestrian hit by a vehicle, or fall from a height greater than 3 m.[5,24] Clinical signs of significant aortic injury include unequal upper limb pulses, pseudocoarctation or interscapular murmur, but these are often absent.

Historically, chest radiography has been the screening test (to detect mediastinal haematoma), and aortic angiography the diagnostic test for blunt aortic injury.[22] Helical CT chest angiography is now the diagnostic test of choice, although transoesophageal echocardiography may be more appropriate in certain circumstances[23,25]:

- *Chest radiograph* features of blunt aortic injury are caused by distortion of normal mediastinal contour by periaortic haemorrhage. A widened mediastinum (greater than 8 cm at the level of the aortic knuckle) is the principal finding (Box 79.4).[26] A supine chest radiograph accentuates mediastinal width and in the acute trauma setting is often of suboptimal quality. Measurement of left mediastinal width (>6 cm), or left mediastinal width to mediastinal width ratio (>0.6), may improve specificity.[26]

Box 79.4 Chest radiograph signs of blunt aortic injury

SIGNS OF PERIAORTIC HAEMATOMA	INDIRECT SIGNS
Widened mediastinum (>8 cm)	Left haemothorax
Obscured aortic knuckle	Left pleural cap
Opacification of aortopulmonary window	Fractured first or second ribs
Deviation of trachea, left main bronchus or nasogastric tube	
Thickened paratracheal stripe	

Box 79.5 Signs of aortic branch vessel injury

- Supraclavicular haematoma
- Pulse discrepancy in arms
- Brachial plexus palsy or stroke
- Widened upper mediastinum on chest radiograph

- *Multislice helical (multiple row detector) chest CT angiography* (with more than 16 detectors) provides sufficient resolution in multiple planes for CT to be used as the sole diagnostic test, and has largely superseded other imaging modalities for diagnosis of aortic injury.[20,23]
- *Single-slice helical chest CT* may demonstrate direct signs of aortic injury. However, more commonly, aortic injury manifests indirectly with periaortic haematoma, and a further diagnostic test is required.[23] Nevertheless, by differentiating periaortic haematoma from other types of mediastinal haematoma, and excluding other causes of an abnormal mediastinal contour, single-slice helical CT provides a useful screening test[23] where multislice CT is not available.
- *Transoesophageal echocardiography* is rapid and portable, making it suitable for examination of the unstable patient (e.g. in the operating room). It provides high diagnostic accuracy for aortic injury and also allows examination for blunt cardiac injury.[25] However, imaging of the distal ascending aorta, proximal arch and major branches is limited. Thus if signs of mediastinal haematoma are detected, but an aortic injury is not identified, further diagnostic imaging is warranted.[23] It is contraindicated if an upper airway or oesophageal injury is suspected.
- *Aortic angiography* is relatively time consuming and requires transfer of the patient to the angiography room, making it potentially hazardous for the unstable patient. However, it is the preferred diagnostic test if branch vessel injury is suspected (Box 79.5), or if uncertainty remains after other diagnostic imaging.[23] It is also necessary for endovascular aortic repair, and may be required for operative planning.

Significant aortic injury requires prompt surgical or thoracic endovascular aortic repair (TEVAR).[5,20,22,27] However, this should not take priority over other life-saving interventions (e.g. control of external or pelvic bleeding, laparotomy, or craniotomy for intracranial haemorrhage). Open surgical repair requires a left posterolateral thoracotomy and selective right-lung ventilation. Operative techniques include direct repair (clamp and sew), or techniques that maintain distal aortic perfusion (bypass).[5,22,27] The latter reduce the risk of postoperative paraplegia from spinal cord ischaemia, but often require systemic heparinisation, which may exacerbate bleeding from other injuries. Sometimes a lumbar drain for cerebrospinal fluid (CSF) drainage is placed perioperatively to improve spinal cord perfusion and potentially reduce the incidence of paraplegia. Postoperatively, CSF is drained freely to maintain a CSF pressure less than 10 mm Hg. The drain is removed after 3 days if there are no neurological complications. Surgery should be deferred, sometimes indefinitely, if severe associated injuries or co-morbidities make the operative risk unacceptably high. In such cases TEVAR may still be feasible and in many institutions has become the primary method of aortic repair.[5,20,22,27] The procedure involves isolation of the injured section of aorta by deployment of endoluminal stents, usually via cannulation of the iliac or femoral artery. Although less invasive and less time consuming than open repair, long-term outcome data are lacking and complications may occur.[5,20,22,27] Endoleaks can arise from incomplete exclusion of the site of injury, or inadequate apposition along the lesser curve of the aorta. Lesions immediately adjacent to the left subclavian artery may require stent coverage of the artery to fully exclude the site of injury. This may result in endoleak due to retrograde blood flow from the left subclavian artery, or ischaemia of the left upper limb or vertebral artery territory requiring left subclavian to left carotid artery grafting. Device collapse causing catastrophic aortic occlusion can occur if the endograft is oversized. With improvements in technology and operator experience, TEVAR now has a lower risk of mortality, paraplegia and blood loss than open surgery.[20] Serial follow-up imaging is recommended after TEVAR.[5,22]

In patients unfit for immediate intervention, beta blocker +/− vasodilator therapy is given as tolerated to decrease aortic wall shear forces, aiming for a systolic blood pressure <100 to 120 mm Hg and heart rate <100 beats per minute. Delayed repair, after effective blood pressure control, has not been shown to worsen outcome and may reduce the peri-procedural risk of paraplegia.[20]

Minimal aortic injury, with no associated periaortic haematoma or pseudoaneurysm on initial CT can be managed expectantly, with serial imaging.[21] Development of pseudoaneurysm, or periaortic haematoma should prompt consideration for TEVAR.[22]

BLUNT CARDIAC INJURY

Blunt cardiac injury results from compression of the heart between the sternum and the spine, abrupt

pressure changes within cardiac chambers, or deceleration shear injury. A wide spectrum of injuries has been described, but may be classified according to the clinical sequelae and the need for intervention[6]:

- *Minor ECG and cardiac enzyme abnormalities:* sinus tachycardia and premature beats are common, but usually resolve within 24 hours without intervention.
- *Complex arrhythmias:* these may cause heart failure, or persistent hypotension, and may warrant antiarrhythmic therapy.
- *Free wall rupture:* this is usually fatal, but atrial rupture may present with haemopericardium +/− tamponade. Immediate drainage and repair is required.
- *Heart failure:* this may develop from gross myocardial injury, septal rupture (causing left to right shunt), or valvular injury (causing regurgitation). The latter may not manifest until weeks later. Septal rupture and severe valvular injury require surgery. Myocardial dysfunction may require inotrope therapy.
- *Coronary artery injury:* this is very rare and ST elevation on ECG is more likely to be due to a primary myocardial infarction.

All patients should have an ECG on admission. If this is normal and the patient is young, haemodynamically stable and has no history of cardiac disease, the risk of significant injury is very low and no further cardiac evaluation is required. Other patients should be monitored for late sequelae of significant cardiac injury (arrhythmia or heart failure).[6,28] Patients who remain haemodynamically stable with only minor ECG changes, and who have a normal troponin level at 6–8 hours post injury, have a low risk of cardiac complications.[28]

Echocardiography is indicated for patients with hypotension unexplained by other injuries, heart failure or persistent arrhythmias.[2,28] Undisplaced sternal fracture does not of itself warrant cardiac evaluation.[28,29]

TRACHEOBRONCHIAL INJURY

Blunt rupture of the trachea or bronchi results from crush injury or rapid deceleration with shearing of the airway between a fixed trachea and mobile lungs. The proximal right main bronchus is the most common site of injury.[2,30] Large injuries present with respiratory distress, subcutaneous emphysema and haemoptysis (see Box 79.3).[31] The chest radiograph demonstrates pneumothorax and mediastinal emphysema. Dramatic deterioration may follow the institution of positive-pressure ventilation (see Box 79.2). With smaller injuries, initial findings are often overshadowed by associated injuries with delay in diagnosis. Persistent pneumothorax with a large air leak, or recurrent pneumothoraces and pulmonary collapse, should prompt further investigation. Flexible bronchoscopy confirms the diagnosis and identifies the level of injury. Treatment is usually primary repair, although non-operative management has been described.[32] Late complications of either approach include post-obstructive pneumonia, empyema or bronchiectasis.[30]

With penetrating trauma the cervical trachea is most commonly injured. Immediate management involves tracheal intubation (preferably with flexible bronchoscopy) with the cuff positioned distal to the tear to ablate the air leak. With a large neck wound the endotracheal tube can be passed directly through the wound in emergency situations.

DIAPHRAGMATIC RUPTURE AND DIAPHRAGMATIC PARESIS

The usual mechanism of diaphragmatic rupture is gross abdominal compression from direct vehicular intrusion. The risk of rupture is higher with lateral impact collisions, but not seat belt use.[33] Associated injuries are very common.[33] Rupture of the left hemidiaphragm is more common because the right hemidiaphragm is congenitally stronger and protected by the liver.

Symptoms (dyspnoea and chest pain) are non-specific. Rarely bowel sounds are audible on chest auscultation. Diagnostic chest radiograph findings are herniation of bowel into the thoracic cavity and nasogastric tube above the left hemidiaphragm. Indirect signs include an elevated or distorted diaphragmatic outline, or pleural effusion, but these may be obscured by adjacent pulmonary pathology, phrenic nerve injury or by positive-pressure ventilation.[34] The low diagnostic accuracy of chest radiography often results in delayed diagnosis unless further imaging is performed. Multislice helical CT has high diagnostic accuracy, but magnetic resonance imaging, or video-assisted thoracoscopic surgery (VATS) may be required if uncertainty persists.[34,35] Prompt operative repair is important to prevent bowel incarceration or perforation. The choice of surgical approach (laparotomy or thoracotomy) is dictated by associated injuries.

Traumatic phrenic nerve palsy, or postoperative diaphragmatic dysfunction, may go unrecognised whilst the patient is on mandatory positive-pressure ventilation. With the transition to spontaneous ventilation, paradoxical abdominal and chest wall movement, reduced vital capacity and difficulty weaning from ventilatory support become evident.

OESOPHAGEAL INJURY

Rupture of the oesophagus from blunt trauma is rare. Penetrating trauma is more likely to injure the cervical portion of the oesophagus than the thoracic portion. Oesophageal perforation may also result from attempted endotracheal intubation or gastric tube insertion during resuscitation of the trauma patient.[36] Clinical features of thoracic oesophageal injury include

chest pain, dysphagia, pain on swallowing, haematemesis and subcutaneous emphysema (see Box 79.3). Chest radiograph findings include pneumothorax and/or hydrothorax, mediastinal emphysema, or widened mediastinum.[31] Suspected oesophageal injury from blunt trauma to the chest, or penetrating trauma to the chest or lower neck (zone 1), should be investigated with CT angiography.[14,36] Perioesophageal air and/or fluid on CT should be investigated further with oesophagoscopy or oesophagography (gastrografin swallow).[36] Treatment is immediate surgical repair.[36] Postoperatively, nutrition is provided by an enteral feeding tube, with nil per oral for 5 days, until confirmation of healing with a normal oesophagography.[36] Occasionally, stable patients with a small, isolated thoracic oesophageal injury can be managed with oesophageal stenting, clips and thoracoscopic debridement and drainage.[36] Delayed recognition or repair (more than 12 hours post injury) leads to septic shock from mediastinal contamination. Extensive irrigation and drainage is then required, but postoperative complications are common.[36]

PULMONARY INJURY

Pulmonary contusion is characterised by interstitial haemorrhage and oedema, with a secondary inflammatory reaction. Clinically there are signs of increased work of breathing, associated with impaired gas exchange and sometimes haemoptysis. The chest radiograph demonstrates patchy interstitial infiltrates, or consolidation not confined to anatomical segments. Gas exchange and radiographic findings may initially be unremarkable, with deterioration over the first 24–48 hours.[3,10] CT and lung ultrasound are more sensitive at detecting contusion, and quantification of lung volume affected predicts risk of acute respiratory distress syndrome (ARDS).[37,38] In the absence of complications (ARDS, pneumonia or aspiration) clinical and radiological recovery can be expected within 3–5 days.[10]

Treatment is supportive with humidified oxygen therapy, and encouragement of deep breathing and coughing in the spontaneously breathing patient. Non-invasive ventilation can be used in selected patients if gas exchange is poor. Intubation and mechanical ventilation is indicated for refractory hypoxaemia, or if intubation is required for non-pulmonary reasons. Routine corticosteroids are not indicated. Antibiotics should be reserved for superimposed pneumonia.[3] After adequate initial fluid resuscitation, unnecessary further fluid resuscitation should be avoided.

Pulmonary laceration occurs when disruption of lung architecture, with formation of an air or blood-filled cavity, occurs after blunt or penetrating trauma. On chest radiography, lacerations are often initially obscured by adjacent contusion, but typically take many weeks to resolve and may be complicated by abscess formation or bronchopleural fistula.[10]

BONY INJURIES

Half of all rib fractures are missed on plain chest radiography, but should be suspected if there is localised tenderness over the chest wall. Good analgesia to prevent pulmonary complications from sputum retention is essential.[39] This risk may not be clinically apparent initially, but deterioration in respiratory status over the next few days should be anticipated, especially in the elderly, smokers or patients with pre-existing pulmonary disease. First- and second-rib fractures, scapula fracture and sternoclavicular dislocation are markers of high-energy trauma.[3]

Most sternal fractures occur in restrained occupants involved in frontal impact vehicular crashes. Associated thoracolumbar spine fractures are common.[29] Blunt cardiac injury should be suspected with displaced sternal fractures.[29]

FLAIL CHEST

The fracture of at least four consecutive ribs in two or more places results in a flail segment with paradoxical movement of the chest wall during tidal breathing (Fig. 79.5).[3] Associated pulmonary contusion is often present. Younger patients with no other major injuries, no pulmonary co-morbidities and good analgesia can often be managed with non-invasive ventilation or oxygen therapy alone.[40] Deteriorating gas exchange and sputum retention are indications for intubation and mechanical ventilation. Prolonged ventilatory support is often not necessary in patients whose associated injuries and co-morbidities are not severe. Surgical stabilisation has been advocated for severe flail (without severe pulmonary contusion) to reduce duration of ventilation, although the optimal technique for surgical fixation remains uncertain.[41,42]

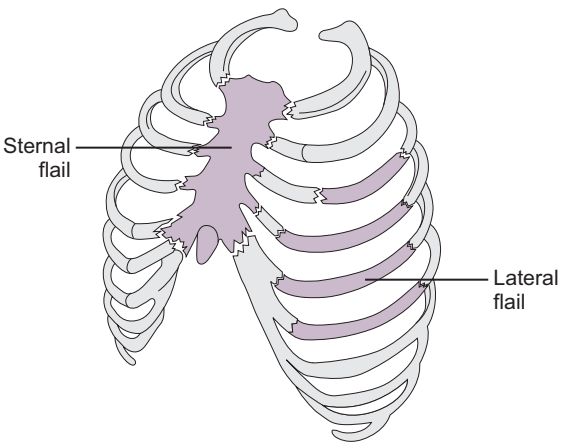

Figure 79.5 Types of flail chest. *Modified from Wanek S, Mayberry JC. Blunt thoracic trauma: flail chest, pulmonary contusion, and blast injury.* Crit Care Clin. *2004;20:71–81.*

EXTRAPLEURAL HAEMATOMA

Traumatic extrapleural haemorrhage arises when chest wall bleeding does not enter the pleural space.[43] Chest radiography shows a parietal shadow that does not cause blunting of the costophrenic angle or shift with gravity. A large haematoma should be evacuated with an intercostal tube or by thoracotomy.

SYSTEMIC AIR EMBOLISM

This is more frequent with penetrating injuries and is immediately life threatening. The typical presentation is circulatory collapse after the institution of positive-pressure ventilation, when the pulmonary air-space pressure exceeds pulmonary venous pressure (see Box 79.2). Focal neurological changes in the absence of head injury also suggest the diagnosis. Characteristic head CT findings have been described.[44]

When suspected, maintenance of spontaneous ventilation is preferred. If positive-pressure ventilation is necessary, an inspired oxygen concentration of 1.0 should be used, with ventilatory pressures and volumes reduced to a minimum. Selective lung ventilation, using a double-lumen endotracheal tube or bronchial blocker, and/or high-frequency ventilation, should be considered.[44] However, urgent thoracotomy, with hilar clamping or lung isolation, is usually indicated.[13] Hyperbaric oxygen therapy has been used to treat cerebral air embolism, but is often impractical.[44]

COMPLICATIONS AND INTENSIVE CARE UNIT MANAGEMENT

On admission to the ICU, rewarming, correction of coagulopathy and ongoing fluid resuscitation are often required. Pericardial tamponade and persistent air leak should be anticipated in post-thoracotomy patients.[17] A restrictive approach to fluid therapy is indicated for patients who have undergone lung surgery. However, care should be taken to ensure adequate fluid resuscitation. A judicious transfusion policy should be employed with all patients.[45]

As with other critically ill or injured patients, prophylactic measures against thromboembolism[46] and upper gastrointestinal stress ulceration should be used. Adequate nutrition is important to ameliorate the hypermetabolic and catabolic metabolic changes, reduce the incidence of sepsis and improve outcome. Nutrition should be instituted early, preferably via the enteral route.

ACUTE RESPIRATORY FAILURE AND MECHANICAL VENTILATION

Respiratory complications are common. When acute lung injury occurs early after trauma, common causes are pulmonary contusion, aspiration, massive transfusion and prolonged shock or delayed resuscitation with severe systemic inflammatory response. Aspiration with persistent lobar collapse is an indication for bronchoscopy to exclude bronchial obstruction from particulate obstruction. When lung injury develops several days later, sepsis of either pulmonary or non-pulmonary origin is a more likely cause.

The approach to mechanical ventilation for intubated patients follows the same principles as with other critically ill patients.

- Patients with acute lung injury/ARDS should be ventilated with a lung-protective strategy. However, high positive end-expiratory pressure (PEEP) and permissive hypercapnia are contraindicated if there is associated head injury.
- Patients with pneumothorax or tracheobronchial injury should be managed with low PEEP, low peak airway pressures, and early transition to spontaneous ventilation if possible.
- Patients with flail chest may benefit from the splinting effect of moderate levels of PEEP.
- Failure to wean from mechanical ventilation should raise suspicion of fluid overload, diaphragmatic injury, cardiac dysfunction or flail.

Select patients with hypoxaemia refractory to optimal mechanical ventilation may be supported with venovenous extracorporeal membrane oxygenation.

SPUTUM RETENTION

Sputum retention leads to progressive pulmonary collapse, with impaired gas exchange, increased work of breathing and increased risk of infection. Smokers, or patients with pre-existing respiratory disease, are particularly at risk. In the spontaneously breathing patient, good analgesia and incentive spirometry facilitate coughing and deep breathing. In the intubated/ventilated patient, humidification, tracheal suctioning and regular position changes are important.

ANALGESIA

Adequate analgesia is essential for deep breathing and effective coughing, which, if achieved, will reduce the likelihood that endotracheal intubation will be needed for less severely injured patients. Analgesia also facilitates chest physiotherapy and early mobilisation, reducing pulmonary morbidity. The choice of analgesia depends on the severity of illness and may vary over time. Options include the following[39]:

- *Intravenous morphine or fentanyl by frequent small boluses or continuous infusion:* this is the mainstay of analgesia for severely injured patients who are intubated and ventilated. Patient-controlled analgesia can be used for cooperative unintubated patients.
- *Thoracic epidural infusion of combined opioid and local anaesthetic agent (e.g. fentanyl 2 μg/mL + bupivicaine*

0.125% at 5–15 mL/h): this may be the preferred option for unintubated patients, particularly the elderly, if four or more ribs are fractured, or if there are cardiopulmonary co-morbidities. It may also be used to facilitate successful extubation of ventilated patients who still have significant analgesia requirements.

- *Intercostal nerve block:* this can be used if only a few lower ribs are fractured. Either a single bolus (20 mL of 0.5% bupivicaine) can be injected into one intercostal space, or smaller amounts can be injected at multiple levels. Repeated injections may be required.
- *Paravertebral block:* this is rarely used unless thoracic surgery is performed.
- *Non-steroidal anti-inflammatory agents:* these should be used only in fully resuscitated patients with normal renal function and no other contraindications.
- *Paracetamol:* this is given regularly except in the presence of hepatic dysfunction.

PNEUMONIA

Sepsis is the principal cause of late death after major trauma. Breach of the skin surface barrier, devitalised tissues and the presence of invasive drains and catheters make the trauma patient especially prone to bacterial invasion. In the chest-injured patient, pulmonary contusion, emergency intubation, shock, blood transfusion and the presence of extrathoracic injuries increase the risk of nosocomial pneumonia.

Early-onset pneumonia (within the first few days of hospitalisation) may result from aspiration at the time of injury, particularly after head injury. Common pathogens are *Haemophilus influenzae*, *Pneumococcus* and anaerobes. Later-onset nosocomial pneumonia is more likely to be due to aerobic Gram-negative bacilli and *Staphylococcus aureus*.

The diagnosis of pneumonia is suspected if there are new or progressive infiltrates on the chest radiograph and deterioration in respiratory status. However, new infiltrates may also be caused by pulmonary contusion, pleural fluid collections, atelectasis, aspiration and pulmonary oedema. Infection is supported by the presence of purulent sputum, new fever and leucocytosis. Confirmation depends on culture of tracheal aspirate or bronchoscopic samples.[47]

Antibiotic therapy should be targeted at causative organisms. Prompt empirical antibiotics should be started in unstable patients, with re-evaluation at 48–72 hours.

Preventative measures include careful hand cleansing, reduced duration of intubation and ventilation, semirecumbent position, enteral nutrition, avoidance of excessive sedation or hyperglycaemia, and avoidance of prolonged prophylactic antibiotics.[47]

RETAINED HAEMOTHORAX AND EMPYEMA

Haemothorax that is not adequately drained within a few days becomes clotted and unable to drain via intercostal tube. The clot becomes organised and fibrosed with progressive pleural thickening (fibrothorax). This results in loss of lung volume, impaired pulmonary compliance and increased risk of empyema formation. Patients with persistent opacity on chest radiograph after intercostal tube placement should undergo ultrasound or CT imaging to determine whether a significant retained haemothorax is present.[12,14] Small haemothoraces (<300 mL) in clinically stable patients where the pleural cavity has not been breached may be observed. However, in the presence of respiratory compromise, suspected empyema, or retained haemothorax over 300 mL, further intervention is required. Several management options are available, but complete drainage should be achieved within 3–7 days, before the development of fibrothorax or empyema.

If the initial intercostal tube is poorly positioned, or blocked, a second tube may be placed through a different skin incision, preferably under ultrasound or CT guidance. In other circumstances a second intercostal tube should be avoided because of the increased risk of empyema formation and a high failure rate.[12,14,48] If the initial intercostal tube remains patent, evacuation of the retained haemothorax can be attempted with intrapleural administration of a fibrinolytic agent, after the exclusion of a bleeding diathesis or intrathoracic organ injury.[12,49] Fibrinolysis is most likely to be successful if attempted within 3 days of initial haemothorax. Tissue plasminogen activator 50 mg in 100 mL saline is instilled into the intercostal tube for 1 hour each day, for up to 3 days, until resolution of haemothorax with minimal further drain losses.[12,49] Intrapleural administration of a combination of tissue plasminogen activator and DNase has been advocated to assist drainage of early retained empyema, but has not been evaluated for retained haemothorax and may increase the risk of bleeding.[50]

VATS is the recommended approach in haemodynamically stable patients who can tolerate single-lung ventilation.[12,14,35,48,51] Failure of these techniques, or empyema formation, requires formal thoracotomy +/− decortication.[51] VATS and thoracotomy allow direct inspection for a missed pulmonary, diaphragmatic or oesophageal injury.[35]

Patients who did not require initial intercostal tube drainage, but who subsequently develop respiratory compromise or opacification on chest radiograph, should be imaged with ultrasound or CT to look for delayed haemothorax. This should also prompt reconsideration of an occult injury to the diaphragm or an intrathoracic organ.

FAT EMBOLISM SYNDROME

Fat embolism is very common in patients with long-bone fractures[52] and frequently causes oxygen desaturation, which may be severe and prolonged in patients with parenchymal lung injury.[53] However, fat embolism *syndrome*, with pulmonary, neurological and cutaneous

sequelae, is rare. The treatment of fat embolism is supportive, but early resuscitation and fracture stabilisation are important preventative measures.[52] Early (<24 hours) intramedullary nailing is the fixation method of choice, resulting in fewer orthopaedic complications than other fixation methods, and fewer pulmonary complications than delayed surgery.[54,55] However, internal fixation may provoke further fat embolism, require a longer operative time and result in more blood loss than external fixation.[54] Thus in severely chest-injured patients, temporary stabilisation using external fixation with intramedullary nailing several days later is preferred.[54]

PROGNOSIS

Risk of death and length of intensive care stay depend on severity of chest injury, extent of extrathoracic injuries and pre-existing co-morbidities.[1,55] Initial physiological markers that predict adverse outcome are a low Glasgow Coma Scale score, hypotension and a high respiratory rate. In patients with severe blunt trauma the mortality is significantly higher with bilateral than with unilateral chest injuries, and depends more on the extent of parenchymal lung injury than the extent of chest wall injury.[56] Older age correlates strongly with worse outcome, even though the elderly are more likely to suffer rib fractures than parenchymal lung injury.[55,56] In the elderly the risk of death or pneumonia increases with each additional rib fractured.

Spinal injuries

Sumesh Arora, Oliver Flower

INTRODUCTION

Spinal cord injury (SCI) has immense consequences for patients, their families, health care resources and society. Initial management of SCI and prevention of secondary injury may make substantial differences to long-term functional outcome. SCI is best managed in specialised spinal injury units, with specialist medical, nursing, and allied health expertise.[1,2] The prognosis for SCI has improved tremendously in the last 50 years, and despite their disability, survivors often report high levels of life satisfaction years after their injury.[3] Non-traumatic SCI, from a broad range of aetiologies, shares many clinical and pathological features with traumatic SCI. However, as the specific differences in managing non-traumatic SCI are beyond the scope of this chapter, we will focus on traumatic SCI.

EPIDEMIOLOGY

Approximately 5% of trauma victims have spinal fractures, and 20% of these have SCI.[4] The incidence of traumatic SCI ranges from 2.3 to 83 cases per million population per year, with a prevalence ranging from 236–1800 cases per million population in developed countries.[5] Approximately 80% of victims are male, usually in the 15–35 age group. Motor vehicle accidents are the commonest cause, followed by falls and sports-related injuries. The proportion of injuries related to falls, especially in people over the age of 60 years, is increasing.[4,6] Pre-existing spinal pathology such as spinal canal stenosis, osteoporosis or ankylosing spondylitis increases the risk of SCI from relatively minor trauma. Improved availability and quality of pre-hospital treatment has increased prevalence of SCI survivors. The epidemiology of neurological level of injury (NLI) varies, depending on location. In developed countries, more than 50% are cervical SCI, but developing countries report lower rates. This may be because of early mortality, as well as aetiological, geographical and economic global variation.[5] Approximately one-third of patients are tetraplegic and half of patients with SCI have complete injuries.[7]

PATHOGENESIS

APPLIED ANATOMY AND PHYSIOLOGY

The spinal cord extends from the foramen magnum to approximately the L1-L2 level. The conical lower end of spinal cord is called the conus medullaris, from which a filament of fibrous tissue, known as filum terminale, continues inferiorly. The cauda equina refers to the bundle of spinal nerves, for the lumbo-sacral segments, that continue below the spinal cord. Compared to the spinal cord in the cervical and thoracic regions, the cauda equina is less susceptible to injury due to a relatively larger canal size in the lumbar region.[8] Corresponding to each intervertebral level, dorsal and ventral roots exit the spinal cord and join within the dural sac to form the spinal nerve. The spinal nerves run caudally within the spinal column until they reach the corresponding vertebral levels, then exit through the spinal foramen. During development, the vertebral column elongates more than the spinal cord, so there is an increasing discrepancy between the anatomical level of spinal cord segments and their corresponding vertebrae as we go caudally.

The sympathetic nerve supply originates from the intermediolateral column of segments T1-L2. The parasympathetic outflow originates from S2-S4 level and supplies the pelvic viscera. A cross section of the spinal cord is shown in Fig. 80.1.

SPINAL CORD INJURY

The pathophysiology of SCI is described as biphasic, consisting of primary and secondary phases.

PRIMARY INJURY

Direct mechanical injury may produce focal compression, haematoma, laceration or traction injury to the cord. Actual transection is unusual. Ischaemic injury may result from injury to the segmental spinal

ABSTRACT

Spinal cord injury (SCI) commonly affects young people, and results in permanent disability. Judicious management in the intensive care unit may reduce secondary SCI and prevent complications. Cervical SCI results in severe respiratory dysfunction, and weaning from the ventilator may take several weeks to months. Patients with cervical SCI may have unique cardiovascular problems like autonomic dysreflexia, which may be life threatening. In this chapter, we discuss the epidemiology, classification, imaging, intensive care management and outcome of SCI.

KEYWORDS

Spinal cord injury
tetraplegia
neurological level of injury
autonomic dysreflexia

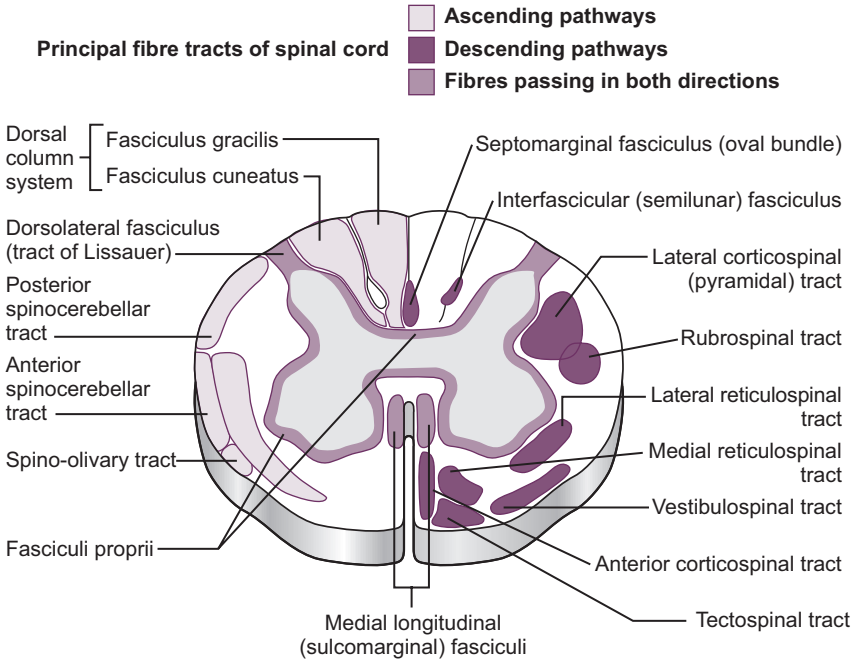

Figure 80.1 Cross-section of the spinal cord. *(From Principal Tracts of Spinal Cord, Image ID: 60477, published in Rubin M, Safdieh JE, Gross anatomy of the brain and spinal cord. In:* Netter's Concise Neuroanatomy*; 2007:49.)*

arterial supply. Initial pathological changes include the traumatic severing of axons, blood vessels and cell membranes.[9,10]

SECONDARY INJURY

Local ischaemia begins at the site of injury, extending progressively, over several hours, from the site of injury in both directions. There is loss of autoregulation of blood flow to the spinal cord, often complicated by arterial hypotension in high SCI. Other mechanisms that may contribute to the secondary injury include release of free radicals, reactive oxygen species, eicosanoids, calcium, proteases, phospholipases and excitotoxic neurotransmitters (e.g. glutamate).[9,10]

Petechial haemorrhages begin in the grey matter, progress over hours, and may result in significant haemorrhage into the cord. There is oedema, cellular chromatolysis and vacuolation, and ultimately neuronal necrosis. Apoptosis, especially of oligodendrocytes, also occurs.[9] In the white matter, vasogenic oedema, axonal degeneration and demyelination follow. Polymorphs infiltrate the haemorrhagic areas. Late coagulative necrosis and cavitation subsequently take place.[11]

INITIAL ASSESSMENT AND MANAGEMENT

Early management of SCI should focus on prevention of secondary injury and provide optimum conditions for neurological recovery. This is achieved by immobilisation until the spine is stable, prevention of hypoxia, defending blood pressure and avoiding metabolic abnormalities.

In general, the principles of managing severe trauma are outlined in Chapter 77. Resuscitation must occur simultaneously with evaluation, initial investigations and management. The specific considerations in the acute setting are outlined in Table 80.1.

NEUROLOGICAL ASSESSMENT

A thorough neurological examination should be performed as early as feasible after presentation, prior to administration of any sedative or paralytic agents. The International Standards for Neurological Classification of Spinal Cord Injury (ISNCSCI) outlines a comprehensive clinical exam for patients with SCI (Fig. 80.2). The American Spinal Injury Association (ASIA) impairment scale[12] is the most validated instrument for diagnosing and classifying SCI. It is currently the only standardised neurological examination available that allows prognostication, and has sufficient inter-rater reliability for local and international data collection and comparison. A bilateral sensory and motor exam, including digital rectal examination, determines a single NLI, completeness of injury and the ASIA grade (see Fig. 80.2). Table 80.2 describes the grades of the ASIA impairment scale.[12]

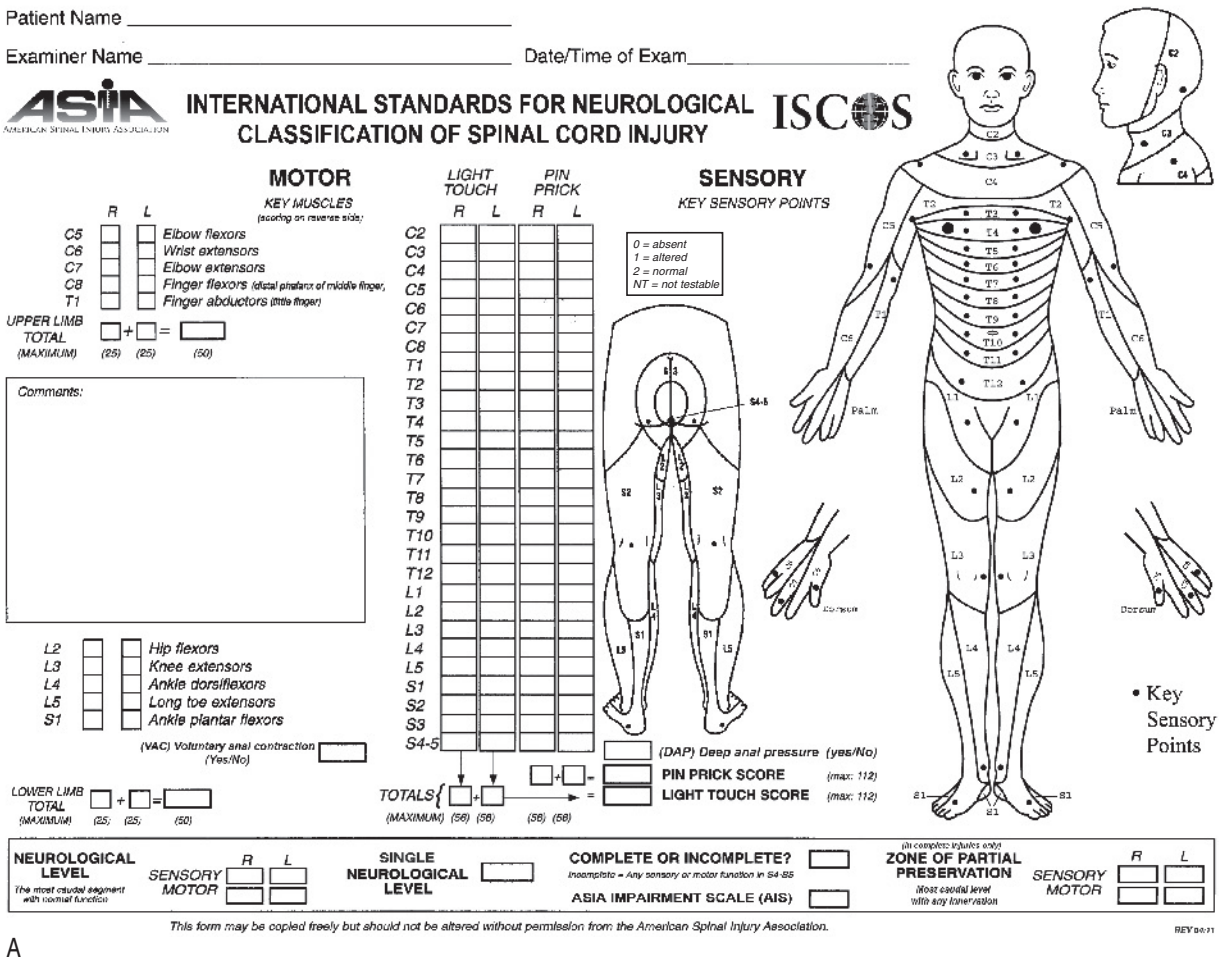
Table 80.1 Acute issues following spinal cord injury

ISSUE	PATHOPHYSIOLOGY RELEVANT TO SCI	MANAGEMENT
Need for intubation	Paralysis of muscles of respiration below NLI Increased secretions and bronchospasm from loss of sympathetic innervation	Consider intubation for Respiratory failure Decreased level of consciousness Transport to another hospital or for imaging Surgical intervention
Intubation	Excessive movement of neck in unstable cervical injury may cause further spinal cord damage	If intubation is urgent, rapid sequence induction & intubation with manual in-line stabilisation Minimise neck movement Video laryngoscopy improves view and minimises movement Consider awake fibre-optic intubation if time and expertise available
Hypotension	Loss of vasomotor tone below NLI Bradycardia for NLI above T1 Traumatic abdominal or long-bone haemorrhage presents differently in patients insensate below the NLI	Must exclude hypovolaemia/haemorrhagic shock Vasoplegia and bradycardia from SCI causes neurogenic distributive shock Give fluids initially Have low threshold for inserting central line and using vasopressors Consider targeting a MAP of 85 mm Hg to maintain spinal cord perfusion
Bradycardia	Loss of cardiac sympathetic innervation (T1-T4)	May require anticholinergics (e.g. atropine), chronotropics (e.g. isoprenaline) or pacing
Neurological examination	NLI and ASIA grade may be difficult to assess once patient is intubated	Obtain NLI and ASIA grade if patient alert, before sedation or intubation
Medications	Sedation may prevent accurate assessment of neurological status	Use short-acting sedatives and analgesics to permit repeat neurological assessment Avoid paralytic agents if possible
Pressure area care	Loss of sensation and paralysis predisposes to early decubitus ulcers	Transfer off hard board as early as possible Change collar to Miami J as soon as possible Roll every 2 h Skin inspection twice a day
Hypothermia	Vasoplegia Loss of thermoregulatory control Exposure during resuscitation Pre-hospital environmental factors	External passive and active warming may be required
Urinary retention	Paralysis of detrusor Loss of bladder sensation	Indwelling bladder catheter
Gastroparesis	Loss of gastrointestinal sympathetic innervation Ileus Gastroparesis	Nasogastric insertion
Refer & transfer	Better outcome in specialist spinal care centres	Early liaison and transfer to SCI specialist unit

ASIA, American Spinal Injury Association; *MAP*, mean arterial pressure; *NLI*, neurological level of injury; *SCI*, spinal cord injury.

In conscious, alert patients, SCI may be obvious, with weakness, reduced sensations and absence of reflexes below the NLI, vasodilatation, priapism, urinary retention and paralytic ileus. When assessing sensation, it should be remembered that the C4 dermatome can extend as low as the nipple line, misleading the examiner to believe that T4 dermatome has sensation. An initial ASIA classification may reliably predict long-term motor outcome.[13] However, other injuries, pain, alcohol or the administration of analgesic or other drugs may make initial assessment impossible. Signs of SCI in unconscious or uncooperative patients include:

- Response to pain above, but not below, a suspected level of injury



A

Figure 80.2 American Spinal Injury Association. International Standards for Neurological Classification of Spinal Cord Injury, revised 2011. *(From Kirshblum SC, Burns SP, Biering-Sorensen F, et al. International standards for neurological classification of spinal cord injury (Revised 2011).* J Spinal Cord Med. *2011;34(6):535–546.)*

- Flaccid areflexia in the legs and/or arms
- Paradoxical pattern of breathing with in-drawing of upper chest during inspiration (in the absence of upper airway obstruction or chest injury)
- Inappropriate vasodilatation (in association with hypothermia, or in the legs but not the arms with thoracolumbar SCI)
- Unexplained bradycardia, hypotension
- Priapism
- Loss of anal tone and reflexes

TERMINOLOGY OF SPINAL CORD INJURY

The terminology for SCI has now been standardised by the ISNCSCI.[12]

Tetraplegia

Tetraplegia (preferred to quadriplegia) is defined as impairment of motor and/or sensory function in the cervical segments of spinal cord due to damage of the neural elements of the spinal canal. Tetraplegia typically affects both upper and lower limbs.

Paraplegia

Motor and/or sensory deficits affecting only lower limbs due to SCI in the thoracic, lumbar or sacral (but not cervical) segments of the spinal cord. The term is also used in referring to the cauda equina or conus medullaris injuries.

Neurological level of injury

The most caudal cord segment with normal sensory and antigravity motor function bilaterally, provided there is intact sensory and motor function rostrally (above the level). As differences often exist, it is preferred to describe the individual motor (better than antigravity power) and sensory levels on each side.

Muscle Function Grading

0 = total paralysis

1 = palpable or visible contraction

2 = active movement, full range of motion (ROM) with gravity eliminated

3 = active movement, full ROM against gravity

4 = active movement, full ROM against gravity and moderate resistance in a muscle specific position.

5 = (normal) active movement, full ROM against gravity and full resistance in a muscle specific position expected from an otherwise unimpaired peson.

5* = (normal) active movement, full ROM against gravity and sufficient resistance to be considered normal if identified inhibiting factors (i.e. pain, disuse) were not present.

NT = not testable (i.e. due to immobilization, severe pain such that the patient cannot be graded, amputation of limb, or contracture of >50% of the range of motion).

ASIA Impairment (AIS) Scale

☐ **A = Complete.** No sensory or motor function is preserved in the sacral segments S4-S5.

☐ **B = Sensory Incomplete.** Sensory but not motor function is preserved below the neurological level and includes the sacral segments S4-S5 (light touch, pin prick at S4-S5: or deep anal pressure (DAP)), AND no motor function is preserved more than three levels below the motor level on either side of the body.

☐ **C = Motor Incomplete.** Motor function is preserved below the neurological level**, and more than half of key muscle functions below the single neurological level of injury (NLI) have a muscle grade less than 3 (Grades 0-2).

☐ **D = Motor Incomplete.** Motor function is preserved below the neurological level**, and at least half (half or more) of key muscle functions below the NLI have a muscle grade ≥ 3.

☐ **E = Normal.** If sensation and motor function as tested with the ISNCSCI are graded as normal in all segments, and the patient had prior deficits, then the AIS grade is E. Someone without an initial SCI does not receive an AIS grade.

**For an individual to receive a grade of C or D, i.e. motor incomplete status, they must have either (1) voluntary anal sphincter contraction or (2) sacral sensory sparing with sparing of motor function more than three levels below the motor level for that side of the body. The Standards at this time allows even non-key muscle function more than 3 levels below the motor level to be used in determining motor incomplete status (AIS B versus C).

NOTE: When assessing the extent of motor sparing below the level for distinguishing between AIS B and C, the ***motor level*** on each side is used; whereas to differentiate between AIS C and D (based on proportion of key muscle functions with strength grade 3 or greater) the ***single neurological level*** is used.

Steps in Classification

The following order is recommended in determining the classification of individuals with SCI.

1. Determine sensory levels for right and left sides.
2. Determine motor levels for right and left sides.
   Note: in regions where there is no myotome to test, the motor level is presumed to be the same as the sensory level, if testable motor function above that level is also normal.
3. Determine the single neurological level.
   This is the lowest segment where motor and sensory function is normal on both sides, and is the most cephalad of the sensory and motor levels determined in steps 1 and 2.
4. Determine whether the injury is Complete or Incomplete. (i.e. absence or presence of sacral sparing)
   If voluntary anal contraction = **No** *AND all S4-5 sensory scores =* **0** *AND deep anal pressure =* **No,** *then injury is COMPLETE. Otherwise, injury is incomplete.*
5. Determine ASIA Impairment Scale (AIS) Grade:

Is injury Complete? If **YES,** AIS=A and can record ZPP (lowest dermatome or myotome on each side with some preservation)

NO ↓

Is injury motor Incomplete? If **NO**, AIS=B (Yes=voluntary anal contraction OR motor function more than three levels below the motor level on a given side, if the patient has sensory incomplete classification)

YES ↓

Are at least half of the key muscles below the single neurological level graded 3 or better?

NO ↓ AIS=C YES ↓ AIS=D

If sensation and motor function is normal in all segments, AIS=E
Note: AIS E is used in follow-up testing when an individual with a documented SCI has recovered normal function. If at initial testing no deficits are found, the individual is neurologically intact; the ASIA Impairment Scale does not apply.

B

Figure 80.2, cont'd

Table 80.2 American spinal injury association impairment scale

A	Complete: No sensory or motor function is preserved in the sacral segments S4-S5
B	Sensory Incomplete: Sensory but not motor function is preserved below the neurological level and includes the sacral segments S4-S5
C	Motor Incomplete: Motor function is preserved below the neurological level, and less than half of key muscles below the neurological level have a muscle grade ≥3
D	Motor Incomplete: Motor function is preserved below the neurological level, and half or more of key muscles below the neurological level have a muscle grade ≥3
E	Normal: Sensory and motor function is normal and the patient with previous SCI. If initial testing after injury does not show any impairment, this classification does not apply.

SCI, Spinal cord injury.

The single NLI is then the most rostral of these levels. Note that as the spinal cord is shorter than the vertebral column, with more caudal SCI, the NLI may differ from the radiological level of injury (see Fig. 80.2).

Complete spinal cord injury

SCI is complete when there is absence of both motor and sensory function in the lowest sacral segments, S4 and S5 (i.e. no voluntary anal contraction and no perianal sensation).

Zone of partial preservation

This term is used to describe complete (ASIA A) SCI. This refers to the spinal segments that have any motor or sensory function below the NLI.

Spinal shock

The period of flaccid paralysis, anaesthesia, loss of bowel and bladder function, and areflexia following a spinal injury is called spinal shock. It may last from 48 hours to several weeks. Emergence from spinal shock occurs gradually. During emergence, deep

plantar reflex and the cutaneous reflexes (e.g. bulbocavernosus, cremasteric reflex) recover first, within 1–3 days. This is followed by reappearance of deep tendon reflexes, usually after a few weeks.[14] Only once spinal shock has resolved may autonomic dysreflexia (AD) manifest.

Neurogenic shock

A form of distributive (cardiovascular) shock following SCI due to loss of sympathetic tone in peripheral vasculature.

SYNDROMES OF INCOMPLETE SPINAL CORD INJURY

Incomplete SCI may occur in the form of characteristic syndromes.[12]

Central cord syndrome

Weakness and sensory loss, greater in the arms than the legs. Typically follows a hyperextension injury in patients with pre-existing canal stenosis, such as an elderly person falling onto chin. Ischaemia or haematoma in the centre of the cord predominantly affects the cervical segment due to the pattern of lamination of the corticospinal and spinothalamic tracts.

Anterior cord syndrome

Loss of motor function, pain and temperature sensation below the level of injury, with preservation of fine touch and proprioception. Anterior cord syndrome typically follows interruption of the blood supply to the anterior spinal cord, and may be seen in patients with aortic pathology or surgery.

Brown-Séquard syndrome

Ipsilateral loss of motor, proprioception and fine touch, with contralateral loss of pain and temperature sensation below the level of injury. It usually follows a penetrating SCI damaging only one half of the spinal cord.

Conus medullaris syndrome

Flaccid paralysis of external anal sphincter, faecal incontinence, bladder distension and incontinence, impotence and saddle or perianal anaesthesia. Weakness in lower limbs may result from injury to adjacent lumbar and sacral nerve roots. Caused by injury at T12-L1 level.

Cauda equina syndrome

Results from injury to the cauda equina, leading to asymmetrical, lower motor neuron lower limb weakness with sensory loss in the territory of affected nerve roots, with bladder and bowel areflexia. Caused by injuries below L1 damaging the lumbosacral nerve roots.

Because of proximity of cauda equina and conus medullaris, a single injury may affect both structures, and classification of the injury to one specific syndrome may not be possible.

ASSOCIATED INJURIES

Overall, in major trauma, the incidence of cervical spine injury (CSI) is 1%–3%; 2%–10% of patients with head injuries have a CSI. The more severe the head injury, the more likely is CSI to be present. Patients with head injuries should be assumed to have a CSI until proved otherwise. Among patients with a cervical SCI, 25% have some degree of head injury, with 2%–3% having a severe injury.[9]

Chest injuries are often present in association with thoracolumbar injuries and are difficult to assess due to inability to take an erect chest X-ray, or presence of a mediastinal haematoma associated with the vertebral injury. Computerised tomography (CT) of the chest may be used to assess other chest injuries, with contrast to exclude aortic injuries. There should be a high index of suspicion of abdominal injuries, as the lack of sensation, hypotension and bradycardia from the SCI may mask the usual presentation.

IMMOBILISATION

If traumatic SCI is suspected, initial management involves manual support of the head in a natural, neutral position, limiting angular movement of the head and spine. Padding under the head (approximately 2 cm) may optimise the neutral position.[15] Semi-rigid cervical collars carry significant risks and, if used at all, should be exchanged for softer collars as soon as possible. Hard spinal boards cause rapid development of pressure injury. This risk can be minimised by transferring the patient off the hard board as soon as feasible, and providing meticulous pressure area care. Of the available hard collars, Miami J and Philadelphia collars restrict cervical movement more than Aspen or Miami J/Occian back. The Miami J and Miami J/Occian back cause the lowest levels of mandibular and occipital pressure.[16] Complications of prolonged immobilisation and spinal precautions include cutaneous pressure ulceration, difficult intubation, potential venous obstruction leading to high intracranial pressure, reduced options for central venous access, higher risk of venous thromboembolism (VTE), increased risk of respiratory infections due to restricted physiotherapy, gastroparesis and an inability to provide optimal oral care.[17]

IMAGING

IS IMAGING REQUIRED?

Some trauma patients may not require cervical spinal imaging and the inherent risks that this entails. Two clinical decision tools are used in this context: The National Emergency X-Radiography Utilization Study

(NEXUS) criteria and the Canadian C-Spine rule (CCCR). NEXUS suggests cervical spine imaging is indicated for patients with trauma unless they meet all of the following criteria[18]:

- No posterior midline cervical spine tenderness
- No evidence of intoxication
- Normal level of alertness
- No focal neurological deficit
- No painful distracting injuries

NEXUS criteria have a very high sensitivity (99.6% for significant injuries) if used as initially intended, although the specificity is only 12.9%. They require there to be no evidence of any intoxication (including even an odour of alcohol), an alert level of consciousness sufficient to allow *three object recall at five minutes*, no focal neurological deficits and there should be no painful distracting injuries. This subjective component includes any long-bone fractures, de-gloving injuries, deep lacerations, visceral injuries, crush injuries, large burns or any injury that causes any acute functional impairment. The Canadian C-Spine rules have a higher degree of sensitivity (100%) and specificity (45%), but were based on a smaller cohort of patients than NEXUS.[18] Again, they only define which patients may be clinically cleared without imaging.

IMAGING MODALITIES

PLAIN RADIOGRAPHS

Adequate, three-view combination (A-P, Lateral and odontoid peg view) plain radiography misses injuries of the spinal column in both alert and obtunded patients, with a pooled sensitivity of detecting significant injuries of 52%.[19] Despite reducing thyroid radiation exposure in comparison to CT, plain radiography has no role in this context, unless other modalities are not available.[20]

DYNAMIC STUDIES (DYNAMIC FLUOROSCOPY OR FLEXION/EXTENSION RADIOGRAPHY)

This imaging modality poorly visualises the relevant anatomy[21] and has a low sensitivity to detect injury.[22] It is labour and resource intensive[23] and has now been superseded by CT and magnetic resonance imaging (MRI).

COMPUTERISED TOMOGRAPHY

CT technology has improved considerably in recent years, with multidetector row CT (MDCT) offering sensitivity of detecting spinal injuries, including ligamentous injury, close to 100%.[24] MDCT is readily available, easily performed as part of a polytrauma evaluation and is more time and cost-effective than plain radiography. However, MDCT may miss some significant and unstable injuries (subsequently detectable by MRI) in approximately 4%, with 0.29% requiring surgical stabilisation. Other disadvantages include significant thyroid radiation exposure and transport of a trauma patient to CT.[17]

MAGNETIC RESONANCE IMAGING

To investigate cord injury, MRI provides superior imaging to any other modality.[25] MRI provides a detailed image of spinal cord, spinal ligaments, intervertebral discs and paravertebral soft tissues. It is the most sensitive screening test available to detect soft tissue and ligamentous injuries that could contribute to instability of the cervical spine[26] and MR angiography may detect associated vertebral artery injury. In the setting of trauma, MRI imaging supplements the information obtained from CT scan, and does not replace the need for a CT.

Timing of MRI is another contentious issue as with time, the MR signal may change due to a decrease in ligamentous oedema. The Eastern Association for the Surgery of Trauma guidelines recommend that MRI should be performed within 72 hours[27]; however, there is only limited evidence that delay between injury and imaging results in a false negative MRI.[28]

AN APPROACH TO IMAGING

There is currently no universal consensus. If there is no neurological deficit but the other conditions of the Canadian C-Spine Rule or NEXUS rules are not met, then high resolution MDCT of the entire spine is indicated. For the obtunded blunt trauma patient who is likely to be un-assessable for a prolonged period, an MRI may follow the MDCT. Following trauma, if there is evidence of any new neurological deficit attributable to a SCI, an urgent MRI should be performed.

Policy for the use of MRI in this context should be discussed at an institutional level, with the knowledge that MDCT alone may miss a small percentage of injuries that would otherwise have required intervention, but the false-positive rate of MRI may result in significant morbidity to patients with no injuries who are kept immobilised.[17]

The risk of vertebral artery injury is high in patients with CSI associated with fracture extending to the transverse foramen, basilar skull fracture, facet joint subluxation/dislocation or co-existing disease like diffuse idiopathic skeletal hyperostosis or ankylosing spondylosis.[29]

INTENSIVE CARE MANAGEMENT OF SPINAL CORD INJURY

PREVENTION OF SECONDARY NEUROLOGICAL INJURY AFTER SPINAL CORD INJURY

Spinal cord compression may occur due to misalignment of spine, oedema or haemorrhage. Incomplete injury with spinal cord compression should be urgently decompressed. Stability is the ability of the spine,

under physiological loads, to limit patterns of displacement, which would result in neurological injury, pain, or deformity.[30] It is affected by fracture morphology and osteo-ligamentous integrity. Most unstable spinal injuries require operative intervention. Where indicated, early surgery within 24 hours of injury is safe, may improve neurological outcome, reduces length of stay in acute care, permits early mobilisation and commencement of deep vein thrombosis prophylaxis and lowers hospital cost.[31] Most spinal surgeons prefer to operate as early as possible in patients with incomplete or cervical SCI.

Many pharmacological agents have been investigated for preventing secondary injury and aid recovery of damaged neurons; however, none of these have proven successful. NASCIS 2[32] and NASCIS 3[33] were the largest trials that investigated the role of corticosteroids after SCI. Both were negative studies, showing no significant difference in motor score between treatment groups at any time. Post-hoc sub-group analysis of this data that suggested improvement in neurological outcome was fundamentally flawed. The lack of evidence for efficacy, and significant adverse effects such as detrimental effects on concomitant head injury, has resulted in decline in steroid use in recent years. Other agents that have been investigated with no evidence of benefit include GM-1 ganglioside, tirilazad, naloxone and nimodipine.

Induced hypothermia has been reported to be beneficial in case reports, but there is not enough evidence to recommend this intervention.[34] Fever may worsen outcome and normothermia should be maintained.

Patients typically spend several weeks to months in the hospital. Early referral to a rehabilitation team specialising in management of SCI should be made so that acute management and rehabilitation may proceed hand in hand.

RESPIRATORY DYSFUNCTION

Respiratory dysfunction is a major cause of morbidity after SCI, especially after cervical SCI. Diaphragm, external intercostals, scalene and sternocleidomastoid are the key muscles of inspiration. Quiet expiration is passive, but forceful expiration and cough requires abdominal muscles, interosseous part of internal intercostals, latissimus dorsi, serratus posterior and inferior, triangularis sterni and quadratus lumborum. The effect of SCI on respiratory function depends upon the NLI. Various effects of cervical SCI on respiratory function are listed in Table 80.3. The diaphragm is innervated by C3-C5. If the NLI is above C5, sternocleidomastoid (innervated by cranial nerve XI and anterior rami of C2, C3), and scalene medius and posterior (innervated by C3-C4) become important muscles for inspiration. The abdominal muscles are innervated by T7-L1, and in higher injuries, cough is generated only by the muscles of upper chest, particularly pectoralis major.[35]

RESPIRATORY MANAGEMENT AFTER CERVICAL SPINAL CORD INJURY

Intubation may be required for respiratory failure, secretion clearance, surgery, decreased level of consciousness or because of other injuries. Almost 75% of patients with cervical SCI will require intubation and mechanical ventilation.[36]

The cervical spine should be immobilised during endotracheal intubation. If time and expertise are available, awake fibre-optic intubation minimises the movement of the neck. Video laryngoscopes may improve the glottic view when the neck is immobilised. Direct laryngoscopy with manual inline stabilisation does not eliminate all movement at the cervical spine, but there is no evidence that it is associated with worse neurological outcome than other intubation techniques.

Table 80.3 Effect of cervical spinal cord injury on respiratory function

Decreased vital capacity	Paralysis of diaphragm and intercostal muscles Distortion of rib cage in inspiration due to paralysed intercostal muscles
Reduced compliance of lungs and chest wall	Spasticity of intercostal muscles Altered articulation of ribs to sternum and vertebrae Low functional residual capacity Atelectasis Possible alteration of surfactant
Increased abdominal compliance	Paralysis of abdominal muscles
Increased bronchial tone and secretions	Sympathetic denervation
Poor cough	Reduced vital capacity Abdominal muscle paralysis
Sleep disordered breathing (develops within 6 months)	Unknown cause Increased adipose tissue around neck Antispasticity drugs

In the initial period after cervical SCI, ventilator settings are dictated by associated injuries and other co-morbidities. For example, in patients with severe traumatic brain injury, normocapnia should be maintained. Once acute issues have resolved, mechanical ventilation should be tailored to SCI. Baseline spirometry should be obtained to allow monitoring of progress.

Tidal volume (V_T) more than 10 mL/kg is often used in patients with cervical SCI. The rationale for high V_T ventilation is to prevent atelectasis and reduce the sensation of 'air hunger' experienced following SCI. This avoids the need for high-level positive end-expiratory pressure (PEEP) that may lower the position of diaphragm to one of mechanical disadvantage. In many spinal centres, V_T of 10–20 mL/kg is used routinely,[37] and in small studies has not resulted in higher incidence of ventilator-induced lung injury.[38] With high V_T, dead-space may have to be incorporated into the circuit to avoid hypocapnia. Another approach is to use more conventional V_T and higher PEEP to prevent atelectasis. Until better quality evidence is available, an individualised approach to ventilator settings should be used.

Extubation after mechanical ventilation in patients with cervical SCI requires careful consideration of several factors (Table 80.4), with failure likely to result in reintubation followed by tracheostomy. Extubation failure is commonly due to retained secretions, inadequate cough and sputum plugs. Patients may benefit from extubation to non-invasive ventilation directly, which may be required for several days. A variety of non-invasive ventilation interface devices should be available and nasal skin should be protected from developing pressure ulcers. Aggressive chest physiotherapy and assisted coughing are required to clear secretions.

Table 80.4 Checklist prior to extubation

1.	No further procedure or imaging outside ICU anticipated in next 24 h
2.	No significant hypoxia or reversible respiratory pathology
3.	Ability to tolerate non-invasive ventilation
4.	No contraindication for the assist cough or chest physiotherapy (e.g. rib fractures, major laparotomy)
5.	Minimal respiratory secretions
6.	Negative inspiratory force >20 cm H_2O
7.	Vital capacity >10 mL/kg
8.	Presence of cuff leak (particularly after spinal fixation by anterior approach)
9.	Airway plan and equipment ready for re-intubation

ICU, Intensive care unit.

The tracheostomy rate after cervical SCI varies between 20% and 60%. Complete injuries above C5 usually require tracheostomy.[39] A high NLI, complete SCI, associated facial fractures, thoracic trauma and emergency intubation are associated with need for tracheostomy. Percutaneous tracheostomy is as safe as surgical tracheostomy.[40] Early tracheostomy may reduce the duration of mechanical ventilation and intensive care unit (ICU) length of stay and it does not increase the risk of wound or implant infection even after anterior spinal fixation.[41]

Weaning from mechanical ventilation after cervical SCI may take considerable time. In some centres, high-level tetraplegics are cared for in chronic respiratory care facilities rather than the ICU. It is important that a long-term weaning strategy is agreed upon and adhered to by all members of the multidisciplinary team. Accurate neurological assessment, progressive ventilator-free breathing, adequate rest periods with controlled ventilation, and secretion control with aggressive physiotherapy are associated with successful weaning.[42] Inspiratory muscle training uses an inspiratory resistor to increase strength of inspiratory muscles. While more studies are needed to clearly delineate the role of inspiratory muscle training in weaning of patients with cervical SCI, its use makes physiological sense and is being used increasingly.[43] It should be remembered that most patients with cervical SCI ventilate more easily when supine compared to being upright, as their abdominal contents can push the diaphragm up into a position of better mechanical advantage in supine position. An abdominal binder may be used in the sitting position, which also helps in this regard.

Inhaled anticholinergics and beta-2 agonists reduce airway resistance but have not been shown to improve success of weaning. Anabolic steroids like oxandrolone do not improve respiratory function but may cause hepatotoxicity and dyslipidaemia. Phrenic nerve or direct diaphragmatic pacing systems are occasionally used for respiratory support in high-level tetraplegics.

The NLI is the strongest predictor of successful weaning.[44] Patients with complete injuries at or above C3 are likely to need permanent ventilation. Early identification of patients who cannot be weaned helps reduce their ICU length of stay and expedites the arrangements for equipment and care personnel required for home ventilation or transfer to a chronic respiratory care facility. Overall, approximately 2% of patients with SCI, mostly with complete injures at C1-C4, require life-long ventilation.[45]

CARDIOVASCULAR DYSFUNCTION AFTER SPINAL CORD INJURY

The heart receives its sympathetic innervation from the upper thoracic segments via the superior, middle

and inferior cervical ganglions. Vasomotor tone of the peripheral vasculature is also controlled by segmental sympathetic innervation. The heart's parasympathetic innervation comes from the vagus, and therefore is not affected by SCI. Following SCI, loss of sympathetic supply and unopposed vagal activity may cause profound vasoplegia combined with bradycardia, resulting in hypotension and neurogenic shock. This occurs in 19% of patients with cervical and 7% of thoracic SCI.[46] Other causes of hypotension, particularly hypovolaemic shock, must be excluded before a diagnosis of neurogenic shock is made. Bradycardia and even asystole may occur during routine ICU procedures like endotracheal suction or repositioning in bed after cervical SCI. This occurs most commonly in the first week and generally resolves within 2–6 weeks after injury.[47]

There is some low-quality evidence that maintaining a higher mean arterial pressure (MAP) following SCI may improve cord perfusion pressure, prevent secondary injury and improve neurological outcome. Much is still unknown about this aspect of treatment, including the ideal MAP to target, optimal duration of blood pressure augmentation, the best vasopressor to use and whether the injury being complete or not is significant. Ongoing trials seek to answer some of these questions. Current guidelines recommend systolic blood pressure should not be less than 90 mm Hg at any time and that an average MAP above 85–90 mm Hg be maintained for 7 days following injury.[48] A recent study noted that, compared to dopamine, noradrenaline was associated with lower intrathecal pressure for same spinal cord perfusion pressure.[49]

CARDIOVASCULAR COMPLICATIONS

Autonomic dysreflexia

AD is a medical emergency characterised by acute hypertension due to severe sympathetic stimulation in patients with injuries above T6. It occurs following the resolution of spinal shock and is a frequent cause for admission to ICU. AD occurs due to dysregulated sympathetic activation leading to intense vasoconstriction below the level of lesion. Compensatory parasympathetic activation leads to bradycardia, vasodilatation and sweating above the NLI.[50] Other symptoms include headache, blurred vision, nausea and nasal congestion. The precipitants, investigations and treatment of precipitating factors are outlined in Table 80.5.

Initial management includes primarily detecting and treating the precipitant, sitting the patient up (to induce an orthostatic hypotensive response), loosening tight clothing and antihypertensives. Sublingual or transdermal glyceryl trinitrate is used initially. Nitrates should be avoided in patients who have taken sildenafil for erectile dysfunction in the preceding 24 hours due to risk of severe and protracted hypotension.[51] Sublingual captopril or oral prazosin may be used in unresponsive patients before intravenous agents such as sodium nitroprusside or glyceryl trinitrate infusions are used. Invasive blood pressure monitoring is required if intravenous agents are used. Some patients may develop chronic, severe AD requiring multiple antihypertensives. It must be remembered that in the setting of chronic hypotension that may follow SCI, systolic blood pressure of even >150 mm Hg may be life threatening,[52] and cause intracerebral haemorrhage or myocardial ischaemia.

Table 80.5 Precipitants, investigations and treatment of autonomic dysreflexia

PRECIPITANT	INVESTIGATION AND TREATMENT
Bladder distension (cause in 75%–85%)	Insert or change bladder catheter
Faecal impaction (cause in 13%–19%)	Digital examination Laxatives Enema Manual dis-impaction
Urinary tract calculi	CT scan of urinary tract Cystoscopy or surgery to remove calculi
Urinary tract infection	Urinary microscopy and culture Appropriate antibiotics
Haemorrhoids or anal fissure	Laxatives Dietary management
Decubitus ulcers, with or without infection	Rule out underlying osteomyelitis Pressure area care Consider plastic surgery Consider antibiotics
Foot disease including ingrown toenails	Nail care
Procedures (e.g. suprapubic catheter insertion, cystoscopy, urodynamic studies)	Spinal anaesthesia may prevent AD
Heterotopic ossification	Bone scintigraphy Measure C reactive protein and creatine kinase Physiotherapy Surgery
Pelvic stimulation (sexual activity, menstruation, labour)	Education Be prepared in peripartum period
Skeletal fractures	High index of suspicion below NLI

Venous thromboembolism

If inadequate or no prophylaxis is used, VTE following SCI has a very high incidence of up to 100%.[53] With prophylaxis, this incidence has reduced, but 5% of patients with SCI will still develop VTE,[54] and pulmonary embolism remains a leading cause of death. Commencement of adequate VTE prophylaxis is easier if all planned surgical procedures can occur as soon as practicable. The risk of venous thromboembolism increases significantly if prophylaxis is started more than 72 hours after the injury.[55] The Consortium for Spinal Cord Medicine recommends use of low-molecular-weight heparin for thromboprophylaxis after SCI.[56] Low-dose unfractionated heparin (e.g. 5000 units, twice daily) has not been shown to be useful after SCI.[56] The duration of prophylaxis should be at least 8 weeks in patients with limited mobility. If pharmacological VTE prophylaxis is contraindicated, a retrievable inferior vena cava filter should be considered.[57]

GASTROINTESTINAL COMPLICATIONS

Paralytic ileus and acute gastric dilatation are common in the first few days following SCI. Unopposed parasympathetic activity results in stomach hyperacidity, necessitating a proton pump inhibitor for ulcer prophylaxis in early days after the injury.

The upper motor neuron bowel syndrome seen in lesions above the T10 is characterised by increased colonic transit time, increased anal sphincter tone, and impaired sensation of fullness of the rectum, which results in constipation and faecal retention.

Stool softeners (for example, coloxyl) are generally required. Stimulants (for example, Senna) may be used at night time. Rectal stimulation is often necessary, and may be achieved by glycerine suppository, enema or digital stimulation. (The so-called 3-2-1 regimen employs three times a day coloxyl; two tablets of Senna at night time; and rectal stimulation once before the planned time of defaecation.) In patients who can eat, bowel motions should be planned after breakfast, taking advantage of the gastrocolic reflex. Other components of bowel management programs include adequate fluid intake, adequate dietary fibre, abdominal massage and, rarely, surgery (e.g. colostomy) or electrical stimulation. Opioids and other constipating medications should be avoided where possible.[58]

In lower motor neuron bowel syndrome, seen in cauda equina injuries, the external anal sphincter is lax but colonic peristalsis is inhibited, leading to both constipation and overflow incontinence. These patients benefit from increasing stool bulk (with fibre) and usually require manual evacuation.

URINARY TRACT COMPLICATIONS

Most patients with an NLI above L1 experience detrusor overactivity with sphincter dyssynergia. This results from the upper motor neuron lesion causing overactivity of both detrusor and the bladder sphincter. As a result, the detrusor contracts against closed sphincter, leading to high intravesical pressure, vesicoureteral reflux, high residual volume, incontinence, bladder spasm and an increased risk of urinary tract infections. Most patients with complete cervical SCI will require a suprapubic cystostomy, while thoracolumbar injuries may be managed by intermittent self-catheterisation. Detrusor overactivity, leading to bladder spasms, is common. Anticholinergics like oxybutynin (oral or transdermal), tolterodine, or solifenacin are used for treatment. In severe cases, intradetrusor botulinum toxin injection may be required. The anticholinergic side effects of these agents may be significant. Most patients require a combination of two anticholinergic medications.

Following SCI, there is a marked alteration in calcium homeostasis, with potential hypercalcaemia, hypercalciuria and a significant risk of calcium oxalate nephrolithiasis.

MUSCULOSKELETAL COMPLICATIONS

Muscle spasticity is a common but late complication. It develops after resolution of spinal shock and is characterised by increased muscle tone, hyperreflexia and muscle spasms below the NLI. Nociceptive stimuli below the level of injury (e.g. constipation, urinary tract infection) should be ruled out in patients with spasms. The initial treatment is oral baclofen. Its side effects include sedation, fatigue and confusion that may interfere with weaning from mechanical ventilation or participation in rehabilitation program. Intrathecal baclofen, local botulinum toxin, gabapentin, pregabalin and benzodiazepines are also used for severe spasticity.[52] Physiotherapy is needed to preserve a full range of movement and prevent contractures.

SKIN CARE

Pressure ulcers are common due to immobility and lack of sensation. Nearly 30% of patients with SCI develop pressure ulcers during their hospital stay, and half of these occur within the first month.[59] They are a source of significant morbidity and are associated with increased hospital length of stay, life-threatening infections, chronic osteomyelitis and AD. Skin healing in denervated skin is significantly delayed, so prevention is vital. The incidence of pressure areas may be reduced by:

- Twice daily skin inspection to detect early pressure areas
- Scheduled, frequent patient repositioning
- Good bowel and bladder care
- Pressure relieving mattress
- Prevention of accumulation of moisture
- Optimal nutrition
- Patient participation in their skin care programme

PSYCHOSOCIAL SUPPORT

Prolonged supportive care is necessary for both patients and their families to help them accept and adapt to neurological disability. Depression is common after SCI. Major depression should be differentiated from depressed mood. Health care workers may have the tendency to overdiagnose depression and conversely, depressive symptoms may be misinterpreted as somatic symptoms (for example, fatigue). Since many patients require antidepressants for pain and are also on drugs with anticholinergic effects (e.g. tolterodine, oxybutynin), management of depression is complex and specialist psychiatric consultation should be sought.

CHRONIC PAIN

Chronic pain is a frequent complication after SCI that occurs in up to two-thirds of patients. Pain after SCI may be classified as nociceptive pain from stimulation of nociceptors, or neuropathic pain from damage to sensory system itself. Most patients will report onset of chronic pain within 6 months after the injury, and frequently whilst still in ICU. Gabapentinoids (gabapentin and pregabalin) for neuropathic pain have the strongest evidence to support their efficacy.[60] Tricyclic antidepressants such as amitriptyline are effective for neuropathic pain in patients who also have depression. Infusions of opiates, ketamine and lignocaine are effective for neuropathic pain in the short term.[60] Behavioural therapy may be useful in addition to pharmacological treatment. Consultation with a pain specialist should be sought in patients with severe, refractory pain.

READMISSION TO THE INTENSIVE CARE UNIT

Common causes for readmission to the ICU for patients with pre-existing SCI are infections (urinary tract infections, pneumonia), AD, VTE and surgery (commonly after urinary tract procedure for renal stones). Meticulous attention should be given to skin care. All usual medications should be continued if possible. Abrupt withdrawal of baclofen may lower the seizure threshold. Risk of venous thromboembolism may be higher, and thromboprophylaxis should be used as appropriate for the clinical condition. The use of succinylcholine for intubation may precipitate severe hyperkalaemia.

OUTCOMES FOLLOWING SPINAL CORD INJURY

Hospital survival after SCI is now more than 90%, with long-term survival substantially better than it was 40 years ago. Factors predictive of higher mortality include higher NLI, complete SCI, older age and presence of co-morbidities.[61] Depending on the individual circumstances, it may be appropriate to have limitations of treatment for elderly patients with complete and high NLI. Most deaths are now due to respiratory and cardiovascular disease, with a decreasing proportion due to urinary complications. The neurological outcome post SCI is best prognosticated with an accurate neurological assessment using the ASIA impairment scale. Even during the first 24 hours, a reliable exam is highly predictive of outcome. Complete (ASIA A) injuries have the least potential for recovery, with only 7% converting to ASIA B by 1 year and none becoming motor-incomplete. However, 54% of ASIA B patients convert to ASIA C or D by 1 year with much better functional outcomes, and nearly all ASIA C under 50 years of age and all ASIA D patients are expected to be ambulatory on discharge from rehabilitation.[13] In the absence of a clinical exam, an MRI may be used to prognosticate, but is far less reliable. Despite significant disability, functional ability may be surprising to those who only manage the acute phase of SCI. For example, someone with a C5 ASIA A SCI may be able to mobilise with a power wheel chair with hand controls, drive a modified vehicle, have a family and a rewarding career.

The treatment offered to the patient may be influenced by the physician understanding of the outcome, quality and satisfaction with life after SCI. Physicians may imagine the quality of life following SCI to be more negative than it actually is.[62] It is vital that critical management decisions, particularly those related to treatment limitation, are not made in haste.

Abdominal and pelvic injuries

Sarah McNeilly

Almost 25% of major trauma admissions suffer injury to the abdomen or pelvic contents.[1] Mortality from pelvic injury is nearly 10%, whereas abdominal injuries carry a mortality of 8%.[2,3] Haemorrhage is the most common cause of preventable trauma death.[4,5] Injuries can be divided into blunt or penetrating, with most abdominal and pelvic injuries being caused by blunt trauma. Penetrating aetiologies can account for up to a quarter of cases, depending on the society concerned.[6]

MECHANISMS OF INJURY

BLUNT INJURIES

Road traffic collisions (RTCs) are the most common cause of blunt trauma to the abdomen and pelvis.[7] Other common causes include falls, assaults, sporting accidents and industrial accidents. Associated injuries are frequent, involving the thorax, head and extremities. Seat belts and airbags considerably reduce mortality in RTCs, but airbags can be associated with thoracic injuries, including occult injuries to the great vessels and heart, particularly in decelerating incidents with an unstrained passenger.[8,9]

PENETRATING INJURIES

Stab and gunshot wounds account for most penetrating injuries to the abdomen.

STAB AND LACERATION WOUNDS

Neither entry sites nor implement used accurately predict the nature of deeper injury. With penetrating injury in the thoraco-abdominal area, damage to both thoracic and abdominal organs should be suspected, including damage to the diaphragm. Laparotomy remains the treatment of choice for patients with haemodynamic compromise, peritonism, evisceration or impalement but there is considerable debate on the management of the stable asymptomatic patient. Patients are managed with serial examinations or laparoscopy in some centres.[10,11]

GUNSHOT WOUNDS

Injuries depend on missile calibre, its velocity and trajectory. Both injuries and mortality are substantially greater than with stab wounds. Laparotomy should be performed in all cases with haemodynamic instability, signs of peritonism, associated injuries (or intoxication) that prevent serial abdominal examinations or confirmed rectal, bladder or ureter injuries. A non-operative approach for selected low-risk patients has been shown to be safe but is not yet universally accepted.[12]

INITIAL TREATMENT AND INVESTIGATIONS

RESUSCITATION

Initial assessment and resuscitation of the patient are performed simultaneously. The traditional ABC (airway, breathing, circulation) order of assessment and resuscitation has been replaced by <C>ABC, where <C> stands for 'catastrophic haemorrhage'.[13] This concept originated on the battlefield where there was a high mortality from external peripheral haemorrhage. Essentially, any massive haemorrhage is controlled with compression, tourniquet, haemostatic dressing or splintage before airway and breathing are addressed.

The aim of damage control resuscitation (DCR) is to provide haemostasis, with permissive hypotension to decrease bleeding and regain homeostasis in patients with life-threatening haemorrhage. Resuscitation with blood and blood products and the avoidance of crystalloid aims to treat and control coagulopathy early in the process and has been shown to improve survival.[14,15] (See haemorrhage and coagulopathy section.)

CLINICAL ASSESSMENT AND INITIAL INVESTIGATIONS

An initial primary survey is performed by an experienced clinician with the aim of identifying major life-threatening injuries requiring immediate attention. Mechanism of injury can give important information in terms of likely injury patterns. In crush injuries,

ABSTRACT

Abdominal and pelvic trauma is common and has a mortality of around 10%. Preventable death is often from haemorrhage. Blunt trauma is most common, often from falls and road traffic collisions. These patients require concurrent assessment and management to identify and treat life-threatening injuries. Computed tomography (CT) scanning is the most helpful mode of imaging in detecting abdominal and pelvic injuries, which may be complex and involve multiple organs. In major haemorrhage, damage control resuscitation improves mortality and is continued during a damage control laparotomy to stop bleeding. Increasing numbers of injuries are being treated by angio-embolisation, avoiding the need for laparotomy. On the ICU, management includes further resuscitation often followed by management of a patient with an open abdomen. Complications include haemorrhage, coagulopathy, sepsis and entero-cutaneous fistulae.

KEYWORDS

coagulopathy

abdominal organs are crushed between the abdominal wall and spine or ribs; sudden extreme external compression may also cause the rupture of the hollow viscera. Rapid deceleration causes shearing forces which mean adjacent structures move in opposite directions, tearing at points of fixation such as vascular pedicles and mesenteric attachments.[16]

Physical signs and symptoms of internal injury in the abdomen are often unreliable, especially if the patient has other injuries (particularly head) or is intoxicated.[3] The rectum should be examined for tone, prostatic position, blood and evidence of other injury if the patient can be log-rolled.

Pelvic injuries can be difficult to detect by clinical examination alone. Patients may present with a pelvic binder in situ having been applied in the pre-hospital phase and this should not be removed for examination. If no binder is in situ, but pelvic injury is suspected, then one should be applied as part of the primary survey. The pelvis should not be 'sprung' to look for instability, as this may disrupt clots and cause further haemorrhage.[17] A log-roll should also be avoided if there is suspicion of pelvic fracture.

Pain around the pelvic area or lower back, asymmetry of the lower limbs or pelvis, or bruising around the perineum and scrotum can all indicate a pelvic fracture. Blood at the urethral meatus or haematuria are indications that there are associated urethral or bladder injuries.

Initial investigations should occur simultaneously with the primary survey. Bloods should be sent for full blood count, clotting studies, renal and liver function and group and screen with cross-match if bleeding suspected. Venous blood gas analysis should also be performed to assess for acidaemia and to measure the lactate level. Thromboelastography also provides rapid information on deficiencies in clotting factors, clot strength and clot breakdown, which helps to guide transfusion.[18]

CHOICE OF INVESTIGATIONS

The aim of the initial assessment and investigations of a patient with major trauma should be to rapidly identify and treat life-threatening injuries. The choice of diagnostic investigation should streamline this process. In patients with major haemorrhage, immediate computed tomography (CT) should be considered if they are responding to resuscitation or haemodynamically normal. Other diagnostic imaging (plain X-rays or focused assessment with sonography for trauma [FAST]) should be the minimum needed to direct interventions in those too unstable for CT scan.[19]

PLAIN X-RAYS

Portable plain anteroposterior (AP) X-rays of the chest and pelvis are often performed during the primary survey to exclude life-threatening tension pneumothorax and unstable pelvis fracture, though these are often excluded if the patient is going for immediate CT scan and should not delay this process.[16,19] Plain AP X-ray of the pelvis may appear normal, even with the presence of an unstable pelvic fracture, if there is a well-fitting pelvic binder in situ.

COMPUTED TOMOGRAPHY

In the polytrauma patient, the CT scan has become the imaging of choice to identify the patient's injuries, though this may not occur until after emergency haemostatic interventions such as laparotomy or angioembolisation. It has been shown to be superior to the combination of clinical evaluation and diagnostic peritoneal lavage (DPL) for the diagnosis of important abdominal injuries.[16] Current guidelines from the National Institute for Health and Care Excellence (NICE) recommend a whole-body CT (from vertex to toe on the scanogram and vertex to mid-thigh for the CT scan) in the blunt polytrauma patient.[19]

A single bolus of intravenous contrast agent is used and the use of a multidetector scanner allows the capture of arterial and portal venous phases and a delayed phase if necessary. The arterial phase will demonstrate vascular injury or ongoing arterial bleeding from, for example, a displaced pelvic fracture. Oral contrast is no longer required to help detect abdominal injuries.[3]

With isolated gunshot wound to the abdomen in stable patients, CT scan can aid the decision for conservative management, as the bullet trajectory is shown alongside any organ damage caused. Conversely in stabbings, it is no more sensitive than serial clinical examinations and may add little to the management of the patient.[20]

ULTRASONOGRAPHY

The FAST has become an important part of the primary survey of unstable trauma patients in the resuscitation room.[3] The bedside assessment of the heart, pericardium and abdomen allows the rapid detection of life-threatening conditions, expediting their immediate treatment. More recently, the extended-FAST (E-FAST) has taken over, which includes assessment for pneumothoraces. Ultrasound has shown to be more specific and sensitive for pneumothorax than the plain chest X-ray.[21]

In the stable trauma patient, E-FAST combined with clinical examination has been shown to be adequate in ruling out life-threatening injuries before CT scan, meaning routine plain imaging of the chest and pelvis is unnecessary.[21] In the very early post-injury phase, false negatives may be found when looking for fluid in the peritoneum. It is also poor at identifying retroperitoneal fluid and intra-abdominal organ injury without bleeding.[22] Like most imaging, E-FAST is operator dependent.

Table 81.1 Criteria for positive diagnostic peritoneal lavage

CLINICAL		
Initial aspiration of >10 mL frank blood		
Egress of lavage fluid via chest tube or urinary catheter		
Bile or vegetable material in lavage fluid		
LABORATORY		
	BLUNT INJURY	PENETRATING INJURY
RED CELLS		
Definite	>100 × 10⁹/L	>20 × 10⁹/L
Indeterminate	50–100 × 10⁹/L	5–20 × 10⁹/L
White cells	>0.5 × 10⁹/L	0.5 × 10⁹/L
Amylase	>20 IU/L	>20 IU/L
Alkaline phosphatase	>10 IU/L	>10 IU/L

PERITONEAL LAVAGE

The use of E-FAST and rapid CT scanning has meant that diagnostic peritoneal lavage (DPL) is now rarely indicated.[3] It may still be used if there is no access to either E-FAST or CT scanning. DPL detects intraperitoneal injury with up to 98% accuracy, but its high sensitivity can result in a significant non-therapeutic laparotomy rate.[23]

DPL is unjustified when an indication for laparotomy already exists. It is relatively contraindicated in pregnancy, significant obesity and previous abdominal surgery.

Generally accepted criteria for a positive DPL are shown in Table 81.1.

LAPAROSCOPY

Diagnostic laparoscopy may be useful in the haemodynamically stable patient. It is good for visualising the diaphragm and identifying the need for laparotomy, but may miss specific injuries in blunt abdominal trauma, particularly of the bowel. Surgical expertise is crucial. Laparoscopy appears best suited for the evaluation of equivocal penetrating wounds where it has both a diagnostic and potentially therapeutic role.[10]

MANAGEMENT OF THE UNSTABLE PATIENT

In patients with abdominal or pelvic trauma with haemorrhage, rapid transfer to either theatres or the angiography suite for either a laparotomy or angiography is required. These procedures are both diagnostic and part of the definitive treatment of the patient. Resuscitation should continue throughout this time.

INTERVENTIONAL RADIOLOGY

Angioembolisation is now a widely accepted treatment option for patients with solid organ injury and evidence of active contrast extravasation on CT scan.[24] It is also now the standard of care for patients with retroperitoneal arterial bleeding from pelvic fractures.[25] It allows rapid haemorrhage control in an area which is difficult to access surgically whilst avoiding the need for laparotomy. Stents can also be used to repair damaged vessels.

The interventional radiology suite should have suitable facilities to allow anaesthesia and continued resuscitation of the unstable patient during the procedure. Some centres are now combining an interventional radiology suite and operating theatre to allow simultaneous treatment of multiple injuries with surgery and angioembolisation.[26] This reduces the amount of time taken for resuscitation and definitive treatment of haemorrhage.[27]

LAPAROTOMY

In the unstable patient who requires surgery, all efforts should be made to get the patient to surgery as soon as possible and it may be that imaging such as the CT scan is delayed until after surgery.

Damage control surgery (DCS) is the concept of an abbreviated laparotomy to gain control of haemorrhage and limit contamination rather than definitive treatment of injuries identified. Physiology is prioritised over anatomy and it has been shown to improve survival in critically injured, shocked patients.[28,29] This limited operating time ensures rapid transit to the intensive care unit (ICU) for continued resuscitation, correction/prevention of the lethal triad of acidosis, hypothermia and coagulopathy and a thorough further examination (with imaging if necessary) of the patient to ensure all injuries are identified. Once physiology is normalised the patient can return to theatre in a planned way for definitive treatment of the injuries identified.[30]

In massive haemorrhage, the four quadrants of the abdomen are packed sequentially to control venous and solid organ haemorrhage. Arterial haemorrhage may require occlusion of the aorta to gain control. To minimise contamination, simple bowel perforations may be repaired and more complex injuries may be resected. Primary anastomosis and stoma formation are not done at this point to save time, so the bowel is left in discontinuity. At the end of surgery the abdomen is left open, preventing abdominal compartment syndrome, and as further surgery will be required.

DCS is not without its complications and has been shown to increase morbidity and length of stay.[29] For these reasons, it should be reserved for those who are truly reaching the end of their physiological reserve.

Studies are now beginning to identify the exact physiological parameters and injury patterns that require DCS to prevent patients having this type of surgery unnecessarily.[30]

DAMAGE CONTROL RESUSCITATION

Regardless of the method of haemorrhage control, resuscitation of the patient should start in the pre-hospital phase continuing into the ICU. It is now clear that coagulopathy and hyperfibrinolysis occur early in the disease process of major trauma and these should be addressed early.[14,31] DCR describes the concept of minimising crystalloid administration, permissive hypotension and a balanced transfusion of 1:1:1 of clotting factors:platelets:blood to prevent/correct coagulopathy. This method of resuscitation has been shown to increase survival and reduce the overall amount of blood and blood products required.[15,32–34]

SPECIFIC INJURIES

SPLEEN

Alongside the liver, the spleen is the organ most frequently injured by blunt trauma.[24] Injuries vary from a small subcapsular haematoma to hilar devascularisation or shattered spleen and are graded according to the American Association of Surgery for Trauma (AAST) splenic injury scale (I–V). Associated injuries include fractured left-sided ribs, and injuries to the left hemi-diaphragm, pancreas and bowel. Minor injury to the spleen may have few symptoms and other injuries may mask the symptoms. Minor trauma may cause splenic injury when the spleen is enlarged (e.g. from malaria, lymphoma and haemolytic anaemia).

Management can be conservative or via surgery or interventional radiology. Lower grade injuries in stable patients without active bleeding are managed conservatively, whereas higher grade injuries with evidence of contrast blush on CT scan can be managed extremely successfully with angioembolisation – treatment of the source of haemorrhage can restore haemodynamic stability rapidly.[24] If the patient is haemodynamically unstable and proceeding to theatre for laparotomy, 97% of those with splenic injury end up with a splenectomy, though splenic salvage is technically possible. Benefits of autotransplantation of splenic tissue during splenectomy remain unproven.

Overwhelming post-splenectomy infection by encapsulated organisms, such as *Pneumococcus*, can occur early or late (even years) after splenectomy in 0%–2% of individuals. Current UK guidelines recommend the administration of pneumococcal vaccine, meningococcal conjugate vaccine, annual influenza vaccination and vaccination against *Haemophilus influenza* type B post splenectomy.[35]

LIVER

The liver is commonly injured after blunt abdominal trauma, most frequently from motor vehicle collisions. The potential for massive haemorrhage coupled with multiple possible delayed complications means that the morbidity and mortality rate is high with early death most often caused by massive haemorrhage.[36,37] Diagnosis is made either on CT scan or during laparotomy in those too unstable for CT. Injuries range from small subcapsular haematomas to major parenchymal disruption and laceration of hepatic veins or even hepatic avulsion and are graded according to the AAST liver injury scale (I–V). The most commonly identified injury pattern is lacerations to the liver.[16]

Over 80% of patients with blunt hepatic injury are now managed non-operatively, which is up to 100% successful.[36] In patients with active bleeding from hepatic injury who respond transiently to resuscitation, angioembolisation should be the first-line treatment option. For the more unstable option, a laparotomy with packing is recommended followed by angioembolisation.[38] Follow-up CT scans can show the resolution of injury, which typically takes 2–3 months. Complications from non-operative management include hepatic necrosis (most common), hepatic abscesses and infected hepatic collections, bile leak/biloma, gall bladder infarction, ascites and delayed haemorrhage (5%–12%). The complication rate is higher with higher grades of injury. In the completely asymptomatic patient, management can be conservative with monitoring and serial examinations with the facility for further investigation or treatment if the situation changes.

Some patients will still require laparotomy despite apparently successful embolisation. These are the patients requiring ongoing resuscitation after embolisation. The injuries are likely to be high-grade lacerations and often have significant juxta-hepatic venous injuries and ongoing venous haemorrhage requiring DCS and packing. With the advent of hybrid operating suites, the option of simultaneous operative and non-operative management of these complex patients is possible.[26]

GASTROINTESTINAL TRACT

Injury to the gastrointestinal tract (GIT) is common following penetrating trauma but only occurs in approximately 5% of blunt abdominal trauma.[16] Over 90% of patients with abdominal gunshot wounds have injuries requiring operative management mandating laparotomy, though there may be a small sub-set of patients in whom this is unnecessary.[11,12] Laparoscopy can be used to both identify and treat injuries from penetrating trauma in stable patients when peritoneal violation cannot be excluded.[10] Posterior stab wounds are more challenging as they may damage retroperitoneal structures.

Blunt abdominal injuries include perforation or devascularisation of stomach, duodenum, small intestine, colon and their mesenteries, all of which are difficult to evaluate. Physical signs are often absent or non-specific.[3] E-FAST will identify free fluid in the abdomen, which may be due to an intestinal injury but is unable to differentiate between blood, urine, fluid from the breach of a luminal organ or from a chronic condition such as ascites. It will also not identify retroperitoneal fluid.

CT scan is the imaging of choice to search for injuries to the GIT and its blood supply. There are both specific and non-specific signs on CT scan of injury to the bowel which may be extremely subtle. Some of the specific signs include intramural haematoma, interruption of the bowel wall and extraluminal spillage of enteric contents. Some of the non-specific signs include extraluminal air collection, intraperitoneal fluid, bowel wall thickening, abnormal bowel wall enhancement and abnormal 'intestinal behaviours' (variations in tone, motility, shape and location of intestinal loops).[39]

Mesenteric injury ranges from simple contusions to complete traumatic avulsion. Injury to mesenteric vessels and bleeding may lead to bowel ischaemia and infarction, which may require resection of the affected section of bowel. Infarction of the bowel takes time to develop and may not show up initially on the CT scan. Mesenteric 'fat stranding' is a non-uniform increase in density of parts of the mesenteric fat and represents microhaemorrhagic foci. It is a non-specific sign of injury but should raise suspicions of injury to the mesentery and/or bowel.

Uncomplicated bowel injury can usually be managed by primary repair and anastomosis rather than colostomy. A faecal diversion procedure with delayed repair is indicated in significant peritoneal contamination or severe perineal injury or in DCS for speed.

PANCREAS

Pancreatic injury is relatively uncommon and accounts for up to 2% of all trauma patients. In blunt trauma, the pancreas is compressed against the spinal column, causing crush injury or transection in the region of the neck of the pancreas. It is often associated with injury to other abdominal organs, especially major vascular structures; 50% of penetrating injuries to the pancreas also have a concomitant vascular injury. CT is the most useful initial investigation; however, it is insensitive in detection of pancreatic duct injury, particularly early on. Endoscopic retrograde cholangiopancreatography is the most sensitive method for diagnosing duct injury, though logistically challenging to obtain in trauma patients.[16] Serum amylase levels are neither sensitive nor specific for injury and may be normal on presentation.

Treatment is becoming more conservative, and the use of external drains and distal pancreatectomy has been shown to decrease morbidity and mortality. Minor injuries require simple drainage only, whereas more severe injuries to the body and tail of the pancreas are best managed by distal pancreatectomy. Severe proximal injuries involving the duct or disruption of the head are difficult to manage. There is a move to more conservative management with closed drainage alone. Very complex surgery is required if there is concurrent duodenal injury, though there is no current consensus on what is best and occasionally pancreatico-duodenectomy is required. Mortality in these cases is high. Complications such as pancreatitis, fistula, abscess and pseudocyst are common with late complications of sepsis, multiorgan failure and respiratory failure occurring after more severe injury.[40]

KIDNEY AND URINARY TRACT

Blunt injury to the urinary tract is more common than penetrating injury with up to 10% of patients with blunt abdominal trauma having renal injuries.[41] Haematuria, micro- or macroscopic, after abdominal trauma, is a good indicator of injury to the kidneys or urinary tract.[16] Conversely, injuries to the renovascular pedicle or ureters may not cause any haematuria and its absence does not rule out renal injury.

Like liver and splenic injuries, renal injuries are graded on the AAST scale, with most injuries, even the higher grades, being managed conservatively.[41,42]

CT is the examination of choice, allowing early, accurate detection of renal tract injury. Urinary extravasation may be identified only on a repeat scan 10–20 minutes after contrast injection or on a formal retrograde (CT) cystogram. Stable patients with renal injury are most often managed conservatively, which avoids unnecessary surgery and nephrectomy and preserves renal function. Immediate intervention is needed in those with instability to stop bleeding and repair the kidney if possible. This may be done with interventional radiology, but nephrectomy is often the end result if the patient undergoes laparotomy. Parenchymal collecting system injuries often resolve without intervention but injury to the renal pelvis or proximal ureter avulsion require urgent intervention. Higher grade renal injuries treated conservatively require follow up CT at 48 hours, as there is a high rate of complications such as urinoma and haemorrhage. These may require treatment with ureteric stent, percutaneous drainage or percutaneous nephrostomy.[43]

Bladder injury is commonly associated with pelvic fractures. Blunt injury to patients with a distended bladder can cause isolated intraperitoneal bladder rupture. Over 95% of patients with bladder injury have macroscopic haematuria. Retrograde cystography is the investigation of choice. Intraperitoneal bladder rupture requires operative repair and urinary drainage, as it is unlikely to heal spontaneously and puts the patient at risk of bacterial translocation causing

peritonitis. Patients with uncomplicated extraperitoneal injury of the bladder can be managed conservatively with urinary catheter drainage alone.[43,44]

Urethral trauma is caused by direct blunt trauma or in association with pelvic fractures, particularly those involving the pubic diastasis in males.[17] It should be suspected if there is blood at the urethral meatus, perineal injury or abnormal position of the prostate on rectal examination. If there is suspicion of urethral injury, retrograde urethrography should be performed. One gentle attempt at urethral catheterisation by an experienced operator is acceptable, and if this is unsuccessful, then suprapubic catheterisation should be performed by the urologists in conjunction with pelvic surgeons. The timing of definite repair should be organised in conjunction with any required surgery to repair pelvic fractures.

DIAPHRAGM

Diaphragmatic injury occurs in fewer than 5% of cases of blunt injury, is left-sided in 80% of cases, and is rarely an isolated injury. It should be suspected in any penetrating thoracic or abdominal trauma. Diagnosis can be difficult, with up to 50% of chest X-rays having non-specific findings or no abnormality. CT scan has a sensitivity of 61%–87% and specificity of 72%–100% in diagnosing diaphragmatic injury.[45] Multiplanar reconstruction of the images improves on this accuracy further. Mortality is high (30%–60%) in those that are initially missed and present late with intrathoracic strangulation of a herniated viscus.[46]

If there is radiological suspicion of diaphragmatic injury in the stable patient, a diagnostic laparoscopy should be performed to confirm this.[46] Spontaneous healing does not occur, and all defects over 1 cm should be repaired. The risk of associated injuries means that an abdominal approach is most often used.

BONY PELVIS AND PERINEUM

Pelvic fractures in the younger adult are primarily caused by high-energy blunt trauma such as RTCs or falls from height; in the older adult, they are more likely to be due to low-energy falls from standing. Associated injuries are common, to pelvic organs such as the bladder and urethra but also to elsewhere in the body such as head and thoracic injuries. Injuries may be life-threatening and mortality is up to 34% in patients with pelvic fracture and haemodynamic instability.[17,47] Pelvic injury should be suspected in any high-energy injury and is suggested by pain on movement or in the hips, tenderness in the sacral or suprapubic areas, shortening and/or external rotation of a lower limb, gross haematuria or peri-pelvic ecchymosis.

CT is the best mode of imaging to rapidly identify pelvic fractures, any associated injuries or haemorrhage which may be amenable to interventional radiology. Reconstruction of the images will also aid planning the definitive operative fixation of complex fractures. E-FAST in the resuscitation room may identify any intra-abdominal bleeding but will not show associated retroperitoneal haemorrhage.

Pelvic injury is often graded using the Young and Burgess classification where fractures are classified based on the type of force causing the subsequent injury – lateral compression, anterior-posterior compression or vertical shear. Each of these is then subdivided based on severity of ligamentous disruption. An alternative method of classification is the Tile method.[47]

Patients with anterior-posterior compression fractures ('open-book') are more likely to have massive haemorrhage than those with lateral compression fractures, but haemorrhage is always a potential with pelvic fractures and should be identified and treated early.[48] Time to control of haemorrhage has a direct effect on mortality.[49] The management of these patients is difficult and there is no consensus as to what is the best management of the haemodynamically unstable patient with a pelvic fracture. The application of a temporary pelvic binder is often done in the prehospital phase but should be performed in the emergency department otherwise. It reduces bleeding by approximating fracture sites and preventing clot dislodgement by improving stability. The volume of the pelvis doesn't significantly increase when fractured; therefore, there is no tamponade effect from reducing pelvic volume with the binder as originally thought.[47] Although most bleeding in pelvic fractures is venous rather than arterial, in the unstable patient, arterial bleeding is more common.[47,48] Angiography and selective embolisation is highly effective in controlling arterial bleeding, seen as a contrast blush on CT scan with associated retroperitoneal haematoma.[25] This is the treatment of choice in the unstable patient with a negative E-FAST scan if possible. In the unstable patient with a positive E-FAST and pelvic fracture, laparotomy with pelvic packing is used to tamponade bleeding. This may be coupled with external fixation of the pelvis for mechanical stabilisation, reduction of pelvic volume and reduction of bony bleeding.[49,50]

The majority of patients with a pelvic fracture are haemodynamically normal with a stable fracture and moderate ligamentous disruption. These can be fixed on a non-urgent, planned basis.[50] Early operative stabilisation of complex pelvic fractures is preferred in the ICU and can be done externally, internally or as a combination of both; it facilitates respiratory care, pain control and early mobilisation. There is also growing evidence that operative management of pelvic fractures have a better functional outcome in the long term.[47] Compound pelvic fractures involving the perineum, rectum or vagina require aggressive surgery (which may include diversion of the faecal stream) to avoid high mortality.

Early deaths (in the first 24 hours) are due to haemorrhage, whereas late deaths are more commonly due to the systemic inflammatory response (SIRS) to trauma and multiorgan failure.[50]

TRAUMA IN PREGNANCY

The most common causes of trauma in pregnant women include RTCs, assaults and falls.[51] Women injured during pregnancy pose problems of altered physiology, risk to the gravid uterus and foetus, and potential conflict of priorities between mother and foetus. In general, however, the best treatment for the foetus is to treat the mother optimally, which, with major trauma, is a rapid, systematic evaluation of the patient with concurrent treatment of life-threatening emergencies. It must be remembered that the placental blood flow is dependent on maternal arterial blood pressure and has no autoregulation.

The mother should be placed in a left lateral tilt from the start to prevent aortocaval compression and high-flow oxygen should be given until maternal hypoxaemia, hypovolaemia and foetal distress have been excluded. Altered maternal physiology means that shock can be more difficult to detect:

- Increased maternal blood volume by up to 50% with physiological anaemia due to haemodilution
- Increased cardiac output with increased heart rate, reduced systemic vascular resistance and reduction in mean arterial pressure
- Increased respiratory rate and tidal volume with increased oxygen consumption and reduced functional residual capacity and reduced $PaCO_2$; meaning little respiratory reserve if demand increases due to injury and rapid onset of hypoxia
- The uterus is protected by the pelvis up to 12 weeks of pregnancy, after which it encroaches into the peritoneal cavity, displacing maternal organs and becoming more susceptible to injury
- Increased volume of stomach acid, reduced lower oesophageal sphincter tone and reduced gastrointestinal motility, increasing the risk of aspiration
- Pregnancy-induced changes in the airway, coupled with less respiratory reserve, make rapid sequence induction of anaesthesia and intubation of the trachea more difficult in pregnancy.[52]

When considering imaging, the radiation risk to the foetus should be weighed up against the risk to mother and foetus of missing an injury. Imaging that is the standard of care in a non-pregnant patient with potentially life-threatening injuries should remain the same in the pregnant patient.[51] E-FAST is safe in pregnancy and in addition to detecting free fluid in the abdomen, the condition of the foetus can also be assessed.

The injury pattern can change due to the presence of the gravid uterus. There is upward displacement of bowel with the potential for complex intestinal injuries in penetrating trauma of the upper abdomen. The pelvic vasculature is hypertrophied with potential for massive retroperitoneal haemorrhage in pelvic injury. Similarly, the blood supply to the uterus at term is 600 mL/min, meaning there is potential for massive haemorrhage with direct uterine injury. Placental abruption can occur, which may conceal significant blood loss.

Early involvement of the obstetric team is crucial for management decisions and for ongoing monitoring of the materno-foetal unit. Treatment may be expectant or by caesarean section, depending on the condition of the mother and foetus. Uterine rupture is unusual and will often require hysterectomy. In traumatic cardiac arrest, perimortem caesarean section should commence as soon as possible but within 4 minutes for best outcome of mother and foetus.[53]

Following maternal trauma, there is increased risk to the foetus both in the short and long term, especially with more severe trauma. Placental abruption, foetal distress and foetal loss can all occur, as can premature labour.[53] Continuous cardiotocography (indicated at viable gestations) is recommended for all trauma patients to assess foetal well-being and the Kleihauer–Betke tests to identify foeto-maternal haemorrhage has been used to predict patients at high risk for preterm delivery and adverse perinatal outcomes.[51] All Rhesus negative pregnant women who suffer trauma should receive immunoglobulin because of the immunological risk of even minor foeto-maternal haemorrhage.

COMPLICATIONS

HAEMORRHAGE AND COAGULOPATHY

Haemorrhage from injuries due to major trauma is the most common cause of preventable trauma death.[4,5] Acute traumatic coagulopathy (ATC) occurs in up to 35% of patients by the time they arrive at hospital and is associated with significant tissue injury and shock. Endogenous anticoagulation develops in response to the increasingly more procoagulant vasculature due to damaged endothelium. This anticoagulation is due to autoheparinisation, activation of protein C and hyperfibrinolysis. ATC is then worsened by acidosis and hypothermia. Finally, the administration of fluids such as crystalloids or starches further compounds this by causing a dilutional coagulopathy.[14,28,31,32,50]

Treating the massive haemorrhage and coagulopathy associated with major trauma is challenging. DCR, initially developed in the military, should be commenced in the pre-hospital phase. DCR incorporates permissive hypotension, early treatment of the anticipated ATC with use of blood and blood products and limiting the use of crystalloids and early use of tranexamic acid.[28,33] Evidence shows that DCR improves outcome and reduces complications from DCL and may also reduce the number of patients

requiring DCL who can instead have immediate definitive treatment.[33] Equally as important as the treatment of coagulopathy and shock is haemorrhage control using DCS or angioembolisation.

Permissive hypotension aims to avoid the adverse effects of aggressive fluid resuscitation – dilution of clotting factors, hypothermia, increased intraluminal pressure at the site of injury causing dislodgement of clot – whilst maintaining some tissue perfusion for a short period of time.[50] There is little evidence to say what mean arterial pressure is acceptable in this situation, but European guidelines recommend a systolic blood pressure of 80–100 mm Hg, whereas NICE and others recommend a mean arterial pressure of 50 mm Hg.[19,29,54] Permissive hypotension is contraindicated in the presence of concurrent neurological injury where perfusion and oxygenation of the injured brain or spine takes priority.[50]

To address ATC, transfusion with blood and blood products in a 1:1:1 (plasma:platelets:red cells) compared to a 1:1:2 ratio has been shown to improve haemostasis and lead to fewer deaths due to exsanguination in the first 24 hours, although there was no overall improvement in 24-hour or 30-day mortality.[32] This is now being incorporated into guidelines along with the use of major haemorrhage protocols allowing rapid access to blood and blood products.[14,19,28]

Administration of the antifibrinolytic tranexamic acid within 3 hours of injury has been shown to reduce deaths from bleeding without increasing vascular occlusive events in a large study of patients treated in diverse hospital settings.[34] It is commonly given prehospital now, but should be given as early as possible in the resuscitation room if not.[14,19,28]

As trauma in the elderly is increasing, it must be remembered that patients may also be on long-term anticoagulation which may contribute to haemorrhage. This should be identified early and the agent reversed as soon as possible.

OPEN ABDOMEN FOLLOWING DAMAGE CONTROL SURGERY

After DCS, patients are admitted to the ICU with temporary closure of the abdomen. Once their physiology is normalised, they will return to theatre, often several times, for definitive management of the injuries and closure of the abdomen. An open abdomen puts patients at risk of ischaemia-reperfusion injury to the bowel and acute respiratory distress syndrome associated with this; they are also likely to develop a SIRS.[55]

SEPSIS AND ENTERO-CUTANEOUS FISTULA

Entero-cutaneous fistula (ECF), an abnormal communication between the intra-abdominal GIT and the atmosphere, is a significant problem with high morbidity and mortality.[56] It causes multiple complications including sepsis, fluid loss, electrolyte abnormalities, prolonged ICU and hospital stays and complex wound care issues. They are difficult to manage and usually require operative repair. Predisposing factors include:

- Bowel resection
- Bowel left in discontinuity
- Those administrated a large amount of fluids during the first 24 hours
- Multiple abdominal re-explorations
- Delayed closure of an open abdomen.[57]

Early diagnosis and effective lavage and drainage procedures may reduce the incidence of intra-abdominal sepsis. In the absence of sepsis, prophylactic antibiotics for 24 hours are satisfactory for open abdomens after DCS. Infectious complication rates correlate directly with time to fascial closure.[55]

VENTRAL HERNIA

Up to 80% of patients with an open abdomen go on to develop a ventral hernia after delayed fascial closure. This may be planned if there is no other way to close the abdomen.[56] Large ventral hernias may prolong recovery due to discomfort or loss of function. They may be repaired at a later stage with reconstruction of the abdominal wall.

FLUID LOSS AND ELECTROLYTE IMBALANCE

Patients lose large amounts of fluid from the peritoneal cavity resulting in electrolyte imbalance and dehydration. Fluid management after the initial resuscitation is challenging, as excess fluids may lead to increased complications with bowel wall oedema, anastomosis breakdown and abdominal compartment syndrome. Conversely these patients often require extra fluids due to the open peritoneal cavity and SIRS from the trauma. A goal-directed method of fluid therapy should be used.

MALNUTRITION

These patients are highly catabolic and can lose large amounts of protein through the open abdomen. Malnutrition is particularly common in those that develop ECF.[55,56] Nutritional support is crucial and often challenging. Enteral feeding should be commenced early in those with intact intestinal continuity and no obstruction. In those who do not have intestinal continuity (delayed repair of bowel injuries) or have complex injuries, parenteral nutrition may be required.

RAISED INTRA-ABDOMINAL PRESSURE

Although now less common, abdominal distension with raised intra-abdominal pressure may be seen in

the critically injured as a consequence of haemorrhage, bowel oedema, ileus or surgical packs. This can have severe adverse effects on respiratory, cardiovascular and renal function. Alleviation is by surgical decompression and temporary closure, with or without visceral packing. The abdomen is subsequently closed by staged repair as the distension resolves.[56,58]

VENOUS THROMBOEMBOLISM

Pelvic trauma, postoperative status, higher Injury Severity Score and underlying medical risk factors increase the risk of venous thromboembolism 1.5–3 times greater than trauma patients without such factors.[59] Early initiation of mechanical prophylaxis is usually feasible, as is pharmacological prophylaxis when the risk of injury-associated bleeding has reduced. The use of inferior vena cava filters in trauma patients where pharmacological prophylaxis is contraindicated is increasing and reduces the incidence of pulmonary emboli. It is not yet clear which patients benefit most, as there are significant complications related to these devices.[60]

Submersion

Tim Bowles

DEFINITIONS

Drowning was defined by the World Health Organization in 2002 as follows: 'Drowning is the process of experiencing respiratory impairment from submersion/immersion in liquid.'[1] If the victim dies as a result, the event should be referred to as 'fatal drowning'. If the drowning process is interrupted, it should be referred to as 'non-fatal drowning'. The Utstein template can be adopted to provide consistent reporting of drowning events and allow accurate categorisation.[2]

EPIDEMIOLOGY

Drowning causes an estimated 372,000 deaths worldwide per year.[3] Of these, 3700 are reported from the USA (approximately 1.2 deaths per 100,000 population) and 290 (1.4 deaths/100,000 population) from Australia.[4,5] More than 90% of fatal drownings occur in low- or middle-income countries and, worldwide, drowning is the third most common cause of unintentional injury death.[3] In the USA, twice as many non-fatal drownings as fatal ones were recorded in 2009.[4] In Australia, drowning is the leading cause of unintentional injury death in children aged 1–3 years.[6] Males predominate, with peaks at 5 and 20 years of age. Private swimming pools and natural water bodies close to home present the greatest risk to young children.[7] Other sites include bath tubs, fish tanks, buckets, toilets and washing machines. Adolescent drowning tends to occur in rivers, lakes, canals and beaches.[8] Lack of adult supervision commonly contributes to toddler accidents; however, child abuse must also be considered. Alcohol and drug intoxication are associated with up to 40% of adolescent drowning.[9] Other risk factors include epilepsy (18%), trauma (16%) and cardiopulmonary disease (14%).[10]

Among older people who drowned in Australia, 69% had a pre-existing medical condition, most commonly cardiovascular disease, but also dementia, depression, epilepsy and Parkinson's disease. A fall into the water was the most frequent antecedent to drowning among older people, although swimming and watercraft incidents were also common.[11] Hyperventilation prior to underwater swimming suppresses the physiological response to rising carbon dioxide tension, allowing hypoxia to ensue with consequent loss of consciousness and water breathing.[12]

PATHOPHYSIOLOGY

Voluntary apnoea and reflex responses occur upon submersion. The diving response is characterised by apnoea, marked generalised vasoconstriction and bradycardia in response to cold-water stimulus of the ophthalmic division of the trigeminal nerve. Blood is thus shunted preferentially to the brain and heart. In infants the response may be marked,[13] but only 15% of fully clothed adults show a significant response. Although the diving reflex appears to play a powerful role in oxygen conservation in animals, its role in humans is unknown but may be protective.[14]

After airway immersion, breath holding followed by laryngospasm occurs. This causes progressive hypoxia and hypercarbia, eventually resulting in relaxation of airway reflexes and water aspiration.[15] Up to 22 mL/kg of water has been estimated to be the maximal survivable inhaled water volume.[16] This is followed by a phase of secondary apnoea and loss of consciousness. Hypoxaemic death ensues if the person is not retrieved and resuscitated; acute respiratory distress syndrome (ARDS) occurs in up to 72% of symptomatic survivors.[17] Multiple organ dysfunction and cerebral damage may become evident in those who survive to hospital.

SALT- VERSUS FRESH-WATER ASPIRATION

The differences between salt- and fresh-water drowning have traditionally been emphasised. This is largely based on animal data. In canine models, after aspiration of massive volumes of salt water, it was possible to recover by suction or mechanical drainage greater volumes than were initially instilled.[18] The hypertonic salt water was drawing fluid into the pulmonary interstitial space, which was thought to result in

ABSTRACT

Drowning is the process of experiencing respiratory impairment from submersion/immersion in liquid. It is the third most common cause of unintentional injury death, with an international death toll almost two-thirds that of malnutrition and well over half that of malaria. Public health efforts at prevention are now a WHO priority. If early rescue does not occur, the predictable sequence is of water inhalation, triggering acute respiratory distress syndrome (ARDS), followed by hypoxic cardiac arrest. Management is essentially supportive, with non-invasive or invasive ventilation using lung protective strategies, considering the presence of contamination and specific treatment requirements. Associated abnormalities frequently include hypovolaemia and hypothermia; mostly cardiovascular instability resolves with restoration of oxygenation, circulating volume and normothermia. However, co-morbidity, particularly in the older population, is common, and cardiovascular disease should be considered in those who do not improve. Prognostication can be difficult, with assessments in the field often incorrect, and reported survivors despite multiple adverse features.

Drowning
submersion
resuscitation
environmental hazards

hypovolaemia, hypernatraemia and haemoconcentration as well as pulmonary oedema.

Conversely, after fresh-water aspiration in dogs, minimal volumes of fluid were retrievable from the lungs.[19] The hypotonic water was absorbed into the circulation. The pulmonary oedema seen was thought to be secondary to removal of surfactant, and hypervolaemia; dilutional hyponatraemia and haemolysis were expected.

More recent animal data and human case series have demonstrated that the tonicity of the fluid aspirated is not clinically relevant.[20] No clinically detectable difference in the patterns of lung injury is seen between salt- and fresh-water drowning; both types reduce pulmonary surfactant quantity and function, causing pulmonary oedema both directly and by the generation of osmotic gradients, and hypoxia by collapse, atelectasis and shunting, resulting in ARDS.

WATER CONTAMINANTS

The incidence of pneumonia complicating submersion injury may be greater than 15% in those who survive long enough.[22] Rivers, lakes and coastal waters are greater reservoirs for microbes than well-kept swimming pools. In fresh water, Gram-negative bacteria predominate along with anaerobes and *Staphylococcus* spp., fungi, algal and protozoan species. *Aeromonas* spp. are ubiquitous water-borne bacteria and can be responsible for severe pneumonia.[22] Infection with oral commensals is common, as is infection with multiple organisms. Although prophylactic antibiotic treatment is not recommended in general,[23] if infection is suspected then broad-spectrum antibiotics with antipseudomonal cover is suggested, with knowledge of local organism spectrum and resistance patterns.[24]

Chemicals in polluted water, such as kerosene,[25] chlorine[26] and particulate matter like sand,[27] can cause severe pulmonary dysfunction.

TEMPERATURE

Victims of submersion may develop primary or secondary hypothermia. If submersion occurs in icy water (<5°C), hypothermia may develop rapidly and provide some protection against hypoxia. Surface cooling is unlikely to produce adequate protective hypothermia before hypoxia ensues.[14] Most reports of survival after prolonged submersion involve small children in icy water and it has been postulated that protective core cooling occurs rapidly due to cold-water aspiration, ingestion and absorption, though the mechanisms remain controversial.[28]

Of more importance in cold-water submersion are the detrimental 'cold-shock' responses.[28] These responses include a 'gasp' followed by uncontrollable hyperventilation and reduction in maximal breath-hold times, vasoconstriction, tachycardia, hypertension and increased myocardial oxygen consumption. These responses may lead to motor dyscoordination and swimming failure as well as cardiac arrhythmia; hence, even strong swimmers may drown quickly in icy waters.[29]

MANAGEMENT

BASIC LIFE SUPPORT

Prompt retrieval from the water is essential, as is immediate on-site resuscitation. As any cardiac arrest is normally secondary to hypoxaemia, five rescue breaths should be administered first, followed by standard basic life support. Delivery of adequate rescue breaths may take prolonged insufflation due to reduced compliance and increased resistance. External cardiac massage in the absence of expired air respiration is unlikely to be successful. Rescue breathing can be performed effectively in the water; chest compressions cannot.[21]

The risk of cervical spine injury is small (<0.5%), and attempted cervical spine immobilisation can compromise effective rescue and resuscitation in the water. Therefore, spinal immobilisation is indicated only in the presence of severe injury or consistent history.[21] Removal from the water can cause concealed hypovolaemia, from prolonged immersion, to present as cardiovascular collapse – the victim should be kept in a horizontal position as far as possible.[21]

Regurgitation of stomach contents and swallowed water is common – if it prevents ventilation completely, the victim can be turned to the side and aspiration attempted using direct suction if available. Rewarming should be commenced immediately with the use of blankets and further heat loss should be avoided. When experienced personnel arrive, bag and mask ventilation and advanced cardiac life support are initiated.

INITIAL HOSPITAL MANAGEMENT

Resuscitation continues on arrival to hospital. Endotracheal intubation and mechanical ventilation are instituted if hypoxaemia is severe despite high-flow oxygen or assisted bag and mask respiration. Ventilatory failure, characterised by increasing respiratory distress and rising carbon dioxide levels, and the presence of an impaired conscious level or severe agitation may also necessitate intubation. Airway management may be complicated by large volumes of gastric regurgitation, significant pulmonary oedema obscuring the view of the larynx, and reduced lung compliance preventing the use of a supraglottic airway. The stomach should be decompressed by insertion of a nasogastric tube if possible but this may be difficult in a hypoxic agitated patient. Early active rewarming is indicated for severe hypothermia, but hyperthermia should be meticulously avoided.[21]

ASSESSMENT

HISTORY

Attempts should be made to elucidate the time and the duration of submersion, the presence of polluted water and likely contaminants, details of any cardiac arrest, delay in resuscitation attempts and the likelihood of alcohol ingestion, drug use, pre-existing medical conditions (particularly seizure disorders) and co-existing trauma. If collateral history is available, any symptoms of illness prior to the submersion event should be elicited to rule out or in a medical cause for the drowning that may require treatment.

EXAMINATION

A thorough physical survey is carried out, concentrating on cardiorespiratory examination, looking particularly for signs of respiratory distress, wheeze, crepitations and peripheral circulatory insufficiency. Neurological status should also be assessed. Signs of primary medical cause of drowning should be sought. A trauma secondary and subsequently tertiary survey should rule out the presence of co-existing traumatic injuries. Clinical deterioration in those with minor symptoms and signs can occur and the patient should be reassessed at frequent intervals.

INVESTIGATIONS

These depend on the clinical circumstances and could include:

- *arterial blood gases/lactate level*
- *plasma biochemistry/serum osmolality*: electrolyte abnormalities are unlikely in sea- or fresh-water drowning. CK should be measured as rhabdomyolysis has been reported[30]
- *haematology*: for haemolysis (for example, total haemoglobin (tHb), free Hb and myoglobin concentrations in the plasma and urine)
- *toxicological assays*: for drug and alcohol levels could be considered
- *chest X-ray, 12-lead electrocardiogram (ECG)*
- *microbiology*: tracheal aspirates or sputum for Gram stain, microscopy and culture
- *trauma imaging*: cervical and/or thoracolumbar spine views; computed tomography (CT) scan of the head and cervical spine if head and neck injury is suspected or the patient is comatose. Imaging of other body areas is dependent upon the clinical likelihood of injury.

ADMISSION CRITERIA

Asymptomatic patients with no clinical findings on cardiorespiratory examination and a normal chest radiograph and blood gas are unlikely to develop ARDS and pneumonia and thus may not require hospital admission.[17,31] All other patients should be admitted to a high-dependency area or intensive care unit for continuous monitoring and rewarming.

RESPIRATORY SUPPORT

Severe agitation or coma mandates intubation and mechanical ventilation; otherwise, oxygenation is initially maintained with high-flow oxygen or continuous positive airway pressure by tight-fitting facemask. Superimposed ventilatory failure may be managed with non-invasive bilevel positive airway pressure assistance. Use of non-invasive ventilation may be complicated by regurgitation of swallowed water; nasogastric decompression should be again considered. The use of bronchodilators may reduce air-flow resistance and the work of breathing if evidence of bronchospasm is present. Given the ARDS pathophysiology after drowning, lung-protective strategies should be employed if mechanical ventilation is required. Selective pulmonary vasodilators such as inhaled nitric oxide or inhaled prostacyclin may be useful in severe refractory hypoxaemia, although evidence for efficacy is lacking. In severe cases, extracorporeal membrane oxygenation has been used in some centres.[32]

Resolution of hypoxaemia may be more rapid than in other causes of ARDS.[33] Care should be taken with very rapid liberation from ventilation within the first 24 hours of the drowning event, as pulmonary oedema related to local pulmonary injury may recur.[34]

CARDIOVASCULAR SUPPORT

Prolonged immersion is associated with hypovolaemia related to hydrostatic pressures. Cautious volume expansion and the use of catecholamine infusion may improve cardiac output and blood pressure. Fluid replacement with isotonic fluids is aimed at restoring adequate end-organ perfusion without compromising respiratory function. Where restoration of oxygenation, normovolaemia and normothermia is not associated with resolution of cardiovascular disturbance, the presence of cardiac depression should be considered. Echocardiography is likely to be informative regarding the presence of global myocardial depression associated with the drowning episode, regional ischaemia, or the presence of vasoplegia. In cases where severe circulatory insufficiency or cardiac arrest is associated with severe hypothermia, cardiopulmonary bypass has been used successfully.[35]

CEREBRAL PROTECTION

No evidence exists suggesting that targeted temperature management is beneficial in general after cardiac arrest associated with drowning. However, the strong suspicion of a cardiac arrest causing the drowning

rather than being the result of it could indicate targeted temperature management to a temperature of 36°C.[36] It should be noted that in children, no benefit was observed in hypothermia as opposed to normothermia after cardiac arrest associated with drowning.[37]

No other specific cerebral protective measures have proven efficacy in post anoxic encephalopathy associated with drowning.[38] Maintenance of an adequate cerebral perfusion pressure (mean arterial pressure >80 mm Hg in adults, 60–70 mm Hg in children) is probably reasonable. Prevention of cerebral venous and thus intracranial hypertension can be achieved by neutral neck positioning, avoiding occlusive endotracheal tube ties and head-up positioning. Avoiding hypocapnia ($PaCO_2$ <30 mm Hg [3.99 kPa]), reducing cerebral metabolic rate with sedation, preventing hypoglycaemia and hyperthermia, and the use of anticonvulsants in those with documented seizures are simple measures that may prevent secondary cerebral injury.

OTHER THERAPIES

There is no role for prophylactic corticosteroid therapy in the prevention of acute lung injury after submersion.[15] Prophylactic antibiotic therapy is unproven and the decision to commence therapy is made on the degree of water contamination, need for mechanical ventilation and severity of respiratory failure in each case.[21] Baseline microbiological studies should be sent prior to commencement of therapy.

PROGNOSIS

A large series demonstrated 44% survival to hospital discharge in those with cardiac arrest secondary to drowning.[39] Moderate to severe brain damage is reported in 33% of survivors.[7] The outcome in children is similar, with 30% having selective deficits and 3% with persistent vegetative state.[40] No difference in mortality between fresh- and salt-water submersion has been documented.[10] Lower core temperatures appear to be associated with a better prognosis, except if this occurs after rescue. However, hypothermia in warm-water immersion and severe hypothermia (<30°C) in cold-water immersion is indicative of prolonged immersion and poor outcome.[29] Box 82.1 lists some factors associated with death or severe neurological impairment. None of these predictors is infallible and survival with normal cerebral function has been noted despite the presence of some or all of these factors.[41]

Box 82.1 Predictors of death or severe neurological impairment after submersion

At site of immersion
- Immersion duration >5 min[42]
- Delay in commencement of CPR >10 min[7]

In the emergency department
- Glasgow Coma Score 3[43]
- Fixed dilated pupils[45]

In the intensive care unit (ICU)
- Glasgow Coma Scale <6 on arrival in ICU[45]
- Arterial pH <7.0 on arrival in ICU[44]
- No spontaneous, purposeful movements and abnormal brainstem function 48 hours after immersion[45]
- Abnormal CT scan within 36 hours of submersion

Burns

Ilanit Z Hené, Jacqueline EHM Vet

INTRODUCTION

The last decades have seen a sustained improvement in survival of patients suffering from thermal injury. The most important development has been the establishment of centralised burn care, which has led to the concept of a multidisciplinary burn team, in which all aspects of care are coordinated in an integrated approach to clinical management. Advances in fluid resuscitation, life support techniques and the prevention of infection have been driven by research.[1] With optimal care, children and young adults with burns of more than 80% of total body surface area (TBSA) now stand a reasonable chance of survival.[1] Improvements in survival have gradually led to a shift of emphasis in burn care towards qualitative aspects, such as rehabilitation and quality of life.

PATHOPHYSIOLOGY

LOCAL EFFECTS

Thermal injury produces complex local and systemic responses.[2] The local inflammatory response results in vasodilatation and an increase in vascular permeability. The changes are immediate and the combination produces extravasation of fluid and plasma protein at the site of injury. In extensive burns, oedema becomes generalised. The greatest rate of oedema formation occurs in the first 8 hours, but further extravasation occurs up to 24 hours post burn. The total amount of oedema formed depends on the extent of injury and the volume of fluid administered. Without fluid replacement, hypovolaemic shock occurs, limiting the extent of extravasation. On the other hand, excessive fluid administration will produce excessive oedema and contributes to enlargement and deepening of the burn area.[3–5]

By 24 hours post burn, oedema formation is largely complete and vascular integrity restored.[6]

The process of deepening of the burn wound beyond the area of heat necrosis following injury is at least partly due to microvascular stasis. Events occurring within minutes and hours of injury include microthrombus formation, neutrophil adherence, fibrin deposition and endothelial swelling.[7,8]

SYSTEMIC EFFECTS

Circulatory effects of burn injury become significant in burns of over 20% TBSA. Changes are rapid and the magnitude is roughly proportional to the extent of burn injury. Cardiac output is reduced immediately following injury due to a combination of hypovolaemia, increased blood viscosity and increased levels of agents with myocardial depressant properties, such as interleukin-1 and tumour necrosis factor alpha.[3]

Continuous secretion of endogenous epinephrine, norepinephrine, vasopressin and angiotensin causes an increase in systemic and pulmonary vascular resistance leading to pulmonary oedema.

Cardiac output recovers gradually during the second post-burn day, reaching supranormal levels by day 3 as the hypermetabolic response to burn injury becomes manifest. Circulatory dynamics are complicated by resorption of oedema fluid and by continuing evaporative fluid loss from the wounds. However, prolonged elevation of renin/angiotensin and antidiuretic hormone is well documented and circulating blood volume may remain subnormal into the second week post burn. Loss of vascular integrity contributes to diminished organ perfusion and translocation of bacteriae in the gut.[9]

METABOLIC EFFECTS

Major burn injury (TBSA >20%) results in a hypermetabolic state, which ensues from around the third post burn day. The state is partly sustained by evaporative and radiant heat loss through the wounds, and energy expenditure can be reduced by increasing the ambient temperature and by the use of occlusive dressings.[10] Other factors known to influence the metabolic rate include pain, fear and anxiety. The effect of catecholamines on wound healing and metabolic rate of protein, fat and glucose metabolism contributes to this hypermetabolic state and ongoing catabolism up until 2 years after the injury.[10,11]

ABSTRACT

In the last couple of decades, outcome of severely burned patients has dramatically progressed thanks to development of centralised burn care, improvement of fluid resuscitation, infection prevention and early excision and grafting of the wounds. Thermal injuries cause local and systemic responses leading to vasodilatation, capillary leakage and a hypermetabolic state. The latter can be attenuated by pharmacological agents, early enteral nutrition, proper analgesia, and in time wound treatment. Frequently occurring complications in the treatment of burn patients include over-resuscitation, infection and Multiple Organ Dysfunction syndrome. The three distinct types of inhalation injury (upper airway injury, lower airway injury and inhalation of toxic gases) can increase morbidity and mortality.

hydrogen cyanide

PHARMACOLOGICAL EFFECTS

The pharmacokinetics and pharmacodynamics of many drugs are altered in burn patients. During the first 24 hours, when the cardiac output is depressed and capillary leak is present, distribution and clearance of administered drugs are delayed. Thereafter, increased cardiac output leads to accelerated drug absorption and distribution, while oedema fluid acts as an ill-defined third space and hypoalbuminaemia contributes to elevated free fractions leading to rapid clearance and diffusion in the third space. Antibiotics, like quinolones, β-lactams and aminoglycosides, may therefore fail to reach effective levels at conventional dosages.[12,13] On the other hand, toxic levels may ensue if renal failure supervenes. If possible, therefore, antibiotic administration should be guided by measurement of plasma concentrations and even more so if renal replacement therapy is indicated.

Decreased albumin and increased α_1-glycoprotein levels change the pharmacokinetics of benzodiazepines and opioids due to changes in the free fraction.[14] An increase in peri-junctional acetylcholine receptors significantly alters the pharmacodynamics of muscle relaxants.[15] Patients become relatively insensitive to non-depolarising agents, whereas administration of succinylcholine may give rise to excessive release of potassium and cardiac arrest. The burn wound itself is a significant route of drug absorption as well as drug loss contributing to the altered pharmacodynamics and pharmacokinetics.

CLINICAL MANAGEMENT

FIRST AID

Immediate aid consists of stopping the burn process, followed by the removal of clothing and cooling the wound, preferably with tepid running water, for 10–20 minutes. This provides pain relief and may prevent deepening of the wound.[16]

The initial evaluation of the severely burned patient should follow the principles of the Advanced Trauma Life Support guidelines: assessment and stabilisation of the airway (be aware of spinal cord injuries), breathing, circulation, disability and environment control.[17] Hypothermia should be avoided. Oxygen should be given and patients with burns to the head and neck should be kept in a semi-upright position. Burn injury can only be assessed properly under hospital conditions, and priority should be given to early evacuation of the victim.

GENERAL MANAGEMENT: 0–24 HOURS

On admission, a careful history should be taken of the circumstances of the injury, and of the medical history. The patient should be undressed, weighed and carefully examined to exclude additional (traumatic) injury. The extent and depth of injury are assessed with the aid of printed Lund and Browder charts,[18] or by using the 'rule of nines' (Fig. 83.1).[19] The rule of nines is modified for children (Fig. 83.2). A nasogastric tube and urinary catheter should be inserted in patients requiring resuscitation therapy. Escharotomies may be required for circular burns of the neck, trunk and limbs.

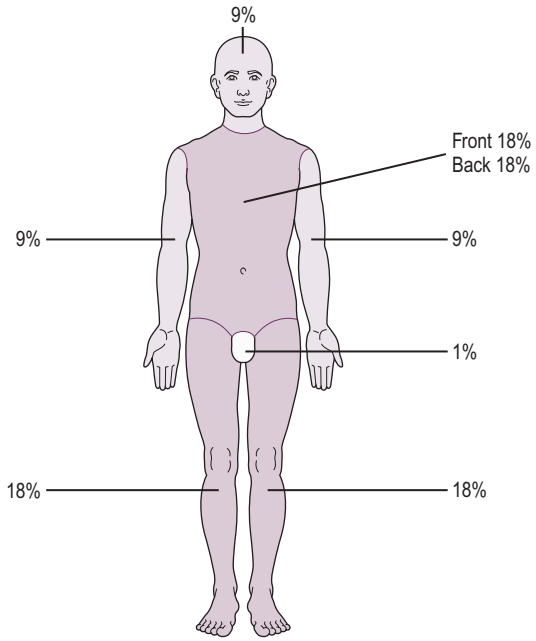

Figure 83.1 'Rule of nine' to estimate body surface area burns in adults.

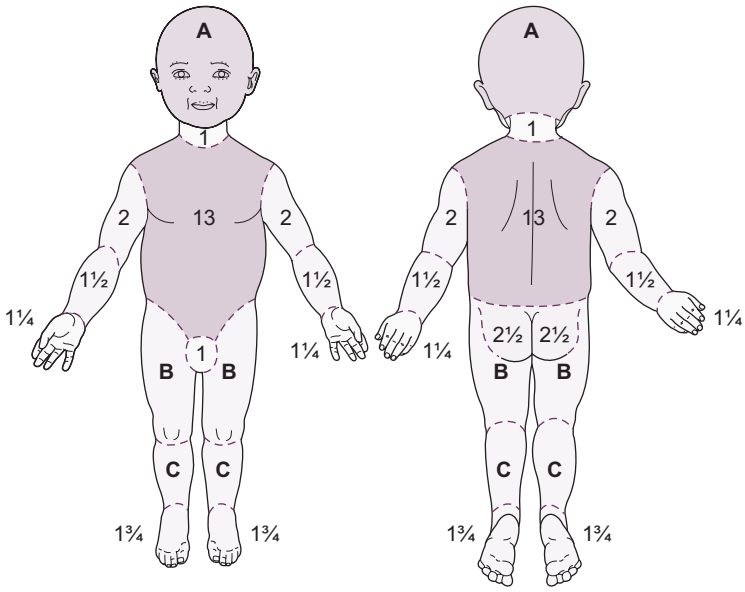
FLUID THERAPY: 0–24 HOURS

Fluid therapy is required for injuries exceeding 15% TBSA (10% in children and frequently in the elderly), preferably by two wide-bore peripheral intravenous (IV) cannulas. The aim is to maintain moderate hypovolaemia to preserve normal organ function utilising as little fluid as possible.

The most widely used resuscitation formula is based on the Parkland Formula,[20] which has been adopted by major training programs such as the Emergency Medicine for Severe Burns:

> *4 mL Ringer-Lactate solution × kg body weight × % TBSA burn in the first 24 hours; of which half should be given in the first 8 hours post burn and the other half in the next 16 hours.*

The formula thus incorporates a faster rate of administration if initial treatment has been delayed. For children, maintenance fluid must be added to compensate for basal needs.



Age	<1 year	1 year	5 years	10 years	15 years	Adult
Area A = ½ of head (%)	9.5	8.5	6.5	5.5	4.5	3.5
Area B = ½ of one thigh (%)	2.75	3.25	4.0	4.25	4.5	4.75
Area C = ½ of one leg (%)	2.5	2.5	2.75	3.0	3.25	3.5

Figure 83.2 Surface area percentages by age.

An increasing concern in recent years has been over-resuscitation in burn patients.[21] Excessive fluid administration increases the risk of circulatory overload in the days following the resuscitation period, resulting in complications such as abdominal or extremity compartment syndrome, deepening of the wounds or multiple organ dysfunction syndrome (MODS).[4,5]

The actual amount of fluid given depends on the clinical condition and the amount of fluid administered can vary widely from what was predicted. Adequacy of resuscitation is monitored by vital signs and a targeted urine output of 0.5–1 mL/kg per hour in adults and 1–2 mL/kg per hour in children. Importantly, this means that the fluid rate should be lowered when the hourly urine output goal has been reached. Requirements are increased in the presence of mechanical ventilation, additional traumatic injury and dehydration (e.g. firefighters, intoxication).

Resuscitation protocols guided by transpulmonary thermodilution (PICCO, PULSION Medical System, Munich, Germany) have been the subject of investigation in the past years. Results show that resuscitation can be achieved with below-normal haemodynamic targets but fluid administration still exceeds the Parkland formula.[22,23] Therefore, transpulmonary thermodilution-guided therapy is not yet incorporated in the standard care of burn resuscitation.

Hypoalbuminaemia develops rapidly and may be extreme. A recent meta-analysis showed that albumin administration may reduce mortality and abdominal compartment syndrome.[24] However, the quality of current evidence is limited and further research needed. In our unit at present, albumin is given to maintain serum albumin above 15 g/L, commencing 12 hours post burn when capillary integrity has been largely restored.

FLUID THERAPY AFTER 24 HOURS

During the second 24 hours, enteral nutritional intake is increased, while the total rate of fluid administration is gradually reduced. At the end of the second day, fluid intake should allow for sufficient urine production, while compensating for evaporative losses through the wounds.

The actual fluid loss through wounds varies widely, and depends on the type of burn and topical wound treatment. A useful formula to obtain a rough estimate for insensible fluid loss per hour is: *(25 + % TBSA) × m^2 body surface area + minimum volume of urine production/h.*

Electrolyte disturbances are common following burn injury and require treatment. Hypernatraemia is often a sign of dehydration, and can be confirmed if the serum urea is elevated. The condition is perilous, especially in the first week post burn, as oliguria and renal failure may develop unexpectedly. The amount of free water given should be increased gradually, particularly in the elderly, to avoid fluid overload. Patients who are in fluid balance may require sodium supplementation to compensate for solute loss in wound exudates.

HAEMOGLOBINURIA/MYOGLOBINURIA

Tissue injury from deep burns, particularly electrical injury, causes the release of myoglobin and haemoglobin from damaged cells. Diagnosis is made on observing discolouration of the urine, from faint pink in mild cases to almost black. Fluid administration should be increased, aiming at a urine output of 1–2 mL/kg per hour to preserve renal function. Additional measures such as mannitol (12.5 g/L resuscitation fluid) to encourage diuresis and bicarbonate to alkalinise the urine have been advocated, but no consensus has been reached.[25]

PAIN THERAPY

During the first 24 hours, pain management is best achieved by incremental doses of an IV opioid. Thereafter, the pain suffered by burn patients may be divided into continuous background pain with breakthrough pain, procedural pain caused by interventions and postoperative pain.[26] The recurring ordeal of dressing changes, physiotherapy exercises and surgical procedures generates apprehension and anxiety, contributes to chronic pain and post-traumatic stress syndrome. In recent years, the advent of slow-release oral opiate medication has greatly improved the administration of analgesia. Procedural pain is best treated with titrated boluses of IV opioids such as remifentanil.[26] Patient-controlled analgesia is effective, although modification of the control button may be necessary for those with bandaged hands. Ketamine in subanaesthetic doses is extremely useful for procedural pain in children and as an adjuvant to opioids in low-dose infusion (0.1–0.2 mg/kg/h) in children and adults. The influence of pain and anxiety on pain perception needs a multidisciplinary approach involving psychological techniques, pain management and a caring environment.[27,28]

NUTRITION

The degree of catabolism is roughly proportional to the extent of injury.[8] In young adults and children with extensive burns, energy expenditure may be doubled. In addition, protein and substantial amounts of trace elements, such as zinc, copper and selenium, are lost in wound exudate.[29] Very early (within 6–12 hours) enteral feeding mitigates the hypermetabolic response and improves outcomes.[29]

Indirect calorimetry is the gold standard to assess energy requirements. In the absence of direct metabolic measurements, the Toronto equation is a well-validated alternative.[29] A high-protein proprietary feed should be supplemented by extra trace elements, vitamins and glutamin.[29]

Patients with extensive burns will require tube feeds, which are generally well tolerated. To minimise interruption of enteral nutrition because of procedures or gastroparesis, post-pyloric feeding is often indicated. PEG tubes are useful when facial burns are present. Adjunctive therapy aimed at promoting anabolism include insulin to maintain normoglycaemia, oxandrolone, and propanolol.[11,26]

WOUND TREATMENT

Treatment of extensive, full-thickness burn wounds by early excision and grafting has been firmly linked to survival.[8] Wound excision should be completed within the first week, before bacterial colonisation and neovascular infiltration of the wound bed develop. These operations are therefore urgent. Successfully grafted wounds will heal within 5 weeks, reducing the time available for bacterial infection to develop, and shortening the period of physiological disturbance. Wounds covered with widely meshed autografts lose large amounts of fluid unless protected by a semipermeable layer, such as allograft or xenograft skin. Autograft donor sites are a further source of fluid loss.

For wounds treated conservatively, the main effort is devoted to the prevention of infection. Topical antimicrobial agents are commonly used, but may have potential side effects (Table 83.1). These compounds change the appearance of the wound and should never be applied until expert wound inspection is complete. A number of biosynthetic materials are currently available, which are designed to improve cosmetic and functional outcome. Despite the use of antiseptic dressings or biosynthetic coverings, there is still a risk of microbial infection developing and unexplained signs of sepsis may necessitate urgent wound revision.

New developments like laser Doppler imaging, electronic mapping and local biomarkers which help to predict whether a burn will spontaneously heal, have the potential to improve outcome.

INFECTION PREVENTION

The most common cause of death in burn injury is MODS caused by sepsis.[30] Infection is facilitated by the skin barrier destruction and the wound presents a favourable medium for bacterial growth. In addition, there is a state of immune dysfunction. Routine surveillance cultures are essential to guide therapy of

Table 83.1 Commonly used topical antimicrobial agents

AGENT	COMMENTS
Silver sulfadiazine (SSD)	The most widely used agent with broad-spectrum cover. Hypersensitivity (rarely) and transient leucopenia have been reported
Cerium nitrate 0.5%	Often added to SSD, and forms a stable eschar. It is reported to bind 'burn toxins'. Methaemoglobinaemia has been reported
Silver nitrate 0.5%	Applied as a soak, and is especially effective against *Pseudomonas*. However, it may increase sodium loss, and potentially can cause methaemoglobinaemia
Mafenide acetate 5%–10%	Effective but short-lived antimicrobial, requiring repeated application. It has good penetration, and its side effects (pain and metabolic acidosis) are less evident with 5% solution
Chlorhexidine	Aqueous solution (0.2%) or 1% gel provides broad-spectrum cover, but is rapidly inactivated, and may cause local pain, and rarely causes hypersensitivity
Nitrofurazone	In polyethylene glycol (PEG) solution it is effective against *Staphylococcus aureus*, but resistance develops early. Side effects include hypersensitivity (common), hyperosmolarity, and renal failure due to PEG absorption has been reported
Povidone iodine	In PEG solution provides broad-spectrum cover, but is rapidly inactivated. It prevents wound maceration. Side effects include occasional hypersensitivity, renal dysfunction due to excessive PEG, metabolic acidosis and rarely dysfunction
Antibiotics	Have been used in solutions, creams, gels and sprays, but selection and development of resistant strains is inevitable, with a risk of systemic toxicity through absorption. Their usage is generally discouraged

burn wound and other infections especially since drug resistance is common.

In an effort to reduce wound colonisation and contamination from cross-infection, barrier nursing of patients with extensive injuries is mandatory. The importance of isolation measures has been stressed, but a significant proportion of patients still become colonised by microorganisms from endogenous reservoirs, which cannot be controlled by barrier nursing alone. Positive experiences have been reported with selective decontamination of the digestive tract but large-scale prospective trials have only been performed in general critical care patients.[31]

SEPSIS

Disruption of wound healing and deepening of the injury together with immune paralysis can easily lead to wound infection and sepsis. However, discrimination between systemic inflammatory response syndrome (SIRS) and sepsis in burns remains arduous. Prodromal signs are common and may include gastrointestinal stasis, increasing positive fluid balance, increasing insulin resistance and increasing pyrexia. As sepsis progresses, clinical deterioration becomes manifest: tachypnoea, circulatory instability, thrombocytopenia and oliguria may herald the onset of multiorgan failure. Leucocyte counts, C-reactive protein levels and procalcitonin are all affected in the acute phase of burns by the SIRS and are unreliable indicators of infection. In the later phase, and for guidance of antibiotic therapy, procalcitonin levels seems to be the most reliable parameter.[32]

INHALATION INJURY

The term inhalation injury includes three distinct types of injury, which often, but not always, occur together. The presence of inhalation injury may increase resuscitation fluid requirements in patients with extensive cutaneous burns.

HEAT INJURY TO THE UPPER AIRWAY

Burns due to the inhalation of hot gases (steam excepted) rarely extend beyond the larynx. The development of mucosal and facial oedema can cause respiratory obstruction, particularly in children.

Facial burn, singed nasal hairs, visible burn to oropharynx and hoarseness are typical features.

If the condition is suspected, early endotracheal intubation is safest, before the procedure is rendered hazardous by oedema formation. However, as mechanical ventilation may aggravate oedema formation, unnecessary intubation should be avoided.

EFFECTS OF SMOKE ON THE RESPIRATORY SYSTEM

Many of the chemicals that are contained in smoke are highly reactive and produce damage to the tracheobronchial tree.[33] Detachment of epithelial cells and the development of tracheobronchial oedema cause airway narrowing and cast formation. Small-airway closure leads to hypoxaemia and respiratory failure. Later, bronchorrhoea and mucosal sloughing

may cause atelectasis and provide a focus for infection. In the absence of a cutaneous injury, the clinical course is usually benign. However, the presence of an extensive skin burn increases the likelihood of acute respiratory distress syndrome; respiratory infection may follow.

There is a history of exposure in a confined space, cough, breathlessness, wheeze, stridor, hypoxaemia, and soot particles in the pharynx. Diagnosis is confirmed by bronchoscopy, which may reveal soot in the bronchial tree, mucosal injury and tracheobronchial oedema.

Treatment is essentially symptomatic. Mild cases may be treated by high-flow oxygen. In severe cases, intubation and ventilatory support are necessary, with positive end-expiratory pressure to maintain small-airway patency. Bronchial toilet by bronchoscopy is recommended on a daily basis to clear debris and to prevent respiratory infection. Endotracheal tubes may become blocked with detritus. As small-airway obstruction is common, ventilation pressures may be adversely affected. Various strategies, such as protective ventilation or high-frequency ventilation, have been advocated to minimise the risks of barotrauma.

Prolonged respiratory assistance may be necessary. The added respiratory requirements of the hypermetabolic state combined with inevitable loss of muscle mass and diaphragmatic atrophy frequently frustrate early weaning efforts. Furthermore, the use of inhaled anticoagulants may improve outcome, although definitive evidence has not been established yet.[34]

INHALATION OF TOXIC GASES

CARBON MONOXIDE

Carbon monoxide (CO), which is released during combustion, is one of the main causes of death following smoke inhalation. The affinity of CO for haemoglobin is 240 times higher than of oxygen. The loss of oxygen transport capacity is dependent on the concentration of inhaled CO and the duration of exposure. In addition, CO binds to intracellular cytochrome systems, inhibiting cellular oxidative processes.[35] The half-life of carboxyhaemoglobin (COHb) is 320 minutes when breathing air, compared to approximately 75 minutes when breathing 100% oxygen.[35]

Carbon monoxide poisoning should be suspected in all cases of exposure to combustion products in a closed space. The classic cherry-red appearance of the CO victim is seldom evident; early signs may be mistaken for inebriation. Symptoms range from a throbbing headache in mild exposure (10%–25% COHb) to weakness, dizziness, confusion and nausea (25%–40% COHb), progressing to collapse, unconsciousness and convulsions (40%–60% COHb). Death is increasingly likely at COHb concentrations of greater than 60%. Patients exposed to high levels of CO may exhibit signs of cardiac instability. Signs of cerebral irritability may persist for days or weeks following apparent recovery.

After exposure, the highest concentration of oxygen available should be administrated. Loss of consciousness is an indication for oxygen delivery via an endotracheal tube. In specific patient groups with severe CO poisoning, hyperbaric oxygen therapy should be considered to reduce long-term cognitive impairment.[35]

HYDROGEN CYANIDE

Hydrogen cyanide toxicity frequently occurs in conjunction with CO inhalation. The cyanide ion binds to metalloproteins, causing cellular asphyxia. Neurological and cardiovascular symptoms can start within seconds to minutes after exposure and the condition can be rapidly fatal. Hydroxycobalamin is the preferred antidote and should be administrated within 2 hours.[36] Be aware that hydroxycobalamin colours urine and skin cherry red. Supportive treatment is as for CO intoxication.

FUTURE PROSPECTS

The outlook for young patients with extensive burn injuries, treated under optimal conditions, is now such that little further progress may be expected in terms of survival alone. Mortality among the elderly does, however, remain high. The major thrust of research is currently directed at improving functional and cosmetic outcome following burns. Although the most visible efforts concern the development of techniques and materials to improve the quality of wound healing, strategies aimed at preventing ventilator-associated morbidity are equally applicable to burn patients, who often require prolonged ventilatory support; new insights into the inflammatory responses may improve the general condition of burn patients, increasing resistance to infection and improving tissue repair. There is growing interest in the psychological effects of thermal trauma, which includes new approaches to the management of pain and mental distress.

In the past, the establishment of burn centres has been largely opportunistic, often depending on the dedication of individual specialists. As the provision of medical services undergoes increasing scrutiny, the organisation of burn care in many countries may be subject to reorganisation. It is of the utmost importance that specialists involved in the field of burn care become actively engaged in this process, in order to guarantee continued quality of care for their population.

Thermal disorders

Stephen W Lam, Richard Strickland

NORMAL TEMPERATURE REGULATION

Humans are endotherms and maintain a remarkably constant core body temperature (T_c) across an ambient range that may exceed 100°C. In order to do so, humans produce heat via oxidisation of food substrates or use of stored energy. At equilibrium:

Energy input = external work + stored energy + heat

Broadly speaking, heat production may be obligatory or facultative. Obligatory production is continuous and arises from processes essential for cell survival. The major components are the basal metabolic rate and the specific dynamic action of food. Facultative production is intermittent and arises from non-shivering thermogenesis in small amounts of brown adipose tissue, from shivering thermogenesis in skeletal muscle and as a by-product of physical activity. If environmental temperature exceeds mean skin temperature, then heat will be gained from the environment; this generally occurs when ambient temperature exceeds 35°C. Heat is lost by radiation, conduction, convection, and vaporisation of water from sweat and the respiratory tract. These mechanisms are limited by high ambient temperature or humidity. A very small amount of heat is lost in urine and stool.

The body may be visualised as having two thermal compartments, an outer shell comprising the skin and subcutaneous fat, and an inner core. The shell acts to protect the core and provide 'feed-forward' signals that allow the body to respond to potential thermal loads.[1] Current models of thermoregulation suggest T_c is maintained in an interthreshold zone or balance point by a series of relatively autonomous thermoeffector loops dependent on a common variable, T_c.[1,2] Whilst there is evidence for central reciprocal cross inhibition of thermoeffector loops, the concept of a centrally regulated set point has been replaced.

Temperature sensing occurs in skin, tissues of the deep core and centrally, providing afferent input to thermoeffector loops. In the dermis and epidermis, temperature activated transient receptor potential (thermo-TRP) ion channels are found on free ending axons of dorsal root ganglia. Over 30 thermo-TRP channels exist and may be cold (predominant) or heat activated at differing thresholds.[3] Input from these channels travel the dorsal root ganglion to ascend via multiple pathways, including Lamina I of the spinal cord and spinothalamic tract to the brainstem, where fibres for discriminative sensation and homeostatic control diverge.[1] Fibres for homeostatic control project to warm sensitive neurons in the preoptic anterior hypothalamus and cold sensitive neurons in the posterior hypothalamus. Similar afferent inputs are derived from deep thoraco-abdominal musculature, large vessels and many organs. In addition, thermosensitive neurons in the preoptic anterior hypothalamus, circumventricular organs, the midbrain and spinal cord provide central sensory input.

When thermoafferent input reaches a threshold, one or more thermoeffector loops are stimulated, with a resultant heat loss or heat gain response, mediated via behavioural, autonomic or endocrine changes. Behavioural responses, which appear to be driven predominantly by peripheral input, are generally more energy efficient, afford the greatest degree of thermoregulation and often pre-empt significant changes in T_c. If behavioural responses are inadequate or unavailable, as in many intensive care unit (ICU) patients, there is recruitment of autonomic regulation.

Autonomic responses are characterised by a threshold, gain and maximal response (Fig. 84.1). An increase in T_c above 37°C results in a heat loss response comprising cutaneous vasodilatation and sweating, mediated via predominantly cholinergic sympathetic nerves. When accompanied by an appropriate increase in cardiac output (≈3 L/min/°C), vasodilation results in core-to-cutaneous heat transfer and increased heat loss. Skin blood flow may increase from a basal rate of 0.2 L/min up to 8 L/min at T_c ≈39.0°C. Reflexes maintaining blood volume and pressure take precedence over thermoregulation. An inability to increase cardiac output or dehydration will reduce both the gain and maximal response of the vasodilator and sweating thermoeffector loops, respectively.[2,4]

A decrease in T_c initiates heat-preserving responses. At a threshold of 36.8°C, sympathetic adrenergic vasoconstriction occurs, and then non-shivering thermogenesis commences in small amounts of brown adipose tissue. This is of more importance in infants and

ABSTRACT

Thermal disorders can affect almost every system. For each patient, its significance and clinical approach to management depends heavily on factors relating to the condition, its cause, associated complications and co-morbidities. Furthermore, manipulation of temperature carries its own complexities. This chapter encompasses the major issues relating to thermal disorders and temperature management.

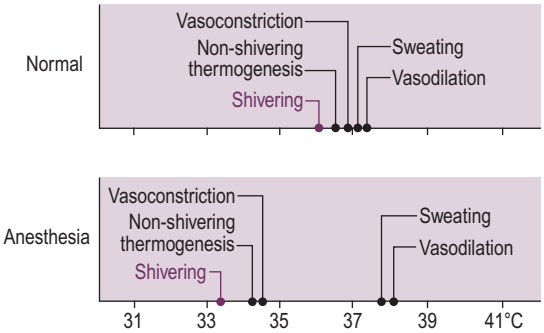

Figure 84.1 A schematic illustrating thermoregulatory thresholds in unanaesthetised and anaesthetised humans. Each response has its own threshold (x intercept) and gain. The interthreshold range is the distance between the first cold response (vasoconstriction) and the first warm response (sweating). *With permission from Sessler DI. Perianaesthetic thermoregulation and heat balance in humans.* FSAEB J. *1993;7:638–644.*

enables heat production by uncoupling proton movement from adenosine triphosphate (ATP) production across the mitochondrial inner membrane.[5] If T_c continues to fall towards 35.5°C, shivering thermogenesis begins, although the threshold and gain are reduced if the substrates for this process are inadequate, as may occur in hypoxaemia or hypoglycaemia.[2] Endocrine response includes increased secretion of cortisol and adrenaline.

The net effect of these mechanisms is maintenance of T_c around 36.9°C ± 0.4°C, with circadian variation of 0.5°C–1.0°C, peaking in the evening and being lowest around 6 AM. T_c is less precisely regulated in young children who may exhibit greater diurnal variation. Whilst T_c is normally maintained in a narrow interthreshold zone, skin temperature may vary widely dependent on ambient temperature and regional cutaneous blood flow. Temperature may vary amongst core organs by as much as 1.5°C during periods of rapid heat loss or gain, as in induction of therapeutic hypothermia (TH) or rewarming from cardiopulmonary bypass. The significance of this is uncertain, although it is worth noting that whilst the balance point at which T_c is normally maintained is close to the upper limit of survival, it is distant from the lower limit.

The ability to regulate temperature diminishes with age. In a thermo-neutral environment, T_c does not change in healthy older adults. When exposed to cold stress, peripheral vasoconstriction and thermogenesis are diminished, both in threshold and maximal response.[6,7] When exposed to heat stress, the elderly exhibit reduced sweat gland output and skin blood flow compared to younger controls.[6] When able, the elderly compensate for diminished autonomic thermoregulation with behavioural thermoregulation; however, this may be impaired when unwell, rendering the elderly prone to thermal insult.[7]

Patients in the ICU are likely to have disturbances of both heat production and heat loss. Anaesthetic agents and opiates significantly reduce the threshold for heat loss response in a dose-dependent manner. Threshold for cutaneous vasoconstriction may fall to 34°C under general anaesthesia (see Fig. 84.1); maximal response is also reduced by some agents, although gain is unaltered.[8,9] Sedative, adrenergic, cholinergic and neuromuscular blocking agents, ambient temperature and exposure, intravenous fluid administration, extracorporeal blood flow, impaired neurological or cardiovascular function, and deficiencies of substrate for thermogenesis are common factors in ICU patients which can affect thermal homeostasis.

FEVER AND HYPERTHERMIA

Hyperthermia results from failure of thermoeffector mechanisms to regulate temperature in the face of uncontrolled endogenous or exogenous heat gain. The primary event is not cytokine mediated and T_c is usually well in excess of 40.0°C. T_c greater than 41°C is usually due to hyperthermia rather than fever.[10]

Fever generally results from a cytokine-mediated change in threshold of thermoeffector loops resulting in regulated thermogenesis and transient elevation in T_c by 1°C–4°C.

Various definitions of fever exist and are acceptable, depending on the desired sensitivity of fever as an indicator of disease. Recognising differences in measurement technique, fever is often defined as a T_c greater than 38.3°C.[11] Fever is common in the ICU with a broad range of aetiologies (Table 84.1).[10] Most are mediated by production of the pro-inflammatory cytokines interleukin-1 (IL-1), IL-6 and tumour necrosis factor alpha (TNFα), which bind to receptors on circumventricular organs and up-regulate phospholipase A_2, resulting in production of prostaglandin E_2 via cyclooxygenase. This in turn stimulates warm sensitive neurons in the preoptic anterior hypothalamus, shifting the threshold of cold sensitive thermoeffectors by as much as 2°C, so inducing vasoconstriction and thermogenesis.[1] As pyrogen levels fall, thermoeffector thresholds return to normal and T_c falls. Fever commonly develops when blood is present in the cerebrospinal fluid (CSF), especially when intraventricular or in large volume.[12]

Mild to moderate fever is a phylogenetically preserved response; however, whether it is beneficial, neutral or harmful is uncertain and may be aetiology dependent.[13,14] There is little evidence to suggest benefit from routine treatment of mild – moderate fever outside the setting of acute brain injury, cardiogenic shock or profound hypoxaemia.[13,14] T_c greater than 38.5°C–40.0°C and the total fever burden, however, is associated with poorer patient outcomes and measures to control T_c should be considered whilst the

underlying disorder is treated.[14] Very high T_c can alter enzymatic function and protein folding, disrupting cellular systems including ion channels, surface receptors, mitochondrial electron transport and cytoskeletal elements. Different individuals and cell lines exhibit different resistance to thermal injury. In general, short-term elevation in T_c to 40.0°C is thought to be well tolerated without harm and may provide transient protection from further thermal injury via upregulation of heat shock proteins.[15,16] Beyond this, cellular and organ system dysfunction occurs. These changes represent a spectrum of disease evolution with progressive damage as T_c or exposure duration increase. A T_c greater than 43°C is immediately life threatening. Major organ system effects as core temperature rises are summarised in Table 84.2.

HYPERTHERMIAS

Major causes of hyperthermia are presented in Table 84.3. Important aspects of some are discussed below.

HEAT STROKE

Heat stroke represents the most severe form of heat-related illness. It is characterised by T_c greater than 40.0°C and neurological dysfunction, ranging from restlessness to delirium, seizures and coma.[17] Heat stroke may be classified as either classic (passive) or exertional (active). Classic heat stroke occurs following exposure to high ambient temperatures in those at the extremes of age or with co-morbid disease or medication that affect thermoregulation (Table 84.4). Exertional heat stroke occurs in healthy individuals who undertake strenuous activity in environments with high ambient temperature and humidity, reducing the efficiency of radiative and evaporative heat loss. Whilst the incidence of certain organ dysfunction varies slightly between the two forms, management is the same and they will be discussed together.

The pathogenesis of organ dysfunction in heat stroke has been the subject of much research and our understanding remains incomplete. Cytokine response may be significant, some components of which may be protective. TNFα and IL-6 levels correlate with severity of heat stroke while TNFα and IL-6 double knockout mice exhibit increased heat stroke mortality. Pro- and anti-inflammatory cytokines may be suppressed during onset of hyperthermia, rising 2–4 hours after reaching maximal T_c.[17–19]

Most patients with heat stroke present with delirium or coma, although focal neurology may occur. T_c is usually greater than 40.5°C and patients are vasodilated with evolving distributive shock and multiorgan dysfunction. Sweating is not always present. Disorders that may present in a similar fashion require exclusion (see Table 84.3). Management is essentially supportive. Principles include:

- Resuscitation
  - Recognise the need for alveolar hyperventilation
  - Restore circulating volume with cold 0.9% saline
- Cooling
  - Accurately monitor core temperature (see temperature measurement)
  - Aggressive cooling to T_c less than 39.0°C (Table 84.6)
  - Non-invasive measures that minimise cutaneous vasoconstriction and shivering are usually adequate
- Organ support
  - Particular attention to cardio-respiratory, renal, hepatic, haematological including disseminated intravascular coagulation (DIC), endocrine and neurological function
  - Hypotension usually responds to adequate cooling and volume replacement

Table 84.2 Organ system effects of change in core body temperature

20°C 28°C 30°C 32°C 34°C 35°C ≈ T_C	ORGAN SYSTEM	T_C ≈ 38.3 →	40.0°C 42.0°C INCREASING TIME	44.0°C →
• Cerebral metabolism falls by around 8%/°C • Confusion progresses to coma, hyporeflexia, unreactive pupils • Cerebral electrical activity is absent below 20°C	CNS	Increased $CMRO_2$ and $CMR_{glucose}$ Reduced cerebral blood flow as $PaCO_2$ falls	• Agitation/delirium • Blood–brain barrier injury • Elevated CSF protein/ lymphocytosis	• Coma, seizures • Cerebral oedema • Cortical infarction – especially cerebellum
• Cardiac output halved at 28°C • Reduced contractility • AF with slow ventricular rate at <30°C, VF at <28°C, Asystole at <20°C • Increasing PR, QRS and QT_c intervals (slowed K^+ flux) Osborne J wave below 33°C (height increasing with severity of hypothermia) • Initial increase in heart rate, then progressive fall (HR = 45–55 at 33°C) • Increased contractility ± mild diastolic dysfunction • V_{O_2} falls 8%/°C	CVS	• Tachycardia, vasodilation • Increased stroke volume • Decrease in CVP/SVR • Small decrease MAP • Increase in V_{O_2} ≈10%/°C	• Progressive tachycardia • Reduced stroke volume & MAP Reduced V_{O_2} if acidaemic	• Hypotension/shock • Myocardial infarction
• Pulmonary oedema • Apnoea • Progressive respiratory depression • Depressed cough reflex • Increased bronchial secretions • Reduced mucociliary clearance • Increase in respiratory rate and minute ventilation	Respiratory	Increased minute ventilation – mild respiratory alkalosis	Marked respiratory alkalosis ± metabolic acidosis	• Intravascular thrombosis • Hypoxaemia • ARDS
• Fluid compartment shifting, haemoconcentration, blood viscosity increases ≈2%/°C • Reduced platelet aggregation and adhesion at <35°C (decreased TxA_2 and glycoprotein Ib-IX) • Reduced coagulation factors and platelet adhesion inhibitor (PAI) function at <33°C • Reduction in both tPA and plasminogen activator inhibitor-1 (PAI-1) activity; however, effect appears non-linear and net result is unpredictable • Hypercoagulability and DIC may also result	Haematological	Increased haematocrit if fluid intake inadequate	• Direct activation of endothelium and platelets (increased vWF) • Increased fibrinolysis • Increased endothelial permeability	• Increased circulating TF • Microvascular thrombosis • DIC • Widespread haemorrhage • Endothelial apoptosis

- Anticholinergics
- Antiparkinsonians
- Antihistamines
- Tricyclics
- Sympathomimetics

ACEI, Angiotensin-converting enzyme inhibitor.

  - Benzodiazepines are considered first-line agents for treatment of seizure
  - Routine antibiotic prophylaxis is not recommended; however, gastrointestinal (GI) barrier dysfunction can occur and if sepsis is clinically suspected, empirical therapy should cover Gram-negative organisms
  - Insulin receptor expression is downregulated during hyperthermia, so there is a risk of hypoglycaemia after cooling if large initial doses of insulin are used
- Identify and manage precipitants (see Table 84.4)
  - Withhold agents impairing thermoregulation
  - Treat underlying infection, dehydration or endocrine disorders.

The use of dantrolene has been reported in case series; however, it has been found to be ineffective.[20] Use of antipyretics is common, although benefit has not been established and there is an association between the use of paracetamol and incidence of hepatic dysfunction.[17] The normal response to recovery from hyperthermia in mammals is biphasic, with initial hypothermia and then mild hyperthermia prior to restoration of thermal homeostasis. Traditional teaching has been to avoid hypothermia during recovery. In murine models, prevention of hypothermia during recovery was associated with greater hypotension and mortality.[19] It is uncertain whether mild hypothermia should be allowed in humans during treatment for heat stroke.

Heat stroke mortality remains high with an in-hospital mortality of 65% being reported in a large, prospective observational study of classic heat stroke.[21] Those factors strongly associated with death included immobility, psychiatric or cardiovascular disease, T_c and number of organ failures at admission. Survivors often have significant long-term morbidity, predominantly secondary to neurological impairment.

MALIGNANT HYPERTHERMIA

Malignant hyperthermia (MH) is a rare, autosomal dominant, pharmacogenetic myopathy with variable penetrance. It is characterised by a hypermetabolic state and skeletal muscle rigidity that manifests when a susceptible individual is exposed to volatile anaesthetics or depolarising muscle relaxants. The disorder results from abnormal sarcoplasmic calcium flux, and in 70% of cases is linked to a mutation in the ryanodine receptor RYR1. Thirty per cent of individuals with MH do not have RYR1 mutations, and other candidate proteins include Calsequestrin-1 or the dihydropyridine receptor.[22] Upon triggering, the abnormal RYR1 receptor is thought to release excessive calcium into the cytosol, resulting in sustained excitation-contraction coupling. Sustained contraction and increased Ca^{2+}-ATPase activity result in increased aerobic glycolysis; however, muscle blood flow is reduced and eventually metabolism becomes anaerobic, with onset of metabolic acidosis.

Almost all cases are associated with use of a volatile anaesthetic ± succinylcholine.[23] The earliest clinical sign is that of masseter spasm; however, this is neither specific nor sensitive. Hypercarbia disproportional to minute ventilation, sinus tachycardia and a rapidly rising temperature are the cardinal features, associated with generalised muscular rigidity in 40%.[23] These usually occur within 2 hours of exposure. In the ICU, early diagnosis may be difficult as hypercarbia and tachycardia are common, although if out of keeping with the clinical situation or associated with other features such as muscular rigidity, the diagnosis of MH should be considered. Fortunately, the incidence of MH is extremely low if volatiles are avoided. Less common signs include tachypnoea, cyanosis, diaphoresis, cola-coloured urine, bleeding and ventricular dysrhythmias.

Triggering agents should be avoided in those with a history or family history of MH. If MH is suspected, immediate management includes the following:

- Cease triggering agents, flush circuits of volatile anaesthetics. Increase minute ventilation.
- Give dantrolene 2.5 mg/kg intravenous rapidly. Repeat 5–10 minutely until hypercarbia and temperature respond. Maximal initial dose 10 mg/kg (median required 6 mg/kg)[21]
- Treat hyperkalaemia/metabolic acidosis with bicarbonate
- Cool the patient to T_c 36°C–38°C
- Identify and treat complications
  - Cardiac arrhythmias
    - Correct hyperkalaemia and acidosis
    - Do not use calcium channel antagonists as these may cause severe hyperkalaemia and cardiac arrest with high-dose dantrolene
  - Rhabdomyolysis
  - DIC.

All cases should be appropriately monitored until resolution. Dantrolene should be continued at 1 mg/kg 4–6 hourly for 24–48 hours. Failure to respond should prompt a search for an alternate diagnosis. Suspected cases should be referred to an MH screening centre. Testing usually includes a caffeine/halothane contracture test and genetic screening of relatives of confirmed cases for RYR1 mutations. Outcome of MH is good with mortality less than 10%. Additional resources are available from the Malignant Hyperthermia Association of the United States (http://www.mhaus.org/).

NEUROLEPTIC MALIGNANT SYNDROME

Neuroleptic malignant syndrome (NMS) is an idiosyncratic reaction characterised by hyperthermia, muscle rigidity, mental state change and autonomic dysfunction. It typically occurs within a month of introduction or dose increment of an antipsychotic agent (including atypical antipsychotics). Other drugs that antagonise central dopamine transmission or rapid cessation of central dopamine agonist may also precipitate NMS.[24]

NMS is thought to occur as a result of central dopamine antagonism, predominantly at the D2 receptor. In the hypothalamus this results in hyperthermia, whilst mesocortical and nigrostriatal blockade results in mental state change and extrapyramidal symptoms, respectively. It is postulated a loss of central integration gives rise to autonomic instability.[24,25]

The clinical presentation is one of hyperthermia (usually <42°C), 'lead-pipe' rigidity, tachycardia, labile hypertension and delirium or coma. This may be accompanied by hypoventilation, diaphoresis, tremor, incontinence or mutism. Onset is usually over hours to days and the diagnosis requires exclusion of other conditions that may mimic NMS (see Table 84.3). A peripheral leucocytosis is common, and creatine kinase is usually above 1000 IU/L; however, it may be much higher. Acute kidney injury (AKI) and DIC complicate severe cases. Neuroimaging studies and CSF analysis are normal in 95% and electroencephalography (EEG) shows generalised slowing.[25]

Differentiation from other hyperthermias relies predominantly on drug and environmental history, the presence of hypertonia rather than hypotonia (heatstroke) and absence of serotonergic features. If there is clinical suspicion of infection, appropriate cultures including CSF should be performed after neuroimaging. If seizures are suspected, an EEG is required.

Usually only severe NMS requires ICU support. Therapy includes:

- Resuscitation
  - Sedation ± neuromuscular blockade may reduce severity of hyperthermia, rhabdomyolysis and other complications
- Cessation of any potentially causative agent or re-introduction of acutely withdrawn dopamine agonist
- Cooling to maintain T_c less than 39°C
- Supportive care and management of complications with particular attention to
  - Respiratory failure
  - Rhabdomyolysis
  - AKI
  - DIC
  - Arrhythmias
- Potential adjunctive therapies include
  - Benzodiazepines or central α-agonist for agitation
  - Benzodiazepines for seizures or catatonia
  - Bromocriptine 2.5–5 mg enterally 8 hourly
    - Case series suggest reduce extrapyramidal symptoms and mortality
    - May worsen hypotension or psychosis
  - Electroconvulsive therapy (ECT) – case series suggest ECT is safe and effective if NMS is prolonged or psychotic symptoms persist, although most patients were not in the ICU.[26]

Dantrolene has been used in severe cases; however, there is no RYR1 abnormality in NMS, and recent meta-analysis of published cases suggests no benefit.[25] Drug withdrawal and supportive measures are usually adequate and mortality is less than 10%. Psychiatric advice should be sought prior to re-introduction of antipsychotics.

SEROTONIN SYNDROME

A wide range of drugs are associated with the syndrome of serotoninergic toxicity. This includes the selective serotonin reuptake inhibitors (SSRIs), selective norepinephrine reuptake inhibitors, monoamine oxidase inhibitors (MAOIs; including linezolid and methylene blue), lithium, amphetamines, pethidine, fentanyl, tramadol, triptans and St. John's wort. Severe serotonin toxicity only occurs after concurrent use of two or more serotoninergic agents, usually an SSRI and MAOI, and is thought to be mediated predominantly via the $5HT_{2A}$ receptor.[27]

Severe serotonin toxicity presents with altered mental state (agitation, delirium, coma), autonomic stimulation (tachycardia, hyperthermia, diaphoresis, tremor) and neuromuscular excitation (clonus, hyperreflexia, rigidity). Features with greater specificity for serotonin toxicity include hyperreflexia, lower limb or ocular clonus and myoclonus. Rigidity tends to be predominantly lower limb.[27]

Management of severe toxicity involves resuscitation, withdrawal of offending agents, cooling and supportive care. Complications are similar to those observed in the other hyperthermias. Adjunctive therapies are of less importance. These include the $5HT_{2A}$ agonist cyproheptadine, 4–8 mg enterally 6 hourly or chlorpromazine if enteral administration is not possible.

SYMPATHOMIMETIC TOXICITY

Hyperthermia may be precipitated by all centrally acting sympathomimetics by increasing release, inhibiting metabolism or preventing re-uptake of noradrenaline, serotonin and dopamine, usually in a dose-dependent fashion. This results in increased muscle thermogenesis and impaired heat loss. In severe cases, the clinical picture is that of a rapidly progressive hyperthermia with marked delirium or coma, rhabdomyolysis, DIC and multiorgan dysfunction. As with other severe hyperthermias, early and aggressive supportive care is indicated. Most require intubation, neuromuscular blockade and aggressive cooling. Plasma potassium may rise rapidly, necessitating dialysis. There are no specific therapies and whilst dantrolene has been advocated, there is insufficient evidence to support routine use.

ANTIMUSCARINIC TOXICITY

A wide variety of antimuscarinic agents exist. Peripheral toxicity causes tachycardia, cutaneous vasodilatation, mydriasis, urinary retention and impaired sweating. Central toxicity gives rise to tremor, delirium and occasionally seizures. Severe hyperthermia with rhabdomyolysis and DIC may occur; however, this is unusual and most antimuscarinic toxidromes are adequately managed with drug withdrawal, benzodiazepines and passive cooling.

HYPOTHERMIA

DEFINITION AND CLASSIFICATION

Hypothermia is defined as core temperature less than 35°C, and may develop due to abnormal thermoregulation or heat loss overwhelming thermoregulatory capacity. Important causes and contributing factors are summarised in Table 84.5.

Severity is somewhat arbitrarily classified by T_c as[28]

- mild (32°C–35°C)
- moderate (28°C–32°C)
- severe (<28°C)
- profound (<24°C).

Hypothermia may also be classified as unintentional (often referred to as 'accidental'), or intentional (such as in cardiopulmonary bypass [CPB], deep hypothermic arrest and TH). This can be further divided into:

- primary (intact thermoregulation)
- secondary (abnormal thermoregulation)
- tertiary hypothermia (induced for therapeutic purpose, as in TH).

PHYSIOLOGICAL EFFECTS OF HYPOTHERMIA

Hypothermia alters a wide range of molecular and cellular functions, some of which may be exploited for

Table 84.5 Important causes and contributors of hypothermia

Increased heat loss
• Surface conduction, convection, radiation or evaporation
• Vasodilatation, dermatological disruption
Reduced heat production
• Endocrine (diabetic ketoacidosis, hypopituitarism, hypoadrenalism, hypothyroidism)
• Energy reserve (e.g. hypoglycaemia, malnutrition)
• Immobility and reduced neuromuscular activity
• Extremes of age
Impaired or abnormal central thermoregulation
• Central nervous system disorders
• Advanced age
• Pharmacological and toxicological (e.g. alcohol, CNS depressants, psychotropics)
• Uraemia
• Sepsis
• Malignancy

CNS, Central nervous system.

therapeutic purpose. However, prolonged or severe hypothermia causes progressive deterioration in organ function. Table 84.2 provides a summary of the physiological effects of hypothermia.

Manifestations of the normal thermoregulatory response predominate in patients with cold exposure or very mild primary or tertiary hypothermia (generally with T_c above 34°C). Patients with abnormal thermoregulatory capacity (especially those with dysautonomia) may lack some of these features and are therefore more prone to developing secondary hypothermia. There is an increase in catecholamine and cortisol secretion, and sympathetic activation is evident with:

- increase in respiratory rate
- increase in heart rate and contractility
- diastolic cardiac dysfunction
- vasoconstriction with reduced tissue perfusion
- increase in muscle tone and shivering.

The Swiss staging system describes five clinical stages of severity in primary hypothermia as a tool for estimation of T_c where reliable measurement of T_c is not possible. Whilst accuracy is somewhat limited,[29] it remains a useful tool for triage and management decisions in some pre-hospital circumstances[30,31]:

- stage I – clearly conscious and shivering (estimated T_c 32°C–35°C)
- stage II – impaired consciousness without shivering (estimated T_c 28°C–32°C)
- stage III – unconscious, vital signs present (estimated T_c 24°C–28°C)
- stage IV – no (or minimal) vital signs (estimated T_c <24°C)
- stage V – death due to irreversible hypothermia (estimated T_c <13.7°C)

MANAGEMENT OF PATIENTS WITH ABNORMAL CORE TEMPERATURE

CORE TEMPERATURE MEASUREMENT

The temperature of blood perfusing the hypothalamus is considered the reference point for T_c, which can be measured by jugular venous bulb (JVB) catheterisation. This is most accurately approximated by pulmonary artery catheter (PAC) measurements.[32]

During rapid temperature change, JVB temperature is closely approximated by PAC measurements except during, and for around 10 minutes after, rapid infusion of intravenous solution. Lag can be significant from other sites of temperature measurement, depending on the rate and magnitude of change.[32]

Whilst accuracy is temperature dependent, when core temperature is stable, compared with PACs[33–37]:

- the most accurate measurements can be obtained from an oesophageal probe in the lower quarter of the oesophagus (0.11°C ± 0.3°C), or urinary bladder catheter (–0.2°C ± 0.2°C).
- nasopharyngeal, rectal and skin/deep tissue measurements can also be accurate; however, sites such as oral, axillary and tympanic membrane are less reliable, more subject to faults in measurement conditions and technique, and can be inaccurate by more than 0.5°C.

Urinary bladder catheter temperature measurements rely on adequate urine output.[32,37] Oesophageal temperature should be measured at the retro-cardiac region at T8-T9 vertebral level and may be influenced by gas temperature in the trachea.[27,32,36,38]

Brain temperature rather than T_c may be of interest in brain injury and during neuroprotective therapy. However, brain temperature targets are uncertain and guidance from clinical data remains based on measurements of T_c. There may be differences of around 1.5°C between regions of the body and brain, particularly during rapid temperature change or periods of high cerebral metabolism.[12,39] Within the brain itself, cerebral thermo-pooling can occur, with deeper regions warmer than the surface by around 0.5°C–1°C. In brain injury, the brain can be warmer than T_c by as much as 2°C, while brain temperature lower than T_c (inverted temperature gradient) is a poor prognostic sign.[12]

PHARMACOLOGICAL EFFECTS OF ALTERED BODY TEMPERATURE

Much work in this area has been performed on animal models; understanding of drug pharmacology in humans during hypothermia or hyperthermia is limited. Whilst each drug requires characterisation across temperatures, some principles provide guidance.

Febrile patients with systemic inflammatory response syndrome (SIRS) may have high cardiac output with resultant increase in renal and hepatic blood flow. Augmented renal clearance of a number of antimicrobials has been well described in subgroups of ICU patients.[40] Although hepatic blood flow may increase, the acute phase response suppresses expression of many cytokines and the net effect of fever on hepatic clearance in humans is uncertain. In severe hyperthermia, organ dysfunction may significantly alter pharmacokinetics.

In hypothermia, absorption of orally administered drugs is significantly slowed. Bioavailability, dependent upon hepatic extraction, varies between drugs. Effect on volume of distribution (Vd) is variable as tissue blood flow, protein binding and ionisation change. For example, the Vd of midazolam increases by 83% at 33°C, whilst the Vd of pancuronium decreases.[41] Altered ionisation is of significance in drugs with a pKa between 7 and 8 and narrow therapeutic window (e.g. lignocaine). In this setting, pH-stat ventilation may be wise.[41] Hypothermia reduces hepatic blood flow and slows enzyme kinetics, resulting in reduced hepatic and

extrahepatic clearance. Renal flow, glomerular filtration rate (GFR) and tubular secretion are also reduced.[42] In moderate hypothermia, clearance of propofol, morphine and vecuronium are reduced by 10%–25%.[41] Pro-drugs, therefore, have a slower onset, while active drugs and those with active metabolites have prolonged duration of action and increased risk of toxicity.

Pharmacodynamic changes with hypothermia are variable and poorly characterised. Rewarming brings about further kinetic and dynamic alterations. In patients with significant alterations in T_c it seems wise to dose parenterally, avoid pro-drugs and agents with multiple active metabolites, and when possible titrate to a clinical endpoint or undertake temperature-corrected therapeutic drug monitoring.

ACID-BASE AND BLOOD GAS INTERPRETATION

Blood gas analysers are calibrated to perform measurements at 37°C. Deviation in body temperature from 37°C therefore results in a difference between the patient's true values and those derived from the blood gas analyser, which may be clinically significant.

The solubility of a gas is inversely related to the temperature of the solution. Therefore, a hypothermic patient will actually have lower Pa_{O_2} and $PaCO_2$ than the values derived from blood gas analysis performed at 37°C, while the opposite is true in fever and hyperthermia (Henry's Law). The relationship between temperature and gas solubility is non-linear and correction factors are required to calculate true blood gas values in the patient from measurements performed at 37°C.[43]

VENTILATION STRATEGIES

Data on ventilatory strategies are mostly derived from patients undergoing hypothermic CPB and TH following central nervous system injury. It is uncertain whether mechanical ventilation should be adjusted to achieve $PaCO_2$ and pH targets according to the arterial blood gas values measured at 37°C (alpha-stat method), or corrected to the patient's body temperature (pH-stat method).

With theoretical arguments for and against each strategy and no definitive data, alpha-stat is generally favoured with the additional advantage of simplicity.[44–46]

Consideration of pH-stat strategy may be particularly relevant in patients with narrower $PaCO_2$ and/or pH targets. Cerebrovascular reactivity to $PaCO_2$ is preserved, and calculation of the patient's true $PaCO_2$ may be relevant in patients with raised intracranial pressure. Maternal acid-base status may also be particularly relevant to the foetus during pregnancy.[47,48] In post-cardiac arrest patients, new data has raised concerns over possible negative effects of $PaCO_2$ disturbance.[31]

Regardless of ventilation strategy, it should always be noted that measured Pa_{O_2} is not the true patient value if T_c is significantly greater or less than 37°C.

ALPHA-STAT STRATEGY

This strategy is based on the theory that maintaining the pH of neutrality (pN) is important for cellular enzyme function and metabolism. The imidazole group of histidine is an important component of protein acid-base buffering, and has a pN which changes with temperature. Imidazole ionisation fraction (denoted as alpha) remains constant as body temperature changes (if CO_2 content also remains constant), thereby maintaining constant net charge of proteins and maximal ionisation of intracellular metabolic intermediates. When applying alpha-stat theory, $PaCO_2$ is adjusted to meet its target value when measured at 37°C without being corrected for actual patient temperature. Whilst cerebral blood flow is lower (predominantly due to lower $PaCO_2$) in alpha-stat compared with pH-stat management of hypothermic patients, it is thought to match the lower cerebral metabolic rate of hypothermia.

PH-STAT STRATEGY

This strategy is based on the theory that pH should be kept at its target value throughout the range of patient temperatures, and that cerebral blood flow autoregulation continues to react to $PaCO_2$. There is no reference range for temperatures other than 37°C, and the pH-stat approach assumes that values appropriate for 37°C remain so for all temperatures. Use of pH-stat in hypothermic patients requires an increase in CO_2 content, and therefore results in cerebral vasodilatation above the brain's metabolic demand, which may worsen pre-existing intracranial hypertension. It does, however, counteract the leftward shift in oxyhaemoglobin dissociation curve caused by hypothermia.

TRANSCUTANEOUS PULSE OXIMETRY RESPONSE TIMES IN HYPOTHERMIA

In hypothermic patients, the detection of changes in haemoglobin oxygen saturation by transcutaneous pulse oximetry may be significantly slower using finger probes compared with forehead sensors.[49]

HAEMOSTATIC ASSESSMENT

In the same manner as blood gas analysis, common tests of haemostasis such as the thromboelastograph, activated partial-thromboplastin time, and prothrombin and thrombin times are measured with blood samples at 37°C. Hypothermic effects on platelet and coagulation enzyme function are reversible with rewarming and hence laboratory values may be misleading when considering the patient's haemostatic capacity.[27,50] Measurements can be performed at other temperatures with prior calibration of equipment.

MANAGEMENT OF CARDIAC ARREST

No recommendations for modification of standard cardiopulmonary resuscitation (CPR) have been made for fever or hyperthermia.

Severe hypothermia can produce a clinical state which mimics prolonged circulatory arrest and poor prognosis with apnoea, asystole, unreactive pupils and areflexia. However, good outcomes have been achieved with prolonged resuscitation (in excess of 2 hours' CPR) in such patients and therefore efforts should continue until a T_c of at least 35°C is achieved.[31] In a very early report of induced hypothermia in a 51-year-old woman, a rectal temperature of 9°C was reached, with 45 minutes' cardiac standstill before initiation of surface rewarming, which gradually returned spontaneous circulation and apparently normal neurological function.[51]

In circumstances where interruption of CPR is considered potentially beneficial (e.g. to allow transportation to a more favourable environment or facility), 5-minute periods of CPR may be interposed with periods of interruption for up to 5 minutes if estimated T_c is 20°C–28°C, and 10 minutes if T_c is less than 20°C.[31]

Rewarming is important in restoring perfusing cardiac rhythm in patients with ventricular fibrillation (VF) or ventricular tachycardia (VT) and may also resolve atrial arrhythmias, atrioventricular block and bradycardia. Pacing may be hindered by reduced cardiac responsiveness and is generally not considered necessary for bradycardia due to hypothermia.[31,52]

The suggested modification for CPR of hypothermic patients involves[31]:

- withholding drugs until temperature is greater than 30°C, then doubling usual drug intervals until temperature is greater than 35°C,
- delivery of up to 3 shocks using maximum energy for VT or VF, and thereafter withholding further shocks until temperature is greater than 30°C. Rhythms other than VF may revert spontaneously with rewarming.

It is noteworthy that the optimal timing and dose of cardiac arrest drugs is not known for normothermic or hypothermic patients, and the use of vasopressors remains controversial.[53] These recommendations for modifying resuscitation are based on concerns over cardiac unresponsiveness to, and possibly injury from, defibrillation, and reduced effectiveness of drugs or drug toxicity with repeated dosing due to reduced drug metabolism.[31] However, animal studies have found vasoactive drugs and defibrillation to be effective in hypothermia.[52,54] Currently, there is inadequate evidence to support strong recommendations to modify standard CPR algorithms in the setting of hypothermia. Using standard algorithms for defibrillation and vasopressor administration in the presence of hypothermia is considered acceptable.[52]

Whilst there is concern over precipitation of ventricular arrhythmias by patient movement and invasive procedures, it is recommended that hypothermia not delay the performance of life supportive manoeuvres in cardiac arrest.[52]

TEMPERATURE MANAGEMENT AND CONTROL

CONTROLLING HYPERTHERMIA AND FEVER

Severe hyperthermia requires early aggressive pharmacological and physical measures to reduce T_c (Table 84.6). Because the balance point is unaltered in hyperthermia, antipyretic medications are not effective in lowering T_c.

In the case of fever, and especially sepsis, the concept of manipulating T_c is somewhat more controversial. Fever burden, especially T_c above 38.5°C, is associated with worse outcomes in critical illness.[14,55,56] Controlling fever appears to reduce vasopressor requirement in septic shock; however, its net effect on immune function, development of acute lung injury and survival are not certain, with some concerns raised over the use of antipyretic medication in sepsis.[13,55,57–59] Whilst benefit from controlled normothermia in patients with primary neurological injury is yet to be conclusively demonstrated, active measures to treat or prevent pyrexia is recommended in this setting based on the available evidence.[54,60–63]

Paracetamol acts predominantly by central inhibition of cyclooxygenase and results in temperature reduction of 0.3°C–0.4°C, without inducing a counter-regulatory response.[64] Other agents that suppress thresholds for thermogenesis and may be appropriate in the non-ventilated patient include magnesium, opiates, benzodiazepines, clonidine and tramadol.

Control of fever or maintenance of normothermia in the non-sedated, non-intubated patient can be challenging if thermoregulation is intact, with the balance point for T_c often being elevated by endogenous pyrogens or direct hypothalamic insult. The application of physical modes of cooling without pharmacological measures to alter thermoeffector response results in undesired shivering and increased cardio-respiratory workload. In such cases, the risks associated with need for sedation and even intubation and paralysis in order to achieve additional cooling must be weighed against potential benefit of temperature control.

CORRECTING HYPOTHERMIA

TECHNIQUES

The various methods of increasing core temperature are summarised in Table 84.6.

In general, it is considered that:

- for patients with intact autoregulatory thermogenesis and temperature greater than 34°C, passive rewarming alone may be adequate
- Patients with spontaneous circulation and temperature less than 34°C often require addition of active external warming
- Patients with temperature less than 30°C usually require active internal warming.

Table 84.6 Methods of temperature manipulation

CLASSIFICATION		METHOD	RATE OF CHANGE (°C/H)
Passive	Warming	Warm (>24°C) environment Insulating blanket	0.5–1
	Cooling	Cool environment Exposure (removal blankets/clothes)	
Active external	Warming	Warm forced-air blankets Water circulating heating control blanket Radiant heaters Temperature control pads (e.g. Arctic Sun, Medivance Inc., Louisville, Colorado)	1 1 1–2 1.5–3
	Cooling	Wet towels/ice packs Water circulating cooling control blanket Evaporative cooling (fan + tepid mist) Temperature control pads	1 1 1–2 1.5–3
Active internal	Warming	Humidified warm inspired gases Intravascular temperature control catheter (e.g. Alsius CoolGard, Irvine, California; Celsius Control System, Innercool Therapies Inc., San Diego, California) Body cavity lavage isotonic saline (gastric, right pleural 200 mL, peritoneal 10 mL/kg, bladder) Extracorporeal • renal replacement circuit • cardiopulmonary bypass	0.5–1 2–4 2–3 5 10
	Cooling	Cool intravenous fluids (4°C: 30–40 mL/kg) Intravascular temperature control catheter Body cavity lavage isotonic saline (gastric, right pleural 200 mL, peritoneal 10 mL/kg, bladder) Extracorporeal • renal replacement circuit • cardiopulmonary bypass	2–3 2–4 3 5 10

Warming of intravenous fluid (generally to around 40°C) prior to administration is important but is an inefficient means of rewarming. Thoracic lavage has been used successfully in cardiac arrest while gastric and bladder irrigation has a somewhat more limited effect.[27] Extracorporeal techniques are the most effective, and extracorporeal membrane oxygenation or CPB is generally favoured in the setting of cardiac arrest.[27]

TARGET RATES AND POTENTIAL HAZARDS OF REWARMING

Concerns with rewarming from hypothermia can be considered as:

1. Handling of the hypothermic patient and procedural risks of rewarming
2. Physiological effects of rewarming, and
3. Possible neurological injury caused by rapid rewarming.

During rewarming, care should be taken to avoid precipitation of cardiac arrhythmias by sudden movement and invasive intervention; however, this concern should not influence the performance of life-supportive manoeuvres such as intubation and central venous catheterisation, and is very rare at temperatures above 30°C.[36,52]

Vasodilatation often results in the need for intravenous fluid administration. In patients who have become hypothermic due to surface heat loss, the temperature of the peripheral compartment may be lower than the core compartment. Active surface rewarming in these patients may cause peripheral vasodilatation resulting in blood circulating from the cooler peripheral compartment to the core compartment at a lower temperature. This 'core temperature afterdrop' may be mitigated by using active internal rewarming prior to or concurrent with surface rewarming.

Rapid rewarming causes cerebral vasodilatation and loss of cerebral blood flow autoregulation. Intracranial hypertension, if present, may worsen.

Hyperkalaemia may develop due to extracellular shifting. The return of insulin sensitivity may result in potentially detrimental hypoglycaemia and high blood glucose variation.[65,66]

NEUROLOGICAL INJURY AND RATE OF REWARMING

Conceptually, it is reasonable to consider TH used for mitigation of neurological injury separately from unintentional hypothermia where there has not been a primary neurological insult. Whether such a differentiation should actually alter management from a patient outcome perspective, however, is not known at this stage.

REWARMING FROM INTENTIONAL AND THERAPEUTIC HYPOTHERMIA

In studies of hypothermia for neuroprotection from ischaemic, reperfusion, or hypoxic neurological insult including CPB, deep hypothermic arrest, and TH for cardiac arrest there is significant concern that rapid rates of rewarming may cause neurological injury and/or attenuate neuroprotective mechanisms of hypothermia.[67,68] These concerns arise from findings of:

- greater neurological injury and compromise of cerebral blood flow autoregulation by rapid rewarming[69,70]
- a possible association with seizures on rewarming[71,72]
- discrepancy between cerebral and core temperatures during rewarming and possible cerebral rebound hyperthermia[38,39,73]
- findings of better neurocognitive and renal function following slow rather than fast rewarming from CPB.[68,74–76]

In stable patients receiving TH for cardiac arrest, it is broadly recommended that rewarming be conducted at a rate not exceeding 0.5°C/h to achieve a controlled target of 36°C, with avoidance of post TH hyperthermia, which may be harmful.[77]

REWARMING FROM UNINTENTIONAL HYPOTHERMIA

Whether cerebral hypothermia or rapid rewarming can themselves cause neurological injury (in the absence of another primary neurological insult) is not well understood. Apparently complete neurological recovery has been achieved after rewarming from 9°C, despite a period of greater than 45 minutes' cardiac standstill.[51] In severe accidental hypothermia, rates of rewarming around 9°C/h via CPB have resulted in good neurological outcomes.[27]

Where hypothermia is unintentional and in the absence of a primary neurological insult, the risks associated with hypothermia and rapid rewarming should be balanced. As outlined above, maximal rewarming rates using extracorporeal techniques where available are currently favoured in hypothermic cardiac arrest.[27]

Failure to respond adequately to T_c-appropriate rewarming techniques as outlined above should precipitate a careful search for underlying causes of secondary hypothermia, most notably drugs and toxins, endocrinopathy and sepsis. Risk of underlying sepsis was found to be high when rewarming in response to treatment occurred at a rate less than 0.67°C/h, and low when rates greater than 1.67°C/h were achieved.[78]

THERAPEUTIC HYPOTHERMIA AND TARGETED TEMPERATURE MANAGEMENT

POTENTIAL MECHANISMS

Hypothermia is potentially beneficial in a variety of circumstances and is the subject of intense research.

Most mechanisms of potential benefit with TH relate to the modification of temperature-sensitive consequences of cellular injury, with particular focus at present on tissues of the central nervous system in the setting of ischaemia or reperfusion. Traumatic or ischaemia/reperfusion injury results in a cascade of destructive processes ranging from subcellular to systemic levels which can continue for several days and perhaps even weeks.[60] A wide range of these processes are temperature sensitive; however, this varies following an insult. The clinical implications of this variability such as the effect on optimal timing and duration of TH has not been fully elucidated.[27] Table 84.7 lists some of the effects of hypothermia with potential benefit for the central nervous system.

With biological plausibility, positive animal laboratory findings and some positive human trial data, the use of hypothermic range targeted temperature management (TTM), commonly referred to as TH, has been introduced in some circumstances.

Table 84.7 Mechanisms of neuronal benefit with hypothermia

Early mechanisms
• Reduction in cerebral metabolism (≈8% reduction per 1°C fall) and thermo-pooling
• Reduction in mitochondrial dysfunction
• Decreased production of nitric oxide and free radicals
• Decrease in excitatory neurotransmitters and calcium influx
Late mechanisms
• Suppression of ischaemia-induced inflammation
• Mitigation of reperfusion-related DNA injury, lipid peroxidation, and leukotriene production
• Reduced cell membrane leakage and cytotoxic oedema, blood–brain barrier-stabilising effect
• Suppression of seizures
• Reduction in apoptosis (inhibition of caspase activation)

Polderman KH. Induced hypothermia and fever control for prevention and treatment of neurological injuries. *Lancet.* 2008;371:1955–1969.

Potential benefit from hypothermia may also be derived from other physiological effects such as those on rate of cerebral metabolism during periods of reduced blood flow, the immune function (in patients with sepsis and septic shock), and reduction of intracranial pressure. Induction of hypothermia for cardio-pulmonary bypass and deep hypothermic arrest in cardiovascular surgery utilises the reduction in cerebral metabolic demand for neuroprotection from ischaemic injury. However, TTM and TH generally refer to the use of hypothermia following an unintended primary neurological injury.

INDICATIONS FOR THERAPEUTIC HYPOTHERMIA

ADULT POST-CARDIAC ARREST TEMPERATURE MANAGEMENT RECOMMENDATIONS

The greatest interest currently is in adult survivors of cardiac arrest. Two landmark clinical trials published in 2002 showed positive outcomes for TH compared with no temperature control for patients who were comatose after achieving return of spontaneous circulation (ROSC) from out-of-hospital pulseless VT or VF cardiac arrest.[79,80] These studies reported no significant difference in complications and therefore potential for harm was thought to be limited if conducted in an appropriate clinical setting. TH was subsequently widely adopted in post-resuscitation management guidelines, although it was acknowledged that the quality of evidence was low and that uncertainties still existed regarding optimal technique/indications and adverse effects other than those reported in these studies.[53,70,81–84]

Nielsen and colleagues subsequently published a large randomised controlled trial in 2013 (the TTM study) which found no significant difference in survival and functional status between normothermic TTM, also referred to as therapeutic normothermia (TN), and TH in adult survivors of out-of-hospital cardiac arrest (OHCA).[85] This international multicentre trial of 939 patients included non-shockable initial cardiac arrest rhythms and also found no significant difference in complications. Whilst this trial brought about significant uncertainty about the benefit of TH over TN, all patients in this trial received TTM and hence the importance of tight temperature control, and especially prevention of fever, remains emphasised.

The core clinical trials outlined above largely set out to investigate the effect of TH; however, interpreted together they perhaps demonstrate more of a benefit in avoidance of post-cardiac arrest fever.[85,86] Therefore, convincing as the experimental animal and laboratory data may be for TH following ischaemia reperfusion, improvement in patient outcomes with TH in clinical practice is yet to be conclusively demonstrated. Potential reasons for this include lack of true benefit, clinical trial methodology and design, ineffectiveness of trialled treatment protocols (patient selection, timing, temperatures, duration, rewarming), and loss of benefit through adverse effects.[87] Whilst these trials reported no difference in the complications studied, more recent data on other factors such as disturbances in $PaCO_2$ and glucose variability which may be brought about by temperature manipulation might in fact be relevant to outcomes.[65,66,77]

The Advanced Life Support Task Force of the International Liaison Committee on Resuscitation (ILCOR) performed an extensive review of the literature published up until December 2014, and made a number of recommendations in 2015 on adult TTM for post-cardiac arrest care. Key points from these and the recommendations made by resuscitation councils in their respective 2015 resuscitation guidelines include[88–90]:

- when TTM is used, a single target temperature value should be prescribed. This value should lie somewhere in the range of 32°C–36°C. The patient's temperature should then be maintained at this value for a period of at least 24 hours.
- It is *strongly* recommended based on *low-quality evidence* that TTM is used for adults who remain unresponsive after achieving ROSC from OHCA with *shockable* initial rhythm (VT or VF).
- Recommendations for the use of TTM is *weak* and based on *very low quality evidence* for
  - **a.** adults who remain unresponsive after achieving ROSC from OHCA with *non-shockable* initial rhythm, and
  - **b.** adults who remain unresponsive after achieving ROSC from in-hospital cardiac arrest (IHCA) of *any* initial rhythm.

PAEDIATRIC POST-CARDIAC ARREST TEMPERATURE MANAGEMENT RECOMMENDATIONS

Data in paediatric patients remaining comatose after achieving ROSC from cardiac arrest is scarce and further studies are awaited. The most important data is from a multicentre prospective randomised study which found no significant difference in primary outcome between TH and TN in OHCA.[91]

Recommendations made by resuscitation councils in 2015 can be summarised as[92,93]:

- For infants and children, it is *strongly recommended* based on moderate quality, non-randomised study evidence that fever be treated after ROSC
- After OHCA, there is a recommendation of *moderate* strength based on moderate quality, randomised study evidence that patients receive either 5 days of TN, or 2 days of TH followed by 3 days of TN
- For IHCA, there is insufficient evidence to recommend one over the other for TN and TH.

NEONATAL HYPOXIC-ISCHAEMIC ENCEPHALOPATHY TEMPERATURE MANAGEMENT RECOMMENDATIONS

Some important recent trial data is also in favour of TH over no temperature control in neonatal hypoxic-ischaemic encephalopathy (HIE).[94]

Recommendations made by resuscitation councils in 2015 can be summarised as[95,96]:

- TH may be considered for neonates born at ≥36 weeks' gestational age with evolving moderate to severe HIE, applied in a manner similar to the major clinical trials with positive outcomes (target 33.5°C–34.5°C, commenced within 6 hours of birth, maintained for 72 hours, rewarmed over at least 4 hours)
- In advanced 'resource-abundant' clinical settings, recommendations are of *moderate* strength that TH be used, based on *high quality evidence* derived from more than one randomized controlled trial (RCT)
- It is still considered reasonable to provide TH in 'resource-limited' clinical environments; however, recommendations for its use in these settings are *weak* and based on *moderate quality* RCT evidence.

OTHER CONDITIONS

TH is also of interest in other conditions, although more supportive data is required to support or refute its use at this stage. These include ischaemic and haemorrhagic cerebrovascular accident, traumatic brain and spinal cord injury, neurosurgery, raised intracranial pressure, liver failure, sepsis and myocardial ischaemia.[97,98]

METHOD OF TH IN ADULTS POST CARDIAC ARREST

Current recommendations on the use of TTM after cardiac arrest in adults are extensively covered in the ILCOR Advisory Statement, upon which the various resuscitation council guidelines have also been largely based. Whilst there is broad agreement on the methodology, it is emphasised that significant uncertainty surrounds almost every aspect of TTM.[88] It is currently recommended that TTM be provided using similar temperature profiles to those used in the major clinical trials outlined above. Important considerations when TH is chosen over TN are summarised below.

- Whilst the indications for TTM have been outlined above, no recommendations exist on which patients should receive TH versus TN. This is decided either in the context of clinical trial protocols or expert consideration on a case-by-case basis.
- A tightly controlled temperature profile over discrete stages of induction, maintenance, reversion, and post TH should be prescribed. The use of imprecise temperature targets and methods of temperature measurement and control is potentially hazardous.[70]
- Since TH seeks to introduce a derangement, it should be performed in a high level ICU with a practice guideline specific for the institution. Outside of this circumstance, it may be reasonable to consider TN as safer than TH.
- Induction of TH is generally carried out as quickly as possible and as soon as possible once the decision for TH has been made.
  - Target temperature should ideally be achieved within 8 hours of ROSC based on earlier trials; however, no absolute time frames have been specified.
  - From a scientific perspective, some destructive processes are only temperature sensitive for a few hours following insult.
  - Rapid achievement of hypothermia also limits shivering, diuresis and electrolyte losses, fluid compartment shifting and haemodynamic fluctuation, as all of these tend to settle at temperatures below 33.5°C.[44]
  - Shivering can increase heat production and oxygen consumption several-fold, but largely settles at temperatures below 34°C. Applying a warm surface in contact with the patient, and the use of alfentanil, fentanyl, pethidine, propofol, dexmedetomidine, clonidine or magnesium are often effective in reducing shivering.
- Methods of rapidly inducing TH include (see Table 84.6):
  - 4°C intravenous crystalloid fluid bolus up to 30 mL/kg over 30 minutes can rapidly lower temperature by around 1°C–1.5°C, but is not sufficient to maintain hypothermia.[79,84] Earlier studies were thought to be encouraging; however, newer data has raised significant concern over safety and its use in the pre-hospital setting is not recommended.[88]
  - surface ice packs or cold air blankets, cooling helmet
  - temperature control devices with external pads (e.g. Arctic Sun) or intravascular catheters (e.g. Alsius CoolGard, Celsius Control System)
  - transnasal evaporative coolant delivery (e.g. RhinoChill, BeneChill, San Diego, California)
  - Temperature control devices use continuous temperature feedback from patient monitoring (such as oesophageal and bladder catheters) or intermittent intravascular temperature measurements (Celsius Control System) to adjust closed loop fluid or catheter temperature. These devices do not involve administration of extra fluid, and use conductive cold or heat between device and skin (surface devices) or blood (intravascular devices). They can achieve cooling rates of up to 2°C/h and are the most precise methods of controlling temperature through all stages of TTM.[89,99–101]

The optimal duration of TH is unknown and may vary between individual cases depending on circumstance and the nature of illness or injury.[27] Current recommendations of greater than 24 hours in adults and 72 hours in neonates are based on the methods used in clinical trials.[88]

Although the optimal rate of rewarming is not known, rewarming is recommended to be tightly controlled at a rate of 0.25–0.5°C/h. Hyperthermia is common following cardiac arrest and is thought to be an important mechanism of secondary neurological damage. Prevention of fever and hyperthermia after neurological insult often requires continued active temperature modulation; however, there is little evidence that this improves patient outcome and the required duration of prevention is not known.[60,77,82]

CLINICAL CONSIDERATIONS DURING THERAPEUTIC HYPOTHERMIA

All of the physiological effects of hypothermia as discussed earlier in this chapter and their implications on patient management should be borne in mind when applying TH. Of particular importance are:

- its effects on potassium and insulin sensitivity/blood glucose
- interpretation of arterial blood gases and acid-base status
- potential masking of fever due to sepsis
- effects on pharmacokinetics and pharmacodynamics
- the use of anticoagulation and thrombolysis
- safety with percutaneous coronary intervention (PCI)
- potential for worsening of cardiac output and arrhythmias
- its implications in pregnant patients
- neurological prognostication following anoxic brain injury.

INSULIN SENSITIVITY AND VENTILATION STRATEGIES

Changes in insulin sensitivity during changes in T_c may contribute to dysglycaemia and increased blood glucose variability, which may be relevant to patient outcomes.[65,66]

Recent data suggests that disturbances in $PaCO_2$ may also be harmful post cardiac arrest, particularly hypocarbia.[31] The current recommendation to maintain normocarbia may therefore have implications on alpha-stat versus pH-stat interpretation of blood gases and ventilation strategies during TH. Alpha-stat management with its associated hypocarbia appears to result in greater jugular venous oxygen desaturation after cardiac arrest; however, data is insufficient at this stage for strong recommendations to be made in favour of either strategy.[102,103]

ANTICOAGULATION AND THROMBOLYSIS DURING THERAPEUTIC HYPOTHERMIA

Bleeding complications have so far not been increased by TH in major clinical trials where patients have received therapeutic anticoagulation and thrombolysis as indicated. Further support for this is emerging in trials combining thrombolysis and TH for stroke.[104] It is currently thought that TH does not significantly increase risk of haemorrhage.[89]

THERAPEUTIC HYPOTHERMIA AND PERCUTANEOUS CORONARY INTERVENTION

Cold skin contact and mild hypothermia can cause vasoconstriction in diseased coronary arteries.[105] There is some suggestion that TH may increase the risk of stent thrombosis; however, results are somewhat mixed in the very limited data available on the impact of TH on complication rates and outcomes in patients receiving PCI.[106–110] It is currently considered safe to provide patients with both TH and PCI.[84]

THERAPEUTIC HYPOTHERMIA IN PATIENTS WITH CARDIOGENIC SHOCK

Hypothermia causes vasoconstriction and uncontrolled shivering increases oxygen consumption and demand. However, hypothermia can also increase contractility and improve haemodynamics.[111–113]

Earlier trials excluded patients with significant shock, whilst there was no difference in mortality between TN and TH amongst patients with mild shock in the TTM study.[79,80,85,110,114]

THERAPEUTIC HYPOTHERMIA IN PREGNANCY

It is currently considered reasonable to use TTM in pregnancy.[31]

There are published cases of TH in pregnancy; however, pregnant patients were excluded in the clinical trials demonstrating benefit with TH. Good maternal outcome with subsequent delivery of apparently normal neonate has been reported following the use of TH at as early as 13 weeks' gestation,[115–117] while foetal demise has also been reported during, but not necessarily as a result of, TH.[118]

The following should be carefully considered regarding TH during pregnancy:

- both hypothermia and rewarming can increase uterine tone and contractions which reduce placental blood flow[119]
- hypothermia shifts maternal haemoglobin-oxygen dissociation curve to the left, reducing placental gas exchange
- maternal acid-base disturbances can further compromise the foetus; temperature should be considered in the interpretation of arterial blood gases, and hypocarbia should be avoided
- normothermic CPB whenever possible is generally favoured during pregnancy, as hypothermic CPB appears to be associated with higher foetal mortality[120–122]

Foetal bradycardia may be associated with foetal distress or hypothermia.[123] Increasing maternal Pa_{O_2} may attenuate foetal bradycardia; however, hyperoxia post cardiac arrest has been found to be associated with increased mortality, possibly due to increased reactive oxygen species in the context of ischaemia-reperfusion injury.[124]

Foetal bradycardia with heart rates around 90–100 beats/min were reported in the case of successful TH in pregnancy.[115]

Maternal hypothermia and alkalaemia decrease foetal Pa_{O_2}.[125] Maternal $PaCO_2$ and pH should ideally be maintained at values normal for gestation. By 12 weeks' gestation, maternal $PaCO_2$ is normally around 32 mm Hg with pH 7.44. Foetal pH is normally around 0.1 less than maternal. In the TH range of 32°C–34°C, corrected values can be estimated by the subtraction of 5 mm Hg per 1°C below 37°C for Pa_{O_2}, subtraction of 2 mm Hg per 1°C below 37°C for $PaCO_2$, and addition of 0.012 per 1°C below 37°C for pH.[43,44]

SEDATION, PARALYSIS AND SEIZURES

Seizures occur in around 36% of patients after ROSC, mostly within the first 24 hours (and therefore coinciding with the period of TH),[126,127] and can result in further brain injury in as soon as 30 minutes.[128,129]

It is not known whether the treatment of seizures impacts patient outcome post cardiac arrest. Nonetheless, based on current understanding of the effects of seizures on brain injury, it is strongly recommended that post-cardiac arrest seizures be treated.[77] The use of paralysis to control shivering during TH may mask seizure activity, and EEG monitoring may need to be considered in paralysed patients.[130,131]

NEUROLOGICAL OUTCOME AND PROGNOSTICATION FOLLOWING THERAPEUTIC HYPOTHERMIA

There is considerable uncertainty about the effect of TH on the reliability of clinical signs as predictors of poor neurological outcome following cardiac arrest. Since findings on clinical examination remain the most important prognosticator, the use of sedatives, muscle-relaxants and the effect of hypothermia on drug metabolism during TH is potentially confounding. The 2006 American Academy of Neurology (AAN) guidelines for neurological prognostication following cardiac arrest appear not to have the same degree of accuracy in patients treated with TH.[53,132–135]

The effects of TH may extend beyond 72 hours from ROSC, which is the minimum recommended interval before neurological prognostication is carried out based on clinical examination.[135] The current level of evidence is considered inadequate to support a specific method of determining with certainty poor neurological prognosis.[53,135] The use of EEG, somatosensory evoked potentials, serum biomarkers (neuron-specific enolase and S-100β) and imaging with computerised tomography and magnetic resonance imaging to supplement clinical examination appears to improve accuracy of predicting poor neurological outcome.[134,135]

Electrical safety and injuries

Lester AH Critchley

Patients suffering from the consequences of electrocution and associated burns occasionally require intensive care unit (ICU) management. Patterns of presentation include post cardiopulmonary arrest, coma, blunt trauma and severe burns – either direct or indirect from electrical arcs, flashes or fires. An understanding of the physical concepts behind electrical power supplies and how electrocution occurs helps in determining the extent of these injuries.

Patients and staff in the ICU are at risk of electrocution from faulty electrical equipment. The necessity of direct patient contact with electrical equipment increases this risk, and when therapy involves an invasive contact close to the heart, microshock is an additional hazard. Thus, strict adherence to internationally accepted electrical safety standards is desirable. Faulty electrical equipment can also result in power failures, fires and explosions. The use of mobile phones and related devices near patient equipment can lead to malfunctioning.

PHYSICAL CONCEPTS

Electricity is produced by the movement of negatively charged electrons. A *potential difference* or voltage, measured in volts (V), exists between two points if the number or density of electrons is greater at one point. When these points are connected by a conductor, the potential difference will cause electrons or an *electric current* (*I*), measured in amperes (A), to flow. *Resistance* (*R*), measured in ohms (Ω), opposes this flow of electrons. Resistance is low in a conductor because electrons can move freely from atom to atom. However, resistance is high in an insulator, as electrons are unable to move freely. Voltage, current and resistance are related by Ohm's law:

$$V = I \times R \tag{85.1}$$

If an electric current flows through a resistance, it dissipates energy as heat. The heating effect per second, or *power*, is measured in joules (J)/s or watts (W):

$$\text{power} = V \times I = I^2 \times R \tag{85.2}$$

A current that flows in one direction, such as produced by a battery, is called a *direct current* (*DC*). Electricity to homes, hospitals and factories is supplied as an *alternating current* (*AC*), which flows back and forth at a *frequency* (i.e. cycles per second or hertz [Hz]). Voltage and frequency specifications vary worldwide. This may cause problems when electrical equipment designed to be used in one region is used elsewhere. Voltage specifications range from 100 V (i.e. Japan) to 240 V (i.e. Australia) with 220 V being most commonly supplied (i.e. Britain, most of Europe and Asia). The frequency most commonly supplied is 50 Hz. North America is a notable exception, where the specification is 110–120 V and 60 Hz.

For efficiency, electricity is distributed from the power station using ultra-high voltages. Main power grids carry greater than 1 million volts, which is stepped down by transformers to greater than 10,000 V to supply local powerlines, that are further stepped down to 120–220 V for domestic, commercial and factory use. Accidental contact with these high-voltage supply lines can be fatal if the current returns to ground with the person in its path. High-voltage currents can also flow via ionised air. This is known as electrical arcing and causes surface or flash burns. If an electrical fault occurs in domestic or hospital equipment, the flow of electricity can be re-routed to ground though a bystander who makes contact, resulting in electrocution.

A current flowing in a circuit produces electric and magnetic fields, which induce currents to flow in neighbouring circuits. When this results in a current flowing between the two circuits, it is called coupling. With *capacitive coupling*, high-frequency currents are most easily passed, and the size of the current is greatest when the circuits are in close proximity. *Inductive coupling* can result from the strong magnetic fields produced by heavy-duty electrical equipment such as transformers, electric motors and magnetic resonance imaging (MRI) machines. The most common problem associated with coupling is electrical interference or 'noise'. Monitoring equipment is designed to 'filter' out this noise. However, in certain circumstances,

ABSTRACT

Critical care admissions include victims of electrocution. Most cases (60%) occur in the work place and involve young men, but domestic electrocution (30%) is common. Patterns of injury include coma, blunt trauma from being thrown, and skin and deep tissue burns. Nerves and vascular supplies to limbs are particularly vulnerable. High voltage and lightning strike are a specific form of electrical injury with devastating effects on victims due to severity of burns and tissue damage. Knowledge of how these injuries occur facilitates treatment. Investigations are aimed at diagnosing extent of tissue and organ damage. Faulty medical equipment poses a risk of electrocution to patients and staff. Direct attachment to electrical devices increases the risk, including microshock. International safety codes exist such as IEC 60601. These codes define levels of risk within hospital or health care facilities and recommended levels of internal wiring, isolation and grounding. Regular equipment checks are recommended.

such as the use of high-frequency surgical diathermy and magnetic resonance, sufficient amperage can be induced to cause microshock and burns.[1,2] Smaller electromagnetic fields emitted by hand-held devices, such as mobile phones, can affect the programming of microprocessors. Cases of patient equipment malfunctions have been reported.[3]

Static electricity has no free flow of electrons. Insulated objects can become highly charged, usually by repeated rubbing. The charge is dissipated by electrons jumping onto another neighbouring object of a different potential. 'Jumping' electrons ionise and heat the air through which they pass, causing a spark, which may ignite an inflammable liquid or gas. Lightning is a type of static electrical discharge. DCs of 12,000–200,000 A and voltages in the millions are involved; however, flow lasts for only a fraction of a second.[4]

ELECTROPHYSIOLOGICAL CONSIDERATIONS

For a current to flow through the body, the body must complete a circuit. Usually this involves the current flowing from its source to ground through the body, often hand to hand or hand to feet. The pathophysiological effects depend on the size and duration of the current, and this depends on the voltage and electrical resistance of the body. The main pathophysiological effects of current passing through the body are: (1) ventricular fibrillation or asystole, (2) sustained muscle contraction or tetany causing the 'cannot let go' phenomenon and asphyxiation, and (3) dissipation of electrical energy as heat, causing burns, often to deep-seated structures as well as skin. Muscle, blood vessels and nerves act as the main conduits for currents flowing through the body, and offer a very low resistance 500–1000 Ω.[5] Most of the resistance to passage of the current, and thus burning effect, occurs at the skin contact, which can vary enormously. Dry skin has a resistance in excess of 100,000 Ω.[5] However, skin resistance is markedly reduced (to 1000 Ω)[6] if the skin is wet, or if a conductive jelly has been applied. Hence, from Ohm's law, dry skin in contact with 240 V mains supply will result in a harmless 0.24 mA current flowing through the body, whereas moist or wet skin will result in a potentially lethal 240 mA current.

ELECTROCUTION

EPIDEMIOLOGY

Most cases of electrocution occur either in the workplace (about 60%) or at home (about 30%).[6] Most data on the incidence of electrocution come from North America, though significant regional differences exist worldwide.[7,8] Children under 6 years are most at risk from domestic electrocution, but with greater electrical safety awareness and the use of ground fault circuit interrupters (GFCIs), the oral burns once seen from chewing power cords are much less common.[9] Young adult men are the most likely victims of electrocution in the workplace. Powerlines and electrified railway tracks are the most common causes of high-voltage injuries.

CAUSES AND PATTERNS

There are a number of causes of electrocution and each has its own pattern of injuries:

1. *Low-voltage AC with or without loss of consciousness or arrest:* these injuries usually involve exposure to less than 1000 V in the home or office setting
2. *High-voltage AC with or without loss of consciousness or arrest:* these injuries can cause extensive thermal burns and usually are occupation related
3. *DC injury:* these injuries often involve trauma due to the victim being thrown due to violent muscle contraction
4. *Conducted electrical weapons (CEWs) such as Tasers used by the police:* CEWs deliver high-voltage currents, either AC or pulses of DC in the order of 50,000 V. Injuries are due mainly to trauma secondary to the Taser shock[10]
5. *Lightning strike:* this is discussed later.

PATHOPHYSIOLOGY

Pathophysiological processes involved in electrical injuries from an electrical engineer's perspective are well described in a short review article by Bernstein.[11] The extent of injury depends on: (1) the amount of current that passes through the body, (2) the duration of the current, and (3) the tissues traversed by the current (Table 85.1). The extent of injury is most

Table 85.1 Origin and pathophysiological effects of different levels of electrical injury

CURRENT (A)	SOURCE	EFFECTS ON VICTIM
10–100 μA	Earth leakage	Microshock (ventricular fibrillation)
300–400 μA	Faulty equipment	Tingling (harmless)
>1 mA	Faulty equipment	Pain (withdraw)
>10 mA	Faulty equipment	Tetany (cannot let go)
>100 mA	Faulty equipment	Macroshock (ventricular fibrillation)
>1 A	Faulty equipment	Burns and tissue damage
>1000 A	High-tension injury	Severe burns and loss of limbs
>12,000 A	Lightning	Coma, severe burns and loss of limbs

directly related to amperage. However, usually only the voltage involved is known. In general, lower voltages cause less injury, although voltages as low as 50 V have caused fatalities.

TISSUE HEAT INJURY

Currents in excess of 1 A generate sufficient heat energy to cause burns to the skin at entrance and grounding points and occult thermal injury to internal tissues and organs. Small blood vessels and nervous tissue appear to be particularly susceptible.[6]

DEPOLARISATION OF MUSCLE CELLS

An AC of 30–200 mA will cause ventricular fibrillation.[12] Domestic frequencies of 50–60 Hz are most dangerous, being three times more likely to stop the heart than direct or high-frequency current sources. Currents in excess of 5 A cause sustained cardiac asystole, which is the principle used in defibrillation. Apart from ventricular fibrillation, other arrhythmias may occur. Myocardial damage is common and may result in ST and T-wave changes. Global left ventricular dysfunction may occur hours or days later, despite initial minimal electrocardiogram (ECG) changes.[13,14] Myocardial infarction has also been reported.[15] Specific markers of myocardial injury, such as cardiac troponin, should be checked in all suspected cases of electrical injury to the heart.[16]

Tetanic contractions of skeletal muscle occur with currents in excess of 15–20 mA. The threshold is particularly low with ACs at the household frequency of 50–60 Hz. Tetanic contraction will prevent voluntary release of the source of electrocution, the 'cannot let go' phenomenon, and violent muscle contractions may cause fractures of long bones and spinal vertebrae.[6]

VASCULAR INJURIES

Blood vessels may become thrombosed and occluded as a result of the thermal injury. Small vessels are at greater risk, as the blood flow in larger vessels dissipates the heat. Compartment syndromes are seen secondary to tissue oedema, causing tissue ischaemia and necrosis. Affected limbs may require fasciotomy and amputation.[17]

NEUROLOGICAL INJURIES

Neurological injuries may be central or peripheral, and immediate or late in onset. Unconsciousness following electrocution may result from cardiorespiratory arrest, trauma to the head or the direct effect of current passing through the brain. This may be one of the main reasons for admission to the ICU. Monoparesis may occur in affected limbs, and the median nerve is particularly vulnerable.[6,18] Monoparesis may be due to the direct effect of electricity passing through the body or delayed effect due to scar formation. Electrocution to the head may result in unconsciousness, paralysis of the respiratory centre, and late complications such as epilepsy, encephalopathy and Parkinsonism.[6,18] Spinal cord damage resulting in para- or tetraplegia can result from a current traversing both arms and the spine.[6,18] Autonomic dysfunction may also occur, causing acute vasospasm or a late sympathetic dystrophy.[6]

RENAL FAILURE

Direct electrical injury to the kidneys is unusual. However, acute renal failure may result from the myoglobinuria and toxins produced by extensive muscle necrosis.[18]

EXTERNAL BURNS

Victims of high-voltage electrocution can incur extensive superficial or deep external burns from electrical arcs passing over the skin surface, especially from clothes catching fire and heated metal objects such as jewellery. Arc formation requires voltages in excess of 350 V and tracks over the body surface. They can generate extremely high temperatures of up to 5000°C that mainly causes skin burns.[11] Victims can also be burnt by the intense flash caused by the electrical discharge.

OTHER INJURIES

High-voltage and direct current electrocution can cause the victim to fall or be thrown, which may result in traumatic blunt injuries. Thus, it is important to get a reliable witness report of the incidence so that the nature of the patients' injuries is properly understood and nothing is missed, like a fractured cervical spine. All unconscious electrocuted patients should be initially treated with neck and spinal protection. High-voltage injuries can commonly rupture the eardrum and affect hearing.[19] Cataracts may later develop.[20]

MACRO- AND MICROSHOCK

The above domestic/workplace electrocution is known as *macroshock*, and occurs when current flows through the intact skin and body.

In the ICU and other high-level patient care areas, the potential for *microshock* electrocution also exists. Microshock occurs when there is a direct current path to the heart muscle that bypasses the protective electrical resistance of the skin surface. Such a pathway may be provided by saline-filled arterial or venous-pressure-monitoring catheters or transvenous pacemaker wires. The current required to produce ventricular fibrillation in microshock settings is extremely small, in the order of 60 μA.[17] Currents of 1–2 mA are barely

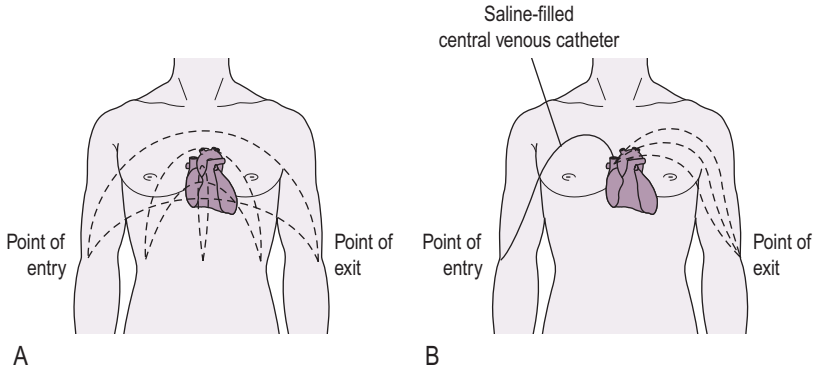

Figure 85.1 Microshock: (a) low current density at the heart; (b) high current density at the heart if there is a conducting pathway, such as a saline-filled catheter.

perceptible and produce tingling of the skin (see Table 85.1). Hence, a lethal microshock may be transmitted to a patient via a staff member who is unaware of the conducted current. Microshock can result from direct contact with faulty electrical equipment, or stray currents from capacitive coupling, or earth leakage. Such small currents are potentially lethal because a high current density is produced at the heart (Fig. 85.1). Patients at risk of microshock require higher levels of electrical safety protection.

HIGH-TENSION AND LIGHTNING STRIKE INJURIES

High-tension electricity (>1000 V) involves voltage much greater than domestic supply, usually many thousands of volts. Sources include powerlines, electrified railway tracks and equipment requiring high internal voltages produced by step-up transformers, although less common today as most high voltage television screens now use liquid crystal technology. Tissue damage is mainly due to the generation of heat, as high-amperage currents are involved. Not only does the current pass through the victim, but electrical arcing may also be involved. Witnesses have described tissues actually exploding.[20]

Lightning injury is a type of high-tension injury. Its incidence depends upon geographical location. Generation of lightning is surprisingly complex and involves a number of steps. The victim of a lightning strike may be hit directly, injured by the side-flash from a nearby object, or electrocuted by ground currents which reroute through the victim's legs.[11]

Victims can be thrown several feet as a result of violent muscular contractions. Electrical arcing of the air causes intense heat, resulting in superficial burns and the clothes igniting. Characteristic entrance and exit site burns are seen, which have a spider-like appearance with redness and blistering. Victims are usually unconscious in the initial phase. However, many victims survive (80%–90%),[4] and good recovery has been reported despite initial hopeless neurological responsiveness (e.g. fixed dilated pupils).[22] Immediate death usually results from cardiorespiratory arrest; asystole is more common than ventricular fibrillation.[4]

MANAGEMENT OF ELECTRICAL INJURIES

Treatment of electrical injuries is mainly supportive. It includes the following.

FIRST AID AND RESUSCITATION

It is imperative to make the immediate environment safe for rescuers. Power sources should be switched off and wet areas avoided where possible. Instinctive attempts to grab the electrocuted victim must be avoided until it is safe to do so. Cardiopulmonary resuscitation is carried out when indicated, and continued even if the prognosis seems hopeless. The neck and spine should be protected because of possible fractures.

INVESTIGATIONS

Investigations are indicated to detect damaged organs. They include ECG, echocardiography, computed tomography (CT) of the head, X-rays of the spine and long bones, haemoglobin, serum electrolytes, cardiac troponin, creatinine kinase and urine myoglobin to assess muscle damage, and nerve conduction studies. Arteriograms may help in the decision to amputate a limb.[17]

HOSPITAL AND INTENSIVE CARE UNIT MANAGEMENT

Management is directed towards treatment of burns, ischaemic and necrotic tissue, and injured organs. The principle of treating electrical burns is complete excision because of the risks of acute renal failure and

sepsis. Fasciotomies and amputations may be necessary. Tetanus toxoid and antibiotics, especially penicillin, are given if indicated.

ELECTRICAL HAZARDS IN THE INTENSIVE CARE UNIT

The ICU has the potential to inflict both macroshock and microshock injuries to staff and patients. Potential sources of these electrical hazards are:

MAJOR ELECTRICAL FAULTS

The casing and insulated wiring of electrical equipment protect against electric shock. Faulty wiring or components, and deterioration of internal insulation, can result in the casing becoming 'live'. Contact with live casing or wires can result in an electric current flowing through the victim to ground. The outcome largely depends on the resistance offered by the body to the current. If it is low, such as in a wet environment, sufficient current can flow to cause death, which is usually due to ventricular fibrillation/asystole or asphyxia from tetanic contraction of respiratory muscles.

MICROSHOCK CURRENTS

EARTH LEAKAGE CURRENTS

Within all pieces of electrical equipment, stray low-amperage electrical currents exist that usually flow to earth, called earth leakage currents. They originate from current leaks across imperfect insulation of wires, capacitive and inductive coupling within the equipment, and coupling from electric and magnetic fields that exist in the working environment, such as the 50–60 Hz mains supply. Normally these currents are small and harmless, but they have the potential to cause microshock.

PACING WIRES AND CENTRAL VENOUS LINES

In certain circumstances, sufficient current to cause microshock can be passed by capacitive and inductive coupling to intracardiac pacing wires and central venous lines. Ventricular fibrillation has been reported from capacitive coupling with thermistor wires in a pulmonary artery catheter.[1]

DIFFERENT EARTH POTENTIALS

Inadequate or faulty earthing can result in separate earthing points being at different resting potentials. If contact is made between the two earthing points, sufficient current can flow to cause microshock.

STAFF–PATIENT CONTACT

Small currents capable of causing microshock can be transmitted unknowingly to a patient by a staff member who simultaneously touches faulty electrical equipment and the patient. If this current returns to earth via an intracardiac connection, a high current density will pass through the heart, resulting in microshock.

INDUCTIVE CURRENTS

Inductive coupling from the strong magnetic fields produced by MRI can cause overheating of wires and equipment. Severe burns have resulted from the use of pulse oximetry during MRI, and specially designed wiring and probes are recommended.[2] Similar problems can exist with any intravascular device containing wires, such as a pulmonary artery catheter. More recently, problems have arisen from the interference caused by personal computers, mobile phones and related devices with patient equipment. Many hospitals have banned the use of such devices in areas where patients are treated.

OTHER RELATED HAZARDS

Electrical equipment has the potential to cause other hazards such as thermal injury, fire and power failures. Preliminary critical incident reports suggest that power failures are the most commonly encountered incidents involving electricity in the ICU. Power failures can be disastrous, as many patients' lives depend on electrically driven 'life support' equipment. One notable emerging hazard is software malfunction, as many newer devices operate using programmable microprocessors. As the intensivist frequently works outside the ICU, they should also be aware of potential electrical hazards outside the ICU.

MEASURES TO PROTECT STAFF AND PATIENTS

EARTHING, FUSES AND CIRCUIT BREAKERS

Earthing reduces the risk of macroshock. The casing in most electrical equipment is connected to ground by a very-low-resistance wire called the earth, which uses the third pin of the electrical socket. If a fault arises, the earth wire offers a low-resistance path to ground. The high-amperage current that results will blow the main fuse or circuit breaker, thus providing protection and warning that a fault is present. However, fuses and circuit breakers do not guarantee patient protection from macroshock and other more sensitive protection strategies are required in patient care locations (see below). Additional protection can be achieved by connecting all the earthing points in a patient care area together by a very-low-resistance wire. This reduces the risk of microshock occurring from earthing points at different potentials, and is commonly used in cardiac protected areas.

ISOLATED POWER SYSTEMS

MAINS ISOLATION

The power supply is isolated from earth using a mains isolation transformer. If contact is made with live faulty circuitry, the risk of electric shock is reduced because stray currents no longer preferentially flow through patient or staff member to earth. Presence of stray earth leakage currents can be detected by using a line isolation monitor. This type of system is particularly useful in wet locations where the body may offer a very low resistance to earth.

INTERNAL ISOLATION

In medical equipment the mains power supply is usually isolated from the patient connection by using internal transformers and photoelectric diodes. The casing is still earthed to protect against faulty circuitry. This method of protection is commonly used in ICU equipment, including most monitoring and patient information systems. Electrical power isolation may limit the use of networks that link patient monitors to printers and information technology systems.

GROUND FAULT CIRCUIT INTERRUPTERS

GFCIs are devices that switch off the electrical supply if small currents are detected flowing to earth. GFCIs are designed to protect against electrocution from faulty electrical equipment. They are commonly incorporated into electrical sockets and require activation. When contact is made with the faulty equipment, an increased current will flow to earth, which trips the system. GFCIs also protect against microshock. A major concern with using GFCIs in critical patient management areas, however, is that power supply to essential life-supporting equipment such as heart–lung machines can be permanently switched off by small-leakage currents.[23,24]

ELECTRICAL SAFETY STANDARDS

Most First-World nations have standards of electrical safety that apply to both the design of medical equipment and their use in health care locations. A number of well-recognised standards exist that can be easily found and uploaded from the Internet. Europe and Great Britain follow the International Electrotechnical Commission Code (IEC) 60601, first published in 1997 and regularly updated, most recently in 2011. The United States follows the National Electric Code, which has a section on Health Care Locations and was most recently updated in 2011. However, since 2013 the Food and Drug Administration (FDA) in the US has used IEC 60601 for approval of new medical equipment. IEC 60601-1 is widely accepted as the benchmark for medical equipment and has become the de facto requirement for medical equipment worldwide. Australia and New Zealand follow similar standards (AS/NZS 3003:2011 and AS/NZS 3200:2010). Hospitals worldwide should establish their own committees to ensure that these standards are applied.

Patient care areas differ in their safety requirements and commonly used classifications are listed below. The ICU should conform to 1(b) and preferably 1(c), as follows:

1. **a.** Unprotected areas, where only routine electrical safety standards are applied
   b. Body-protected areas, where the level of electrical safety is sufficient to minimise the risk of macroshock when the patient is in direct contact with electrical equipment and the skin impedance is reduced or bypassed
   c. Cardiac-protected areas, where the level of electrical safety is sufficient to minimise the risk of direct microshock to the heart
2. Wet locations, where spillage of water and physiological solutions, such as saline and blood, frequently occurs; the US Department of Defense until recently defined wet areas as those used for cystoscopy, arthroscopy and labour/delivery[25]
3. In the past, standards existed for the safe use of inflammable anaesthetic agents.

Currently, the United States only requires GFCIs in wet areas that do not include ICUs and most operating theatres. Other countries, such as Australia, New Zealand and Great Britain, require isolated power systems (IPSs) in operating rooms and ICUs. If cost is not an issue, ideally both internal isolation and GFCIs should be used in 1(a) and 1(b) and wet locations. More stringent controls to protect against microshock are required in 1(c) cardiac-protected locations.

Codes relating to software that run medical devices have recently been introduced. Requirements to make medical equipment more environmentally friendly and provision of safer electrical installations in health care facilities outside the hospital are also being introduced. IEC 60601 now contains over 60 separate codes relating to different medical uses.

EQUIPMENT CHECKS

The purchase of new equipment should be strictly controlled, and circuit diagrams should be provided. All new equipment should be checked that it adheres to the appropriate electrical safety standards, functions properly and for current leaks before it is used in the ICU or other high-risk patient areas. Preventative maintenance of equipment should be done regularly. Dated stickers should be used to show when the equipment was last checked. All faulty equipment must be removed from service, labelled appropriately and recommissioned only after thorough checking.

RESERVE POWER SUPPLIES AND ALARMS

All essential equipment should have a reserve power supply (usually a battery), and alarms that warn of power failure. All hospitals should provide an emergency backup power supply in case of power cuts. Protocol should be in place, or developed, to ensure continuation of ventilation, sedation and other essential life-sustaining therapies in case of complete electrical power failure, or the need to evacuate patients because of fire.

PERSONNEL EDUCATION

Staff should be taught correct ways to handle electrical equipment. Equipment with frayed wires should never be used, plugs should never be tugged, trolleys should never be wheeled over power cords, and two pieces of equipment should never be handled simultaneously. Staff should also respond appropriately to alarms. The increasing use of patient monitoring and information technology systems means that an increasing number of electrical devices are being used at any one time at the patient's bedside, with increasing need for power cords and sockets. Care should be taken when using multiple socket power cables to ensure that their use does not violate electrical safety standards.

Envenomation

James Tibballs

INTRODUCTION

Envenomations by snakes, spiders, bees, ants, wasps, ticks, jellyfish, octopuses or cone shell snails may threaten life, while envenomation by other creatures may cause serious illness.[1-5] Although this chapter focuses on the management of envenomation in Australia, the principles of management are widely applicable in other countries. Immediate advice on the management of envenomation by Australian creatures may be obtained from the National Poisons Centre (Tel: 131126) but decision making rests with the treating physician.

SNAKES

EPIDEMIOLOGY

Australia is habitat to a large number of venomous terrestrial and marine snakes (Families Elapidae and Hydrophiidae). The genera responsible for the majority of serious illness are brown snakes (*Pseudonaja*), tiger snakes (*Notechis*), taipans (*Oxyuranus*), black snakes (*Pseudechis*) death adders (*Acanthophis*), rough-scaled snake (*Tropidechis carinatus*) and Stephen's banded snake (*Hoplocephalus stephensi*).[1] Most recent deaths have been due to brown snakes and tiger snake envenomation.[6]

The death rate after snakebite is not reliably known, but it appears considerably less in Australia than elsewhere despite the fact that the majority of Australia's snakes are among the most venomous in the world. Approximately 3000 snakebites occur annually in Australia. The mean snake bite death rate in Australia over the last decade was 2.3/annum (Australian Bureau of Statistics).[7] Deaths (1/1000 bites) usually occur because of massive envenomation, snake bite in remote locations, rapid cardiovascular collapse out-of-hospital, or delayed or inadequate antivenom therapy. Approximately 500 victims per annum require antivenom treatment. This morbidity and mortality is a very small contribution to the annual world burden estimated by the World Health Organization at 5 million bites with 2.5 million envenomations, at least 100,000 deaths (1 death/50 bites) and three times that number of limb amputations or severe disability (http://www.who.int/mediacentre/factsheets/fs337/en/).

Death and critical illness from Australian snakebite is due to (1) progressive paralysis leading to respiratory failure, (2) haemorrhage, (3) renal failure, (4) sudden cardiovascular collapse (especially with brown snake bites), or (5) combinations. Renal failure occurs as a consequence of rhabdomyolysis and procoagulant coagulopathy causing microangiopathic haemolytic anaemia (MAHA), hypotension, hypoxaemia and to their combinations.

Snake bite is often 'accidental' when a snake is trodden on or suddenly disturbed. However, many bites occur when humans deliberately interfere with snakes or handle them. At special risk are herpetologists and snake collectors who sustain bites in the course of their work or hobby, but who also develop allergy to venoms and to the antivenoms used in their treatment.[8] Contact with exotic snakes has additional problems of sourcing antivenom and expertise in management.

SNAKE VENOMS

Venoms are complex mixtures of protein toxins that kill the snake's prey and aid its digestion. Many toxins are phospholipases.[1] The main toxins cause paralysis, coagulopathy, rhabdomyolysis and renal failure (Box 86.1).

Paralysis is due to presynaptic and postsynaptic neurotoxins. Presynaptic neurotoxins are phospholipases A_2, which destroy the motor neuron terminal and also cause rhabdomyolysis. Examples are taipoxin in coastal taipan (*Oxyuranus scutellatus*) venom, notexin in mainland tiger snake (*Notechis scutatus*) venom and textilotoxin in common brown snake (*Pseudonaja textilis*) venom.[1] The effect of these toxins, once established, is not responsive to antivenom treatment. Postsynaptic neurotoxins (and presynaptic neurotoxins) are found in venoms of death adders.

Coagulopathy is due either to the procoagulant effect of prothrombin activators (factor Xa-like enzymes) with consumption of clotting factors, or to direct anticoagulants. Coagulopathies expose the victim to the risk of spontaneous haemorrhage.

ABSTRACT

Life-supporting treatment may be required after envenomation by numerous species of Australian snakes including brown, tiger, taipan, death adder and black snakes, which cause paralysis, coagulopathies, rhabdomyolysis and renal failure. Several species of spiders (funnel-web spiders, red-back spiders), several jellyfish (box-jellyfish, Irukandji) and stings of hymenoptera (bees, wasps, ants) also cause life-threatening illness. Blue-ringed octopuses, ticks, cone shells, other jellyfish and stinging fish cause serious illness. Fortunately, Australia has available high-quality antivenoms for most envenomations (all snakes, funnel-web spiders, red-back spiders, box-jellyfish, stone-fish), which, when administered early, can neutralise venom toxins and halt progress of the effects of envenomation but cannot reverse established tissue damage for which time and supportive therapy are required. The antivenom dose for an envenomated snakebite victim is two vials but less or more may be required along with low-dose subcutaneous adrenaline to prevent acute allergic reaction. The treatment of hymenoptera stings is that of anaphylaxis.

Box 86.1 Main components of Australian snake venoms

- Neurotoxins
  - Presynaptic and postsynaptic neuromuscular blockers present in all venoms. Cause paralysis
  - Postsynaptic blockers readily reversed by antivenom
  - Presynaptic blockers are more difficult to reverse, particularly if treatment is delayed
  - Some presynaptic blockers are also rhabdomyolysins
- Prothrombin activators
  - Present in brown, tiger, taipan, rough-scaled and Stephen's banded snake venoms
  - Cause procoagulation coagulopathy with possible microangiopathic haemolytic anaemia and acute cardiovascular collapse
  - Intrinsic fibrin(ogen) lysis generates fibrin(ogen) degradation products
  - Significant risk of haemorrhage
- Anticoagulants
  - Present in black snake venoms
  - Prevent blood clotting without consumption of clotting factors
- Rhabdomyolysins
  - Some presynaptic neurotoxins also cause lysis of skeletal and cardiac muscle
  - Apart from loss muscle of mass, may cause myoglobinuria and renal failure

Prothrombin activators are serine proteases which are identifiable in venoms of brown, tiger, taipan, rough-scaled and Stephen's banded snake.[1] With the consumption of platelets and the generation of fibrin(ogen) degradation products by endogenous fibrinolysis, these observations resemble the coagulopathic findings in disseminated intravascular coagulation (DIC) but the phenomenon has also been known as 'defibrination coagulopathy' and 'venom-induced consumption coagulopathy' in which coagulation factors are consumed, serum fibrinogen is depleted and platelets are reduced.

Procoagulant coagulopathy cannot be resolved until venom prothrombin activators have been neutralised with antivenom. However, after circulating venom has been neutralised by antivenom, it may be 4–6 hours or longer before hepatic manufacture of replacement clotting factors can normalise coagulation tests. Procoagulant coagulopathy causes two clinical effects attributable to thromboembolism:

a. MAHA. This is not infrequent and has been observed after brown, taipan, tiger and Stephen's banded snake envenomation.[6,9,10] On blood film, red blood cells are observed as fragmented and haemolysed, and platelets are reduced. Histologically, especially in kidney, capillaries are blocked with fibrin, which damages transiting red blood cells. Renal failure may occur, and support with haemofiltration/dialysis may be needed. The observations resemble those in haemolytic uraemia or thrombotic thrombocytopenic purpura, which are due to deficiency in or antibodies to ADAMST13 (**a** **d**isintegrin **a**nd **m**etalloproteinase with a **th**rombo**s**pondin type 1 motif, member 13) also known as von Willebrand factor (vWf)-cleaving protease, a metalloprotease enzyme that cleaves vWf, a multimeric protein involved in blood coagulation. The absence of breakdown of vWf causes deposition of fibrin and platelets in small blood vessels, especially in the brain and kidney. Plasmapheresis is often undertaken in these conditions to remove the antibody to ADAMST13 and to provide ADAMST13. Activity of ADAMST13 was not reduced in a case of MAHA after a presumed tiger snake bite,[10] but the place of plasmapheresis remains undefined.[9] Haemofiltration/dialysis alone would probably suffice for renal support.

b. Acute cardiovascular collapse. This phenomenon probably explains deaths occurring out-of-hospital, especially after brown snake envenomation.[6,9] The mechanism is probably myocardial ischaemia and/or pulmonary hypertension culminating in transient systemic hypotension, as caused experimentally by brown and tiger snake venoms and their prothrombin activators.[1,11] Indeed, experimentally, thrombus formation within the heart is readily detectible by echocardiography, and embolism to the vasculature system is evident histologically soon after envenomation of dogs with tiger snake prothrombin activator and preventable with heparin.[11] In rats, rapid cardiovascular collapse due to prothrombin activator or release of vasoactive substances by brown snake venom likewise is preventable with antivenom or heparin.[12] Prothrombin activators in venoms gain access to the circulation within minutes after subcutaneous injection. Tachycardia and relatively minor electrocardiogram abnormalities are common. Other causes of hypotension, such as direct cardiac toxicity, are possible.

Anticoagulant coagulopathy occurs after envenomation by black snakes and is amenable to treatment with antivenom.[1]

SNAKE BITE AND ENVENOMATION

Although a bite may be observed, envenomation may not occur because no venom or a small amount of venom is injected; this occurs in about 50% of bites. Bites by Australian snakes may be painful or painless and be unnoticed. This is in marked contrast to bites of many overseas crotalid and viperid snakes, where massive local reaction and necrosis are caused by proteolytic enzymes. In general, Australian snake venoms do not cause extensive damage to local tissues and are usually confined to mild swelling and bruising, and continued slight bleeding from the bite site.

After an Australian snake bite, paired fang marks are often visible but sometimes only scratches or single puncture wounds exist with or without local bruising.

SYMPTOMS AND SIGNS OF ENVENOMATION

Classical symptoms and signs are given in Box 86.2. Sometimes, not all possible symptoms and signs occur. In some cases one symptom or sign may dominate the clinical picture, and in other cases they may wax and wane. These phenomena may be explained by variations in the toxin content of venoms of the same species in different geographical areas, and by variable absorption of different toxins.

Tender or even painful regional lymph nodes are moderately common but are not, *per se*, an indication for antivenom therapy. Lymphadenitis also occurs with bites by mildly venomous snakes that do not cause serious systemic illness.

Occasionally, major or intracranial haemorrhage occurs. In the case of untreated or massive envenomation, rhabdomyolysis may occur. This usually involves all skeletal musculature and sometimes cardiac muscle. The resultant myoglobinuria may cause renal failure.

A high intake of alcohol by adults before snake bite is common, and may confound the cluster of symptoms and signs. Pre-existing treatment with anticoagulant (e.g. warfarin) or disease (e.g. gastrointestinal tract ulceration) may complicate the management of coagulopathy.

Box 86.2 Progressive onset of major systemic symptoms and signs of untreated envenomation

Less than 1 hour after bite
- Headache
- Nausea, vomiting, abdominal pain
- Transient hypotension associated with confusion or loss of consciousness
- Coagulopathy (laboratory testing)
- Regional lymphadenitis

1–3 hours after bite
- Paresis/paralysis of cranial nerves (e.g. ptosis, double vision, external ophthalmoplegia, dysphonia, dysphagia, myopathic facies)
- Haemorrhage from mucosal surfaces and needle punctures
- Tachycardia, hypotension
- Tachypnoea, shallow tidal volume

Greater than 3 hours after bite
- Paresis/paralysis of truncal and limb muscles
- Paresis/paralysis of respiratory muscles (respiratory failure)
- Peripheral circulatory failure (shock), hypoxaemia, cyanosis
- Rhabdomyolysis
- Dark urine (due to myoglobinuria or haemoglobin)
- Renal failure

Note: In massive envenomation or in a child, a critical illness may develop in minutes rather than hours.

SNAKE BITE IN CHILDREN

Snake bite in young children presents additional problems. Envenomation is difficult to diagnose when a bite has not been observed or history is unobtainable. The symptoms of early envenomation may pass unsuspected and the signs, particularly cranial nerve effects, are difficult to elicit. Bite marks may be difficult to distinguish from the effects of everyday minor trauma. Lastly, the onset of the syndrome of envenomation is likely to be more rapid and severe because of the relatively higher ratio of venom to body mass. Presentation may be cardiorespiratory failure. The dose of antivenom is the same as for adults.

IDENTIFICATION OF THE SNAKE

Identification of the snake is helpful but not essential since a venom detection kit (VDK) test is available for snakes of Australia and Papua New Guinea, which guides antivenom selection. If the snake cannot be identified, specific monovalent antivenom, or a combination of monovalent antivenoms or polyvalent antivenom should be administered on a geographical basis (Table 86.1). Nevertheless, identification guides selection of the appropriate antivenom, and provides an insight into the expected syndrome. Administration of the wrong antivenom may endanger a victim's life because a specific monovalent antivenom does not neutralise venoms of other genera. For example, brown snake antivenom does not neutralise venoms of taipans or tiger snakes. On the other hand, tiger snake antivenom neutralises venoms of some black snakes, copperhead snakes, rough-scaled snakes, Stephen's banded snakes and venoms of many lesser venomous species.

Table 86.1 Antivenom and initial dosages when identity of snake uncertain

STATE	ANTIVENOM	UNIT DOSE (VIALS)
Tasmania	Tiger snake	6000 (2)
Victoria	Tiger snake *and* Brown snake	6000 (2) 2000 (2)
New South Wales and Australian Capital Territory; Queensland; South Australia; Western Australia; Northern Territory	Polyvalent	40,000 (2)
Papua New Guinea	Polyvalent	40,000 (2)

Note: (1) If the victim on presentation is critically ill, two to three times these amounts should be given initially. (2) Additional antivenom may be required in the course of management since the absorption of venom toxins may be delayed.

Identification by venom detection kit test

The VDK (Seqirus Australia) is an in vitro test for detection and identification of snake venom at the bite site, in urine, blood or other tissue in cases of snake bite in Australia (and Papua New Guinea). It can be performed at the bedside or in the laboratory. It is an enzyme immunoassay using rabbit antibodies and chromogen and peroxide solutions. A positive result will indicate the type of antivenom to be administered. It detects venom from a range of snake genera including tiger, brown, black, death adder and taipan. Individual species of snake cannot be identified by the test and several genera may yield a positive result in a specified well. The test is very sensitive; it is able to detect venom in concentrations as low as 10 ng/mL, and can yield a visual qualitative result in test wells in approximately 25 minutes. The incidences of false-positive and false-negative tests of the kit are low but not negligible. On occasions, venom may be detected but the patient is asymptomatic and has no signs of envenomation. A decision to administer antivenom should be made only on clinical grounds. A very high concentration of venom in a sample may overwhelm the test and yield a spuriously negative result (Hook effect). If that possibility exists, a diluted sample should be retested.

Identification by physical characteristics

This can be misleading. Not all brown-coloured snakes are brown snakes, not all black-coloured snakes are black snakes and not all banded snakes are tiger snakes. Moreover, brown snakes may have bands and tiger snakes may lack characteristic bands. Non-herpetologists should consult an identification guide with reference to scale patterns to identify a specimen correctly if antivenom therapy is to be based on morphological characteristics alone.

Identification by clinical effects

The appearance of a bite site cannot be used to reliably identify a snake. Likewise, the constellation of symptoms and signs is useful but to a limited degree. For example, paralysis associated with procoagulopathy may be caused by a tiger, taipan, brown, rough-scaled snake, copperhead or Stephen's banded snake, but if rhabdomyolysis also occurs a bite by a brown snake is improbable. Early in the syndrome when procoagulant coagulopathy may be the only clinical effect, it is impossible to distinguish between taipan, brown and tiger snake envenomation. Paralysis associated with anticoagulation may be caused by a black snake or death adder, but if rhabdomyolysis occurs a bite by a death adder is improbable. Paralysis with neither coagulopathy nor rhabdomyolysis may be caused by a death adder bite.

This information is obviously of limited practical importance. It is essential to administer antivenom at the first opportunity when indicated, rather than wait until the full syndrome becomes apparent, to enable an 'educated clinical guess' in selection of the appropriate antivenom by which time the situation may not be amenable to treatment.

MANAGEMENT OF SNAKE ENVENOMATION

The essential management is:

- resuscitation – mechanical ventilation and restoration of blood pressure with intravenous fluids, inotropic and vasoactive agents as needed. Basic cardiopulmonary resuscitation at the scene may be lifesaving.[6]
- application of a pressure-immobilisation first-aid bandage
- administration of antivenom
- performance of investigations.

From a practical point of view, one of three clinical situations usually arises after snake bite. A plan of management for each of these is summarised in Fig. 86.1:

- victim presents with a critical illness
- victim is envenomated but not critically ill
- victim is bitten but clinically does not appear envenomated.

When the envenomated victim is not critically ill, time is available to identify the snake and to administer the specific monovalent antivenom. A pressure-immobilisation bandage should be applied if not already in place, and not removed until antivenom has been administered.

When the victim has been bitten but not apparently envenomated, admission to hospital is advisable with observation, examination and laboratory testing for at least 12 hours.[13] The syndrome of envenomation, particularly neurotoxic signs, may be very slow in onset over numerous hours with an initial period free of symptoms. A test of coagulation should always be performed. If a coagulopathy is present, specific monovalent antivenom should be administered after identification of the species or as indicated by a VDK test. If only a mild coagulopathy is present it may be acceptable to withhold antivenom in the anticipation of spontaneous resolution, but coagulation should be checked at intervals and the victim maintained under surveillance until coagulation is normal.

THE PRESSURE-IMMOBILISATION TECHNIQUE OF FIRST AID

Since at least 95% of snake bites occur on the arms or legs, Sutherland's first-aid pressure-immobilisation technique[14] is applicable in the majority of cases. With this technique, a crêpe (or crêpe-like) bandage, but preferably elasticised, is applied from the fingers or toes up the limb as far as possible, encompassing the bite site. It should be as firm as required for a sprained ankle. Additional immobilisation is applied to the

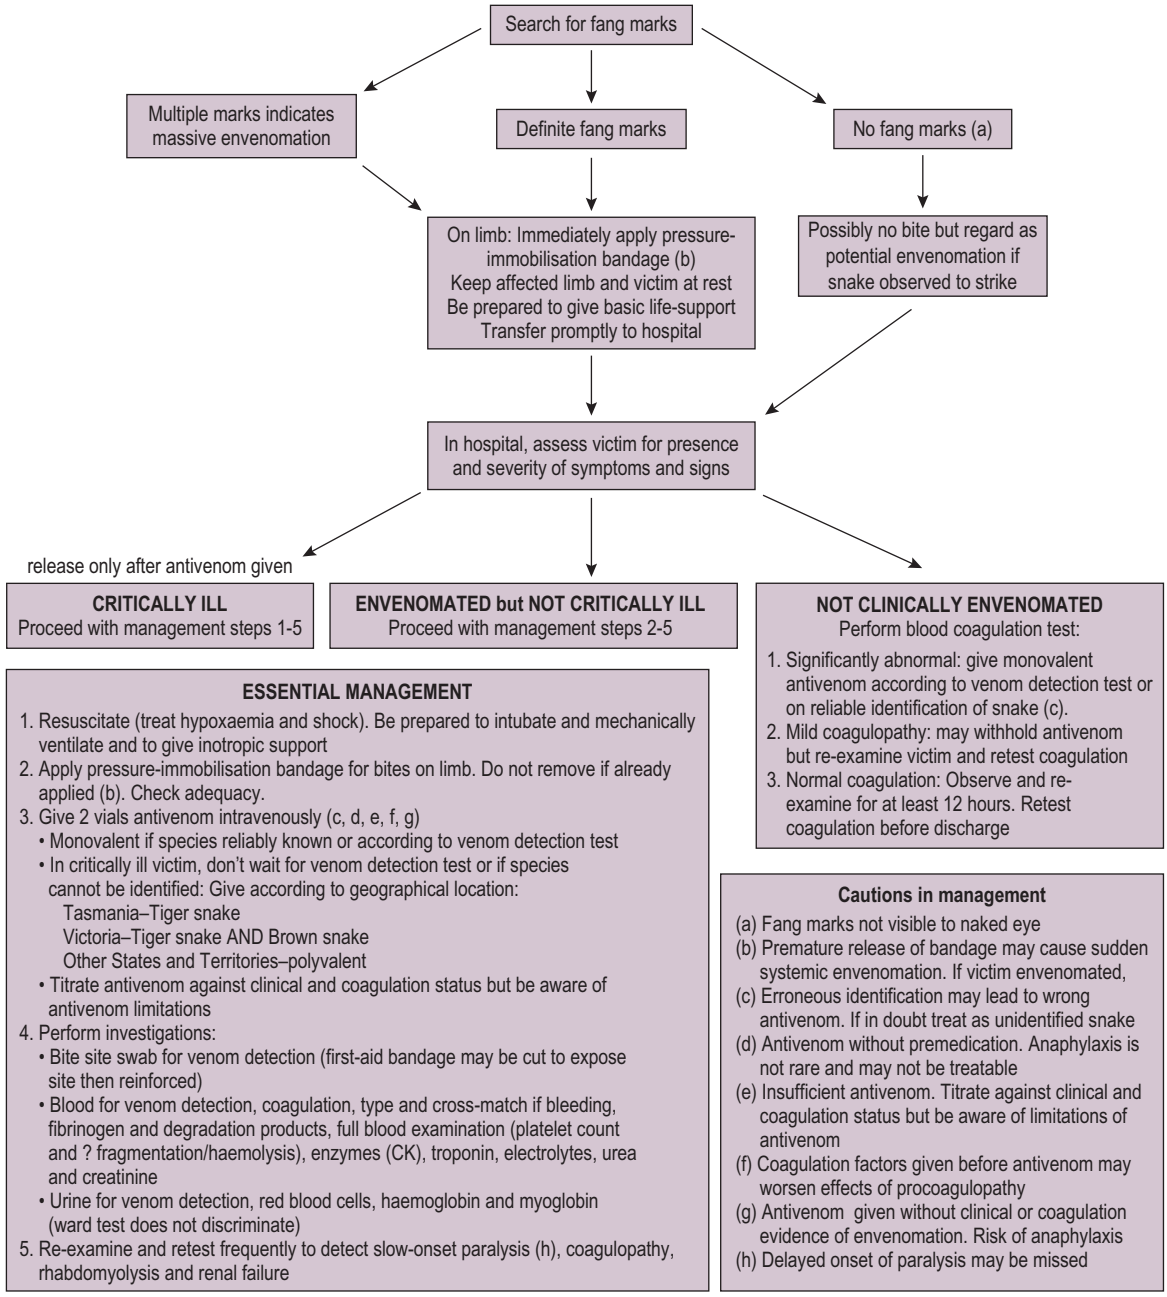

Figure 86.1 Management of snake bite.

entire limb by a rigid splint, with the aim of immobilising joints on either side of the bite site.

Venom is usually deposited subcutaneously. The systemic spread of venom is largely dependent on its absorption by way of the lymphatics[15] or the small blood vessels. Application of a pressure less than arterial to the bitten area when combined with immobilisation of the limb effectively delays the movement of venom to the central circulation. Although it is a first-aid technique designed for use in the field, it should be part of initial management in hospital since it halts further absorption of venom.

Removal of the pressure-immobilisation bandage

Removal in the case of envenomation may precipitate a sudden elevation in blood concentration of venom and collapse of the victim. On the other hand, first aid has not been proven to inactivate venom in humans.

Its removal therefore should be dictated by the circumstance. When an asymptomatic snake-bite victim reaches hospital with the recommended first-aid measures in place, these should not be disturbed until antivenom, appropriate staff and equipment have been assembled. If the victim is symptomatic and antivenom is indicated, the first-aid measures should not be removed until after antivenom has been administered, and reapplied if the victim's condition deteriorates. A swab of the bite site may be obtained by removing the splint temporarily and then cutting a window in the bandage. Thereafter the bandage should be made good and the splint reapplied.

ANTIVENOM

BioCSL Pty Ltd (Parkville, Australia) produces highly purified equine monovalent antivenoms, F(ab')2 fragments of immunoglobulin (Ig)G, against the venoms of the five main terrestrial snakes, including tiger snake, brown snake, black snake, death adder and taipan. A polyvalent antivenom – a mixture of all monovalent antivenoms – is also available. A sea-snake antivenom is also produced from horses immunised with beaked sea snake (*Enhydrina schistosa/Hydrophis zwefeli)* and tiger snake venom.

Antivenom should be administered according to the identity of the snake or if unknown or doubtful, according to the result of a VDK test (Table 86.2). If neither of these criteria can be fulfilled, and if the situation warrants immediate antivenom therapy, the geographical location may be used as a guide since the distribution of many species is known (see Table 86.1). Polyvalent antivenom should not be used when a monovalent antivenom could be used appropriately. For bites by uncommon snakes, when antivenom is indicated, polyvalent antivenom or a monovalent antivenom as indicated by a VDK test should be chosen.

Antivenoms have limitations. Not all toxins in venoms generate antibodies in the immunisation process. Antivenom batches may have different potencies and are manufactured against specific species with less neutralising ability against different species of the same genus or against unrelated species, even when the antivenom chosen is nevertheless appropriate.

Table 86.2 Antivenom and initial dosages when snake identified

SNAKE	ANTIVENOM	UNITS DOSE (VIALS)
Brown snakes	Brown snake	2000 (2)
Chappell Island tiger snake	Tiger snake	12,000 (4)
Copperheads	Tiger snake	3000–6000 (1,2)
Death adders	Death adder	6000 (1)
Mulga (king brown) snake	Black snake	18,000 (1)
Papuan black snake	Black snake	18,000 (1)
Red-bellied black snake	Tiger snake *or* Black snake*	3000 (1) 18,000 (1)
Rough-scaled (Clarence River) snake	Tiger snake	6000 (2)
Sea-snakes	Sea-snake *or* Tiger snake	1000 (1) 3000 (1)
Small-scaled (fierce) snake	Taipan	12,000 (1)
Taipans	Taipan	12,000–36,000 (1–3)
Tasmanian tiger snake	Tiger snake	6000 (2)
Tiger snake	Tiger snake	6000 (2)

*Smaller protein mass tiger snake antivenom preferable. Note: (1) If the victim on presentation is critically ill, two to three times these amounts should be given initially. (2) Additional antivenom may be required in the course of management since the absorption of venom toxins may be delayed.

Dose

In general, the initial dose for envenomation is two vials of an appropriate monovalent antivenom or polyvalent according to whether the identity of the snake is known (see Table 86.2), or unknown (see Table 86.1). Less antivenom may be sufficient for minor envenomation but clinicians should aim to administer two vials at the outset of treatment of envenomation and to administer more antivenom if clinically indicated.

Clinicians should bear in mind the limitations of antivenom treatment: organs and tissues already damaged by venom cannot have function restored by antivenom. Antivenom neutralises accessible toxins and prevents further damage, but time and supportive care are required, for example for nerve terminals and muscle to regenerate after destruction by presynaptic neurotoxins. After bites by species with procoagulant coagulopathic effects, the victim's coagulation status is a useful but not definitive guide to whether more antivenom is required. In the absence of a rapid measurement of exogenous venom procoagulant in blood and of coagulation factors, it is difficult to determine whether continued procoagulant coagulopathy after antivenom administration is due to un-neutralised venom or to the possibility that coagulation factors have not been remanufactured – a process that requires at least 6 hours in the absence of venom.

The neutralisation dose for a particular case is uncertain for numerous reasons. Above all is the fact that the neutralisation dose in humans is unknown. One vial of specific antivenom neutralises in vitro the average yield on 'milking'– a process whereby venom

is harvested by inducing the snake to bite through a latex membrane. Antivenom is tested and doses determined to prevent death in small animals, but the neutralising dose in vivo in humans cannot be extrapolated accurately from such data.

The dose of antivenom required in a particular case is uncertain because the amount of venom injected cannot be determined. Snakes may inject a variable amount of venom.[1] If the amount of venom injected at a bite is greater than the average yield on milking, one vial of antivenom will not be adequate therapy. Moreover, snakes may bite multiple times and absorption of toxins from the bite site is probably a continual process, implying that serial administration of antivenom may be required.

Determination of the neutralisation dose is also confounded by a lack of knowledge of which toxins and to what degree they are neutralised by antivenom antibodies. Moreover, the pharmacokinetics of tissue-bound toxins, penetration of antivenom to tissues and the effect of antivenom on bound toxins in tissues are simply unknown. Victims may present late after envenomation when toxins have already become bound to target tissues and cannot be easily neutralised. Some victims in this circumstance have required mechanical ventilation for many weeks despite large amounts of appropriate antivenom.

The question of neutralising dosing is a controversial issue and excessive doses may have been administered in the past. Arguably, the neutralisation dose should be regarded as the maximum dose beyond which no further improvement is gained with antivenom therapy, but that is very difficult to derive theoretically and in practice in an individual case.

On the basis that a median dose of one vial of antivenom clears the blood of circulating procoagulant toxins, the authors of the Australian Snakebite Study (ASP) of 715 envenomated victims (from 2005 to 2015), proposed that one vial of the relevant antivenom is a sufficient dose for all victims,[6,16] implying that no additional antivenom is indicated. However, the proposition has a number of limitations, including the lack of effect of antivenom on the effects of venom and the use of the median dose derived from all degrees of envenomation. The proposition is also difficult to reconcile with clinical improvement in victims given larger doses, and it is difficult to draw conclusions from the observational evidence of the ASP study, which, although of high quality, is very low or low on any scale of scientific evidence.

According to the ASP study, although less antivenom was used in 2014/2015 compared with 2005 with no differences in mortality, the upper quartile ranges of antivenom doses used in 2014/2015 do not equate to the median dose recommended. In 2014/2015, the upper quartile dose for envenomation by brown snakes was approximately 1.5 vials; for tiger snakes 2.0 vials; and for taipans 1.5 vials (together comprising 61% of envenomations). Only in bites by death adders, mulga snakes and red-bellied black snakes (comprising 23% of envenomations) did the upper quartile range equate to the median dose.

The manufacturers of the antivenoms (bioCSL Pty Ltd)[17] do not support the dosing of one vial and recommend higher doses based on the consensus opinion of an expert committee.

As a general rule, two vials of antivenom would probably suffice, but less or more may be indicated according to the snake involved and the effects on the victim. Undertreatment may be fatal while overtreatment with many vials while unduly expensive is probably not harmful and is attributable to a lack of understanding of the incapability of antivenom to restore established organ dysfunction, and lack of knowledge of the time required for hepatic manufacture of consumed coagulation factors. The consideration of dosing does not relate to adverse reactions, which invariably occur with the first dose of antivenom, nor does it relate to serum sickness, which occurs whatever the dose.[18]

In desperate circumstances of life-threatening envenomation where the patient is seemingly unresponsive to antivenom, it is difficult to differentiate organ dysfunction (which could be reversed) with antivenom and dysfunction (which cannot be reversed), leading to overtreatment.

Administration

The decision to administer antivenom must be based on clinical criteria of envenomation, and not restricted to the result of a VDK test. A positive VDK test of a biological sample confirms a diagnosis of envenomation and the choice of antivenom, but does not imply that antivenom should or should not be given. The VDK test has a false-positive rate and may lead to antivenom being administered to a non-envenomated victim.[6]

If the victim is significantly envenomated, antivenom must be administered as there is no other effective treatment. However, antivenom may be withheld if envenomation is so mild that spontaneous recovery may occur or the consequences of antivenom administration are likely to outweigh the benefit to be gained (e.g. in a herpetologist with minor effects and known to have an allergy to antivenom).

Snake antivenoms must be given by the intravenous route, or in dire circumstances if a vein cannot be cannulated then by the intraosseous route. The large volume of fluid and slow absorption render the intramuscular route useless in emergencies.

A test dose of antivenom to determine allergy should not be done. It is unreliable and a waste of precious time.

Premedication

Antivenom should be preceded by premedication with low-dose subcutaneous epinephrine

(adrenaline), approximately 0.25 mg for an adult and 0.005–0.01 mg/kg for a child, at least 5–10 minutes before commencement of the infusion. In the moribund or critically ill victim, when it is essential to administer antivenom quickly, the epinephrine may be given intramuscularly or even intravenously in smaller doses. However, in general, epinephrine is not recommended by either of those routes because of the risk of intracerebral haemorrhage due to the combination of possible epinephrine-induced hypertension and venom-induced coagulopathy. Although intracerebral haemorrhage has been recorded in the past in association with premedication, all such cases occurred after intravenous epinephrine, and none with subcutaneous epinephrine, which does not cause significant changes in heart rate or blood pressure.[19]

The incidence of all immediate-type reactions and anaphylaxis is about 25% and 10%, respectively,[20] and occasional death after antivenom[21] are sufficient to warrant premedication with epinephrine, which is the only medication proven effective in reducing the incidence of antivenom-induced reactions and their severity.[22,23]

It is not prudent or reasonable to forgo premedication merely on the assumption that if anaphylaxis occurs it will be treatable. Iatrogenic anaphylaxis has a high mortality despite vigorous and expert resuscitation.[24] If an adverse reaction to the first vial of antivenom has not occurred, subsequent vials do not need to be preceded by epinephrine. The reaction rate to polyvalent antivenom is higher than to monovalent antivenoms; they should not be used when a monovalent antivenom or combinations will suffice.

The antihistamine promethazine is ineffective in this setting[25] and indeed contraindicated because it may cause obtundation and hypotension, both of which may exacerbate and confound a state of envenomation. Other drugs, such as steroids and aminophylline, are also not useful in preventing anaphylaxis because their actions, apart from being unproven, are too slow in onset, but steroids are useful for preventing serum sickness.

Infusion

The antivenom may be injected slowly into a running intravenous line or diluted in Hartmann's or other crystalloid solution in approximately 1 in 10 volumes in a burette and administered over 15–30 minutes if the situation is not critical. This method may reduce the risk of an anaphylactoid reaction resulting from its binding with complement. For small children, if multiple vials are required, the dilution may be less to prevent excessive fluid administration. In emergencies the antivenom may be infused quickly in high concentration.

Adverse reactions

Antivenom infusion should be administered in a location equipped and staffed by personnel capable of managing anaphylaxis, which is discussed in detail in Chapter 67. Intramuscular epinephrine is the key treatment in a dose of approximately 0.25–1.00 mg for adults and 10 μg/kg for children. Antivenom therapy should be discontinued temporarily and restarted when the victim's condition is stable.

Lesser degrees of immediate adverse reaction restricted to headache, chest discomfort, fine rash, arthralgia, myalgia, nausea, abdominal pain, vomiting and pyrexia may be managed by temporary cessation of infusion, and the administration of steroids and antihistamine before recommencement.

A delayed hypersensitivity reaction, serum sickness, should be anticipated and patients warned of the symptoms and signs, which usually appear several days to 2 weeks after antivenom administration. Severity may range from a faint rash and pyrexia to serious multisystem disease, including lymphadenitis, polyarthralgia, urticaria, nephritis, neuropathy and vasculitis. The incidence of serum sickness (about 30%) is not dependent on the dose of antivenom administered.[18] Therefore it is reasonable to administer prophylactic treatment, a course of steroids (e.g. prednisolone 1 mg/kg per day for 5 days), to every patient treated with antivenom.

INVESTIGATIONS AND MONITORING

Tests should be performed regularly, interpreted quickly and treated promptly to counter venom effects and its complications. Serial coagulation tests and tests of renal function are especially important. Absorption of venom from the bite site is a continuing process that should be anticipated. Apart from regular monitoring of vital signs and oxygenation, the following are specifically needed:

Bite site

A swab for venom testing should be done. It has the highest likelihood of detecting venom provided the site has not been washed. The bite site may be squeezed to yield venom if it has been washed. A positive result identifies venom but does not prove envenomation.

Urine

Test the urine for venom that may be present when venom in blood has been bound by antivenom and is therefore undetectable. Urine should also be tested for blood and protein. If the urine is pigmented, a distinction should be made between haemoglobinuria and myoglobinuria, which is impossible with simple ward tests. Urine output should be recorded.

Blood

- Coagulation tests should include prothrombin time, activated thromboplastin time, serum fibrinogen and fibrin degradation products.
- A full-blood examination and blood film for haemoglobin level, evidence of haemolysis and

platelet count. A mild elevation in white cell count is expected.
- Electrolytes, urea, creatinine and creatine phosphokinase (isoenzymes and troponin are useful) to monitor rhabdomyolysis and possible renal compromise.

Electrocardiogram

Sinus tachycardia, ventricular ectopy and ST segment and T-wave changes are not uncommon. These effects may be the direct result of venom toxins or from electrolyte disturbances caused by rhabdomyolysis or renal failure.

SECONDARY MANAGEMENT

Coagulation factor and blood transfusion

Although coagulopathy often resolves after several doses of antivenom it does not restore coagulation *per se*; it permits newly manufactured coagulation factors to act unopposed by venom. This is not a failure of antivenom therapy. If haemorrhage is occurring, or if coagulation is not restored after several doses of antivenom over several hours, it is prudent to administer fresh frozen plasma (FFP) and to remeasure coagulation at intervals. FFP 6 hours after antivenom restores the clotting function in most victims.[26] Because regeneration of coagulation factors takes many hours, treatment of isolated coagulopathy entirely with antivenom while waiting for their regeneration exposes the patient to serious haemorrhage. Administration of coagulation factors, such as in the form of FFP, should be preceded by antivenom to neutralise venom prothrombin activator as otherwise consumption coagulopathy may worsen. Platelets and red cell infusion may be required.

Intravenous fluids, rhabdomyolysis and renal protection

After acute resuscitation, administer intravenous fluids in sufficient volume to maintain urine output at about 40 mL/kg per day in an adult and 1–2 mL/kg per hour in a child to prevent tubular necrosis as a consequence of rhabdomyolysis. Life-threatening hyperkalaemia and hypocalcaemia may develop with rhabdomyolysis. Renal failure may also be secondary to MAHA. Haemofiltration or dialysis may be required.

Heparin

Although this anticoagulant has prevented the action of prothrombin activators in animal models of envenomation, it does not improve established consumption coagulopathy. It is not recommended. Instead, the emphasis should be on treating the cause by neutralising venom with antivenom.

Analgesia and sedation

Australian snake bite does not usually cause severe pain but analgesia may be required. However, sedation is required for the mechanically ventilated venom-paralysed victim and analgesia for rhabdomyolysis.

Care of the bite site

Usually no specific care is required. Occasionally the site may blister, bruise, ulcerate or necrose, particularly when a first-aid bandage has been in place for a considerable time or when the bite was by a member of the black snake genus, such as a mulga snake or red-bellied black snake.

Other drugs

Antibiotics are not routinely required but should be considered as for any potentially contaminated wound. Sea-snake bites may cause Gram-negative infections. Tetanus prophylaxis should be reviewed.

SEA-SNAKE BITE

Some sea-snake venoms cause widespread damage to skeletal muscle with consequent myoglobinuria, neuromuscular paralysis or direct renal damage. Many have not been researched. The principles of treatment are essentially the same as for envenomation by terrestrial snakes. The venoms of significant species are neutralised with CSL Ltd beaked sea-snake (*H. zwefeli*, formerly *E. schistosa*) antivenom. If that preparation is not available, tiger snake or polyvalent antivenom should be used. Sea-snake bites are uncommon in Australia and no deaths have been recorded.

UNCOMMON AND EXOTIC SNAKE BITE

Zoo personnel, herpetologists and amateur collectors who catch, maintain or breed species of uncommon Australian snakes or who import or breed exotic (overseas) snakes are at risk, as are personnel in the Australian Quarantine and Inspection Service (AQIS) who encounter exotic species. Specific antivenoms to the venoms of uncommon Australian snakes do not exist, but neutralisation is provided by polyvalent antivenom or by monovalent antivenom, as indicated by the VDK.

Exotic snake antivenoms are maintained by some institutions including Royal Melbourne Hospital (Tel: +61 3 9342 7000), Royal Adelaide Hospital (Tel: +61 8 8222 4000), Ballarat Hospital (Tel: +61 3 5320 4316), Venom Supplies Ltd, Tanunda, South Australia (Tel: +61 8 8563 0001), Australian Reptile Park (Tel: +61 2 4340 1022) and Taronga Zoo (Mosman, Tel: +61 2 9978 4757).

LONG-TERM EFFECTS OF SNAKE BITE

After appropriate timely treatment, recovery is expected but it may be slow, taking many weeks or months, particularly from a critical illness or after delayed presentation involving neurotoxicity,

rhabdomyolysis or renal failure. Isolated neurological or ophthalmic signs may persist. Long-term loss of smell or taste occurs occasionally, especially after bites by black snakes. The psychological effects of snakebite, including depression and post-traumatic stress disorder, may necessitate expert assistance.

SPIDERS

Although several thousand species of spiders exist in Australia, only funnel-web spiders (genera *Atrax, Hadronyche*) and the red-back spider (*Latrodectus hasselti*) have caused death or significant systemic illness. Mouse spiders may also cause significant illness. All spiders have venom but of the numerous other species of spiders in Australia, the bites of relatively few have caused pain and inflammatory signs at the bite site and minor (non-life-threatening) systemic effects. These include members of the families Araneidae (orb-weavers), Clubionidae (sac spiders), Corinnidae (darting spiders), Desidae (lace web spiders, including *Badumna insignis*, black house spider), Lamponidae (white-tail spiders), Lycosidae (wolf spiders), Salticidae (jumping spiders), Sparassidae (huntsman spiders), Zodariidae (spotted or ant spiders) and other Mygalomorphae (trapdoor, mouse and tarantula spiders).[2] Causes for ulcerated skin lesions other than a spider bite should be sought.

FUNNEL-WEB SPIDERS

At least 35 species of the funnel-web genera *Atrax, Hadronyche* and *Illawarra,* inhabit Queensland, New South Wales, Victoria, Tasmania and South Australia,[27] but only species from New South Wales and southern Queensland have caused significant illness and death. Funnel-web spiders are large, dark-coloured and aggressive. A systematic review involving 138 cases identified 77 cases of severe envenomation with 13 deaths, but none occurred after the introduction of antivenom in 1981, and the vast majority (97%) responded to antivenom therapy.[28] All deaths were attributed to the Sydney funnel-web spider (*Atrax robustus*), which inhabits an area within an approximate 160 km radius of Sydney. It may enter houses and seek shelter among clothes or bedding, giving a painful bite when encountered.

Apart from *A. robustus* (Sydney funnel-web), life-threatening illness has been caused by bites from *Hadronyche cerberea* (southern tree funnel-web), *Hadronyche formidabilis* (northern tree funnel-web), *Hadronyche infensa* (Darling Downs funnel-web), *Hadronyche macquariensis* (Port Macquarie funnel-web) and *Hadronyche versuta* (Blue Mountains funnel-web). In contrast to other spiders, male funnel-web spiders have more potent venom than female spiders, but all funnel-web envenomations, irrespective of species and gender, may be treated with funnel-web antivenom.

Bites do not always result in envenomation, but envenomation may be rapidly fatal. The early features of the envenomation syndrome include nausea, vomiting, profuse sweating, salivation and abdominal pain. Life-threatening features are usually heralded by the appearance of muscle fasciculation at the bite site, which quickly involves distant muscle groups. Hypertension, tachyarrhythmias, vasoconstriction, hypersalivation and bronchorrhoea occur. The victim may lapse into coma, develop central hypoventilation and have difficulty maintaining an airway free of secretions. Finally, respiratory failure, pulmonary oedema and severe hypotension culminate in death. The syndrome may develop within several hours but it may be more rapid. Several children have died within 90 minutes of envenomation, and one died within 15 minutes.

The venoms of funnel-web spiders contain hundreds of protein toxins.[2] A family of δ-hexatoxins, comprised of 42–44 residue-peptides with four disulphide bonds creating an inhibitor cystine knot motif, bind to neurotoxin receptor site 3 and exert their effect by slowing inactivation of vertebrate and insect tetrodotoxin-sensitive sodium channels. This action results in massive release of neurotransmitters including acetylcholine at neuromuscular junctions and within the autonomic nervous system and of catecholamines, which may induce acute cardiac failure (Takotsubo cardiomyopathy). The venoms also contain numerous toxins that attack other ion channels in insects but not in humans.

Treatment of envenomation consists of the application of a pressure-immobilisation bandage, intravenous administration of antivenom and support of vital functions, which may include airway support, mechanical ventilation and intensive cardiovascular support, and possibly extracorporeal membrane oxygenation. The antivenom is purified IgG antibody derived from immunisation of rabbits with male *A. robustus* venom, but which is effective against other funnel-web spiders. The appropriate dosing to treat envenomation is not certain but the minimum initial dose of intravenous antivenom for a mild case is 2 ampoules; repeated in 15 minutes if there is no clinical improvement. The dose should be doubled for severe envenomation and thereafter antivenom given according to the clinical status of the victim, but it is uncommon to require more than 6 ampoules of antivenom. In 75 victims requiring antivenom, the median dose administered was 3 ampoules but the range was 1–17.[28] Urgent administration of antivenom is required if any of the following signs are present:

- Muscle fasciculation in the limb involved or remote from the bite, usually first seen in tongue or lips with systemic spread of venom
- Marked salivation or lachrymation
- Piloerection
- Significant tachycardia

- Hypertension in a previously normotensive patient (late in the syndrome the victim may become hypotensive)
- Hypoxaemia, hypoventilation, dyspnoea, pulmonary oedema
- Disorientation, confusion or a depressed level of consciousness.

The venom of Australian mouse spiders (Genus *Missulena*) contains a toxin homologous to the δ-hexatoxins in funnel-web spider venom, and envenomation may be treated if necessary with funnel-web antivenom.[2]

RED-BACK SPIDER

This spider, *L. hasselti*, is distributed throughout Australia and is found outdoors in household gardens in suburban and rural areas. Related species and similar effects of envenomation ('latrodectism') occur in many parts of the world. Red-back spider bite is the most common cause for antivenom administration in Australia. The adult female is identified easily. Its body is about 1 cm in size and has a distinct red or orange dorsal stripe over its abdomen. When disturbed, it gives a pinprick-like bite. However, in contrast to a bite from a snake or funnel-web spider, a bite from a red-back spider is not immediately life threatening, but it may cause severe systemic illness. The bite site becomes inflamed and, during the following minutes to several hours, severe pain exacerbated by movement commences locally and may extend up the limb or radiate elsewhere. The pain may be accompanied by profuse sweating, headache, nausea, vomiting, abdominal pain, fever, hypertension, paranaesthesia and rashes. In a small percentage of cases when treatment is delayed, progressive muscle paralysis may occur over many hours, requiring mechanical ventilation. If untreated, muscle weakness, spasm and arthralgia may persist for months after the bite. No deaths from a red-back spider bite alone have occurred since the availability of antivenom.

The venoms of *Latrodectus* spiders contain numerous toxins; the principle one that affects vertebrates is a protein named α-latrotoxin, which has a molecular mass of approximately 130 kDa. That of *L. hasselti*, α-LTX-Lh1a, comprises 1180 amino acid residues with high homology to others in the genus.[29] As a tetramer or dimer it inserts into the membranes of the nerve endings of neurons, permitting the entry of calcium and the mobilisation of internal calcium stores, which leads to exocytosis of synaptic vesicles and the subsequent release of transmitters.[30] The result of the action of the toxin is the development of a patchy paralysis at the neuromuscular junction and the widespread release of catecholamines.

If the effects of a bite are trivial and confined to the bite site, antivenom may be withheld and analgesia given as required; otherwise, antivenom should be given intramuscularly or intravenously. The antivenom may be given intravenously in cases of refractory pain, but the risk of anaphylaxis may be higher than by the intramuscular route, which is very low (<0.5%). No premedication is recommended but epinephrine should be at hand to treat a severe acute allergic reaction. Several doses of antivenom, several hours apart, may be needed. There is no proven effective first aid, but the application of a cold pack or iced water may help to relieve pain. Bites by *Steatoda* spp. (cupboard spiders) may cause a similar syndrome and can be treated effectively with red-back spider antivenom.[31]

AUSTRALIAN BOX JELLYFISH

The Australian multitentacled box jellyfish, *Chironex fleckeri*, is probably the most venomous creature in the world. It has caused more than 70 deaths in the waters off northern Australia. It has a cuboid bell up to 30 cm in diameter. Numerous tentacles arise from the corners of the bell and trail several metres. It is semitransparent and difficult to see by anyone wading or swimming in shallow water where stings usually occur. The tentacles are lined with millions of nematocysts that, on contact with skin, discharge a threaded barb that pierces subcutaneous tissue, including small blood vessels allowing rapid envenomation. Contact with the tentacles causes severe pain and envenomation, from which death may occur within minutes. Death is probably due to both neurotoxic effects causing apnoea and direct cardiotoxicity, although the precise mode of action of the venom is uncertain. In mechanically ventilated animals, fatal hypotension and cardiac failure occurs rapidly on envenomation, which is probably due to cytolytic poration of cardiac cell membranes, but it is also accompanied by haemolytic hyperkalaemia.[3] The skin that sustains the injury may heal with disfiguring scars and like all jellyfish envenomations it may be subject to recurrent rash of immunogenic origin.[3]

The structures of two of the probable numerous toxins of *C. fleckeri* venom have been determined.[32-36] The *C. fleckeri* toxins CfTX-1 and CfTX-2 cause rapid cardiovascular collapse in rats and have strong haemolytic activity. They have masses 43 and 45 kDa and 436 and 445 amino acid sequences, respectively, and are antigenic to CSL box jellyfish antivenom. They have significant homology with other known protein toxins from other cubozoan and non-cubozoan jellyfish. Additional proteins with pore-forming effects in *C. fleckeri* venom, CfTX-A and CfTX-B, approximately 40 kDa and 42 kDa, respectively, have strong haemolytic activity but minor cardiovascular effects.

First aid is important in the management, which must be administered on the beach, and consists of dousing the skin with acetic acid (vinegar), which inactivates undischarged nematocysts. Adherent tentacles can then be removed. Basic cardiopulmonary

resuscitation may be required on the beach and continued en route to hospital where extracorporeal life support could be considered. Although an ovine antivenom is available and effective in vitro,[3] its effectiveness is doubtful in established critical illness when toxins have already damaged tissues. Several vials should be given in minor illness and up to six vials in critical illness. The prevention of stings is of paramount importance: water must not be entered when this jellyfish is known to be close inshore. Wet suits, clothing and 'stinger suits' offer protection.

Other chirodropid jellyfish, for example, *Chiropsella bronzei* (previously *Chiropsalmus quadrigatus*) may cause a similar but less severe illness and should be treated as for *C. fleckeri* envenomation.[3]

IRUKANDJI SYNDROME

Stings by the carybdeid jellyfish *Carukia barnesi* (Barnes' jellyfish), and by numerous other carybdeid jellyfish may cause a clinical syndrome known as 'Irukandji syndrome'.[37] *C. barnesi* is a small translucent cubozoan jellyfish with a squarish bell a little more than 1 cm in diameter. Single tentacles trail from its four corners. When submerged it is almost invisible.

The sting of *C. barnesi* is mild and marked only by a small area of cutaneous erythema. However, severe general illness may follow with abdominal cramps, hypertension, back pain, nausea and vomiting, limb cramps, chest tightness and marked distress. A sting may result in acute cardiac failure, resembling Takotsubo cardiomyopathy and necessitating mechanical ventilation and inotropic support. The severe syndrome is consistent with endogenous release of catecholamines[38] by toxins acting on sodium channels, and by cytolytic toxins causing pore-formation of cardiac cell membranes. Two deaths attributed to stings were the result of systemic hypertension causing cerebral haemorrhage.

Management of the syndrome includes relief from pain, which is the most important feature in mild to moderate cases. In a case series of 10 victims with Irukandji syndrome, intravenous magnesium salts provided pain relief and a reduction in blood pressure,[39] but these observations were not supported by a randomised trial, which showed that magnesium salts did not influence the required amount of analgesia.[40] Antihypertensive therapy with phentolamine or a 'titratable' nitrate may be required in the initial phase of management but if acute cardiac failure develops, an inotropic agent is required.

Although initially recognised in Australia and typified by the sting of *C. barnesi*, it is being increasingly recognised in victims of stings by similar jellyfish in other oceanic regions. Some protein toxins of *C. barnesi* and a related carybdeid, *Malo kingi*, have molecular mass of 43–46 kDa and have some homologies with cytolytic pore-forming toxins of Chirodropids *C. quadrigatus* and *C. fleckeri* and homologies with ion channel neurotoxins of sea anemones.[4]

AUSTRALIAN PARALYSIS TICK

This tick (*Ixodes holocyclus*) injects a toxin that causes flaccid paralysis after some 3–5 days of feeding on humans. The onset of illness resembles that of Guillain–Barré syndrome. Prompt, careful and entire removal of tick(s) is necessary, followed by a period of observation to ensure that late-onset paralysis does not occur. No antitoxin is available and mechanical ventilation may be required for several days until spontaneous recovery.

BEES, WASPS AND ANTS

Anaphylactic reactions to bee, wasp and ant stings cause approximately the same number of deaths in Australia each year as do snake bites. In the 14-year period from 2000 to 2013, ant, bee and wasp stings caused 17,000 admissions at an annual average of 1200.[7] The 32 arthropod deaths in this period (2–3/annum, 0.11/million population per year) were all due to hymenoptera stings by bees (25), ants (5) and wasps (2). The venoms of these arthropods contain numerous allergenic toxins.[5] The common European honey bee (*Apis mellifera*) is largely responsible. Jumper and bull ants (*Myrmecia* spp.) may also cause anaphylaxis. Refer to Chapter 67 for treatment. Persons who develop reactions to bites should undergo immunotherapy and always carry two doses of injectable epinephrine.[5]

BLUE-RINGED OCTOPUSES

Several species of *Hapalochlaena* inhabit the Australian coastline. When handled, these octopuses bite and inject tetrodotoxin, which is a neurotoxin found in many different species of marine animals. It causes rapid onset of flaccid paralysis. Approximately a dozen deaths have been recorded. The required treatment is mechanical ventilation until spontaneous recovery occurs.

STINGING FISH

Numerous marine and fresh-water fish carry venom in glands attached to stinging spines. The most dangerous is the stonefish (*Synanceia* spp.). When this fish is trodden on, venom is injected. The immediate effect is extreme pain. Several deaths have been recorded, which are presumably due to the known depressive effects of the toxins on cardiovascular and neuromuscular function, and myotoxicity. An antivenom (bioCSL Pty Ltd) is available. Local or regional nerve

blockade may be required for pain relief. Other stinging fish, such as the fresh-water bullrout (*Notesthes robusta*) also cause excruciating pain when their spines are contacted. Immersion of the affected limb in warm-to-hot water provides pain relief.

VENOMOUS CONE SHELLS

Many gastropod molluscs fire a venom-laden harpoon to almost instantaneously immobilise and kill prey. The numerous conotoxins, which are short proteins, stimulate or block neuronal and neuromuscular receptors, causing rapid death. A handful of human deaths have been recorded when shells have been carelessly or unwittingly handled. There is no antivenom. Mechanical ventilation would be required until spontaneous recovery occurs.

Blast and ballistic trauma

Michael C Reade, Peter D (Toby) Thomas

Although still uncommon, the number of mass casualty events involving firearms (e.g. the Paris Bataclan theatre, 2015) and explosions (e.g. Brussels, 2016) has increased in developed countries in recent years, but most deaths still occur in the developing world and therefore are under-reported in Western media.[1] Civilian single-victim firearm attacks and accidental explosions are even more numerous. The principles of managing blast and ballistic trauma are not well appreciated outside the military.[2] Misunderstandings can result in counterproductive planning (e.g. needlessly emptying intensive care units, or failing to understand the requirement for repeated wound surgery over many weeks) and treatment (e.g. needless extensive debridement). This chapter will hopefully remain a curiosity in an otherwise intensely studied book. For the increasing minority who need to read it in detail, perhaps unexpectedly, we hope it provides useful advice.

EPIDEMIOLOGY OF BLAST AND BALLISTIC TRAUMA

Military conflicts result in variable wounding mechanisms, summarised in Table 87.1.[3–5] The trend towards more head and neck wounds in recent conflicts (Table 87.2)[4,6] is attributed to better thoraco-abdominal body armour. The ratio of killed to wounded depends on weapon systems employed, physical surroundings, protective equipment and medical support. The mortality associated with different weapons systems in combat is shown in Table 87.3.[4,7] In modern war, the overall wounded:killed ratio ranges from 2:1 to 13:1,[8] with an average over time of around 4:1.[4,6] Body armour and better medical care are possible explanations for the higher survival (ratio 10:1) of US casualties in Iraq[9] and Afghanistan,[10] although the higher proportion of blast casualties probably also contributed.

Firearms used in a civilian context are more lethal than on the battlefield, with wounded:killed ratios ranging from 0:1 to 1:3,[8] probably because civilian shootings occur at close range with unarmed victims who cannot escape. Higher than expected mortality in war suggests executions rather than combat deaths, and has been used as evidence of war crimes.[8]

The epidemiology of blast trauma conforms to one of five distinct patterns (Table 87.4).[11] Understanding the context of blast provides vital clues to clinical management priorities and to hospital and trauma system planning for these events. For example, few civilian blast survivors (approximately 15%) require surgery, and even fewer (6%–13%) require admission to intensive care.[17]

CAUSES AND TIMING OF DEATH IN BLAST AND BALLISTIC INJURY

Of blast and ballistic trauma deaths, 70% occur due to brain injury or exsanguination within 5 minutes of wounding,[4] and almost none are survivable regardless of treatment. However, most ballistic wounds are not fatal. Of the US combatants who died in the Vietnam War,[6] 25% had potentially correctable surgical causes, and 12% died of infections and other complications. Improvement in hospital care has virtually eliminated the third mortality peak in trauma,[18] leaving pre-hospital care the main target to reduce further preventable mortality. Of the preventable deaths, 60% are due to haemorrhage from extremities, 33% from tension pneumothorax and 6% from airway obstruction.[19] Military personnel are trained to treat these three mechanisms,[20] although these figures can skew training priorities as they report on patients who died rather than those who survived, because comparatively simple interventions (e.g. airway opening) were, in fact, performed correctly.

BLAST TRAUMA

An explosion occurs when a substance rapidly undergoes a chemical or nuclear reaction, releasing energy in the form of a pressure wave, gas (usually) and heat. This chapter discusses 'conventional' rather than the particular effects of nuclear explosions. A *high explosive* produces a supersonic pressure wave, while slower burning (*deflagration*) does not. The first force felt by an affected body is the static pressure wave, depicted in Fig. 87.1. There is no mass movement of gas; rather pressure rapidly increases then becomes

ABSTRACT

Blast wounds by several mechanisms: the blast pressure wave (causing injury at interfaces of different tissue density, such as the lung, ear and bowel), acceleration of projectiles (causing penetrating trauma), physical displacement of the casualty or their surroundings (causing blunt trauma) and miscellaneous effects such as burns and inhalation of toxic gases. Five distinct types of blast (open-air, enclosed-space, underwater, associated with structural collapse and civilian low-explosive blast) cause distinct epidemiological patterns. Ballistic trauma (caused by projectiles) is a component of blast, and also includes wounding by firearms. High- and low-energy transfer wound characteristics determine the extent of tissue injury. Modern principles of treating burn and ballistic trauma build on centuries of experience through the application of evidence-based medicine, and include effective triage; rapid haemorrhage control; early, repeated but minimal debridement; modern ventilator and infection management; and vigilance for predictable late effects, most of which are not within the routine experience of civilian clinicians.

sub atmospheric. Hard surfaces reflect pressure waves, increasing the transmitted force in enclosed spaces.[11] The second force felt by a body in air is the mass movement of gases liberated by the exploding substance: the 'blast wind', which, near its origin, will contain sufficient thermal energy to cause burns. The momentum of solid objects accelerated by the blast wind can wound well beyond the danger zone of the blast wave or wind.

MECHANISMS OF BLAST INJURY

The classification of blast injury mechanisms is shown in Table 87.5 and Fig. 87.2.

PATHOPHYSIOLOGY OF PRIMARY BLAST INJURY

Primary blast injury is a common cause of death due to military blast,[21] but (except in confined environments or underwater) is uncommon (e.g. 7% in one series)[22] in survivors. If the casualty is close enough to suffer a primary blast injury, secondary and tertiary effects are usually fatal. Civilian low-energy explosive-burn casualties very rarely have primary blast trauma. The exception is 'enhanced' blast mechanisms that cause a prolonged overpressure: most commonly in civilian settings caused by the combustion of air/dust mixtures in grain silos or coal stores, and boiling liquid-expanding vapour explosions (BLEVEs) when gases stored as liquids under pressure explode at temperatures above their boiling points (e.g. liquid petroleum gas bottles in a fire).

The immediate response to a blast to the chest is vagal-mediated hypotension, bradycardia and apnoea. Alternating overpressure and underpressure causes injury due to shear forces, spalling and compression/expansion at the interfaces of tissues of different densities. This especially affects gas-containing organs, of which the ear is the most sensitive. The eardrum can be ruptured (usually inferiorly in the pars tensa) by overpressures of approximately 35 kPa; above 100 kPa rupture is nearly universal. There may be membrane haemorrhage without rupture. Rupture of the

Table 87.4 Epidemiological patterns of blast injury

	OPEN AIR HIGH-EXPLOSIVE BLAST	HIGH-EXPLOSIVE BLAST IN A CONFINED SPACE	HIGH-EXPLOSIVE UNDERWATER BLAST	BLAST CAUSING STRUCTURAL COLLAPSE	CIVILIAN LOW-EXPLOSIVE BLAST
Immediate mortality, % total injured	4 (0–9)	8 (1–14)	Not reliably reported	25 (6–44)	Not reliably reported as incidents usually involve one to two casualties
Any pulmonary effects, % survivors	7 (4–11)	21 (0–46)	84[13]	5 (2–7)	13%[14] (although difficult to separate from the effects of inhalational burn)
Blast lung syndrome, % survivors	5 (3–9)	16 (0–37)	Not specifically reported	1 (0–3)	Not specifically reported; most likely very low
Tympanic membrane rupture, % survivors	5 (0–15)	35 (16–54)	Not reliably reported; most likely very low for patients floating at the surface at the time of the blast	2 (1–4)	0[14]–4[12]
Abdominal injury from blast wave, % survivors	0 (0–2)	3 (0–6)	75[13]	1 (0–6)	0
Penetrating trauma from blast fragmentation	12[16]	15[16]	0	Uncommon, but not reliably reported	Not specifically reported
Blunt trauma (e.g. from falling masonry)	Uncommon, but not reliably reported	Uncommon, but not reliably reported	0	47[15]	Not specifically reported
Burn	10[16]	28[16]	0	2[15]	100[14] – likely to be an overestimate as study was conducted at burn centre – but the true rate is nonetheless high
Summary characteristics	Largest numbers of casualties; smallest proportion of severe injuries, most of which are penetrating blast fragmentation	Highest proportion of survivors with primary blast effects	Mechanism is almost exclusively primary blast-wave injury. Very high incidence of severe blast lung and abdominal injury	Largest number of casualties and immediate fatalities. Blast effects in survivors are rare	Burns are the most common consequence; blast effects are rare

See references 11–16.

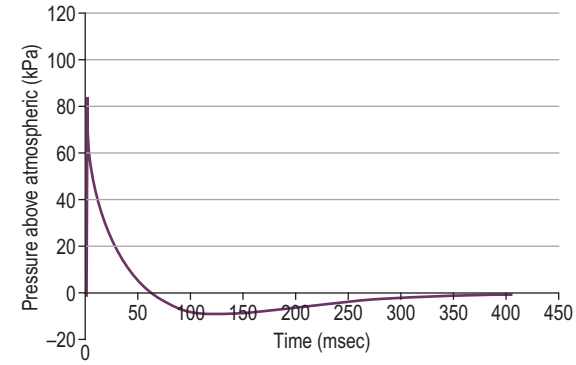

Figure 87.1 (a and b) A blast pressure (Friedlander) wave in air, with the peak overpressure shown diagrammatically in (a) visible as a change in the refractive index of air (marked by *arrows*) in (b). Interactions with surfaces including the ground commonly distort this wave. In many cases this increases the magnitude of the peak pressure at certain positions, resulting in different forces applied to casualties' located similar distances from the blast origin. *Photograph and associated R&D by Dr Fan Zhang, © Her Majesty the Queen in Right of Canada, as represented by the Minister of National Defence, 2016.*

tympanic membrane can cause tinnitus, pain, hearing loss and abnormal vestibular function. One-third of casualties experiencing rupture of the tympanic membrane will have permanent hearing loss.

Tympanic membrane sensitivity to blast led to recommendations it be used as an effective screen for blast injury to other organs, but this is unsupported by clinical experience. Tympanic membrane disruption was present in only 50% of patients with other significant blast injury.[22] Head orientation to the blast is a key determinant of vulnerability.

Blast injury at the alveolar–capillary interface can cause air emboli, pneumothorax, lung contusion, haemothorax, alveolar haemorrhage, mediastinal air and subcutaneous emphysema.[23] As alveoli flood with fluid and cellular debris, the result is 'blast lung' (Fig. 87.3), with hypoxaemia caused by ventilation–perfusion mismatch. Blast lung typically develops over 24–48 hours and takes 7–10 days to resolve. Presentation ranges from mild hypoxaemia to frothy sputum, profound hypoxaemia and subcutaneous emphysema. A chest radiograph will distinguish pneumothorax, haemothorax or pulmonary parenchymal damage from blast or other causes (e.g. inhalation of toxic gases). The effect can appear similar to pulmonary contusion from blunt chest trauma. Arterial air emboli from alveolar–pulmonary venous communications cause most early deaths. Signs of air emboli include cerebral dysfunction such as altered affect, confusion or focal neurological signs. Emboli to the coronary arteries can cause arrhythmias or ischaemia.

Primary abdominal blast injury is rare other than with blast in enclosed spaces and underwater. It most frequently presents late with signs of peritonism indicating visceral rupture. The colon is most commonly affected. Rarely, rupture of the liver or spleen may occur.

The role of primary blast injury in mild traumatic brain injury (mTBI) is unclear. mTBI can cause debilitating symptoms, many of which are shared with post-traumatic stress disorder.[24] Diffusion tensor imaging magnetic resonance imaging (MRI) shows abnormalities in mTBI, but these appear to correlate poorly with clinical signs.[25]

PATHOPHYSIOLOGY OF SECONDARY AND TERTIARY BLAST INJURIES

Secondary blast injuries were more than three times more common than primary blast injuries during Operation Iraqi Freedom[26] and were the commonest cause of death, mainly from penetrating wounds to the head, neck or chest. Survivors of blast fragmentation injuries often have many low-energy superficial wounds ('peppering' or 'battle acne': Fig. 87.4). Up to 80% of military blast casualties will have ocular trauma if they are not wearing eye protection[27] – more than reported in civilian studies – although eye injuries in urban environments containing shattering glass are also common.

Traumatic limb amputation is only partly an effect of the blast wind. Primary blast injury fractures long bones, and the blast wind then detaches the distal portion. This is thought to explain why such amputations are typically not through joints.[28]

MANAGEMENT OF BLAST INJURY

Explosions often cause 'mass casualty' events. Triage should usually be well away from the incident, as placing further explosive devices is a common tactic targeting medical personnel.

EXTREMITY INJURIES

Recent military experience has convincingly demonstrated the value of the pre-hospital windlass arterial tourniquet in stopping life-threating bleeding in both blast and ballistic trauma (Fig. 87.5).

Table 87.5 Mechanisms of blast injury

TYPE OF BLAST INJURY	MECHANISM	EFFECTS
Primary	Static pressure wave, causing barotrauma due to overpressurisation then underpressurisation	Affects mainly air-filled organs: Tympanic membrane rupture 'Blast lung' Hollow viscera rupture (colon) Mild traumatic brain injury (mTBI) Eye (globe rupture, hyphaema, serous retinitis)
Secondary	Effects of projectiles propelled by the explosion	Penetrating injury Soft tissue trauma Traumatic amputation
Tertiary	Effects due to mass movement of air ('blast wind'), either directly or by interaction with the surroundings, incl. collapse of buildings	Blunt and penetrating injury Bone fracture Traumatic amputation Open or closed TBI Crush injury Entrapment
Quaternary	All other effects of blast, including burns, oxygen depletion, creation of dust	Surface and airway burns Inhalation of toxic gases (carbon monoxide, cyanide) Exposure to radiation Asphyxiation

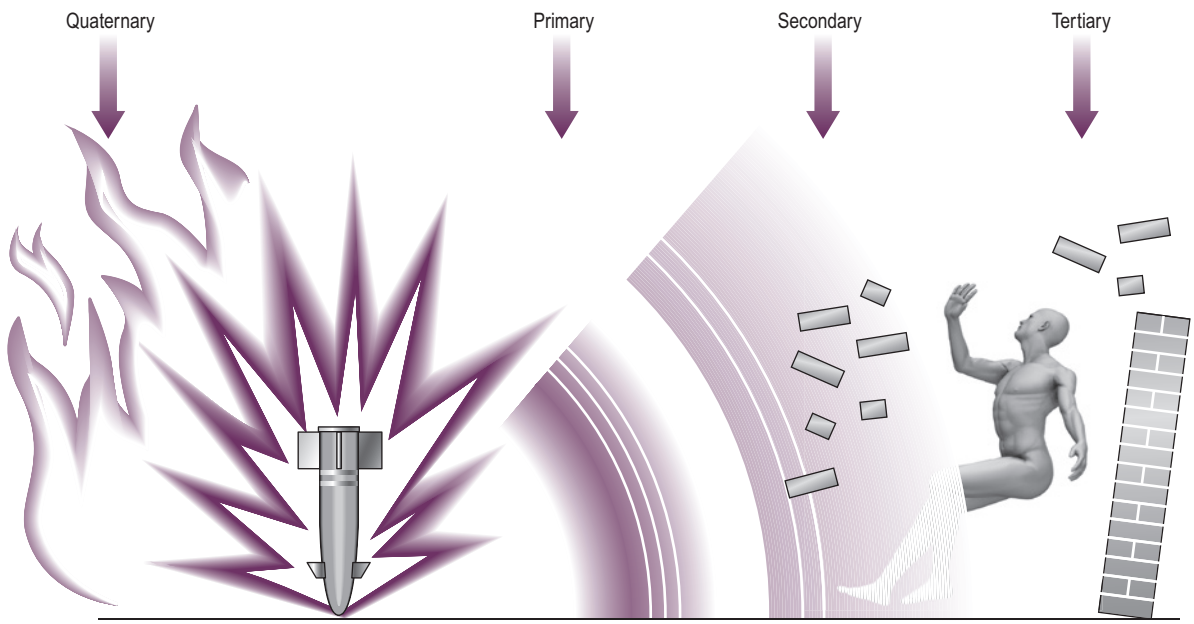

Figure 87.2 Mechanisms of blast injury. *Courtesy of Lieutenant Colonel Anthony Chambers FRACS RAAMC.*

EAR INJURIES

Tympanic membrane rupture is treated conservatively, as most heal spontaneously. About 25% will require delayed surgical closure.

BLAST LUNG

Recommendations for blast lung are mostly extrapolated from those for other causes of acute respiratory distress syndrome, despite the known differences in pathogenic mechanisms. Risk of systematic air embolism increases with mechanical ventilation, suggesting that minimising peak inspiratory pressures and permissive hypercapnia may be useful. Excessive fluid administration should be avoided to minimise contusion. Pumpless arteriovenous extracorporeal oxygenation has been used successfully to transport

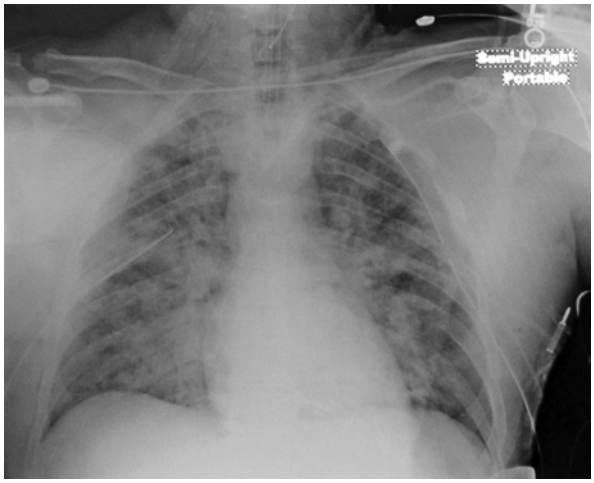

Figure 87.3 Blast lung, showing characteristic perihilar infiltrates. Computed tomography is more sensitive than plain radiography. *Courtesy of Australian Defence Force, Afghanistan, 2012.*

profoundly hypoxaemic casualties from field hospitals to definitive care.

ABDOMINAL INJURIES

Computed tomography (CT) or focused assessment sonography for trauma (FAST) scanning will guide early management, but clinical suspicion in the days after the injury is even more useful given the likelihood of delayed presentation. Primary anastomosis for blast colorectal injuries is unwise because of the high incidence of leak (30%), so most patients require colonic diversion.[29]

Figure 87.5 Pre-hospital improvised arterial tourniquets, insufficient to stop arterial haemorrhage, supplemented effectively by windlass Combat Application Tourniquets. Note the potential for iatrogenic tissue damage from the improvised devices. In hospital, standard pneumatic tourniquets quickly replace pre-hospital devices. *Courtesy of Australian Defence Force, Afghanistan, 2013.*

TRAUMATIC BRAIN INJURY

Central nervous system blast effects, including diffuse axonal injury, contusion and traumatic subdural haematoma, are all managed according to conventional guidelines.[30] A patient with brief loss of consciousness after blast should have brain CT or MRI if there is persistent headache, vomiting, localising neurological signs or a Glasgow Coma Score less than 15, noting that traumatic brain injury after blast can evolve over 48 hours, with around one-third missed on initial evaluation.[12]

Heterotopic ossification: a late complication of blast injury

Blast considerably accentuates the risk of post-traumatic heterotopic ossification, with an incidence as high as 64% (Fig. 87.6).[31] Heterotopic ossification causes pain, ulceration and loss of function, along with poor fitting of prostheses. Very early low-dose radiotherapy and non-steroidal anti-inflammatory drugs appear effective, but radiotherapy is impractical in the deployed environment and both are accompanied by risk of adverse effects. Surgical excision of extensive lesions remains the only effective treatment.[31]

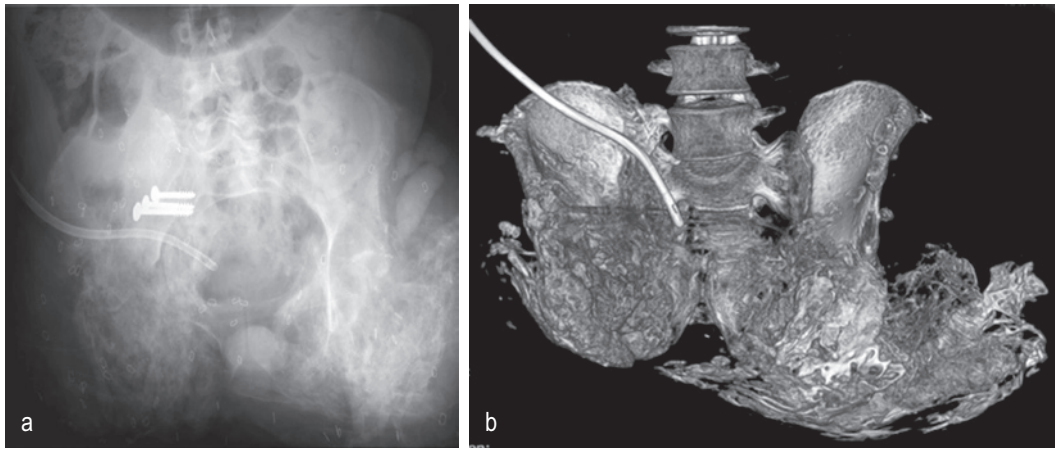

Figure 87.6 (a and b) Radiograph (a) and three-dimensional computed tomography rendering (b) of a patient with severe pelvic heterotopic ossification after bilateral hip disarticulations due to combat-related blast injuries. *From Alfieri KA, Forsberg JA Potter BK. Blast injures and heterotopic ossification.* Bone Joint Res. *2012;8:192–197.*

BALLISTIC TRAUMA

Penetrating ballistic trauma can be caused by fragments energised by explosive devices, or by projectiles from firearms.

BLAST FRAGMENTATION

Casing fragmentation multiplies the range and effect of small blast weapons many times, such as grenades, mines and mortar bombs, producing fragments that optimise range, kinetic energy and dispersion. Larger blast weapons (bombs) rely on their greater energy to create fragments from surrounding rocks or debris. Fragments from casings or surroundings are incorrectly referred to as '*shrapnel*'; blast-fragmentation is correct. The term 'improvised explosive device' (IED) covers a wide range of weapons, from the low-yield 'home made' explosives buried in palm-oil containers that typified much of the post-2001 Afghanistan conflict, to powerful explosive-formed penetrators made from repurposed military munitions used to defeat armour during the post-2003 Iraq insurgency.

BULLETS FROM FIREARMS

A *bullet* is a single projectile shot from a firearm. Modern bullets are attached to *cartridge cases* containing the *percussion cap* or *primer* and *propellant*; the entire structure forms a *round* of *ammunition*. Firearms firing bullets include *rifles* (with a long barrel that is 'rifled' with spiralling grooves inside that make the bullet rotate, increasing gyroscopic stability), *revolvers* (handguns with chambers that rotate to present each round to the barrel) and *pistols* (with short barrels but no rotating chambers). A *shotgun* with a smooth-bored barrel usually fires *shot* (round metal balls) rather than a single formed projectile.

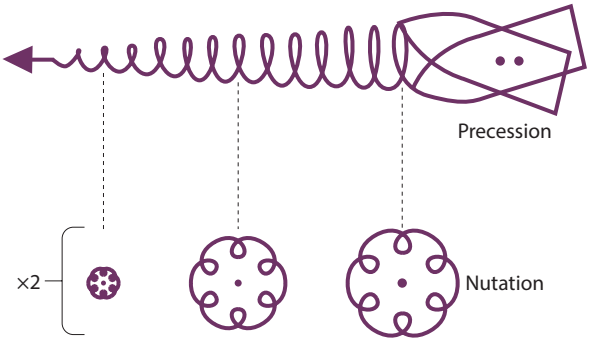

Figure 87.7 Precession and nutation. Both decrease as distance from the barrel increases. *From Volgas DA, Stannard JP, Alonso JE. Ballistics: a primer for the surgeon.* Injury. *2005;36(3):373–379.*

PROJECTILE BALLISTICS

Rapidly expanding propellant gas accelerates the projectile through the firearm barrel. Projectile trajectory is determined by gravity, air friction and pressure resistance, wind, contact with solid objects (causing *ricochets*) and stability in flight. Most bullets in flight have their centre of mass behind their centre of pressure, causing *yaw*; this is opposed by gyroscopic stability, leading to a composite movement of *spin* (rotation around the long axis), *precession* (rotation of the rotational axis) and *nutation* (swaying of the rotational axis as it precesses). During flight, yaw progressively reduces. A bullet is therefore more likely to hit point-on after 100 m of flight than after 3 m (Fig. 87.7).[32,33]

WOUND BALLISTICS

Wound ballistics describe the interaction between a projectile and the biological tissue it hits. The amount of energy that is transferred is determined by the:

- *kinetic energy (KE) of the projectile:* KE = mass × velocity^2/2 × g. The kinetic energy *transferred* to the tissue is mass × (impact velocity – exit velocity)^2/2 × g;
- *rotational energy of the projectile in flight:* usually negligible;
- *shape and impact angle of the projectile:* an aerodynamically shaped bullet will impart more energy if it hits side-on; the degree to which this occurs is determined by its properties in flight, including the distance travelled and whether it has hit anything during flight;
- *projectile deformability and fragmentation;*
- *degree to which the projectile 'tumbles':* a rapid end-over-end motion does not occur; rather, the bullet typically tumbles through 180 degrees and comes to lie base-first. Tumbling is the main reason why full metal jacket exit wounds are often larger than entry wounds; and
- *specific gravity of the tissue hit.*[34]

The terms 'high' and 'low' velocity are not as useful as 'power', incorporating projectile mass, and are even less useful than the concept of energy transfer. Although most rifles are 'high-powered' and most pistols/revolvers 'low-powered', projectile energy is only one determinant of wound magnitude. A 'high-powered' rifle bullet may cause less trauma if it misses ribs and traverses a short path through the chest than a 'low-powered' pistol bullet that fragments after hitting a rib. Notwithstanding this, the kinetic energy of most rifle bullets is many times that from a pistol. Hitting bone, a pistol bullet frequently causes a simple fracture, whereas a rifle bullet causes fragmentation and extensive bone loss.[35] Most individual wounds caused by blast fragmentation (when the patient survives the explosion) are low-energy transfer, but the sum energy transfer (and tissue damage) caused by multiple projectiles over a large body surface area can be substantial.

Further determinants of the effect of the projectile are:

- the function of the tissue affected (e.g. the eye is damaged by minimal energy transfer)
- the ability of the affected tissue to tamponade haemorrhage (e.g. liver bleeds more than muscle).

BULLET DEFORMABILITY

Bullets are typically made of lead or lead–antimony, as high density preserves kinetic energy in flight. Lead bullets melt at velocities of greater than 2000 ft/s (≈600 m/s),[34] necessitating a 'full metal jacket' (a misnomer, as the base of the bullet may have no covering) of a harder substance (e.g. copper/zinc, copper/nickel or steel). Military bullets (according to Third Hague Convention of 1899) must not flatten on contact with the body, thereby avoiding 'unnecessary suffering'. The 'full metal jacket' therefore serves two purposes. By increasing the chance of non-lethal injury, an unintended consequence is to increase combat effect: a wounded enemy soldier consumes more resources than one who is dead. In contrast, hunting rifle bullets have a soft lead or polymer tip, increasing the chance of killing quickly and so reducing suffering. Bullets with hollowed-out points have greater air drag and shorter range, but deform so extensively that exiting the target is unlikely. This is beneficial for police wishing to reduce risk to bystanders.

Doctors are sometimes asked by people concerned with compliance with the laws of armed conflict to classify the type of bullet found in a patient. *Any* bullet can deform and fragment. For example, the North Atlantic Treaty Organisation (NATO) 5.56 mm bullet fragments into two at reproducible wound depths. Finding no intact fully jacketed bullets does not allow this question to be answered.[36]

MECHANISMS OF TISSUE DAMAGE

Bullets cause crushing/laceration, shock waves and cavitation. Crushing and laceration are caused by the direct force of the bullet, and are the principal mechanisms of injury due to 'low-powered' firearms. Shock waves are caused when a 'high-powered' bullet compresses tissues. They cause little damage to most tissues[37] but can rupture gas-filled organs[34] and possibly cause neurological injury.[38] The inertia imparted to tissues by a high-powered bullet causes cavitation: as the tissues continue to move away from the bullet track, subatmospheric pressure sucks in debris. The *temporary cavitation* disrupts cells and their microcirculation, producing dead tissue around the wound track *up to* 30–40× the diameter of the bullet.[34] Cavitation depends on tissue elasticity; for example, liver is more affected than muscle. The temporary cavity collapses to a much smaller permanent cavity, but the size of the permanent cavity is not an indicator of the extent of devitalised tissue. Inelastic gelatine blocks overemphasise the implications of temporary cavitation in many tissues,[39,40] and are additionally misleading by not replicating the effect of passage through tissues of different density upon the bullet track.

MANAGEMENT OF PENETRATING BALLISTIC TRAUMA: BASIC PRINCIPLES

The International Committee of the Red Cross (ICRC) recommends as basic principles: early and thorough wound excision and irrigation; no unnecessary dressing changes; delayed primary closure; antibiotics as

an adjuvant; antitetanus vaccine and immunoglobulin if necessary; no internal bone fixation; and early physiotherapy.[4]

DAMAGE CONTROL SURGERY

Damage control surgery aims to stop haemorrhage, restore blood flow and control wound contamination.[41] Wounds are left packed if necessary, and temporarily closed. Restoration of bowel continuity, definitive debridement and wound closure are all deferred until physiology is optimised. This concept fits well with the ICRC basic principles and, as it requires general rather than specialist surgical expertise, can be performed in small hospitals close to the wounded.

DEFINITIVE MANAGEMENT

In general, re-inspection within 24–48 hours will be required for major wounds, with further debridement if required. This process continues every 48 hours until the wound can be closed. Even apparently clean wounds should not be closed before 4–5 days. Of 16,172 patients in the ICRC database, 41% required two operations, 14% three and 20% four or more.[4] Serial debridement is resource-intensive; in mass casualties or resource-poor environments, the ICRC recognises this approach may be impossible and advises wider initial excisions.[4]

There are exceptions to the 'no primary closure' rule. The head, neck and genitals have such good blood supply that primary closure is possible in all but the most contaminated wounds. Oral mucosa should always be closed primarily if possible. In penetrating brain injury the dura should also be closed, if necessary with a patch of pericranium or muscle aponeurosis.[4] Blood vessels that have been repaired should be covered by viable muscle if possible, with the skin left open.

MANAGEMENT OF SPECIFIC TYPES OF PENETRATING BALLISTIC WOUND

EXTREMITY WOUNDS: WOUNDS THAT DO NOT REQUIRE DEBRIDEMENT

Military[42] and civilian[4] consensus guidelines agree that not all bullet wounds require debridement. Extremities with entry and exit wounds less than 1 cm and no swelling or signs of injury to vital structures can have narrow skin margins excised and the channel irrigated with gravity-fed crystalloid. Wounds that do not penetrate deep fascia require only scrubbing, irrigation, dressings and antibiotics.

EXTREMITY WOUNDS: HOW MUCH TISSUE TO DEBRIDE?

Many published accounts[3,39,43] and the authors' own experiences suggest that surgeons sometimes perform extensive debridement around high-powered bullet tracks in the belief that microvascular tissue damage is more extensive than can be seen. This approach, although once advocated in military texts,[44] ignores empirical studies[43] and the distinction between projectile energy and energy transfer.

In penetrating ballistic trauma, muscle viability was historically assessed using the 'four C's'[7] – *capillary* bleeding when cut, *contracts* when pinched, *colour* of red meat and firm *consistency*. However, apparently dead muscle is often later found to be viable.[39,40,45] Along with substantial consensus,[7,37,39,46] we advocate initial debridement of only tissue and bone that is clearly ischaemic or not attached, with re-inspection and reassessment after 2–3 days. Drawing on experience in Afghanistan and Iraq, detailed consensus recommendations for extremity war wound debridement have been published.[42]

SUPERFICIAL BLAST FRAGMENTATION

There is debate about the optimal management of blast fragmentation penetrating trauma. Historically, military teaching was that all wounds should be surgically debrided, as most fragments carry bacteria. However, few open wounds develop infection,[47] implying that at least some can be managed non-operatively. The smaller superficial wounds in Fig. 87.4 were cleaned with a surgical scrub brush; no infection developed and the resultant scars were smaller than if each perforation had been explored. Published indications for surgical debridement of blast fragmentation wounds derived from case series are listed in Table 87.6.[48,49]

BALLISTIC FRACTURE MANAGEMENT

Bone fragments without any soft tissue attachments should be removed.[35] However, *any* soft tissue attachment makes the assessment of viability difficult, and at initial surgery such fragments should be retained. High-energy transfer fractures and fractures of the proximal tibia and fibula[50] often require fasciotomy to prevent compartment syndrome. Infection risk argues

Table 87.6 Indications for surgical debridement of blast fragmentation wounds

Ordog et al. (1993)[48]	Bowyer (1997)[49]
Presentation >24 h after wounding, without basic cleansing before presentation	Involvement of bone, pleura, peritoneum or major vessels
Wound size >1–2 cm	Wound entry or exit >1–2 cm
Failure to comply with wound care instructions	Evidence of wound cavitation
Factures	Obvious signs of infection Wounds due to buried mines

strongly for plaster, external fixation or traction rather than internal fixation of ballistic fractures.[35,51,52]

ABDOMINAL PENETRATING WOUNDS

Low-energy bullets and blast fragmentation tend to produce discrete injury to abdominal organs. Up to 30% of civilian anterior abdominal and 67% of lower back gunshot wounds can be managed safely without surgery. This approach is increasing in US civilian practice,[53] probably associated with better and more widespread CT imaging; however, it fails in 21% of cases, and failure is associated with increased mortality.[53] High-energy transfer, haemodynamic instability, peritonitis, or lack of reassuring imaging all indicate laparotomy. In the military context, definitive surgery can avert a more prolonged admission for observation. Without comprehensive imaging, it is our practice and that of others[47] to explore all penetrating abdominal wounds. If CT imaging is available, in the light of observational studies,[54] UK military guidelines allow for a selective non-operative approach in the minority of casualties with no peritonitis or haemodynamic instability who can be intensively monitored.

THORAX

Penetrating thoracic injury is either rapidly fatal (e.g. 93% of patients with aortic injuries die before reaching hospital),[55] or managed with simple measures. Of the penetrating thoracic trauma patients who reach medical care, 85% can be successfully managed with intercostal catheter (ICC) drainage alone.[56] An ICC should be placed through a new incision rather than the wound to prevent further haemorrhage. On placement of the ICC, Early Management of Severe Trauma[57] teaching is that greater than 1500 mL initial haemorrhage or greater than 200 mL/h ongoing loss for greater than 2–4 hours necessitates operative thoracotomy. Emergency anterolateral thoracotomy should be considered in patients with penetrating thoracic injuries who arrive pulseless but with electrocardiograph (ECG) activity within the last 6–10 minutes, with the intention of releasing cardiac tamponade, controlling haemorrhage (by cross-clamping the aorta or pulmonary hilum) and allowing internal cardiac massage to 'buy time' for aggressive fluid resuscitation. Thoracic penetrating injury below the level of the nipple, a positive FAST scan or abdominal signs suggests the projectile has traversed the diaphragm.

RETAINED FOREIGN BODIES

Easily accessible projectiles should be surgically removed. However, projectiles buried in healthy tissue (including brain) *unequivocally do not need to be removed*, with some exceptions:

- those lodged in joints or the subarachnoid space, in order to prevent lead arthropathy and systemic toxicity, joint destruction or neural damage;
- those that appear to become the source of systemic infection;
- those lying next to an internal organ (e.g. bronchus, heart), with the risk of subsequent erosion;[40] and
- those causing persistent pain, with the caveat that the psychological effects of a retained projectile are often profound, and this can influence pain perception.

Figure 87.8 Scout computed tomography image showing numerous metallic fragments after blast-fragmentation injury from an improvised explosive device. *Courtesy of Australian Defence Force, Afghanistan, 2012.*

Blood lead levels from projectiles retained in muscle peak at 1 month and in synovial fluid at 6 months.[58] If lead toxicity is the sole indication for projectile removal, the threshold serum levels are 10 µg/dL in children and 40 µg/dL in adults. Projectile removal should be attempted only after chelation with EDTA, dimercaprol, D-penicillamine or dimercaptosuccinic acid.[4]

HELPFUL INVESTIGATIONS

Pre- and intraoperative physical examination is the best single method of evaluating ballistic wounds.[43] However, projectiles often follow unpredictable paths. Radiology can be useful in triage, operative planning and the selection of cases for non-operative management. The extent of blast-fragmentation wounds, such as those in Fig. 87.8, would be almost impossible to assess without radiology. In Iraq and Afghanistan, all patients with substantial ballistic trauma had whole-body CT scanning if it was available, unless operative intervention was immediately required to save life.

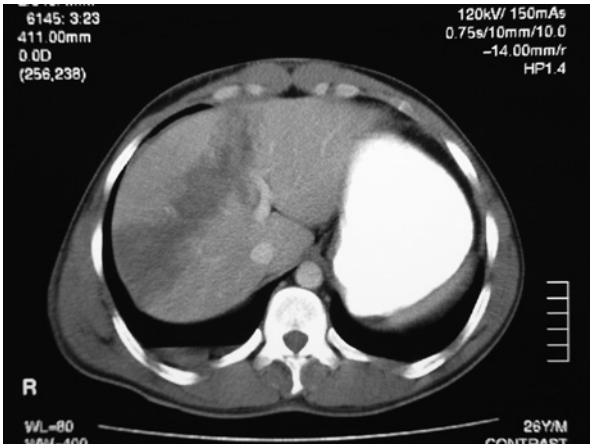

Figure 87.9 Computed tomography image demonstrating the wound track of a 9 mm bullet through the liver. *Courtesy of Dr Daron Cunningham, Cape Town, 2003.*

Figure 87.10 Extensive wound contamination and tissue loss due to blast fragmentation from an improvised explosive device. *Courtesy of Australian Defence Force, Afghanistan, 2013.*

Wound paths can be plotted using CT images, allowing surgical planning (Fig. 87.9).

INTERNATIONAL COMMITTEE OF THE RED CROSS WOUND CLASSIFICATION

The ICRC wound classification system[4] categorises disease severity by measuring the size of the entry wound, exit wound and wound cavity, and the involvement of fractures, vital structures and metallic foreign bodies. The result is a grade and type of wound. Unable to capture all aspects of anatomy and physiology and not accounting for multiple wounds, the ICRC system is a poor predictor of outcome, but is nevertheless useful for quantifying the effects of weapon systems.

SPECIAL CASES OF BALLISTIC TRAUMA

LANDMINES AND IMPROVISED EXPLOSIVE DEVICES

Antipersonnel landmines wound by a combination of blast and fragmentation from their casing and from rocks and soil. Buried mines explode upwards through the leg, commonly resulting in traumatic amputation through the midfoot or distal tibia, with debris driven up fascial planes (Fig. 87.10). Wound severity depends on the quantity of explosive, the point of foot contact, the debris near the mine and the footwear.[44] Bounding mines contain two charges: a small explosion propels a tethered casing upwards to 1–2 m, which then explodes propelling fragments 50–100 m. Horizontal spray mines also cause most of their effect by blast fragmentation. Air-dropped 'butterfly' mines rely on primary blast effect to maim when handled. IEDs often mimic the effects of mines, but, being made from anything from artillery shells to household chemicals, their effects are more difficult to predict. All the principles articulated above apply to mine wounds, with particular emphasis on the need to remove soil. Topical negative-pressure dressings are perceived to be particularly useful,[59] but are still not supported by trial evidence.

INCENDIARY DEVICES (NAPALM, WHITE PHOSPHOROUS)

Military forces use white phosphorus and napalm as incendiaries, and white phosphorus is also used to create smokescreens. However, both are effective psychological weapons due to their capacity to inflict severe wounds. Napalm produces an adherent burning gel, invariably producing full-thickness burns involving muscle. A 10% burn typically causes rhabdomyolysis and renal failure.[4] Napalm commonly undergoes incomplete combustion, so carbon monoxide poisoning is common. White phosphorus fragments on explosion and ignites on air contact. Immediate treatment is to scrape off visible particles – for example with a bayonet – followed by keeping the wound moist to exclude air. Dilute (1%) copper sulphate makes white phosphorus safer and easier to remove by turning it black. Alternatively, phosphorus particles glow in low light. Systemically absorbed white phosphorus causes hypocalcaemia and hyperphosphataemia, requiring intravenous calcium.[60]

BEHIND ARMOUR BLUNT TRAUMA

Body armour, consisting of woven textiles and ceramic plates, effectively reduces the lethality of

ballistic trauma. However, rifle bullets larger than 5.56 mm can still kill by the transmission of a force wave.[61] The immediate effects of behind armour blunt trauma (BABT) are vagally mediated apnoea and hypotension,[62] commonly accompanied by pulmonary and myocardial contusion, rib fractures, haemo- and pneumothorax.

INFECTION IN BALLISTIC INJURY

The two requirements for serious wound infection – dead tissue and a deep inoculum of bacteria – are frequently present in ballistic trauma. This is particularly true of military wounds, with typically three to six different bacterial species isolated compared with only one in infected civilian wounds.[35] Bacteria are mainly introduced into gunshot wounds by cavitation, but the bullet is not sterilised by firing and can also lead to infection.[34] Historically, the major causative organisms have been beta-haemolytic streptococci and clostridia. Although 'the best antibiotic is good surgery',[4] infection with both organisms is effectively prevented by prophylactic penicillin. Antibiotics alone may be sufficient for wounds left open with sufficient drainage.[63] US 2011 consensus guidelines for antimicrobial prophylaxis of combat-related wounds, drawing on experience of modern conflict, remain sound.[64] Essential points are summarised in Box 87.1.

Soil potentiates the ability of contamination to cause infection. Wounds contaminated with soil should be thoroughly cleaned, potentially requiring more wound excision than otherwise. Infection is also particularly likely in haematomas,[40] which should be drained. If a wound requires debridement, earlier surgery is associated with less infection. For example, the 10% infection rate in wounds debrided in less than 6 hours after wounding rose to 25% in wounds debrided later.[65]

Box 87.1 Infectious Diseases Society of America and Surgical Infection Society guidelines for the prevention of infections associated with combat-related injuries

IV antibiotic prophylaxis is indicated as soon as possible (ideally <3 h) after wounding.

Cefazolin 2 g IV every 6–8 h (+metronidazole 500 mg IV q8–12 h for oesophageal, abdominal organ, CNS) is appropriate for all wounds except penetrating eye injury, for which Levofloxacin 500 mg IV/PO once daily is recommended.

Alternate agents depend on site of wounding:

- Extremity; thoracic (excl. oesophageal); maxillofacial: Clindamycin (300–450 mg PO TID or 600 mg IV q8 h)
- Oesophageal; abdominal: Ertapenem 1 g IV or moxifloxacin 400 mg IV
- CNS: Ceftriaxone 2 g IV q24 h. Consider adding metronidazole 500 mg IV q8–12 h if gross contamination with organic debris. For penicillin allergic patients, vancomycin 1 g IV q12 h plus ciprofloxacin 400 mg IV q8–12 h

Duration of therapy in the absence of signs of infection: extremity; thoracic – 1–3 days; abdominal – 1 day after definitive washout; maxillofacial – 1 day; CNS: 5 days or until CSF leak is closed, whichever is longer.

Tetanus toxoid and immune globulin should be used as appropriate to immunisation status.

Enhanced Gram-negative coverage with aminoglycoside or fluoroquinolone is not recommended.

Addition of penicillin to prevent clostridial gangrene or streptococcal infection is not recommended.

Redose antimicrobials in the setting of large volume blood produce resuscitation.

Use only topical antimicrobials for burns.

CNS, Central nervous system; *CSF*, cerebrospinal fluid; *IV*, intravenous; *PO*, per os (by mouth); *TID*, ter in die (three times a day).

CONCLUSION

Medical planning and training in the management of ballistic trauma require balancing modern evidence-based medicine with the study of lessons acquired over centuries of conflict. Combatants might be compelled to repeat the mistakes of the past; doctors should not.

Chemical, biological, radiological and nuclear exposure management

Sophia De Maria

The concept of using toxins to inflict death and destruction has been around for over 2000 years. As far back as around 600 BC, historians report that the Athenian military tainted the water supply of the besieged city of Kirrha with the poisonous hellebore plant, which then rendered its population so weak with diarrhoea they were unable to fight.[1] However, in today's environment, an 'All Hazards' approach opens our thinking to beyond just chemical and biological warfare. CBRN refers to weaponised and non-weaponised chemical, biological, radiological and nuclear materials that can cause great harm and pose significant threat in the wrong hands. In the context of hazardous materials being used as weapons, the aim is to intimidate, incapacitate, or eradicate crops, livestock and personnel. There have been multiple examples of large-scale chemical attacks, the first being the German gas attack with chlorine on 22 April 1915 in Ypres, Belgium, and most recently chemical attacks in Syria, but also the use of mustard and nerve gases in the Iran/Iraq war and the dissemination of Sarin on the Tokyo underground.[2] As health care providers, we are required to treat and care for casualties of chemical, biological, radiological, nuclear and explosive warfare (CBRNE; see Table 88.1).

CLASSIFICATION

Multiple classification systems exist for CBRN agents and are based on physical properties of the agent or physical or clinical effects on the victim.

The all-hazards approach to classifying agents enables most to be categorised into the three following groups:

Damaging: Examples of damaging agents are mustard gas or low-dose radiation. Patients exposed to these agents are unlikely to die from their exposure, but they will require medical attention, which will impact on available medical resources.

Incapacitating: These agents cause a temporary inability to function either mentally or physically.

Lethal: Examples of this type of agent would be nerve agents, cyanide, phosgene, inhaled anthrax and high-dose radiation.

PHYSICAL PROPERTIES

Persistent: This refers to less volatile and viscous agents such as mustard gas and VX nerve agent, as well as dry powder and particulate matter (e.g. anthrax, asbestos and radioactive debris). These agents can remain in the area for up to several weeks, or even years (e.g. radioactive elements and anthrax spores), and have the potential to cause harm via skin contact or inhalation. These agents require formal decontamination procedures, which will vary depending on the agent.

Non-Persistent: These are volatile substances or gases that evaporate and disperse quickly, such as hydrogen cyanide and carbon monoxide. Exposure to these agents can be limited by ambient conditions and extraction from the affected area. However, some chemicals may be absorbed into clothing and equipment; therefore any clothing should be removed to limit ongoing exposure to the patient and any potential exposure to the rescuer.

ROUTES OF EXPOSURE

There are multiple ways that CBRN agents can enter the body and will result in localised or systemic effects, or both.

Inhalation: The agent – gas, vapour, particles and smoke – is breathed in (e.g. cyanide, carbon monoxide, chlorine, anthrax). This route is probably of greatest significance for critical care due to the significant effects on the airway and the lungs.

Ingestion: Agent – liquid, solid – eaten or drunk (cyanide, anthrax, salmonella). Ingestion may result in the affected patient becoming a reservoir of hazardous chemical that may pose an off-gassing hazard

ABSTRACT

Chemical, biological, nuclear and radiological (CBRN) warfare is an ever-increasing threat and is no longer confined to the conventional battlefield, and therefore it is important to be able to recognise and treat the effects of potential agents.

Managing the potential CBRN casualty, or indeed casualties, should follow the <C>AaBC approach, where <C> is catastrophic haemorrhage and 'a' is antidote (or specific treatment), combined with a quick identification of the potential agent to ensure the appropriate antidote/specific treatment is given in a timely manner.

As with all CBRN casualties, the need for careful decontamination and isolation should be carefully evaluated to avoid potentially affecting carers and other patients.

Table 88.1 Examples of confirmed and suspected chemical, biological, radiological and nuclear materials events

TYPES OF OPERATIONS/SCENARIOS	LOCATION	AGENTS
Armed conflict	Western Front (1915–1918) Manchuria (1938–1945) Hiroshima, Nagasaki (1945)	Chlorine, phosgene, mustard, cyanide Plague, anthrax, cholera, typhoid Nuclear detonation
Civil war	Yemen (1967)	Phosgene
Insurgency	Iraq (2007)	Chlorine
Counter-insurgency	Moscow (2002)	Fentanyl analogue
Civil-ethnic conflict	Halabja (1988) Syria (2017)	Mustard, nerve agent, ?cyanide Sarin/sarin-like agent
Terrorism	Tokyo (1995) Eastern US (2001)	Sarin Anthrax
Assassination	London (1978) London (2006) Kuala Lumpur, Malaysia (2017)	Ricin Polonium-210 VX nerve agent
Disease non-battle injury (DNBI)	Bagram (2002)	Norovirus
Humanitarian operations	Zaire (1994)	Cholera
Accidental	Sverdlovsk (1979)	Anthrax

(cyanide salts reacting with stomach acid to produce hydrogen cyanide gas).

Inoculation: Any penetration of the skin to introduce the agent be it liquid or solid (e.g. in 1978, an assassin used an umbrella to fire a ricin-loaded pellet into Georgi Markov, the Bulgarian dissident's leg).[3,4]

Wound: Any contamination that occurs after the skin has been broken, mainly by live biological agents (tetanus, methicillin-resistant *Staphylococcus aureus* [MRSA]).

Transcutaneous: Agent – liquid, solid – which is absorbed through the skin without initially breaking it. This includes VX (nerve agent), mustard gas, acids and alkalis causing blister wounds.

Ocular: Agent – gas, vapour. This may have a localised effect on the eye but have limited or no systemic effect (e.g. low-level nerve gas causing pinpoint pupils).

MANAGEMENT APPROACH

Management of the patient to any CBRN exposure should follow the <C>AaBC approach – Catastrophic haemorrhage, airway, antidote where applicable, breathing and circulation and a 'quick-look' assessment to establish the responsible agent (Table 88.2).

CHEMICAL AGENTS

A chemical weapon or agent is a 'chemical substance which is intended for use in military operations to kill, seriously injure or incapacitate people due to its physiological effects'.[5] These are substances that can be relatively inexpensive to produce and can cause large number of casualties with small quantities of agent.

Chemical agents can be classified according to the mechanism of action in addition to the previously mentioned properties. These include:

Nerve agents: North Atlantic Treaty Organisation (NATO) classified G series and V series.
- G Series: Tabun (GA), sarin (GB), soman (GD) and cyclosarin (GF) – developed in Germany
- V Series: VE, VG, VM and VX – developed in the United Kingdom

Cyanides: Including hydrogen sulphide (previously categorised as 'blood agents')

Vesicants or blistering agents: Mustard gas and Lewisite

Pulmonary agents (previously categorised as 'choking agents'): Chlorine and phosgene.

NERVE AGENTS (SARIN)

Nerve agents are the most lethal chemical warfare agents and are potent, rapid acting organophosphate compounds that bind irreversibly to and inactivate anticholinesterase resulting in a cholinergic (both muscarinic and nicotinic) toxidrome.[6]

SARIN

Sarin (isopropylmethylphosphofluoridate), a potent organophosphate nerve agent, is a colourless, odourless liquid in its pure form at room temperature. Sarin is volatile and water soluble but will cling to clothing and release slowly over 30 minutes.

Table 88.2 Quick-look table of agents and their toxidromes

	CONSCIOUS LEVEL	RESPIRATORY RATE	EYES/PUPILS	SECRETIONS	SKIN	OTHER
Nerve agent	Fitting ↓	↑↑	Pinpoint	↑↑	Sweaty	Fasiculations
Cyanide	Fitting ↓	↑↑/↓	Normal/dilated	Normal	Pink/cyan	Sudden onset
Vesicant	Normal	↑	Normal/red	Normal/↑	Red (delayed)	Mustard (delayed)
Pulmonary agent	Normal	↑↑	Normal/red	↑	Cyan	Pink sputum
Botulinum	Normal	↓	Dilated	↓	Dry	Descending paralysis
MetHb	Agitated	↑	Normal	Normal	Cyan	Chocolate blood
Atropine	Normal	↑	Dilated	↓	Dry	
Opiate	↓	↓	Pinpoint	Normal	Normal	

Table 88.3 Effects of nerve agent

NERVE AGENTS	
Mechanism: Anticholinesterase inhibition leads to over stimulation of the parasympathetic system, motor neurons and the CNS.	
Mild	Eye symptoms: meiosis, red, painful eyes
Moderate	Increased secretions, wheezing, nausea and vomiting, diarrhoea and difficulty breathing
Severe	Muscle weakness, respiratory arrest, seizures, death
Antidotes	Anticholinergics, oximes, diazepam
Other agents	Organophosphates. Treat as above

CNS, Central nervous system.

SYMPTOMS OF EXPOSURE

Symptoms will depend on the route and duration of exposure (see Table 88.3).

The immediate action is to extricate the casualty from the source, remove clothing and decontaminate skin, ideally with a mild alkaline solution. Eyes are irrigated with water or normal saline.

TREATMENT

Direct compromise of the airway can be due to excessive secretions, or to a reduced level of consciousness, and respiratory failure may be due to severe pulmonary oedema (requiring aggressive suctioning), bronchospasm and muscle weakness.

Circulatory collapse from the excessive secretion production may require fluids and vasopressor support.

ANTIDOTE/SPECIFIC TREATMENT

Anticholinergics: To antagonise muscarinic effects. Intravenous (IV) atropine 2 mg (20 micrograms/kg [max 2 mg] in a child) every 3–5 minutes until symptoms subside (skin becomes dry, pupils dilate and bradycardia resolved). Atropine may need to be continued as an infusion for 24 hours.

Oximes: A cholinesterase reactivator at the nicotinic sites. Pralidoxime chloride 30 mg/kg IV over 20 minutes should be started promptly. (Alternative: obidoxime.)

Benzodiazepine: Diazepam 5 mg (any route) for the management of seizures.

CYANIDES

Cyanides asphyxiate by inhibiting cytochrome oxidase and subsequent impairment of aerobic respiration. This leads rapidly to a severe, refractory metabolic (lactic) acidosis.

At room temperature, hydrogen cyanide is a colourless liquid with a boiling point of 26°C. Due to its high volatility, it is difficult to use in warfare outdoors, but can rapidly reach lethal levels in confined spaces. The most important route of poisoning is through inhalation, but skin contact with both liquid and gaseous hydrogen cyanide can result in significant poisoning.

SYMPTOMS OF EXPOSURE

Symptoms typically are signs of significant hypoxia; nausea, vomiting, agitation, tachypnoea, confusion, followed by loss of consciousness, seizures, coma, respiratory arrest and death.

TREATMENT

Initial assessment in the more severe cases may reveal the need for airway and ventilatory support due to

reduced Glasgow Coma Score (GCS) and hypoxic ventilatory failure, and fluids and vasopressors in patients showing signs of circulatory collapse.

The mainstay of treatment is oxygenation and to assist the body's ability to excrete cyanide via the endogenous enzyme rhodanese, and ultimately renal excretion.

ANTIDOTE/SPECIFIC TREATMENT

Oxygen should be administered to all patients with cyanide poisoning.

Dicobalt edetate: (only in confirmed severe cyanide toxicity as it can cause seizures, upper airway oedema, chest pain, hypotension). 300 mg IV over 1 minute, followed by 50 mL of 50% dextrose to protect against toxicity. Second and third doses can be given if no immediate improvement is seen.

Hydroxycobalamin: (a vitamin B12 precursor) will scavenge cyanide to form cyanocobalamin (Vit B12), a non-toxic by product which is then renally cleared[7,8] and will release the cyanide molecule at a slow rate allowing for detoxification by rhodanese. This is considered a safer option, especially in cases of smoke inhalation as it does not cause methemoglobinaemia or hypotension; 5 g IV over 15 minutes and a second dose of 5 g can be given if necessary.

Sodium/amyl nitrite with sodium thiosulphate is an alternative therapy.

VESICANTS/BLISTER AGENTS (MUSTARD GAS)

Vesicants or blister agents are alkylating agents that inhibit glycolysis at the cellular level resulting in cellular necrosis. They are readily absorbed through the eyes and mucous membranes, respiratory tract and skin.

Mustard gas is a yellow oily liquid at room temperature, which evaporates and can penetrate clothing. The effects of mustard gases are typically delayed by 2–4 hours.

SYMPTOMS OF EXPOSURE

The degree of symptoms will depend upon the nature of exposure (gas vs liquid) and the duration of exposure. Contact with mucus membranes results in erythema and subsequent bullae formation, which rupture on contact. Contact with the eyes can cause temporary blindness due to corneal damage, whereas inhalation causes airway burns with possible subsequent obstruction and acute respiratory distress syndrome (ARDS).

TREATMENT

There is no specific antidote for mustard gas exposure and management is supportive.

Inhaled mustard gas can cause respiratory distress/failure requiring ventilatory support due to direct damage to the mucosa, as well as triggering the systemic inflammatory response syndrome (SIRS).

Patient with large burns are treated as any other burn injury with fluid resuscitation, analgesia and addressing any secondary infections.

With mustard burns, vesication may progress for up to 2 weeks after the initial insult[9] and wound healing is protracted, taking at least 12 weeks to heal.

Eye lesions, aided by saline irrigation and topical antibiotics, usually heal in 2 weeks.

PULMONARY AGENTS (CHLORINE AND PHOSGENE)

Pulmonary agents act by direct irritation of the airway mucosa by direct cellular damage (chlorine), or by inflammatory response and free radical formation (phosgene).

The water-soluble chlorine results in predominantly upper airway symptoms but also lung damage with prolonged/high concentration exposure, whereas the low water-soluble phosgene usually exhibits lower airway symptoms rather than upper airway symptoms.

SYMPTOMS OF EXPOSURE

Chlorine

Rapid onset upper airway symptoms, including conjunctivitis, rhinitis and pharyngitis predominate, even when exposed to relatively low concentrations. Airway oedema, laryngospasm and dyspnoea can develop with more prolonged exposure or at higher concentrations.

Phosgene

Symptom onset is usually delayed with lower airway symptoms such as pneumonitis and non-cardiogenic pulmonary oedema presenting 12–24 hours after exposure.

TREATMENT

There is no specific antidote for chlorine or phosgene exposure and treatment is supportive.

The patient may require early intubation if there is evidence of significant upper airway oedema or laryngospasm.

Both chlorine and phosgene exposure result in increased permeability of the alveolar-endothelial membrane leading to non-cardiogenic pulmonary oedema, alveolar collapse and a type 1 respiratory failure pattern. Specific respiratory management includes reducing the closing capacity and alveolar recruitment with continuous positive airway pressure (CPAP) or positive end-expiratory pressure (PEEP). However, both should be used with caution if there are concerns about the haemodynamic stability of the individual, and patients should be adequately volume expanded to maintain venous return.

There may be some role for bronchodilators and inhaled steroids, although systemic steroids are more

controversial with inadequate evidence to support this at present.

The patient may require cardiovascular support, especially if the patient has sustained other injuries.

ANTIDOTE/SPECIFIC TREATMENT

There is no specific antidote treatment for chlorine or phosgene exposure.

BIOLOGICAL AGENTS

Biological weapons achieve their effect by infecting people, animals or plants with a disease causing microorganism or other replicative entity, including viruses, fungi, prions or biological toxins. The extent of the effect depends upon many factors including immunological status of the host population, nutrition and the environment (e.g. sanitation, temperature, water quality, population density).[10]

Biological agents can be classified as:

Live agents: including bacterial, viral, fungal, chlamydial and rickettsial.

Toxin: A toxin can be considered to be a chemically active agent of biological origin. It does not self-replicate and therefore is not transmissible once decontamination has occurred. Biological toxins can be derived from microbes (botulinum), animal (snake and scorpion venom) and plant (ricin and digitalis).

ANTHRAX

In 2001, anthrax spores were disseminated through the United States postal system in envelopes containing threatening notes sent to prominent politicians and media figures. This resulted in five deaths, and anthrax remains the most likely organism to be used in a biological terrorist attack.[11,12]

Bacillus anthracis, the causative agent of anthrax, is a large, Gram-positive, spore forming, aerobic bacillus. The organism readily forms spores, which are highly infectious. Several manifestations of the disease exist, depending on the route of exposure; that is, cutaneous anthrax, gastrointestinal (GI) disease, pulmonary anthrax and anthrax meningitis, and some or all of the forms could present themselves in a mass casualty scenario (e.g. aerosolised spores disseminated over a large urban population by an aircraft). Of these presentations, pulmonary anthrax and anthrax meningitis have the highest mortality.[13]

SYMPTOMS OF EXPOSURE

Pulmonary exposure

Pulmonary exposure is likely to be the primary form of exposure in a mass casualty scenario due to its ease of dissemination. The median incubation period for pulmonary anthrax is 4 days but ranges from 2 to 60 days have been reported. The initial symptoms of infection are non-specific with fever, malaise, non-productive cough, nausea and vomiting, confusion before progressing to respiratory failure and cardiovascular collapse. Chest X-ray (CXR) shows infiltrates, pleural effusion and a widened mediastinum due to lymphadenopathy and haemorrhagic mediastinitis.

Cutaneous exposure

Cutaneous anthrax accounts for greater than 95% of all human cases worldwide and is more often self-limiting than the other forms of anthrax infection.[14] Anthrax eschars are usually seen on the exposed unprotected areas of the body such as upper limbs, face and neck with incubation periods ranging from as little as 9 hours to 3 weeks, with the majority of individuals developing symptoms between 2 and 6 days. The infection starts as a papular lesion accompanied by marked oedema before progressing to the characteristic black eschar, which may take several weeks to fully develop and resolve. Large lesions may require skin grafting, and surgical intervention may be required due to scarring in areas such as the eyelid.

Gastrointestinal exposure

This usually follows ingestion of infected meat and presents with abdominal pain and bloody diarrhoea followed rapidly by cardiovascular collapse and death.

TREATMENT

Immediate severe sepsis management is the mainstay of treatment, including a multidrug therapy regime. Patients may not require airway and ventilator support initially but may progress to ventilatory failure as sepsis progresses.

ANTIDOTE TREATMENT

Ciprofloxacin 400 mg IV 12-hourly plus 1 or 2 of the following;

Penicillin (amoxicillin in pregnant patients and children), rifampicin, vancomycin, imipenem, clindamycin or clarithromycin according to sensitivities and convert to oral dosing as tolerated.

Treatment is prolonged and requires antibiotics for 60 days.

Passive immunisation: Consider immunoglobulins if available and appropriate.

BOTULINUM TOXIN

Botulism is caused by several neurotoxins (types A–G) produced by the anaerobic, Gram-positive bacillus, *Clostridium botulinum.* The botulinum toxins act at four different sites in the body: The neuromuscular junction, autonomic ganglia, and postganglionic parasympathetic and sympathetic nerve endings that release acetylcholine. The neurotoxin acts by direct, irreversible inhibition of receptors at the pre-synaptic surface

of neurons. This prevents the fusion of acetylcholine vesicles with the pre-synaptic membrane and the subsequent release of the acetylcholine.[15] The blockade is most evident clinically in the parasympathetic autonomic nervous system and at the neuromuscular junction. A biological warfare attack with botulinum toxin delivered by aerosol or as an inoculation would be expected to cause symptoms similar to those observed with food-borne botulism.

SYMPTOMS OF EXPOSURE

Patients typically present responsive, afebrile, with a rapidly descending flaccid paralysis with intact sensation. Early signs and symptoms include ptosis, generalised weakness and dizziness. Motor symptoms are usually present in the early stages; cranial nerves (mainly bulbar) are affected first with diplopia, dilated pupils, ptosis, dysphagia, dysphonia and dysarthria. This is followed by a symmetrical, descending flaccid paralysis of the extremities along with weakness of the respiratory muscles with potentially abrupt respiratory failure. Symptoms of parasympathetic inhibition may also be present.

The diagnosis is primarily clinical with confirmation with the mouse inoculation studies and immunoassays. Differential diagnoses include Guillain-Barré syndrome (Miller Fisher variant), myasthenia gravis and tick paralysis.

TREATMENT

Patients should have frequent assessment of gag, cough reflexes, inspiratory force and vital capacity as respiratory failure can be sudden. Mechanical ventilation and supportive therapy may be protracted with nosocomial infections requiring antibiotics (aminoglycosides and clindamycin are contraindicated due to their ability to increase blockade[16,17]).

ANTIDOTE/SPECIFIC TREATMENT

Early administration of the polyvalent antitoxin (types A, B and E) is essential to neutralise circulating toxin, and administration is advised where botulism is a differential diagnosis. Pregnant women, children and immunocompromised patients have been treated with the equine antitoxin safely.

Caution: Hypersensitivity reactions are a problem and may be severe, including anaphylaxis, and should be prepared for prior to administration. All patients should be skin tested for sensitivity.[18]

Contacts with infected patients should be observed closely and treated with antitoxin, a neutralising antibody and the pentavalent toxoid vaccine at the first signs of illness.

PLAGUE

Plague is a zoonotic disease caused by the Gram-negative, coccobacillus *Yersinia pestis* from the *enterobacter* species. Under natural conditions, humans become infected as a result of contact with rodents and their fleas causing bubonic and septicaemic plague. A proportion of bubonic plague patients develop pneumonia, which may then spread by droplets causing primary pneumonic plague. In a bioterrorist scenario, the plague bacillus is likely to be airborne, resulting in multiple casualties with pneumonic plague, which is highly contagious (transmissible).

SYMPTOMS OF EXPOSURE

Pneumonic plague: For primary (inhaled) pneumonic plague, the incubation period is short (2–3 days) and presents with high fever, headache, myalgia, chest pain and cough productive of bloody sputum. The pneumonia progresses rapidly to respiratory failure, circulatory collapse and multiorgan failure. Mortality in untreated patients is 100%. The diagnosis can be confirmed on blood cultures and with antibody testing. CXR shows evidence of bronchopneumonia.

Bubonic plague: Bubonic incubation period is 2–10 days. Onset is acute with high fevers, malaise and tender lymph nodes (buboes). Inguinal lymphadenitis predominates but cervical and axillary lymph nodes can also be affected. The nodes are tender, fluctuant and necrotic.

Septicaemic plague: The bubonic form may spontaneously progress to the septicaemic form with central nervous system (CNS) and respiratory involvement. Mortality in untreated patients in this group is 50% due to circulatory collapse, haemorrhage and peripheral thrombosis.

TREATMENT

Pneumonic plague is highly transmissible and isolation and universal precautions should be implemented. Immediate resuscitation treatment should follow standard sepsis management.

ANTIDOTE/SPECIFIC TREATMENT

Antibiotics for severe infection

Gentamicin 5 mg/kg IV OD
Streptomycin 1 g intramuscularly 12-hourly or
Ciprofloxacin 400 mg IV 12-hourly
add chloramphenicol 25 mg/kg four times per day if evidence of plague meningitis

Antibiotics: Mild infection
Ciprofloxacin 500 mg PO or
Doxycyline 100 mg PO 12-hourly
(Consider ofloxacin and levofloxacin if evidence of resistance to doxycycline.)

SMALL POX

Small pox is an acute viral illness caused by the variola virus, orthopoxvirus. An illness specific to humans, it was a cause of significant morbidity and mortality

in the developing world until recent times. The last recorded case of the natural disease was in Somalia in 1977, and the world was declared free of the disease in 1979 following a global immunisation campaign led by the World Health Organization. The virus now officially exists in only two laboratories in the world, in Russia and the United States. Although there was a human infection case in 1983 (laboratory worker), the appearance of human cases outside of these laboratories would signal the use of the virus as a biological weapon.

Transmission of the virus is by direct contact with an infected case and by the airborne route. The smallpox virus is very stable and can retain its infectivity for long periods outside the body, for example, on clothing.

The disease has been eradicated outside of the laboratory and, as a result, routine immunisation stopped in 1972. A related zoonotic virus, monkeypox, clinically resembles smallpox and has caused sporadic human disease in West and Central Africa.

CLINICAL FEATURES

There is a flu-like prodrome lasting 2–3 days with malaise, fever, rigors and headache. This is followed by the synchronously evolving maculopapular rash progressing to vesicles and then to pustules. The rash tends to involve the face and extremities rather than the trunk. The pustules eventually form crusts and drop off leaving depressed, de-pigmented scars. The patient is contagious from the appearance of the fever until the last scab has healed.

In unvaccinated individuals, the mortality rate is approximately 35%. In a subset of patients, haemorrhagic diathesis and disseminated intravascular coagulation (DIC) develop and has a poor prognosis.

Investigations, such as taking skin, vesicular fluid or pus samples for direct electron microscopy and agar gel immunoprecipitation confirms the diagnosis.

TREATMENT

Small pox is highly transmissible; isolation and universal precautions should be implemented. The mainstay of treatment is supportive and management of secondary sepsis.

ANTIDOTE/SPECIFIC TREATMENT

Active vaccination with the small pox vaccine (vaccinia) should be given within 4 days of exposure, especially in high-risk groups such as pregnancy, HIV infection, chemotherapy, immune disorders and eczema. Also a ring vaccination strategy should be considered as a method of containing any outbreak.[19]

RICIN

Ricin, a glycoprotein toxin extracted from the beans of the castor plant, is one of the most toxic biological agents known, and is of significance as a biological weapon due to its availably worldwide, its ease of production and its extreme pulmonary toxicity. The most notorious case of ricin being used as a weapon was against the Bulgarian broadcaster, Georgi Markov, in London in 1979 who was killed with a ricin-contaminated pellet injected into the back of his leg using a modified umbrella.[4]

The ricin toxin acts by altering the ribosomal mRNA processing and thus inhibiting protein synthesis in eukaryotic cells leading to cell death. The effects of ricin poisoning would depend upon the route, the amount of ricin exposure and the patient's premorbid condition. Ingestion and mastication of three to six castor beans is estimated to be a fatal dose in adults, although most cases of ingestion of the whole castor bean do not result in poisoning as the protective coating of the bean prevents absorption (providing the bean has not been chewed). In addition, ricin is not well absorbed through the GI tract. Inhalation or injection of ricin would result in more rapid onset and severity of toxicity for the equivalent dose.

CLINICAL FEATURES

The clinical picture of ricin toxicity depends on the route of exposure and much of the information is based on animal studies.

Ingestion: All recorded episodes of ingestion have followed a similar clinical picture of rapid onset nausea, vomiting, abdominal cramps and severe diarrhoea followed by cardiovascular collapse and death within 3–4 days.

Inhalation: In mice, the inhalation of ricin resulted in necrotising, suppurative airway lesions and interstitial pneumonia with perivascular and alveolar oedema seen as early as 3 hours post-exposure.

Investigations to confirm ricin toxicity include enzyme-linked immunosorbent assay (ELISA), immunohistology and serology. Other non-specific laboratory findings include: metabolic acidosis, deranged liver and renal function, haematuria and leucocytosis.

TREATMENT

Treatment is supportive, which may include respiratory support, fluids and seizure prevention.

ANTIDOTE/SPECIFIC TREATMENT

An antitoxin is currently under development.

RADIATION AND NUCLEAR HAZARDS

Radiological and nuclear hazards can be either intentional (e.g. 'dirty bomb') or accidental (e.g. a radioactive source has been abandoned at a waste dump/disused medical facility). In the case of intentional exposure, this can either be in the form of an explosive

device where the patient may suffer contaminated traumatic injuries, or a covert radioactive source left in a public place causing significant irradiation without causing any contamination.

The casualty type will depend upon the scenario and will include the following in isolation or combination:

External contamination
Internal contamination
Wound contamination
Irradiation
Combined injuries (irradiation and trauma).

TYPES OF RADIATION

There are four biologically significant types of ionising radiation that may be encountered, including those derived from a nuclear detonation:

Alpha particles: Charged helium nuclei (two protons and two neutrons) are relatively heavy with low penetrating power and are absorbed by the first 20 micrometres of exposed tissue. Alpha particles can therefore be shielded by paper, overalls and mask to prevent internal and wound contamination. However, following ingestion of alpha-emitting radioactive material by ingestion or inhalation, significant damage can occur to the sensitive tissues of the respiratory and GI tract. Ingestion of this type of radiation is associated with cellular damage rather than acute radiation syndrome (ARS).

Beta particles: Energetic electrons emitted from neutron-rich atomic nuclei. Beta particles are significantly smaller than alpha particles and can penetrate skin and cause damage to the epithelial basal stratum. Beta particles can be shielded by layers of plastic or a sheet of metal.

Gamma (high-energy photon) radiation: This radiation is high-energy electromagnetic radiation and is capable of creating ionisation. High-energy photons are highly penetrating and a large fraction may pass through the body without interaction. Dense materials, such as lead or concrete, are used to attenuate gamma radiation.

Neutrons: These are uncharged particles and are usually associated with the nuclear fission process. These particles are highly penetrating and cause significant damage to biological tissue.

Ionising radiation causes its effect by its interaction with DNA. At low levels, radiation causes damage to the DNA increasing the chance of mutation and cancer. At very high levels; that is, levels greater than two sieverts (approx 1000 × the annual background radiation dose in the United Kingdom or approx 100,000 CXR) radiation causes cell death. The most sensitive tissues are those that have the greatest turnover such as bone marrow and GI mucosa. Death following large radiation dose exposure is generally due to coagulopathy or infection. The failure of these systems due to radiation is called ARS.

ARS has been divided into four main phases:

1. An initial 'prodromal phase' occurring during the first few hours after exposure.
2. A 'latent phase', which decreases in time with increasing dose exposure.
3. The 'manifest illness' (clinical) phase involving haematological, GI and neurovascular systems.
4. Recovery or death.

The severity of the symptoms will increase and the duration of each phase will shorten with increasing acute radiation dose.

Diagnosis of ARS is made on a history of significant exposure to radiation, and the fall in circulating lymphocytes can be used as a crude biodosimetry tool to estimate the effective radiation dose received.

SYMPTOMS OF EXPOSURE

Prodromal phase: This phase is characterised by the rapid onset of nausea, vomiting, malaise, headache, and in severe cases, diarrhoea. This is thought to be due to serotonin and histamine release. These symptoms can resolve very quickly and the diagnosis of ARS can be overlooked.

Latent phase: The patient is relatively symptom free during this phase, and the length of this phase depends on the nature of the manifest illness.

Haematopoietic syndrome: the latent phase may vary between 2 and 6 weeks.

GI syndrome: this tends to be shorter, lasting a few days to a week.

Neurovascular syndrome: this is the shortest latent phase lasting only a few hours.

Manifest illness: The manifest illness phase presents with the clinical symptoms associated with the cell death of the major organ system exposed (i.e. bone marrow, GI tract and neurovascular systems). These sub-syndromes are dose dependent.

Haematopoietic: Bone marrow suppression resulting in pancytopaenia will result in:
Haemorrhage (thrombocytopaenia)
Immunosuppression followed by infection (leucopaenia)
Anaemia (reduced red cell count).

The changes in the peripheral blood profile may occur as early as 12 hours post-irradiation although the exact time sequence of depression of various cell lines will vary. The onset of clinical effects range from 10 days to 6–8 weeks post-exposure and death occurs from overwhelming infection and/or haemorrhage.

GI: The main symptoms encountered are nausea, vomiting, loss of appetite, abdominal pains and after a short latent period of a few days to a week, progress

to the characteristic severe fluid losses secondary to haemorrhage and diarrhoea. GI syndrome has a poor prognosis as it is almost always accompanied by bone marrow suppression. The mucosal damage of the GI tract allows the translocation of gut bacteria causing a bacteraemia, which is compounded by the accompanying immunosuppression. Survival is possible with aggressive sepsis and fluid management, and haemorrhage control.

Neurovascular: This syndrome occurs with high, acute doses of radiation and has a short latent phase varying from a few hours to 1–3 days. It presents with symptoms of dizziness, headache followed by a steadily decreasing level of consciousness with eventual coma and death. This rapid and invariably fatal deterioration is due to increased microvascular membrane permeability leading to cerebral oedema, hypotension and cerebrovascular insufficiency. Seizures may or may not occur and there may be little or no evidence of raised intracranial pressure. Due to the high doses of radiation required to cause this syndrome, individuals close enough to a nuclear detonation to be exposed to this dose would generally be located well within the 100% lethality radius for blast and thermal effects.[20]

Cutaneous: This encompasses effects from localised skin exposure through to effects from whole body irradiation. Damage to the skin can present in three ways:

Cutaneous syndrome from whole body irradiation

Local radiation due to close contact with gamma radiation

Beta burns.

Skin changes usually happen within a few hours of irradiation and consist of redness, itching followed by blistering and ulceration of the irradiated site. Large doses can cause permanent hair loss, damage to sebaceous and sweat glands, atrophy and fibrosis. Cutaneous changes are usually seen at radiation doses associated with both haematopoietic and GI syndromes.

TREATMENT

Treatment of any forms of irradiation exposure follows the <C>AaBC principle with sepsis management for neutropaenic patients, blood products such as cytokine (stimulation) therapy and transfusions and eventually cell stem transplant as clinically indicated. Survival from the haematopoietic syndrome will be based on early diagnosis, replacement therapy, infection prevention and bone marrow regeneration.

Acknowledgement

I would like to take this opportunity to acknowledge and thank Dr Steve Bland for his assistance and guidance on this chapter.

Pharmacokinetics, pharmacodynamics and drug monitoring in acute illness

Christine Chung

PHARMACOKINETICS

The basic terms used in pharmacokinetics (PK) include bioavailability (F), target (desired) plasma concentration (C_p), volume of distribution (V_d), clearance (Cl) and half-life ($t_{1/2}$).

Bioavailability is the fraction of the administered dose that reaches the systemic circulation[1] and is dependent on many variables including absorption (see later). The value of F for the intravenous (IV) route is usually 1 unless the drug in question is a prodrug (i.e. requires metabolism to its active form). For an oral dosage form, F would also be less than 1 in the majority of cases as a certain percentage of the drug can be lost at each stage of the journey from the gastrointestinal tract to its site of metabolism. For example, bioavailability of digoxin tablets is 0.63 and the liquid 0.75.[2] Therefore, strictly speaking, converting from an oral to an IV dose requires a 20%–30% reduction to provide an equivalent amount of drug. In practice, it is recommended that the dose is reduced by 25%. C_p is the desired plasma concentration.[1]

ABSORPTION

In order for a drug molecule to be absorbed, it is required to cross a membrane. Membranes are comprised of a phospholipid bilayer, with a hydrophilic exterior and a hydrophobic core. Fat-soluble drugs use passive diffusion to cross the membrane barrier. Extremely small water-soluble molecules gain entry through narrow aqueous membrane channels. The majority of water-soluble drugs travel by other mechanisms (e.g. via an active transport process facilitated by an energy source, i.e. adenosine triphosphate [ATP]).[3]

Unionised molecules pass freely through membranes; ionised molecules do not.

Therefore, lipid-soluble drugs, such as phenytoin, can be easily absorbed from the gastrointestinal tract whereas large, water-soluble and polar drugs, such as gentamicin, cannot (Fig. 89.1).

Enteral

The majority of drugs used in critical care are administered via the IV route. There are occasions, however, where an essential drug exists only in the oral form. How much is absorbed via the enteral route is governed by many factors such as:

- site of drug absorption in the gastrointestinal tract; that is, whether it can be accessed (e.g. small bowel obstruction) or if its absorptive capacity is compromised by hypoperfusion in septic shock, for example
- delayed gastric emptying may increase the absorption for drugs absorbed in the acidic environment of the stomach. Conversely, basic drugs usually absorbed in the small intestine may be reduced due to increased degradation in the stomach prior to delivery
- apical drug transporters (e.g. P-glycoprotein/multidrug resistance protein-1 that return drugs back to the intestinal lumen) limit bioavailability[4] but are also affected by systemic inflammatory conditions, such as sepsis, in an unpredictable manner
- whether the pH of the stomach is optimal (e.g. bioavailability of atazanavir is significantly reduced by agents used for stress ulcer prophylaxis. Proton pump inhibitors reduce atazanavir's solubility by raising the pH of the stomach.[5] Weak basic drugs, such as atazanavir, require a low pH for absorption)
- presence of enteral feed that may significantly reduce the efficacy of certain drugs (e.g. phenytoin is best administered in the middle of a 4-hour rest period from enteral feed)[6]
- presence of other drugs that may bind and reduce bioavailability if administered at the same time (e.g. ciprofloxacin and ferrous fumarate)[7]
- formulation of drug administered (e.g. liquid vs tablet)
- gut transit time (e.g. profuse diarrhoea may lead to reduced time for absorption and potentially therapeutic failure)
- gut integrity and perfusion (often reduced in the critically ill)
- extent of first-pass metabolism (see metabolism), which can significantly reduce the amount of drug reaching the systemic circulation or lead to drug toxicity if the liver is failing.[8]

Intramuscular and subcutaneous

The effects of drugs given via intramuscular (IM) or subcutaneous (SC) routes can be erratic and unpredictable

ABSTRACT

Pharmacokinetics (PK) describes a drug's journey through the body. It is the study of a drug's absorption, distribution, metabolism and excretion over time. Pharmacodynamics (PD) is the physiological effect of a drug on the body. The relationship between the two can be used to individualise dosing regimens by predicting how a drug will behave in a given patient.

Manufacturer's dosing ranges are often based on the PK-PD of a normal patient population. While there may be guidance on dosing in special populations (e.g. liver and renal failure) there is rarely advice on dosing in the critically ill.

The effect of critical illness on PK and PD is complex, variable and often unpredictable. Optimisation of treatment remains a therapeutic challenge with drugs that do not have measurable parameters to determine dosing. As a patient improves or deteriorates clinically, drug regimens require adjustment to maximise benefit while minimising adverse toxic effects. The aim of this chapter is to provide the reader with the basic principles of PK and PD to aid in their understanding of drug dosing in the intensive care unit patient.

depending on local blood flow to tissues, adipose and muscle mass. Muscle perfusion is often significantly reduced in patients with haemorrhagic shock making it an undesirable route of administration if rapid systemic effects are required; for example, anti-Factor Xa levels can be severely reduced in patients who are administered SC low-molecular-weight heparin that can predispose them to a venous thromboembolic events; SC oedema as a consequence of aggressive fluid resuscitation in sepsis can also reduce bioavailability of drugs administered via this route.

Local blood flow into adipose tissues is approximately 5% of cardiac output compared to approximately 70% for lean tissues.[9] Therefore obese patients have reduced peripheral perfusion and lower SC adipose tissue concentrations of drugs (see effects of obesity on PK).

Also, patients with a coagulopathy may be at increased risk of bleeding from the IM injection site.

Intravenous

The IV route is the most common form of drug administration in the intensive care unit (ICU) as it usually guarantees 100% bioavailability. However, several factors can still affect drug efficacy:

- drug–drug incompatibility when drugs of very different pHs are administered via the same IV line (e.g. propofol [near neutral pH] and atracurium [acidic pH])[10]
- drug–diluent incompatibility when a very acidic drug (e.g. amiodarone) is diluted with sodium chloride 0.9% (near neutral pH)[11] or a very basic drug (e.g. furosemide) is diluted with dextrose 5% (weakly acidic).[12]

The resultant salt-formed precipitates can lead to line occlusion, loss of drug efficacy and possible danger of systemic embolisation.

- Temperature and light can lead to degradation of, for example, parenteral nutrition,[13] or sodium nitroprusside to cyanide ions,[14] which explains the need for an opaque covering
- Too much diluent (e.g. amiodarone diluted beyond 0.6 mg/L comes out of solution, leading to loss of efficacy).[11]

DISTRIBUTION

Volume of distribution (V_d) is the theoretical volume of fluid into which the total drug administered would have to be diluted to produce the same concentration in plasma. It is unrelated to volume of the body or its fluid compartments but rather to its distribution.[15] V_d is increased by factors decreasing plasma drug concentration[1]:

- reduced protein binding (increased drug available for tissue binding)
- increased tissue binding
- increase in body fat (for fat-soluble drugs)
- oedema, ascites, effusion fluid (for water-soluble drugs)
- sepsis (endothelial damage and increased capillary permeability where fluid leaks into the interstitial space for water-soluble drugs)

- positive-pressure mechanical ventilation (for water-soluble drugs).

Decreased V_d results from the opposite of the above.

Calculation of V_d:

$$V_d = \frac{A}{C} \quad (89.1)$$

where V_d = apparent volume of distribution (L), A = total amount of drug in organ (mg), C = plasma concentration of drug (mg/L).

For example, gentamicin, a hydrophilic drug with minimal protein binding, has a low V_d similar to the extracellular fluid volume (0.25 L/kg).[16] In a septic, mechanically ventilated patient, the V_d of gentamicin increases as the effective extracellular volume increases, and a larger dose is required to obtain therapeutic levels.[17,18]

Phenytoin, a lipophilic drug, is 90% protein bound with a V_d similar to total body volume (0.65 L/kg).[1] Hypoalbuminaemia in critical illness increases the free, pharmacologically active fraction of phenytoin. This should be taken into account when interpreting phenytoin levels. The latter is normally reported as total serum concentrations that assume normal protein binding.

Morphine extensively binds to tissue and has a high V_d (4 L/kg).[19] Uraemia displaces drugs, such as morphine, from their tissue-binding sites, thereby increasing their plasma concentration while reducing the V_d, and this can lead to toxicity.

A drug with a high V_d will take considerable time to reach organ equilibration (approximately four to five times the half-life)[1]:

$$t_{1/2} = 0.693 \times V_d / Q \quad (89.2)$$

where Q = organ blood flow.

V_d is used to calculate the *loading dose* (L_d); that is, the dose required to rapidly achieve a desired therapeutic concentration (C_p) of drug:

$$L_d = \frac{V_d \times C_{pss}}{S \times F} \quad (89.3)$$

where C_{pss} = desired plasma concentration at steady state, S = salt factor of drug, F = bioavailability as a fraction.

For example, the L_d of phenytoin sodium for a 70-kg patient via the IV route would be:

$$L_d = \frac{0.65\ \text{L/kg} \times 70\ \text{kg} \times 15\ \text{mg/L}}{0.92 \times 1} = 741.8\ \text{mg}$$

The dose is usually rounded to the nearest easily measurable value (i.e. 750 mg in this case). (**NB:** This differs considerably from the standard 15 mg/kg dose often used in emergency practice where other prior antiepileptic medicines may have been given.)

Critically ill patients sometimes demonstrate subtherapeutic levels of phenytoin despite accounting for the unbound fraction due to hypoalbuminaemia. A possible explanation is that, as there is more of the free fraction available, more is available for metabolism and excretion. Alternatively, reduced hepatic function may lead to accumulation.[20]

METABOLISM

Metabolism can occur using either or both of the following[21]:

- *Phase I reactions* involve addition or exposure of a polar group, for example –OH. Oxidation or reduction reactions in liver microsomes are catalysed by cytochrome P-450 (CYP) enzymes and hydrolysis of esters to alcohol and carboxylic acid by esterases. Phase I metabolism can therefore be affected by reduced oxygenation delivery as a result of hypoperfusion.
- *Phase II reactions:* these increase a drug's hydrophilicity, promoting its renal or biliary excretion. Conjugation or synthesis takes place in the liver or the lung (e.g. glucuronidation, sulphation, acetylation, methylation). The kidney can excrete the drug metabolite by both filtration, and potentially, by active secretion, into the urine. Usually metabolites are less active than their parent compound, are more polar and more readily excreted in bile or urine.

Extensive first-pass metabolism refers to a drug that is significantly metabolised by the liver prior to becoming available to the systemic circulation.

ELIMINATION

CLEARANCE IN AN ORGAN

The liver and the kidney are the main organs involved in drug removal from the body. The liver can either transport a drug from the blood into the bile or metabolise it into another chemical entity (metabolite).

The rate (R) that the liver or kidney can remove drug from the body is usually proportional to the concentration of drug in the blood (C) (first-order kinetics). This proportionality constant is known as the drug's clearance (Cl) (Fig. 89.2).

Clearance is related to the half-life ($t_{1/2}$) of the drug.

Half-life is the time taken for the plasma drug concentration to fall by 50% and is dependent on V_d:

$$t_{1/2} = \frac{0.693 \times V_d}{Cl} \quad (89.4)$$

(Note: alpha $t_{1/2}$ refers to the distribution $t_{1/2}$; beta $t_{1/2}$ refers to the terminal elimination $t_{1/2}$.)

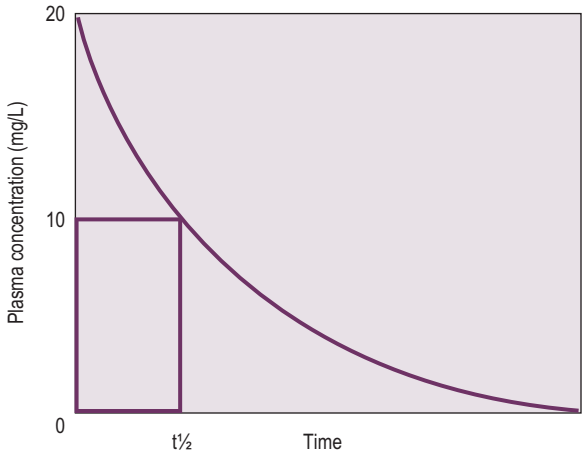

Figure 89.2 First-order elimination graph (plasma drug concentration vs time).

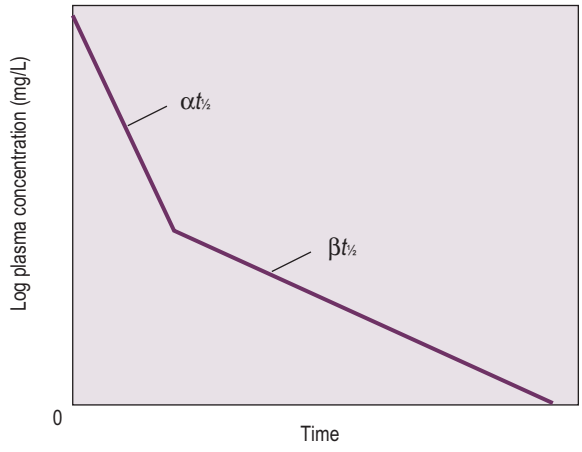

Figure 89.3 Graph of α $t_{1/2}$ and β $t_{1/2}$.

Fig. 89.3 shows the graph of alpha and beta $t_{1/2}$.

Any process that reduces V_d without affecting clearance will shorten $t_{1/2}$ and vice versa.

$t_{1/2}$ can also be expressed as an equation involving the elimination rate constant (fraction of total drug removed per unit time):

$$k = \frac{Cl}{V_d} \quad (89.5)$$

This assumes the drug follows first-order kinetics (i.e. Cl and V_d do not change with dose or concentration).

Caution must be taken with interpreting half-lives with respect to a drug's duration of action. Simply using terminal elimination $t_{1/2}$ to predict the length of drug effect may not be accurate. For example, lipophilic fentanyl exhibits a three-compartment PK model following an IV bolus[22]:

1. *Short-distribution phase:* high concentrations are achieved rapidly in well-perfused organs (brain, kidneys, lungs)
2. *Slower redistribution phase:* in other tissues, skeletal muscle, fat
3. *Elimination phase.*

The terminal $t_{1/2}$ is 3.7 hours, but the duration of action of fentanyl may vary due to 80% protein binding (see effects of hypoalbuminaemia above) and redistribution into body compartments. Hepatic impairment prolongs $t_{1/2}$.

Steady state

$t_{1/2}$ can be used to predict the time for a drug to reach 'steady state' (i.e. when the rate of drug administered equals the rate it is eliminated). Usually this is reached within 4 or 5 half-lives. Similarly, the time taken for a drug to be eliminated from the body would also be 4 to 5 half-lives. A drug that is 90% dependent on metabolic clearance compared with 10% renal will, in hepatic failure, be eliminated primarily by the renal route, but total clearance will still remain at 10% so accumulation will occur.

Hepatic drug clearance

Hepatic drug clearance is affected by blood flow to the liver and the fraction of drug removed as it passes through – that is, the extraction ratio (ER)[23]:

$$\mathrm{ER} = C_{in} - C_{out}/C_{in} \quad (89.6)$$

where C_{in} = concentration in; C_{out} = concentration out.

- *High-extraction drugs (>0.7); for example, morphine:* have significant first-pass metabolism and low oral bioavailability: There is a relative excess of the enzymes that metabolise a drug (i.e. a high intrinsic clearance) and a high proportion of the drug is removed by the liver before reaching the systemic circulation. The rate-limiting step is supply of the drug to the liver. Hepatic clearance therefore depends on hepatic blood flow, which is proportional to cardiac output, and is unaffected by changes in the amount of active enzyme (and therefore enzyme inhibition or enzyme induction) and changes in free fraction of the drug. In advanced sepsis the hepatic blood flow is reduced, but in hyperdynamic sepsis the hepatic perfusion may be spared as blood is diverted to vital organs (see section Renal Drug Clearance). Conversely, in cirrhosis, functional hepatocytes are bypassed when intrinsic clearance falls or portosystemic shunts form, both of which increase drug bioavailability.
- *Intermediate-extraction drugs PKs (0.3–0.7); for example, midazolam:* are more complex to predict. Drugs that fall into this category include those that are normally in the high ER group but alter in this respect when used in patients with hepatic dysfunction. Hepatic

dysfunction and reduced metabolism lead to accumulation of active drug. This is further enhanced if drug metabolites are also active.

- *Low-extraction drugs (<0.3); for example, lorazepam:* have negligible first-pass metabolism and high oral bioavailability: There is a relative deficit of enzymes that metabolise the drug (i.e. a low intrinsic clearance) and the rate-limiting step is enzymatic activity. Hepatic clearance is independent of hepatic blood flow but is influenced by enzyme inhibition or enzyme induction, other competing drugs and changes in free fraction of the drug (the form accessible to the enzyme). Reduced liver perfusion and a fall in ER do not significantly affect drug bioavailability.
- Hepatic dysfunction can reduce the effects of prodrugs that require metabolism to become active.

Box 89.1 lists high and low hepatic extraction drugs.

Zero-order metabolism Most drugs follow first-order PK (i.e. rate of metabolism correlates proportionally with plasma concentration). However, drugs such as phenytoin follow zero-order PK. In this situation metabolism reaches its peak as the enzyme system is saturated and relative clearance falls as plasma concentrations rise. The process is concentration-independent and so an increase in dose will produce a disproportionate rise in plasma levels. The rate of metabolism is constant regardless of the amount of drug present (Fig. 89.4).

Box 89.1 High, intermediate and low extraction ratio drugs

High ER	Intermediate	Low ER
Propranolol	Omeprazole	Lorazepam
Morphine	Codeine	Theophylline
Fentanyl	Amiodarone	Chlordiazepoxide
Propofol	Erythromycin	Phenytoin

ER, Extraction ratio.

Renal drug clearance[24]

Renal clearance of a drug or metabolite is influenced by glomerular filtration, tubular secretion and tubular reabsorption.

Glomerular filtration usually allows the passage of the free but not protein-bound drug into the renal tubules. Drugs that are not subject to tubular secretion or reabsorption therefore have a renal clearance that equals the glomerular filtration rate. Conversely, drugs that undergo active tubular secretion can have higher renal clearances up to a theoretical maximum of renal blood flow. Such drugs are usually charged and can have a high affinity for transporter sites, which allows the passage of even protein-bound drugs. Tubular secretion normally occurs in the proximal tubule and is assumed if clearance rate exceeds calculated filtration rate.

Tubular reabsorption involves the passive diffusion of drugs back across the tubule into the systemic circulation. Such drugs are usually lipophilic and uncharged. The extent of reabsorption is determined by the degree of ionisation and the concentration gradient determined by urine pH and flow rate, respectively. Reabsorption is assumed if the clearance rate is less than the calculated filtration rate (e.g. fluconazole reabsorption is considerable in normal renal function but reduced in acute kidney injury; therefore dose reduction is not necessary, and even an increase may be warranted).

Augmented renal clearance (ARC; C_rCl>/ = 130 mL/min/1.73 m^2) and hepatic clearance can occur as a result of increased cardiac output, and therefore

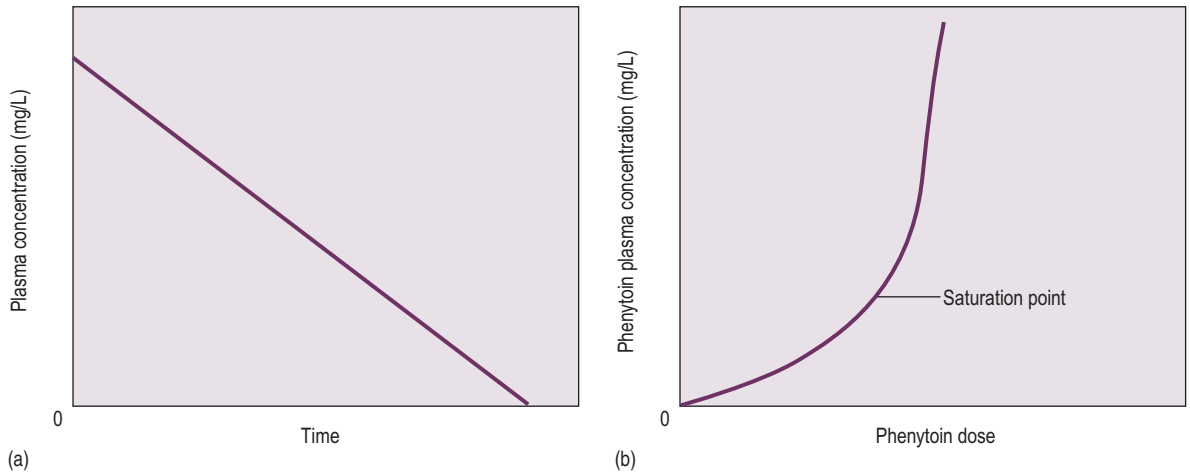

Figure 89.4 (a) Zero-order elimination. (b) Saturation point phenytoin pharmacokinetics.

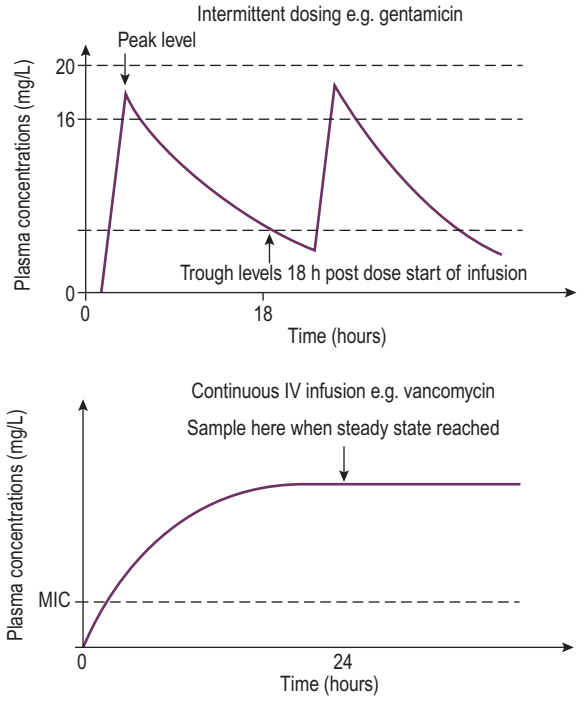

Figure 89.5 Graphs of intermittent drug dosing versus continuous infusion. *MIC*, Minimum inhibitory concentration.

enhanced perfusion to the kidneys and liver by fluid resuscitation, inotropic support or the hyperdynamic phase of sepsis. Unfortunately, this often results in increased metabolism and clearance of drugs. Young (<60 years old) trauma patients with low Sequential Organ Failure Assessment (SOFA) scores (</=4) were particularly susceptible to ARC.[25] Time-dependent antibiotics, which are dosed at intermittent intervals and which rely on the free (unbound) antimicrobial concentration time above the minimum inhibitory concentration (f*T* > MIC) for optimal bactericidal effect, will be at risk of therapeutic failure. The introduction of extended infusions of time-dependent antibiotics has attracted interest from the critical care community. Several studies appear to support its use[26,27] while others are not as convincing,[28,29] and further studies are required. Nevertheless, some ICUs have adopted the practice. The occupancy of an IV line for an extended period of time may be undesirable in a patient with limited IV access.

Fig. 89.5 shows graphs of intermittent dosing versus continuous infusion.

Biliary drug clearance[1,3]

Large molecules can be actively transported by hepatocytes and excreted in the bile either unchanged or conjugated. Conjugated molecules can undergo enterohepatic recirculation (i.e. be hydrolysed by gut bacteria, secreted into the ileum, reabsorbed into the systemic circulation and transported back to the liver via the portal vein). Phenytoin and loperamide are examples of drugs that undergo significant enterohepatic circulation. Biliary obstruction will increase levels of active drug and metabolites excreted via this route.

Other drug clearance routes

Atracurium is an example of a drug that is independent of hepatic or renal clearance and is eliminated via two non-oxidative routes to inactive metabolites[30]:

1. Hydrolysis by non-specific blood esterases in the blood
2. The main route, a non-enzymatic pathway (Hofmann elimination) occurring at physiological pH and body temperature; the elimination rate is increased at higher pH or temperatures and vice versa.

Pulmonary drug clearance[31]

CYP enzymes are also involved in pulmonary metabolism, though the levels of the latter are significantly lower than those in the liver. There is negligible evidence that they substantially contribute to systemic clearance but are first-line defence against pulmonary toxicity.

Pharmacokinetics–pharmacodynamics data on antimicrobials

The majority of PK-pharmacodynamics (PD) in the medical literature focus on the effects of critical illness on antibiotic penetration to their target sites. Plasma levels can be a guide but are not always accurate predictors of tissue interstitial fluid concentrations where most infections occur. Also, therapeutic drug monitoring (TDM) is only performed on antibiotics with a narrow therapeutic range. It is possible for a subtherapeutic drug dose to go unnoticed for some time before clinical manifestations and rising inflammatory markers suggest therapeutic failure. Multiple reviews and studies emphasise the inability to achieve PK-PD target concentrations due to the labile nature of the critically ill. Therefore, it is essential to optimise dosing from the outset and adjust where necessary.

The two main parameters mentioned in all PK-PD literature are the effects of critical illness on V_d and *Cl* of concentration-dependent, time-dependent antibiotics and those that are both.

Examples of such agents are detailed in the table below[32]:

CONCENTRATION DEPENDENT (C_{max}/MIC)	TIME DEPENDENT (f*T* > MIC)	CONCENTRATION AND TIME DEPENDENT ($AUC_{0-24\,h}$/MIC)
Gentamicin	Tazocin	Fluconazole
Amikacin	Meropenem	Linezolid
Daptomycin	Vancomycin	Ciprofloxacin

AUC, Area under the curve; C_{max}, peak concentration; *fT*, free (unbound) antimicrobial concentration; *MIC*, minimum inhibitory concentration.

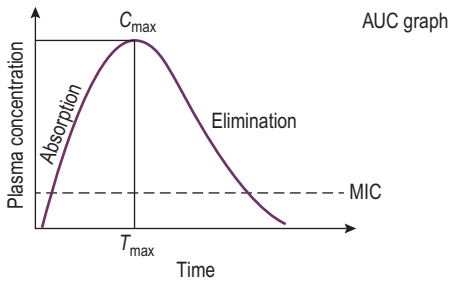

Figure 89.6 Area under the curve (AUC). *MIC*, Minimum inhibitory concentration.

A graph of plasma concentration of drug versus time (area under the curve) is shown in Fig. 89.6.

- C_{max} is the maximum plasma concentration achieved during the time course of the drug.
- T_{max} is the time taken to achieve C_{max}.
- $t_{1/2}$ is the time taken for the plasma level to fall by 50%.
- k is the elimination rate constant.

Concentration-dependent antibiotics are affected by changes in V_d. An increase in V_d will reduce their peak level, often resulting in therapeutic failure. Studies on critically ill septic patients often recommend a higher than the usual recommended dose to achieve PK target levels.

Time-dependent antibiotics are affected by changes in *Cl*. A reduced *Cl* will prolong the fT > MIC but may lead to unnecessarily high peaks and toxic effects.

PRACTICAL APPLICATIONS

REPEAT BOLUS VERSUS INFUSION

Drugs with relatively long half-lives and wide therapeutic indices can be administered by repeat bolus administration (e.g. cefuroxime); those with short half-lives and narrow therapeutic indices (e.g. catecholamines) should be administered in a more predictable and titratable manner by continuous infusion.

OFFSET TIMES

The half-life for some drugs depends on the duration of the infusion (e.g. fentanyl's half-life increases with the duration of continuous infusion). This is particularly evident for drugs with high distribution volumes and with bolus kinetics governed significantly by redistribution rather than clearance. For short infusions, the plasma half-life after the infusion will be less than the terminal elimination half-life. However, as the duration of infusion becomes sufficient to achieve steady state, the half-life upon stopping the infusion will increase until it equals the terminal elimination half-life.[33]

PHARMACOKINETICS–PHARMACODYNAMICS CHANGES IN ORGAN FAILURE

CIRCULATORY FAILURE

Circulatory failure diverts blood flow to essential organs, such as the heart and brain, at the expense of the peripheral tissues. This results in:

- increased levels of drug in the heart and brain
- decreased levels of drug in the peripheries
- reduced renal blood flow and shunting of blood from cortical to juxtamedullary nephrons; glomerular filtration rate (GFR) and tubular excretion fall, decreasing extraction of drugs and renally excreted metabolites
- reduced hepatic blood flow; liver function may be impaired, decreasing the clearance of both highly extracted drugs (reduced delivery to the liver) and poorly extracted drugs (reduced cellular metabolism).

Mechanical ventilation may cause further decline in hepatic perfusion by increasing intrathoracic pressure and therefore decreasing venous return.

The initial effect is a significant decrease in drug V_d and *Cl*. More profound effects are seen in drugs, such as sedatives, that undergo rapid distribution. Fluid and inotropic therapy may briefly alter these effects. In volume overload, there may be an increase in V_d of water-soluble drugs and a prolonged distribution $t_{1/2}$.

HEPATIC FAILURE

Drug dosing in hepatic failure is more difficult to predict compared with renal failure. Derangements in liver function tests do not usually serve as a strict guide for the extent of dose reduction compared with trends in creatinine clearance and other parameters used to estimate renal function.

Absorption

Bioavailability of lipid-soluble drugs is reduced in cholestasis where bile salts are used to enhance their absorption.

Distribution

Patients with ascites may require larger loading doses of water-soluble drugs due to increased V_d.

Hypoalbuminaemia, as a result of catabolism, sepsis, reduced protein intake and synthesis, leads to an increase in the free fraction of highly albumin-bound drugs (e.g. phenytoin). Total serum concentration may appear low or within range but lead to toxic effects if the pharmacologically active free fraction is unaccounted for. Conversely, increased concentrations of α_1-acid glycoprotein (an acute-phase glycoprotein often raised in sepsis), to which phenytoin is 20% bound, can decrease the free fraction.[20] Phenytoin therefore exhibits complex and sometimes unpredictable PK in the critically ill.

Metabolism

See extraction ratio (ER).

Elimination

Cholestasis can reduce elimination of active drug or their metabolites that undergo biliary excretion and enterohepatic circulation. Concomitant renal dysfunction as in hepatorenal syndrome may require a dose reduction of renally excreted drugs.

RENAL FAILURE

Absorption[18]

Uraemia has been linked to reduced gut integrity in animal studies.

Certain drugs used in, for example, chronic renal failure, such as phosphate binders, can reduce the enteral absorption of certain drugs (e.g. ciprofloxacin).

Distribution[18]

Significant fluid retention due to volume resuscitation or reduced diuresis increases the V_d and therefore the distribution $t_{1/2}$ of water-soluble drugs (e.g. gentamicin and beta lactams).

Reduced plasma protein binding of acidic drugs (e.g. amiodarone) can occur. Possible explanations include the displacement of acidic drugs from their albumin-binding sites by endogenous substances that accumulate in renal failure and compete for a position (see Metabolism below).

Plasma protein binding for basic drugs (e.g. epoprostenol) is not usually affected; however, certain interventions, such as haemodialysis, can raise levels of α_1-glycoprotein, an acute-phase protein to which basic drugs usually bind.[23]

Metabolism

Certain drugs that are mainly or completely eliminated from the body by non-renal mechanisms can still accumulate in renal dysfunction; that is, their metabolism is impaired by renal failure. Possible explanations for this include reduced activity of metabolic enzymes.[24]

An accumulation of metabolic products can reduce the protein binding of drugs. For example, uraemia displaces penicillins from their binding sites. The reduced affinity of plasma proteins for phenytoin increases the drug's free fraction. Therefore a non-uraemic patient with a normal free fraction of phenytoin of 0.1 and a total phenytoin level of 7 mg/L will have the same free phenytoin concentration as a uraemic patient with a free fraction of 0.2 and a total phenytoin level of 14 mg/L[1]:

(89.7)

$$C_{paj} = \frac{\text{total phenytoin level (mg/L)}}{0.9 \times (\text{albumin level/normal albumin level}) + 0.1}$$

where C_{padj} = adjusted phenytoin level (free phenytoin concentration), and normal albumin = 40 g/dL.

Elimination

Reduced renal clearance prolongs the terminal elimination $t_{1/2}$.

Renal failure can lead to toxicity if dose adjustments are not made to account for the accumulation of drugs and their active metabolites cleared primarily by the kidneys. Dose can either be reduced, for instance vancomycin (time-dependent bacterial kill), or their dosing intervals increased, for instance gentamicin (concentration-dependent kill). Renal failure usually affects glomerular function more than tubular function, so the excretion of aminoglycosides, which depend more on glomerular filtration, is affected more than that of penicillins, which are dependent on tubular function.

Serum creatinine is usually a poor guide to renal function in the critically ill because creatinine is:

- a by-product of muscle often reduced in critical illness, the elderly or low-weight patients
- influenced by diet (recent protein intake, which can often be insufficient due to variable absorption if administered via the gastrointestinal tract)
- increased or reduced by drugs or disease states without necessarily influencing GFR (e.g. trimethoprim inhibits the renal secretion of creatinine without reducing renal clearance)
- used to calculate C_rCl based on a normal population data of healthy individuals
- usually fluctuating in the critically ill
- a very late marker of renal dysfunction – the GFR has to fall by at least 50% before a significant rise in creatinine is seen; it is better to monitor levels for accumulation of renally cleared drugs (e.g. vancomycin) or electrolytes (e.g. potassium).

Renal replacement therapy drastically alters volumes and clearances of drugs. Effects vary with the mode of dialysis, the filter life, the type of membrane in use and the drugs in question.

RESPIRATORY FAILURE

Insufficient gaseous exchange can disrupt the normal acid-base balance and consequently affect protein binding and V_d. Mechanical ventilation increases intrathoracic pressure, reducing cardiac output, hepatic and renal perfusion. Therefore drugs with a high ER or those that are predominantly renally cleared may be at risk of accumulation. The V_d of water-soluble drugs (e.g. aminoglycosides) and the risk of a stress ulcer are also increased by mechanical ventilation.

EFFECT OF OBESITY ON PHARMACOKINETICS

Total body weight (TBW) is used to guide dosing of lipophilic drugs (e.g. phenytoin) which distribute extensively into adipose tissue. Hydrophilic drugs (e.g. aminoglycosides) have limited distribution into adipose and the increase in lean mass can account up to 40% of excess body weight; therefore adjusted body weight (ABW) is used. To calculate dosing (where IBW = ideal body weight):

$$\text{ABW} = \text{IBW} + 0.4\,(\text{ABW} - \text{IBW}) \quad (89.8)$$

where IBW = ideal body weight.

Decreased metabolism can occur due to hepatic dysfunction caused by fatty liver. An increase in renal clearance of hydrophilic drugs can occur due to the relative increase in kidney size and renal perfusion (Table 89.1).

THERAPEUTIC DRUG MONITORING

TDM is used to guide dosing of drugs with a narrow therapeutic range (i.e. a small therapeutic to toxic window), for example gentamicin, phenytoin and theophylline. Toxicity may be associated with peak drug concentrations (e.g. seizures and arrhythmias from theophylline) or trough concentrations (e.g. ototoxicity from aminoglycosides). Table 89.2 displays examples of drugs with a narrow therapeutic window.[36–38] Hospital laboratories measure total plasma drug concentration. However, it is the unbound drug fraction that is pharmacologically active (see phenytoin).

Regardless of measured concentration, evidence of clinical efficacy or toxicity must be monitored regularly (e.g. altering the maintenance dose of digoxin in a patient with a subtherapeutic level is unnecessary if the ventricular rate is adequately controlled). Conversely, it would be prudent to reload a previously stable epileptic patient presenting with seizures if the phenytoin level is subtherapeutic. If the phenytoin level is therapeutic and the patient's convulsions persist, a neurology review is required. This usually results in the addition of, or a change to, another agent.

Table 89.1 Effect of obesity on dosing and pharmacokinetics

DRUG	EFFECT OF OBESITY ON PK PARAMETER	RECOMMENDED DOSING BASED ON TBW ABW/LBW
Alfentanyl	No effect on V_d ↓Cl and ↑$\beta t_{1/2}$	LBW
Gentamicin	Negligible effect on V_d	ABW
Phenytoin	↑V_d	TBW

ABW, Adjusted body weight; *LBW*, lean body weight; *PK*, pharmacokinetics; *TBW*, total body weight.

SAMPLING TIME FOR DRUG LEVELS

The ideal sampling time for a drug level is either just prior to the next due dose, or once distribution into the tissue is known to be complete. If taken prior to distribution, the levels will be falsely interpreted as higher than expected for the dose administered. For example, an IV loading dose of phenytoin takes at least 2 hours for distribution.[1] A level taken prior to this time would not be a true reflection of the dose administered and subsequent dosing based on the result will be incorrect.

The majority of drug levels are obtained as a 'trough'; that is, a pre-dose level as suggested in the case of phenytoin. Usually, levels should not be taken prior to steady state being reached; for example, it would take approximately 10 days following a formulation change for phenytoin to reach steady state. However, if the patient's PK is suspected not to follow the normal population, as in the case of the critically ill, and if there is a risk of accumulation or underdosing before this time, it would be prudent to sample much sooner so the dose can be promptly optimised.

THE EFFECT OF DRUG INTERACTIONS ON PHARMACODYNAMICS

Multiple drug therapy in the critically ill increases their vulnerability to the effects of drug interactions. It could also be argued that ICU patients are monitored more closely than their counterparts on general wards so any adverse effects are likely to be identified sooner. Nevertheless, if a patient does not demonstrate a normal response to a drug treatment, it may be due to a drug interaction.

The consequence of drug interactions is naturally dependent on the drugs in question. Table 89.3

Table 89.2 Therapeutic drug monitoring in the critically ill

DRUG	THERAPEUTIC CONCENTRATION	TOXIC EFFECTS
Digoxin	1–2 µg/L	Central nervous system and visual disturbances, dizziness, nausea and vomiting[1]
Gentamicin	<1 mg/L (trough)	Nephrotoxicity, ototoxicity[14]
Amikacin	<5 mg/L (trough)	Nephrotoxicity, ototoxicity[33]
Vancomycin	20–25 mg/L (continuous infusion)	Nephrotoxicity, ototoxicity, reversible neutropenia[34]
Phenytoin	10–20 mg/L	Nystagmus, ataxia, dysarthria, cardiovascular collapse[5] Correct for hypoalbuminaemia Caution in uraemia
Theophylline	10–20 mg/L	Arrhythmias, nausea, vomiting[35]

Table 89.3 Examples of drug–drug interactions in intensive care unit patients

DRUG A	DRUG B	INTERACTION	COMMENT
Dexmedetomidine	Amiodarone	Enhanced bradycardic effects when administered with drugs of similar effects	Can result in bradycardia
Midazolam	Amiodarone	Amiodarone is an inhibitor of cytochrome P450 isoenzyme by which midazolam is metabolised	Results in ↑ levels of midazolam
Midazolam	Fluconazole	Fluconazole is an inhibitor of cytochrome P450 isoenzyme by which midazolam is metabolised	Results in ↑ levels of midazolam
Haloperidol	Amiodarone	Both drugs prolong QT interval	Results in ↑ risk of ventricular arrhythmias
Phenytoin	Hydrocortisone	Phenytoin is a potent enzyme inducer	↑ Hydrocortisone metabolism, ↓ therapeutic and adrenal suppressant effects
Amiodarone	Simvastatin	Amiodarone is an inhibitor of cytochrome P450 isoenzyme by which simvastatin is metabolised	↑ Risk of myopathy

provides a few examples of interactions involving commonly used drugs in the ICU.

SUMMARY

The relationship between PK and PD can be used to predict a dosing regimen for a patient. However, wide interpatient variability and the labile nature of the critically ill means careful consideration needs to be applied when formulating an appropriate dose. Best clinical judgement is required. Treatment may need to be individualised and titrated, especially when the outcome does not follow the normal expected clinical response. Levels should be taken to guide dosing in drugs with narrow therapeutic windows, but caution must be taken with interpretation, especially when the clinical symptoms do not correlate with apparently therapeutic readings. For drugs with 'silent' PDs, other markers of therapeutic effect should be sought; for example, a reduction in temperature, C-reactive protein (CRP) and white cell count (WCC) in anti-infectives with a wide therapeutic index. At the same time, the optimising dosage in the ICU should take into account the adverse effects of accumulation if higher doses are used beyond what is normally recommended.

In line with non-drug therapies in the ICU, drug kinetics and dynamics are never simple nor straightforward, and rarely does one dosage regimen fit all. For further advice, please consult your pharmacist.

Poisoning and drug intoxication

Brendan R Murfin, Nicholas A Barrett

Acute poisoning remains one of the commonest medical emergencies, accounting for 5%–10% of hospital medical admissions. Although in the majority of cases the drug ingestion is intentional, the in-hospital mortality remains low (<0.5%).[1] There are specific antidotes available for a small number of poisons and drugs; however, in most intoxication, supportive care is the main management strategy simply allowing time for the intoxicant to be metabolised and excreted. This chapter is a hands-on guide to the general management of acute poisoning and drug intoxication. For more detailed information than can be provided here, please refer to Internet-based information services (e.g. Toxbase in the United Kingdom – http://www.spib.axl.co.uk) or a local/regional/national telephone poisons information service (e.g. National Poisons Information Service in the United Kingdom – 0844 8920111).

Clinical toxicology remains an experience-based specialty; consequently, many recommendations are based on a small literature of case reports or on pharmacological principles rather than on controlled clinical studies. Additionally, a variety of position statements and clinical guidelines have been produced.

GENERAL PRINCIPLES

The general principles of the management of poisoned patients are diagnosis, based on history and clinical features, clinical examination, resuscitation, investigations and continued supportive care. Measures to reduce absorption or enhance elimination, and specific treatments, may be indicated in some cases. In the more acute situations, these actions often have to be carried out simultaneously.

AIRWAY, BREATHING AND CIRCULATION

In acutely poisoned patients who are unconscious, dentures should be removed and the oropharynx cleared of food and vomit. Tracheal intubation and airway protection is almost always necessary when a patient tolerates insertion of an oropharyngeal airway – perhaps the only exception to this rule is patients who have taken gamma hydroxybutyric acid (GHB) or gamma butyrolactone (GBL) where consciousness can be reliably predicted to return within 2–4 hours. Inadequate spontaneous ventilation, determined clinically or by arterial blood gas (ABG) analysis, obviously requires ventilatory support. Venous access should be established, and circulatory assessment must be made. Basic observations, including blood pressure, pulse rate, temperature, peripheral perfusion and urine output, should be recorded.

CLINICAL EXAMINATION

The clinical examination should include looking particularly for needle marks or evidence of previous self-harm. The Glasgow Coma Scale, designed for head-injured patients, is frequently used, but descriptive documentation of the degree of impaired consciousness is much more valuable. In an unconscious patient with no history available, the diagnosis depends upon excluding other common causes of coma (Box 90.1) and circumstantial evidence. Specific attention should be paid to the temperature, pupil size, blood pressure, respiratory and heart rate, as these may help to restrict the list of potential toxins (Box 90.2). Patients should also have a detailed neurological examination, preferably before the administration of any muscle relaxants, documenting the presence/absence of abnormal tone and reflexes, spontaneous/inducible clonus and/or ocular clonus.

INVESTIGATIONS

Important initial investigations include the following:

- *Urinalysis*: keep a sample for later analysis if required. Although rapid reaction dipsticks are available to screen for common drugs of abuse/recreational drugs by immunoassay, their routine use is not recommended owing to false-positive results, detection of metabolites rather than parent drug and/or cross-reactivity with prescription and over-the-counter medicines.
- *Basic biochemistry*: given the dependence on renal elimination for many drugs, acute or chronic renal insufficiency will alter patient management.

ABSTRACT

Poisoning and drug intoxications management remains an important part of emergency and critical care practice. Despite increasing diversity in pharmacopeia and toxin exposures, and limited antidotes, mortality remains low, due predominantly to the deployment of supportive therapies. Data are limited due to the difficulty inherent in developing controlled trials in this field. However, recent developments based on new data and expert work group review has improved our understanding and implementation of protocols and specific managements in many intoxications. These guidelines and commentaries have provided a framework for future review along with easily accessible web-based information available to clinicians at the bedside. This chapter provides a general systematic approach to emergency and supportive management and specific treatments of some common exposures.

KEYWORDS

Poisoning
intoxication
gastric decontamination
enhanced elimination
antidotes
extracorporeal treatments

Box 90.1 Common causes of coma other than acute poisoning

Intracranial bleeds
- Subarachnoid haemorrhage
- Subdural/extradural haematomas

Meningitis or encephalitis
Diabetic comas
Uraemic encephalopathy

Box 90.2 Clinical effects of the common poisons

Convulsions
Tricyclics, isoniazid, lithium, amphetamines, theophylline, carbon monoxide, phenothiazines, cocaine
Skin
Bullae: barbiturates, tricyclics
Sweating: salicylates, organophosphates, amphetamines, cocaine
Pupils
Constricted: opioids, organophosphates
Dilated: hypoxia, hypothermia, tricyclics, phenothiazines, anticholinergics
Temperature
Pyrexia: anticholinergics, tricyclics, salicylates, amphetamines, cocaine
Hypothermia: barbiturates, alcohol, opioids
Cardiac rhythm
Bradycardia: digoxin, beta blockers, organophosphates
Tachycardia: salicylates, theophylline, anticholinergics
Arrhythmias: digoxin, phenothiazines, tricyclics, anticholinergics

- *ABG analysis*: metabolic and/or respiratory acidosis is most common. Aspirin may initially cause a respiratory alkalosis, which in more significant ingestions can be followed by a metabolic acidosis or combined picture of a respiratory alkalosis/metabolic acidosis. Metabolic alkaloses are unusual.
- *Anion gap* = ($[Na^+]$ + $[K^+]$) − ($[Cl^-]$ + $[HCO_3^-]$): it is normally 10–14 mmol/L. Ethanol, methanol, ethylene glycol, metformin, cyanide, isoniazid or salicylates are the most frequent causes of a high anion gap metabolic acidosis in clinical toxicology.
- *Chest X-ray*: inhalation of gastric contents is not uncommon; X-ray changes consistent with aspiration should be sought.
- *Drug levels*: these are rarely helpful except in specific poisonings. They include paracetamol, salicylates, iron, digoxin and lithium. It is important to note that, for most poisonings, drug concentrations guide rather than dictate treatment.

GUT DECONTAMINATION

EMESIS

Ipecacuanha-induced emesis is not recommended.[2] It is ineffective at removing significant quantities of poisons from the stomach, limits the use of activated charcoal (AC) and can increase the risk of aspiration in those patients who have a reduced level of consciousness.

GASTRIC LAVAGE

The joint American and European toxicologists' statement suggests that gastric lavage removes an insignificant amount of poison, and may only propel unabsorbed poison into the small intestine; therefore it is no longer routinely recommended.[3] Additionally, it is important to note that gastric lavage often delays the use of AC, which is likely to have greater benefit with less unwanted effects or risks. Finally, gastric lavage may result in aspiration, particularly in obtunded patients.

ACTIVATED CHARCOAL

AC remains the first-line treatment for most acute poisonings.[4] Owing to its large surface area and porous structure it is highly effective at adsorbing many toxins with few exceptions. Exceptions include elemental metals, pesticides, alcohols including ethanol, strong acids and alkalis, and cyanide. It should be given to all patients who present within 1 hour of ingestion of a potentially toxic amount of a drug or drugs; it should not be given to those patients who are drowsy (unless they have a protected airway). International guidelines recommend administration of AC within 1 hour, so it is vital to rapidly identify those who present after a potentially serious overdose so that it can be given swiftly.[5] Longer than 1 hour it may still be effective if it follows an overdose of a substance that slows gastric emptying (e.g. opioids, anticholinergics, tricyclic antidepressants [TCA]), but this depends on the clinical condition of the patient and the amount ingested.

Repeated doses of AC can increase the elimination of some drugs by interrupting their entero-enteric and enterohepatic circulation.[6] Indications for repeated dose AC are shown in Box 90.3. It should be considered in patients who have ingested a modified or slow-release preparation or significant salicylate ingestions; in these situations multiple doses of AC are being administered to reduce absorption rather than enhance elimination. AC is given in 50 g doses for adults and 0.5–1 g/kg (max 50 g) for children. It commonly causes vomiting; therefore consider giving an antiemetic prior to administration. Multiple doses can be associated with constipation so patients should be given an appropriate laxative. Repeated doses are given at 4-hourly intervals until it is clinically indicated

Box 90.3 Drug intoxications where multiple-dose activated charcoal may be beneficial

Carbamazepine
Theophylline
Digoxin
Quinine
Phenobarbital
Dapsone
Sustained-release preparations

to stop. Obtunded patients with any airway compromise should have their airway secured prior to the use of AC.

WHOLE BOWEL IRRIGATION

This is a method of gut decontamination that is indicated for a limited number of poisons.[7] Whole bowel irrigation involves administration of non-absorbable polyethylene glycol solution to cause a liquid stool and reduce drug absorption by physically forcing contents rapidly through the gastrointestinal (GI) tract. Polyethylene glycol preparations are still occasionally used in surgical units for 'bowel preparation' prior to surgery. It may have a role in treating large ingestions of drugs that are not absorbed by AC. Indications include large ingestions of iron or lithium, ingestion of drug-filled packets/condoms ('body packers'), and large ingestions of sustained-release or enteric-coated drugs (e.g. theophylline or calcium channel blockers). Whole bowel irrigation may lead to significant shifts in fluid and electrolyte composition; hence they should only be considered in patients in whom careful monitoring can be instituted.

ENHANCING DRUG ELIMINATION

In the overwhelming majority of patients who present after an overdose, gut decontamination techniques and supportive care are all that is required. In a limited number of acute poisonings it may be necessary to consider methods to enhance elimination.

URINARY ALKALINISATION

Urinary alkalinisation (previously termed *forced alkaline diuresis*) may be useful for serious poisonings with:

- salicylates
- phenobarbital (with repeated dose AC)
- chlorpropamide
- methotrexate.

Intravenous 8.4% sodium bicarbonate is infused (the joint American and European toxicologists' statement recommends 225 mL over 1 hour in adults) to achieve a urine pH of approximately 7.5–8.5. The term 'urine alkalinisation' emphasises that urine pH manipulation is the prime objective of treatment; the terms 'forced alkaline diuresis' and 'alkaline diuresis' should be discontinued. According to international position statements it should be considered the treatment of choice for moderate to severe salicylate poisoning.[8] Care must be taken to ensure the potassium does not fall rapidly, and the urine pH should be measured every 30 minutes.

EXTRACORPOREAL TECHNIQUES

Numerous extracorporeal techniques are potentially available to aid drug removal in the poisoned patient, as well as correct metabolic and biochemical abnormalities as a result of the poisoning. These include plasmapheresis, haemodialysis, haemofiltration, haemodiafiltration and haemoperfusion. There are limited data on drug clearance by these techniques in the literature and it is not possible to extrapolate from one system to the other. At present, knowledge of the principles of the methods and the kinetics of the drug involved is relied upon.

An international multidisciplinary working party called EXTRIP (EXtracorporeal TReatments In Poisoning) is currently reviewing the role of extracorporeal elimination and have, to date, recommended extracorporeal treatments in severe salicylate, lithium, theophylline, carbamazepine, paracetamol, methanol and select phenytoin poisoning, and advise against the use in tricyclic and digoxin poisoning.[9–16]

Extracorporeal techniques should be considered for specific drugs, in patients with significant renal impairment (and therefore delayed clearance), when there are clinical features or markers of severe toxicity or there is failure to respond to full supportive care coupled with poisoning by a drug that can potentially be removed. The use of extracorporeal techniques is probably worthwhile only if total body clearance is increased by at least 30%. Although some drugs have improved clearance with haemodialysis rather than haemofiltration, ultimately using filtration rates of greater than 50–100 mL/kg per hour is likely to be as effective as other approaches and is widely available in intensive care units. Haemoperfusion is rarely available, but may have a role in hepatically cleared drug poisonings.

LIPID EMULSION THERAPY

Intravenous lipid emulsion (ILE) using 20% Intralipid is now recognised as an effective treatment for local-anaesthetic-induced cardiovascular collapse with a recommended initial dose of 1.5 mL/kg followed by an infusion of 15 mL/kg/h. If cardiovascular instability persists give a repeat bolus dose of 1.5 mL/kg every 5 minutes (two further doses) and increase the rate to 30 mL/kg/h.[17] The maximum cumulative dose is

12 mL/kg.[18] The mechanism for benefit is not entirely clear, but is thought to relate either to the formation of an enlarged lipid sink, which may help to remove the offending drug from target tissues, or as an energy substrate for a shocked myocardium. Based on the lipid sink hypothesis, ILE has been considered a potential treatment for severe acute poisoning from a range of lipophilic drugs. There are an increasing number of case reports where ILE has been used in other poisonings; however, its use is not routinely recommended at this time, outside local anaesthetic toxicity. There have been reports of recurrence of toxicity after initial dosing with ILE, as well as complications such as pancreatitis. For patients with ongoing cardiovascular instability or intractable arrhythmias, measures including extracorporeal support with veno-arterial extracorporeal membrane oxygenation or cardiac bypass should be considered. It is important to remember that the significant lipaemia following ILE therapy may rapidly render the oxygenator non-functional and an urgent oxygenator change may be required if this occurs.

CONTINUED SUPPORTIVE THERAPY

General supportive care of the unconscious unstable patient is required. This includes monitoring and provision of organ support when necessary, as well as fluid balance, correction of electrolytes, initiation of nutritional support and prompt treatment of nosocomial infection. Overall, despite the significant initial physiological disturbance, this group of patients usually has a good outcome.

SPECIFIC THERAPY OF SOME COMMON OR DIFFICULT OVERDOSES

This section emphasises only those features that may aid clinical diagnosis or prognosis. These are always intended to support those measures described under general principles.

AMPHETAMINES INCLUDING 'ECSTASY', 3,4-METHYLENEDIOXY-METHAMPHETAMINE (MDMA)

CLINICAL FEATURES

Symptoms of mild overdose include sweating, dry mouth and anxiety. Although the majority of ecstasy patients are dehydrated, a proportion have hyponatraemia from drinking water to excess; therefore it is important to measure serum sodium and electrolytes early in the patient's management. More severe features include tachycardia, hypertonia, hyperreflexia, hallucinations and hypertension. Supraventricular dysrhythmias may follow with coma, convulsions and the risk of haemorrhagic stroke. A hyperthermic syndrome may develop with hyperpyrexia leading to rhabdomyolysis, metabolic acidosis, acute renal failure, disseminated intravascular coagulation (DIC) and multiple organ failure. Where hyperthermia is suspected it is important that core body temperature (e.g. oesophageal, blood or rectal) is measured to accurately record the degree of hyperthermia.[19]

TREATMENT

AC should be considered up to 1 hour post-ingestion. Benzodiazepines are useful for agitated or psychotic patients and may have a central effect in reducing tachycardia, hypertension and hyperpyrexia. If benzodiazepines fail to control hypertension, other classes of antihypertensives should be started, such as alpha blockers or direct vasodilators. Beta-blockers, even specific ones, should not be used due to the risk of unopposed alpha stimulation and subsequent hypertension or coronary vasospasm developing. In a recent review, this occurred in approximately 1 in 200 patients and although there is no evidence to support this, it may be worth considering drugs with alpha antagonism or mixed alpha/beta antagonism such as labetolol.[20] It should be noted that most patients are fluid-depleted rather than fluid-overloaded, and measurement of sodium concentrations should be undertaken early in fluid resuscitation. Hypertonic saline may rarely need to be considered in severe hyponatraemia, particularly if seizure activity is present. Hyperthermia should be treated in the standard manner, including administration of cold (4°C) IV fluids, general cooling measures and benzodiazepines. For patients whose temperature remains elevated (particularly above 39°C), consider PO/NG (oral/nasogastric) cyproheptadine (a $5HT_{2A}$ antagonist) – the initial dose is 12 mg followed by 2 mg every 2 hours until temperature and other symptoms have settled. Benzodiazepines and cyproheptadine should also be used in those patients with evidence of moderate/severe serotonin toxicity.[21] Additional methods for cooling, such as external and internal cooling devices or those used for maintenance of body temperature post-cardiac arrest, can be considered for rapidly reducing body temperature.

BENZODIAZEPINES

CLINICAL FEATURES

Overdose is common, but clinical features are not usually severe unless complicated by other central nervous system (CNS) depressant drugs (such as alcohol), pre-existing disease or the extremes of age. Toxicity commonly produces drowsiness, dysarthria, ataxia and nystagmus. Paradoxical agitation and confusion can occur less commonly.

TREATMENT

AC can be given if patients present within 1 hour of ingestion, yet supportive treatment is usually all that is required. Flumazenil is a specific antagonist that is not licensed for use in poisoning and may be dangerous

due to the risk of significant cardiovascular (ventricular tachycardia) and neurological (status epilepticus) toxicity, as well as precipitating withdrawal in benzodiazepine-dependent patients.[22] Its use is therefore not recommended.

BETA BLOCKERS

CLINICAL FEATURES

There is a wide variation in the individual response to beta-blocker overdose. Those with cardiac disease are more at risk of complications. Hypotension and bradycardia predominate and are often refractory to standard resuscitation measures. The degree of heart block can range from a prolonged PR interval through to complete heart block and asystole. Cardiogenic shock and pulmonary oedema are not uncommon.[23]

TREATMENT

AC should be considered up to 1 hour post-ingestion and multiple-dose charcoal in patients who have ingested sustained-release preparations. There is limited evidence to support the use of atropine, although it is commonly used in patients who have bradycardia and hypotension. If symptomatic treatment with IV fluids for hypotension fails, glucagon (up to 10 mg IV as an initial bolus) is the next step. Further boluses and/or an infusion may be beneficial in addition to the initial bolus. Further options include hyperinsulinaemic–euglycaemic treatment, as described in the calcium channel blocker section, is indicated. Inotropes/vasopressors and cardiac pacing (higher-voltage capture may be required) can be considered and based on the patient's clinical condition. Other measures including extracorporeal support with veno-arterial extracorporeal membrane oxygenation or cardiac bypass should be considered if the simpler methods are not able to stabilise the patient.[24]

BUTYROPHENONES (INCLUDING HALOPERIDOL)

CLINICAL FEATURES

Drowsiness and extrapyramidal effects are most common. Rarely hypotension, QT prolongation, arrhythmias and convulsions develop. Serious toxicity is uncommon.

TREATMENT

AC should be considered up to 1 hour post-ingestion, otherwise treatment is supportive. Extrapyramidal symptoms can be treated with procyclidine (5–10 mg IV/intramuscularly in adults) or diazepam (10–20 mg in adults). IV lipid emulsion therapy has been reported as a successful strategy in one case report, and although it cannot be recommended for routine use, it may be an option to consider in the event of life-threatening overdose.

CALCIUM CHANNEL BLOCKERS

CLINICAL FEATURES

The cardiac effects of these drugs predominate in overdose, particularly hypotension and atrioventricular block, although reflex tachycardia occurs with nifedipine. Hypotension occurs owing to peripheral vasodilatation and negative inotropy. The therapeutic selectivity of actions is not typically seen in overdose. Severe toxicity may occur in patients who initially appear well, when sustained-release preparations have been ingested.

TREATMENT

AC should be considered up to 1 hour post-ingestion and multiple-dose charcoal in patients who have ingested sustained-release preparations. Treatment remains supportive; however, IV calcium chloride (10 mL of 10% solution) is often given in patients who remain hypotensive despite fluid administration. Further boluses and/or an infusion should be administered as guided by the clinical response. If calcium gluconate is used then administer 30 mL of 10% solution (it has one-third the ionised calcium compared with calcium chloride, and therefore doses should be increased threefold where calcium gluconate is used). In those patients requiring multiple doses and/or an infusion, monitor the serum calcium concentration to ensure it remains below 3 mmol/L. Atropine is often used for bradycardia, and occasionally cardiac pacing may be necessary. In those with persistent hypotension not responding to IV fluids and calcium, the next step, hyperinsulinaemic–euglycaemic therapy, is indicated.[25] An initial bolus of 1 unit/kg of short-acting insulin should be administered with 25–50 mL of 50% dextrose, followed by an infusion of 0.5–2 units/kg/h short-acting insulin; higher doses may be required in severely compromised patients. Careful monitoring of blood glucose and serum potassium should be undertaken, with replacement as necessary. There is anecdotal evidence that increasing glucose requirements suggest that the cardiovascular toxicity is starting to diminish. For patients with ongoing cardiovascular instability or intractable arrhythmias, measures including extracorporeal support with veno-arterial extracorporeal membrane oxygenation or cardiac bypass should be considered.[24]

CARBAMAZEPINE

Absorption is slow and unpredictable; moreover, maximum serum concentrations may not be achieved until 72 hours after ingestion. Carbamazepine undergoes enterohepatic recirculation leading to a prolonged overall half-life and is metabolised to an active metabolite.

CLINICAL FEATURES

Nystagmus, ataxia, tremor and fits are common; however, in severe overdose, fluctuating coma and

severe tachycardia or bradycardia may occur. Plasma concentrations of carbamazepine and the active metabolite can be measured, although they do not correlate well with toxicity. Life-threatening toxicity typically occurs with plasma concentrations greater than 40 mg/L (170 nmol/L).

TREATMENT

Multiple-dose AC is indicated in large ingestions or symptomatic patients, and may help elimination even if initiated several hours after the overdose. Further measures are based on the clinical course. Currently intermittent haemodialysis (IHD) is recommended in severe poisoning with intermittent haemoperfusion (IPF) and continuous renal replacement considered acceptable if IHD is not available.[12]

CARBON MONOXIDE

Haldane first described symptoms of carbon monoxide (CO) toxicity in 1919 and the mechanisms of toxicity remain unclear. Smokers may have up to 10% of their haemoglobin bound to CO (i.e. carboxyhaemoglobin [COHb]), without deleterious effects. Whereas coma and/or COHb levels greater than 40% always indicate serious poisoning, delayed deterioration can occur in their absence. Affinity of CO for haemoglobin is approximately 240 times that of oxygen.

CLINICAL FEATURES

Neurological signs vary from mild confusion through to seizures and coma. A history of loss of consciousness should always be sought and may be the only indicator of significant poisoning. ST segment changes may be present on electrocardiogram (ECG). In the absence of respiratory depression or aspiration, PaO_2 will be normal. It is essential that SaO_2 is measured directly by a co-oximeter, and not calculated. Cherry-pink skin is seen only in textbooks; cyanosis is far more common.

TREATMENT

After basic resuscitative measures, high-flow oxygen (up to 100% if possible) should be administered and continued until the COHb level is less than 5%. This sometimes takes up to 24 hours. Hyperbaric oxygen (HBO), although often used, remains controversial. There have been eight randomised controlled trials of HBO versus normobaric oxygen. Unfortunately, many of these are of poor quality, and it is not possible to show any statistical benefit of HBO in reducing neurological sequelae at 1 month.[26] Considering the frequently encountered logistical difficulties in transferring an unconscious patient to an HBO centre, it cannot be routinely recommended based on the data currently available.

CHLOROQUINE

CLINICAL FEATURES

Hypotension, hypokalaemia, convulsions, ventricular arrhythmias and sudden cardiac arrest may result from severe poisoning. As little as 2 g of chloroquine have been reported to be fatal in adults. Symptoms typically tend to occur very early following ingestion, and normally within 3 hours of ingestion.

TREATMENT

AC should be considered up to 1 hour post-ingestion. In patients who have ingested potentially significant amounts of chloroquine or who have features of significant poisoning, then high-dose diazepam (2 mg/kg over 30 minutes) with inotropic and ventilator support should be considered.[27] Hypokalaemia is common and may be protective in the early stage. Hypokalaemia stems from redistribution into cells, rather than an absolute reduction in potassium. Hypokalaemia is therefore self-correcting and consequently aggressive potassium replacement is not recommended.

COCAINE

CLINICAL FEATURES

The clinical features of acute cocaine toxicity are similar to those seen in the amphetamine toxicity. There is the additional risk of cocaine-related vasospasm, which can lead to ischaemia in any vascular bed, but is of particular significance from a cardiac and cerebral perspective. Cocaine-related myocardial ischaemia is due primarily to coronary artery vasospasm; additional mechanisms included increased myocardial oxygen demand due to increased heart rate, decreased vasodilators (nitric oxide), increased vasoconstrictors (endothelin) and increased platelet aggregation.[28]

TREATMENT

The treatment of the common unwanted effects related to cocaine are the same as those seen with amphetamines. In terms of myocardial ischaemia, there are some differences between the management of this compared with classical atherosclerotic-related ischaemia. Patients should be treated with oxygen and aspirin; low-molecular-weight heparin and glycoprotein IIb/IIIa inhibitors should not be routinely used due to the increased risk of cerebral haemorrhage in significant hypertension. Vasodilators (e.g. S/L, buccal or IV nitrates) should be given early in an attempt to reverse coronary artery vasospasm, although care should be taken if there is a significant tachycardia due to the risk of a reflex tachycardia leading to an increased heart rate. Benzodiazepines should be administered to reduce sympathetic nervous system stimulation, thereby reducing myocardial oxygen demand by reducing the heart rate, as well as potentially causing coronary artery

vasodilatation through peripheral cardiac benzodiazepine receptors. Beta blockers are contraindicated as they can lead to unopposed alpha stimulation leading to worsening hypertension; in addition they can worsen cocaine-related coronary artery vasospasm. Other measures in those who fail to respond include other vasodilators (e.g. calcium channel blockers, alpha blockers) and/or primary angiography and angioplasty/intraluminal drug treatment. For patients with ongoing cardiovascular instability or intractable arrhythmias, measures including extracorporeal support with veno-arterial extracorporeal membrane oxygenation or cardiac bypass should be considered.[24]

CYANIDE

CLINICAL FEATURES

Severe toxicity is rapidly fatal; however, features include coma, respiratory depression, hypotension and metabolic acidosis. More moderate features include brief loss of consciousness, convulsions and vomiting. Rescuers must ensure that they do not get contaminated themselves. Expert advice is usually required in the management of these patients owing to the risk of significant toxicity.

TREATMENT

Inhaled amyl nitrate and 100% oxygen may well have been given at the scene, since it is present in 'cyanide antidote kits'. Following this there are a number of options:

1. Pre-hospital hydroxycobalamin 70 mg/kg or 5 g IV over 15 minutes.
2. In-hospital management of moderate to severe poisoning may require a second dose of 5 g hydroxycobalamin. The ARC suggest a third dose if required.
3. In severe poisoning the addition of sodium thiosulphate 12.5 g at 1.25 g/min is recommended. If signs of poisoning continue, half the original dose may be repeated.[29]
4. Patients with a metabolic acidosis should be given sodium bicarbonate.

DIGOXIN

CLINICAL FEATURES

Toxicity may result from ingestion of as little as 2 mg and lethal doses of >10 mg in adults and >4 mg in children. More commonly toxicity results from taking too high a daily dose and/or a reduction in renal elimination. Any cardiac arrhythmia may occur and adverse effects may be delayed for some hours. Severe poisoning can produce hyperkalaemia and hypotension.

TREATMENT

AC should be considered up to 1 hour post-ingestion and multiple-dose charcoal may be effective by interrupting enterohepatic recirculation of the drug. A digoxin serum level may be helpful although it does not equate to the total body burden. Patients with hyperkalaemia should not be administered calcium gluconate (increased risk of cardiac toxicity); initial management is insulin–dextrose therapy. Those patients with persistent hyperkalaemia (>6.0 to 6.5 mmol/L), along with brady- or tachyarrhythmias associated with hypotension, should be treated with digoxin-specific antibody fragments.[30] Other treatments, particularly where digoxin-specific antibody fragments are not available, may be indicated, but expert advice should be sought in these situations. For patients with ongoing cardiogenic shock or intractable arrhythmias, measures including extracorporeal support with veno-arterial extracorporeal membrane oxygenation or cardiac bypass should be considered.

GAMMA HYDROXYBUTYRIC ACID AND GAMMA BUTYROLACTONE

CLINICAL FEATURES

In moderate to high ingestion, coma, convulsions, bradycardia, hypotension and severe respiratory depression can be seen, and other CNS depressant drugs potentiate the effects. Most patients who present to hospital merely require supportive care, and even those who present in coma are often awake within 2–4 hours; very few require intensive care.[31]

TREATMENT

Management is largely supportive; intubation is often not indicated even in those with significantly reduced levels of consciousness as airways reflexes tend to be maintained.[31] Computed tomography scanning should be considered in those with evidence of head injury, focal neurological signs or failure to wake after 1–2 hours. It is important before discharging a patient to determine whether they are potentially dependent users (daily use) and therefore at risk of withdrawal. Expert advice on the management of these patients should be sought.

IRON

CLINICAL FEATURES

Iron poisoning classically has four phases:

- *phase 1:* initial GI symptoms secondary to direct corrosive action on gastric mucosa
- *phase 2:* latent asymptomatic phase
- *phase 3:* systemic iron toxicity
- *phase 4:* GI strictures several weeks after initial ingestion due to the initial direct GI corrosive effects.

The duration of phases 1 and 2 is dependent on the dose of iron ingested; some patients in very large ingestions may progress straight to a combined phase

1/3 presentation. Serum iron concentration is helpful in patient management.

TREATMENT

In those patients who present with features of severe iron poisoning, deferoxamine (also known as desferrioxamine mesilate) should be commenced at an initial rate of 15 mg/kg/h. The maximum licensed dose is 80 mg/kg/day; however, these patients may require more prolonged treatment and appropriate advice should be sought. For those presenting within 6 hours without severe symptoms, the management can be guided by a serum iron concentration 4–6 hours after ingestion (<55 µmol/L does not require treatment, >90 µmol/L treatment is recommended, 55–90 µmol/L treatment may be required depending on whether the concentration is not falling and/or the clinical condition of the patient). For those presenting more than 6 hours after presentation without severe features, the serum iron concentration is not as helpful in determining the need for treatment; expert advice should be sought for these patients.

ISONIAZID

CLINICAL FEATURES

Severe toxicity is characterised by coma, respiratory depression, hypotension and convulsions resistant to conventional treatments, and may result from doses greater than 80 mg/kg. Protracted convulsions can cause rhabdomyolysis and acute renal failure.

TREATMENT

AC should be considered for large ingestions seen within 1 hour. Management of convulsions is initially benzodiazepines (IV 10–20 mg diazepam, or IV 4 mg lorazepam); those who fail to respond should be treated with 1 g of pyridoxine per gram of isoniazid ingested to a maximum of 5 g. Barbiturates, such as thiopentone, should be used as second line therapy for patients with seizure activity, which does not respond to benzodiazepines. Phenytoin should not be administered, as it is ineffective and isoniazid inhibits the metabolism of phenytoin.

LITHIUM

CLINICAL FEATURES

There are two types of overdose: acute in lithium in naïve individuals/those on treatment, and chronic in those on long-term lithium treatment. For the latter this may be secondary to an intentional overdose or due to other factors such as dehydration or use of interacting drugs (e.g. non-steroidal anti-inflammatory drugs [NSAIDs], angiotensin-converting-enzyme [ACE]-inhibitors, thiazide diuretics). Symptoms of toxicity can be divided as follows:

- *mild:* nausea, vomiting, fine tremor, polyuria, weakness
- *moderate:* confusion, urinary and faecal incontinence, myoclonic twitches/jerks, hypernatraemia, hyperreflexia
- *severe:* coma, renal failure, convulsions, cardiac arrhythmias.

TREATMENT

Lithium concentrations should be measured on arrival in chronic cases and then repeated every 4–6 hours; for acute overdoses, lithium concentrations should be measured 6 hours after ingestion and then every 4–6 hours. Patients should be adequately rehydrated, which may help with any renal impairment. Whole bowel irrigation (see above) should be considered in those who have ingested a potentially toxic amount of lithium. Extracorporeal elimination should be considered in those who have either severe features of lithium toxicity, or a serum lithium concentration of greater than 7.5 mmol/L in acute overdoses or greater than 4 mmol/L in chronic-related toxicity. For patients with ongoing cardiovascular instability or intractable life-threatening arrhythmias, measures including extracorporeal support with veno-arterial extracorporeal membrane oxygenation or cardiac bypass should be considered.[24] Seizure activity should be treated with benzodiazepines (first line) or barbiturates (second line). Phenytoin should not be used for seizure control.

METHANOL AND ETHYLENE GLYCOL

CLINICAL FEATURES

Methanol and ethylene glycol are relatively non-toxic themselves, but their ingestion is a medical emergency because of their metabolism (following a latent period of 12–18 hours) to formic acid and glycolic acid, respectively. These toxic metabolites account for the metabolic acidosis, ocular toxicity, renal failure and mortality that are occasionally seen. Mild features include dizziness, drowsiness and abdominal pain. When treatment is delayed, metabolic acidosis develops with drowsiness, coma and convulsions. The osmolal gap initially is elevated but then falls as the methanol or ethylene glycol is metabolised; the anion gap increases as the toxic metabolites build up.

TREATMENT

AC does not adsorb either methanol or ethylene glycol. The metabolic acidosis should be treated with sodium bicarbonate and the serum electrolytes measured. Ethanol prevents formation of the toxic metabolites and previously it has been the most established treatment; its dosing is complex and it requires 1- to 2-hourly blood ethanol measurement and adjustment of the treatment. Additionally, it can cause significant

CNS depression, necessitating critical care admission. Fomepizole (4-methypyrazole) has now become the antidote of choice; it is a twice-daily weight-based infusion without the need for specific monitoring and is not associated with neurological depression.[32] The initial dose is 15 mg/kg over 30 minutes, followed by a twice-daily infusion of 10 mg/kg for the next four doses and then increased to 15 mg/kg per treatment dose until treatment is no longer required. Ongoing management after initial loading dose often requires the involvement of clinical/medical toxicology services to facilitate ethylene glycol/methanol concentration measurement and interpretation of the results. The EXTRIP work group recommends concurrent extracorporeal treatment for severe methanol poisoning defined by the presence of coma, seizures, new vision deficits, metabolic acidosis pH less than 7.15, persistent metabolic acidosis despite adequate supportive measures and antidotes, a serum anion gap greater than 24 mmol/L or serum methanol levels greater than (1) 700 mg/L (21.8 mmol/L) in the context of fomepizole therapy; (2) greater than 600 mg/L (18.7 mmol/L) in the context of ethanol treatment; and (3) 500 mg/L (15.6 mmol/L) in the absence of alcohol dehydrogenase blocker.[33] It is important to remember with both ethanol and fomepizole that, should extracorporeal treatment be required, not only will the toxic alcohol be removed, but so too will the antidote; modifications to treatment regimens will be required.

NON-STEROIDAL ANTI-INFLAMMATORY DRUGS

CLINICAL FEATURES

NSAIDs are commonly ingested in an overdose; symptoms tend to be mild and consist with GI symptoms. GI haemorrhage is not commonly reported in an acute overdose of NSAIDs (apart from secondary to Mallory–Weiss tears). Convulsions can occur, but are usually associated with mefenamic acid (up to 10%–15% of patients). Large ingestions of NSAIDs can be associated with metabolic acidosis and/or renal impairment[34] and rarely hepatocellular injury.[35] Patients who do not develop symptoms within 4 hours are unlikely to experience delayed toxicity.

TREATMENT

AC can be given for large ingestions that are seen within 1 hour of the overdose. Convulsions should be treated with a benzodiazepine. Although there is no indication for routine use, those patients with symptoms of GI irritation can be treated with a short course of an oral proton pump inhibitor. Metabolic acidosis should be treated with sodium bicarbonate and other measures as indicated. Supportive care and appropriate investigation are required for patients with renal impairment.

OPIOIDS

CLINICAL FEATURES

Overdose is characterised by pinpoint pupils, drowsiness, shallow breathing and ultimately respiratory failure.

TREATMENT

AC may be effective for oral ingestions; otherwise, treatment is supportive. Naloxone 100–200 µg boluses should be given IV and increased as titrated to clinical response. In patients who fail to respond to 2 mg, alternative diagnoses should be considered. Those who respond may require repeat doses, particularly where a long-acting or sustained/modified release preparation has been ingested; an infusion of naloxone may be required in these patients. Intubation and mechanical ventilation are required if respiratory failure is not rapidly reversed by naloxone.

PARACETAMOL

There is increased metabolism of paracetamol to its toxic metabolite, *N*-acetyl-*p*-benzoquinonimine (NAPQI) as normal conjugation pathways are exceeded. This toxic metabolite irreversibly binds to hepatocytes leading to cell death and release of inflammatory and cytotoxic mediators and further hepatocyte death. The antidote for paracetamol poisoning is *N*-acetylcysteine (NAC). Recent changes the treatment guidelines for paracetamol poisoning in the United Kingdom removed the need for risk assessment and dropped the treatment line used by 25%. All ingestions greater than 75 mg/kg are considered significant. Although IV acetylcysteine administered more than 16 hours after ingestion may not prevent severe liver damage, it should still be given since outcome from paracetamol-induced fulminant hepatic failure is improved. Although severe hepatic injury has a 10% mortality, the majority of patients recover within 1–2 weeks.[36] Patients with fulminant hepatic failure should have an early discussion with a liver transplant centre, as super-urgent transplantation may be required.

CLINICAL FEATURES

Paracetamol poisoning is often asymptomatic in the early stages (the first 24–48 hours); later presentations may be associated with evidence of acute liver injury/failure. Patients with very significant ingestions (initial 4-hour paracetamol concentrations of >800 mg/L) may present in coma with a lactic metabolic acidosis – this is a direct effect of the paracetamol.

TREATMENT

- Those patients who present within an hour – consider AC in significant ingestions.
- Current UK treatment guidelines for single known time-point ingestions are based on a single treatment

line starting at 100 mg/L at 4 hours post-ingestion. Risk stratification is no longer required to determine the need for treatment.
- For those with staggered, supratherapeutic or unknown time of ingestions, treatment is not required for those who have ingested less than 75 mg/kg in the last 24 hours, but it is required for those who have ingested greater than 150 mg/kg (these are based on actual body weight to a maximum of 110 kg). For those who have ingested between 75 and 150 mg/kg, advice should be sought on whether or not treatment is required.
- NAC 150 mg/kg in 200 mL 5% dextrose is infused over 1 hour, followed by 50 mg/kg in 500 mL 5% dextrose over 4 hours and 100 mg/kg in 1 L 5% dextrose over 16 hours (total dose 300 mg/kg in 20 hours). Maximum protective effect is time dependent. An ingestion–treatment interval of less than 10 hours gives the best results.
- In those patients with evidence of liver injury, the last dose (100 mg/kg in 1 L 5% dextrose over 16 hours) is repeated until the patient's condition and biochemical and haematological results are improving.
- Although there is limited evidence, many recommend the use of prolonged NAC in patients with acute kidney injury.
- Expert opinion should be sought early on from a regional centre if liver failure is progressive since liver transplantation may become necessary.

PARAQUAT

In adult humans the lethal dose is 3–6 g (i.e. 15–30 mL of 20% w/v liquid concentrate). The mortality rate in patients ingesting the liquid concentrate is about 45%.[37] The lung is the primary target organ, with the injury being enhanced by oxygen. Peak concentrations are achieved between 0.5 and 2 hours.

CLINICAL FEATURES

Initial symptoms are GI pain and vomiting with corrosive effects on the mouth, pharynx and oesophagus. Dyspnoea and pulmonary oedema follow within 24 hours, progressing to irreversible fibrosis and death. Cardiac, renal and hepatic dysfunctions are common.

TREATMENT

Those treating suspected paraquat-poisoned patients should wear appropriate personal protective equipment to prevent secondary exposure. An urgent qualitative urine test (dithionite spot test) should be undertaken to confirm exposure; a confirmatory plasma concentration should be measured in those where positive as this may guide prognosis. Management is largely supportive: analgesia for oropharyngeal burns and other measures as indicated by the patient's clinical condition. Oxygen therapy can increase the degree and severity of pulmonary fibrosis. Palliative care may be required in those with high paraquat concentrations who fail to respond to treatment. Expert advice should be sought in these patients to determine whether other treatment options including veno-venous extracorporeal membrane oxygenation may be appropriate.

PHENYTOIN

CLINICAL FEATURES

Absorption is slow and unpredictable; moreover, maximum serum concentrations may not be achieved until 72 hours after ingestion. After initial nausea and vomiting, neurological symptoms develop including drowsiness, dysarthria and ataxia, and may ultimately progress to seizures. Cardiovascular toxicity is rare unless the overdose has been given intravenously.

TREATMENT

Most patients require nothing more than supportive measures. There is some evidence from volunteer studies that multi-dose AC can increase the elimination of phenytoin; it is not clear whether this alters the outcome.[38]

SALICYLATES (ASPIRIN)

Moderate toxicity occurs with serum concentrations 500–750 mg/L (3600–5500 µmol/L) and severe toxicity with concentrations greater than 750 mg/L. Serum concentrations alone do not determine prognosis. The elimination half-life increases significantly with increasing concentrations. Small reductions in pH produce large increases in non-ionised salicylate, which then penetrates tissues.

CLINICAL FEATURES

Tinnitus, deafness, diaphoresis, pyrexia, hypoglycaemia, haematemesis, hyperventilation and hypokalaemia may all occur. Coma, hyperpyrexia, pulmonary oedema and acidaemia are reported as more common in fatal cases, which present late.

TREATMENT

Although multiple-dose AC is not recommended by some experts, most medical toxicologists would recommend its use in large ingestions since concretions of salicylates in the stomach can occur with delayed ongoing absorption. Urinary alkalinisation (see above) decreases the amount of non-ionised drug available to enter tissues and should be considered in those with moderate/severe toxicity. Extracorporeal techniques are very effective in removing salicylates and correcting acid-base disturbance.[9]

SELECTIVE SEROTONIN REUPTAKE INHIBITORS OR 5-HT DRUGS

Selective serotonin reuptake inhibitors (SSRIs) include citalopram, fluoxetine, fluvoxamine, paroxetine and

sertraline. These drugs have increasingly replaced the TCA and generally appear to be much safer in overdose.

CLINICAL FEATURES

Drowsiness, tachycardia and mild hypertension are the commonest features. Seizures and coma can occur, as well as a serotonin syndrome in 14% of cases.[39]

TREATMENT

AC should be considered up to 1 hour post-ingestion, otherwise treatment is supportive. Benzodiazepines should be used to treat agitated or hyperthermic patients. There are case reports of cyproheptadine being used to treat severe toxicity with SSRIs.[40] In those with hyperthermia, the advice (as above) for amphetamines should be followed in terms of assessment of the hyperthermia and the appropriate management interventions.

THEOPHYLLINE

CLINICAL FEATURES

Acute theophylline poisoning is potentially very serious and severe poisoning carries a high mortality. Toxic effects such as agitation, tremor, nausea, vomiting and sinus tachycardia become evident at less than 30 mg/L (167 µmol/L). Concentrations greater than 60 mg/L (333 µmol/L) in acute poisoning or greater than 40 mg/L (222 µmol/L) in chronic usage frequently result in seizures, malignant ventricular arrhythmias, severe hypotension and death.[41] A key feature is hypokalaemia, which predisposes to arrhythmias and rhabdomyolysis. Measuring plasma theophylline levels confirms the ingestion and may help in deciding elimination methods; in the majority of poisoned patients they do not aid management. Sustained-release preparations may result in delayed onset and prolonged toxicity.

TREATMENT

Multidose AC should be considered, particularly in those with serum concentrations of greater than 40 mg/L. Although hypokalaemia does occur, there is not a total body depletion of potassium; therefore only potassium concentrations of less than 3 mmol/L should be cautiously replaced; monitor for a rebound hyperkalaemia. Convulsions should be treated with benzodiazepines and cardiac arrhythmias with beta blockers in non-asthmatic patients. Vomiting is often severe, and requires appropriate antiemetic administration. IHD is recommended in severe poisoning and if not available, IPF and continuous renal replacement therapy (CRRT) are acceptable alternatives.[11]

TRICYCLIC ANTIDEPRESSANTS

CLINICAL FEATURES

These drugs remain the leading cause of death from overdose in patients arriving at the emergency department alive and account for up to one-half of all overdose-related adult intensive care admissions.[42] Features include anticholinergic effects such as warm dry skin, tachycardia, blurred vision, dilated pupils and urinary retention. Severe features include respiratory depression, reduced conscious level, cardiac arrhythmias, fits and hypotension. Arrhythmias may be predicted by a QRS duration greater than 100 ms on the ECG; a QRS duration of greater than 160 ms increases risk of seizures. All forms of rhythm and conduction disturbance have been described, and are not necessarily predicted by the ECG.[43] Amoxapine typically causes features of severe poisoning in the absence of QRS widening. Cardiac toxicity is due mainly to quinidine-like actions, slowing phase 0 depolarisation of the action potential. Other mechanisms include impaired automaticity, cholinergic blockade and inhibition of neuronal catecholamine uptake. Toxicity is worsened by acidaemia, hypotension and hyperthermia.

TREATMENT

After supportive care as outlined above, including multiple-dose AC, continuous cardiac monitoring is essential. Increasing arterial pH to ≥7.45 significantly reduces the available free drug and this may be the best way to avoid TCA toxicity. Mild hyperventilation and 8.4% sodium bicarbonate in 50 mmol aliquots achieves this strategy and may improve the outcome.[31] Bicarbonate should probably be given in all cases of QRS prolongation (even in the absence of metabolic acidosis), arrhythmias with associated hypotension or metabolic acidosis; it should also be considered in those with convulsions. If arrhythmias occur, avoid class 1a agents; lidocaine may be best. For patients with intractable arrhythmias, measures including extracorporeal support with veno-arterial extracorporeal membrane oxygenation or cardiac bypass should be considered.[24] Benzodiazepines are the drug of choice for sedation and the treatment of seizures, and may prevent emergence delirium. Extracorporeal treatment is not recommended.[15]

VALPROATE

CLINICAL FEATURES

Most overdoses follow a benign course, with nausea, mild drowsiness and confusion. Coma can occur in large ingestions with cerebral oedema. There is the potential for metabolic derangement, including metabolic acidosis, hypernatraemia, hypoglycaemia and hyperammonaemia.

TREATMENT

Valproate levels are of little value, except to confirm the ingestion. There is poor correlation between the depth of coma and the free or total valproate levels. Supportive management is all that is usually required. Although in therapeutic use, valproate is extensively

protein-bound, with increasing plasma concentrations there is saturation of this binding leading to increased free drug; extracorporeal treatment is now recommended with haemodialysis the first choice and IPF and CRRT are acceptable alternatives.[44] Additionally, in those patients with significant overdoses, associated hepatic dysfunction and hyperammonaemia, consider the use of L-carnitine.

Sedation and pain management in intensive care

Luke E Torre

Despite the widespread use of sedative and analgesic agents in intensive care unit (ICU), the goals of sedation and analgesia are not well established.[1] Having its roots in anaesthesia, ICUs would historically manage patients with full general anaesthesia, including skeletal muscle paralysis and controlled ventilation modes, and this was maintained until the disease process remitted. Sedation and analgesia were considered a necessary adjunct to the management of critically ill patients.

Combinations of opioids and benzodiazepines (BZAs) are commonly used to provide 'sedation' in the ICU. Because high doses of opioids analgesics may result in significant sedation in their own right and are synergistic with sedative agents, the distinction between sedation and analgesia is blurred. This makes the definition and attainment of clear sedation goals elusive.

SEDATION

There has been a paradigm shift in thinking towards sedation practice in ICUs over the past 30 years. A combination of factors has led to this change, notably:

- improved ventilator technology and modes of ventilation allowing synchronised and spontaneous respiration
- improved drug development for sedation and analgesia with pharmacokinetic profiles that allow prompt titration, and pharmacodynamic profiles with fewer side effects
- the development and implementation of sedation scoring systems in the ICU[2]
- the increasing use of percutaneous tracheostomy and/or non-invasive ventilation for patients requiring prolonged ventilation
- the recognition of critical illness polyneuropathy and myopathy and the risk factors associated with it
- the separation and specialisation of intensive care physicians from other domains
- the emerging high-quality evidence in the field of sedation and analgesia in intensive care
- economic pressures and increased demand for finite intensive care resources.

Currently, sedative use in the critically ill should be for one or more of the following purposes:

- a treatment for disease processes such as: seizures, raised intracranial pressure, serotonin syndrome and alcohol withdrawal
- to facilitate tolerance of intensive care therapies such as intubation, mechanical ventilation and active cooling
- to reduce oxygen consumption by reducing patient arousal, activity and anxiety
- to maintain the safety of patient and carers when dealing with the hyperactive delirious patient
- palliation
- procedural sedation.

Sedation of patients in the ICU is an integral part of what health care workers perceive to be care and compassion for the critically ill patient. Presumed benefits of sedative agents include:

- reducing patient anxiety over their illness, the welfare of relatives or the risk of death
- providing adequate rest
- reducing the distress of unpleasant sensations, invasive treatments and monitoring
- blunting awareness of the environment over which the patient has very little control and in which they may be unable to communicate.

Non-pharmacological methods should preferentially be used to help manage these issues. Avoiding potentially distressing situations, allowing adequate access to caring visitors, maintenance of good communication with the patient and a positive outlook by carers will satisfy many of these goals. Small comforts, such as ice chips by mouth, a comfortable mattress, relaxation music and maintaining a daytime/nighttime environment all help this process.

LEVEL AND ASSESSMENT OF SEDATION

Critical to delivery of sedation is an accurate sedation assessment tool. Sedation scoring systems were first introduced in the 1970s.[2] Since that time, several validated scoring systems for critically ill patients have become available. The Ramsay Sedation Scale (RSS)

ABSTRACT

Sedation and analgesia are mainstays of critically ill patient management, but our understanding and use have changed enormously over the decades. Sedation strategies have become tailored, evidence-based treatments, with continual assessment and adjustment aiming to minimise complications and improve patient outcomes. Interest has centred on dexmedetomidine and its possible role in reducing delirium and the role of volatile agents in intensive care units. Pain assessment and treatment continue to improve with the development of critical care specific pain assessment tools. Opioids are the pharmacological cornerstone of treating pain, and newer agents with more favourable pharmacokinetic profiles are in common use. Multimodal analgesia remains the key to optimal pain management. Future work focuses on understanding and improving sleep in critically ill patients.

Table 91.1 Ramsay sedation scale

LEVEL	RESPONSE
AWAKE LEVELS	
1	Patient anxious and agitated or restless or both
2	Patient cooperative, orientated and tranquil
3	Patient responds to commands only
ASLEEP LEVELS	
4	Brisk response to a light glabellar tap or loud auditory stimulus
5	Sluggish response to a light glabellar tap or loud auditory stimulus
6	No response to a light glabellar tap or loud auditory stimulus

Table 91.2 Richmond agitation sedation scale

POINT	PATIENT RESPONSE TO VERBAL AND PHYSICAL STIMULI
+4	Combative – combative, violent, immediate danger to staff
+3	Very agitated – pulls or removes tubes or catheters; aggressive
+2	Agitated – frequent non-purposeful movement, fights ventilator
+1	Restless – anxious, apprehensive but movements not aggressive or vigorous
0	Alert and calm
–1	Drowsy – not fully alert, but has sustained (>10 s) awakening (eye opening/contact) to voice
–2	Light sedation – drowsy, briefly (<10 s) awakens to voice or physical stimulation
–3	Moderate sedation – movement or eye opening (but not eye contact) to voice
–4	Deep sedation – no response to voice but movement or eye opening to physical stimulation
–5	Unarousable – no response to voice or physical stimulation

Siegel MD. Management of agitation in the intensive care unit. *Clin Chest Med*. 2003;24(4):713–722.

and Richmond Agitation Sedation Scale are two of the most popular used worldwide (Tables 91.1 and 91.2). Despite their availability, validation and evidence base, their incorporation into routine management of intensive care patients remains low.[3]

Electroencephalography (EEG), which may be either 'raw' or 'processed', provides a measure of cerebral activity. This monitor is more suitable for assessing depth of anaesthesia and may be difficult to interpret in the encephalopathic patient. Devices using integrated EEG (e.g. bispectral index [BIS]) are available, but further research is required to establish their role in the ICU.[4] Their use is also limited by practical considerations, such as interference due to movement artefact.

SEDATION STRATEGIES

Although the choice of sedative agent(s) must be a conscientious decision based on pharmacokinetic and pharmacodynamic factors relevant to the critically ill patient, it is perhaps of greater importance to decide on the sedation strategy used.

A variety of strategies have been described:

- goal-directed sedation and early goal-directed sedation
- patient-targeted sedation protocols
- daily interruption of sedation
- intermittent sedation
- 'analgosedation', or analgesia-first sedation
- patient-controlled sedation.

The purpose of these strategies should be to achieve a controlled and predetermined level of sedation in the patient. The chosen level of sedation will be intimately linked to the underlying disease process, patients' characteristics and the treatments and interventions they are receiving. The aim of sedation should be documented by the team and conveyed to the bedside nurse, who will have the largest impact on achieving and maintaining the chosen level. Once instituted, the level of sedation should be regularly assessed.

Goal-directed sedation was the first method described in which sedatives are freely adjusted (usually by the bedside nurse) to attain a prescribed level of sedation from a sedation scoring system.[2] A recent focus is on 'early goal-directed sedation', emphasising sedation titration from its commencement in the ICU. This has stemmed from prospective cohort studies showing worse outcomes (including mortality) in patients with deeper levels of initial sedation.[5,6]

Patient-targeted sedation protocols implement two main features: a structured approach to the assessment of patient pain and distress, coupled with an algorithm that directs drug escalation and de-escalation based on the assessments.[7]

Daily interruption of sedation: this strategy uses a similar goal of sedative and analgesic titration to a desired depth of sedation. In contrast to 'patient-targeted sedation protocols', no formal algorithm has been established for drug escalation. However, the risk of excessive sedation is minimised by a daily interruption of both sedative and analgesic infusions until the patient awakens or exhibits distress that mandates drug recommencement, usually with an initial bolus followed by a reduced infusion rate.[7]

Intermittent sedation administration involves use of longer-acting sedative agents, typically lorazepam, given by intermittent bolus titrated via a sedation scoring system.

'Analgosedation', or analgesia-first sedation, is a more modern approach gaining favour in patients, especially where sedation is not a treatment of their disease process. In these patients, opioid analgesia is instituted first, and after pain is adequately controlled, verbal measures are used to calm the patient to a targeted sedation level (e.g. Ramsay score 3–4). Major tranquillisers (e.g. haloperidol) are given for delirium, and only then are sedative agents (e.g. propofol) used for short-term infusion and promptly ceased.[8]

Proposed benefits of the previous sedation strategies include[7–11]:

- shorter duration of mechanical ventilation
- shorter length of ICU and hospital stay
- economic benefit
- less need for diagnostic studies (e.g. computed tomography [CT] scans) to assess impaired conscious state
- less ventilator-associated pneumonia
- a possible mortality benefit.

Criticisms of these strategies include:

- high self-extubation rates
- promotion of myocardial ischaemia
- triggering of a withdrawal syndrome.

Concerns over increased long-term neuropsychological effects (e.g. post-traumatic stress disorder) have been unfounded. Instead, evidence suggests a reduced incidence using such strategies.[12,13]

More holistic, patient care bundles are being introduced that incorporate sedation strategies. For example, the 'ABCDE' bundle combines a daily interruption of sedation, spontaneous breathing trial, delirium assessment and management and early mobilisation package, aiming to reduce the incidence of ICU-acquired delirium and weakness.[14]

SEDATIVE AGENTS

GABA-A RECEPTOR AGONISTS

Gamma-aminobutyric acid (GABA) is a major neurotransmitter in the central nervous system and one that is involved in the complex process of sedation. It binds to the alpha subunit of the GABA-A receptor and, by activation, causes a conformational change that opens the ligand-gated channel, allowing chloride ion influx into the neuron. This hyperpolarises the neuronal membrane and reduces neuronal activity leading to sedation.[15]

The GABA-A receptor agonists used in intensive care are BZAs, propofol and barbiturates. They all share amnesic, hypnotic, anxiolytic and anticonvulsant effects but have no analgesic properties.

Benzodiazepines

BZAs, as a class, are probably the most widely used sedatives in ICUs. BZAs are good anticonvulsant drugs and provide some muscle relaxation. They bind to the gamma subunit of the GABA-A receptor, resulting in a conformational change causing increased opening frequency of the channel.[16] The commonest agents used worldwide are midazolam, lorazepam and diazepam.

These drugs may be given by many routes but most commonly intravenously (IV) or orally (PO). IV administration is by either continuous or intermittent IV infusion (e.g. midazolam in 1 mg/mL, titrated to effect).

Dosage of these agents may vary widely depending on various pharmacokinetic and pharmacodynamic factors such as:

- prior exposure to BZA (increased tolerance)
- age and physiological reserve
- volume status (hypovolaemic patients are more sensitive)
- renal and hepatic dysfunction
- co-administered drugs (e.g. combined with an opioid)
- history of alcohol consumption (increased tolerance).

Although some BZAs (e.g. midazolam) are short-acting, water-soluble agents, there is potential for accumulation of both parent compound and active metabolites in patients with hepatic and/or renal dysfunction. This is especially pertinent in the critically ill, for whom there may be extensive derangement of BZA pharmacokinetic profiles.[17,18] This may result in prolonged sedation with increased length of mechanical ventilation and ICU stay. Therefore there is some difficulty in predetermining suitable dosages. Midazolam 0.02–0.2 mg/kg/h may be suitable, with the level titrated to individual response. Longer-acting agents, such as diazepam, may be given by intermittent IV injection (e.g. diazepam 5–10 mg) as necessary.

BZAs are often combined with opioids in a compound 'sedative' infusion. This allows lower doses of BZA to be used, while benefiting from the opioid effects of respiratory and cough suppression, to facilitate mechanical ventilation and endotracheal tube tolerance.

Flumazenil (flumazepil), the specific BZA antagonist, may be used to reverse the effect of BZAs to counter unwanted acute side effects, such as severe hypotension or respiratory depression, or to allow acute neurological assessment.

Propofol

The IV anaesthetic agent propofol (2,6-di-isopropylphenol) is frequently used for sedation in the ICU. It binds to the beta subunit on the receptor and causes a conformational change to the chloride channel.[16] It gives more profound hypnosis than BZAs, which have a ceiling effect. It is given by continuous IV infusion.

Propofol has a favourable pharmacokinetic profile compared with BZAs, due to rapid hepatic and extrahepatic conjugation reactions to inactive metabolites. Indeed, clearance of propofol exceeds hepatic blood flow. This gives it a relatively short context-sensitive half-time, resulting in rapid offset, particularly after prolonged infusion.

Although propofol has been shown to reduce time on mechanical ventilation compared with BZA (specifically midazolam) sedation, it has not been shown to reduce time in the ICU.[19,20] However, its combination with remifentanil may result in a shorter ICU length of stay compared with the combination of midazolam with either fentanyl or morphine.[21,22]

Caution is required in hypovolaemic patients or those with impaired myocardial function because severe hypotension may result.[23] Doses for ICU sedation are generally much lower than those required for anaesthesia. The diluent in which propofol is delivered is lipid rich and should be considered a source of nutrition and indeed cause of hyperlipidaemia, depending on dosage and duration of therapy. Disodium edetate, present in the propofol solution, does not appear to be harmful in patients receiving long-term infusions of propofol.[24]

There continues to be concern about propofol infusion syndrome (PRIS), particularly in paediatric patients who have developed severe heart failure (preceded by metabolic acidaemia, fatty infiltration of the liver and striated muscle damage) after prolonged, high-dose infusions of propofol.[25] The pathophysiology of this condition remains elusive but may relate to uncoupling of oxidative phosphorylation in mitochondria. There may also be a genetic susceptibility.[26] Caution should therefore be exercised when using propofol for prolonged periods, and infusion rates should be limited to 4 mg/kg/h. Hyperlipidaemia may be a warning sign for development of the syndrome and serum triglyceride monitoring should be considered in patients at risk.[27] Management requires immediate cessation of propofol and cardiovascular supports, which may necessitate extra-corporeal membrane oxygenation (ECMO).[28] The condition, although rare, has a high mortality.

Barbiturates

Thiopentone is reserved for specific indications, such as management of intractable intracranial hypertension, or for the treatment of status epilepticus. It is not commonly used as a general sedative agent due to a long context-sensitive half-time when given by continuous infusion.

VOLATILE ANAESTHETIC AGENTS

The use of volatile anaesthetic agents for sedation in the ICU has been limited by:

- the cost of prolonged administration
- the more complex setup required for the administration of these agents (vaporiser, scavenging apparatus, etc.)
- specific side effects, such as 'halothane' hepatitis; accumulation of fluoride ions and consequent renal dysfunction (sevoflurane [fluoromethyl hexafluoroisopropyl ether] and isoflurane), compound A accumulation and possible renal dysfunction (sevoflurane and absorbent interaction)
- occupational health and safety concerns (e.g. spontaneous miscarriage).

Isoflurane and sevoflurane provide hypnosis, amnesia and, at higher concentrations, immobility of the patient. They have no analgesic properties. Their mechanism of action remains hotly debated. Desflurane, due to its low boiling point, has not yet been successfully incorporated into intensive care ventilator systems.

Volatile agents are useful for short periods of anaesthesia during invasive procedures in the ICU. They have classically been used for longer periods of sedation in acute severe asthma, due to their bronchodilator effect.

Newer vaporiser systems, such as the AnaConDa (Anaesthetic Conserving Device), allow safe administration and recirculation of volatile agent through a standard ICU ventilator. Approximately 90% of the volatile agent is recirculated, greatly reducing cost.[29]

Studies generally show a reduced time to extubation and duration of mechanical ventilation with volatile agents compared with GABA-A agonists, with the time benefit being greater as the duration of sedation increases.[29–31] Other potential advantages include:

- lack of a withdrawal syndrome
- predictable offset independent of renal or hepatic dysfunction
- cardioprotective effects
- no tachyphylaxis
- lower incidence of delirium
- ability to measure and titrate end-tidal volatile concentration.

N-METHYL-D-ASPARTATE RECEPTOR ANTAGONIST

Ketamine acts by blocking *N*-methyl-D-aspartate (NMDA) receptors. It produces a sedative state known as 'dissociative anaesthesia', with the following characteristics:

- mild sedation
- amnesia
- analgesia
- reduced motor activity.

The lack of respiratory and cardiovascular depression at lower doses makes this a relatively safe drug for use in the ICU. Limitations to its use include hallucinations, and delirium during the recovery/withdrawal phase. These may be ameliorated by BZA or dexmedetomidine administration.[32] Ketamine may be used specifically for sedation in severe asthmatics (for its bronchodilator effect), in patients following head injury

(for its effect at the NMDA receptor) or in patients where analgesia is difficult (e.g. extensive burns).[33,34]

MAJOR TRANQUILLISERS

Butyrophenones (e.g. haloperidol and droperidol) and phenothiazines (e.g. chlorpromazine) are very useful agents for the sedation of delirious patients in the ICU. They act via a range of receptors including dopaminergic (D1 and D2), α-adrenergic, histamine, serotonin and cholinergic receptors. Main actions include:

- reduced motor activity
- apathy and reduced initiative
- sedation and drowsiness
- reduced aggression
- antiemetic.

Unwanted effects with these drugs are common and include:

- extrapyramidal effects (dystonia, akathisia and parkinsonism)
- endocrine effects (e.g. lactation)
- anticholinergic effects (e.g. blurred vision, dry mouth, urinary retention, constipation)
- hypotension
- neuroleptic malignant syndrome.

The advantage of major tranquillisers is that they can be used to gain control in difficult situations (e.g. when delirious patients may be a risk to themselves or their carers), without major risk of respiratory depression. They should not be used for long-term sedation, except for the specific treatment of psychosis. Typically, haloperidol, diluted to a 1 mg/mL solution, may be given by repeated IV injection in doses of 1–20 mg/h until the delirious patient is approachable. Repeat dosages would then be titrated to allow easy arousal of the patient. Haloperidol may also be given PO or by intramuscular (IM) injection.

Atypical antipsychotic agents, such as olanzapine and quetiapine, are also efficacious agents for the management of delirious patients.[35] They have a lower side-effect profile than the 'typical' antipsychotics, especially with respect to extrapyramidal side effects. They are usually given PO, although olanzapine may be given as sublingual wafers, a particularly useful route of administration in these patients.

α_2-AGONISTS

Dexmedetomidine is a highly selective α_2-agonist with a half-life of 2 hours. It provides safe analgesia and sedation in the ICU when given as a single agent by IV infusion.[36–39] Although originally licensed in Australia for 24-hour use, longer-duration infusions have been safely administered.[40,41] Compared with BZAs, dexmedetomidine results in less delirium and shorter time to extubation.[42] Furthermore, its use in isolation, or in combination with traditional sedative agents, may be effective in both preventing and treating hyperactive delirium in ICU patients.[14,43–45] This has subsequent benefits on ventilator-free days, ICU length of stay, costs and potentially mortality. Results of future trials in this area are eagerly awaited.

Dexmedetomidine aims to deliver a cooperative, calm and tube-tolerant patient, without respiratory depression.[37] Extubation is usually performed with the agent still infusing to maintain the tranquil cooperative state. Opioid analgesic requirements are fewer compared with GABA agonist sedation.[40]

A loading dose of 1 μg/kg over 10 minutes is recommended in healthy patients, but this should be avoided or attenuated in the critically ill. Infusion rates of 0.2–1.0 μg/kg/h are recommended. Higher rates have been reported, but bradycardia is more frequently seen.[36,41,46] Side effects may be predicted from the mechanism of action and include hypotension and bradycardia.

Clonidine, an established long-acting α_2-agonist, may be used to enhance sedation and analgesia when GABA-A agonists and opioids are used. The usual IV dose range is 50–150 μg, 4–6 hourly.

ANALGESIA

Pain management is a priority in the care of critically ill patients. Skilled use of analgesics in the modern ICU aims to ensure that critically ill patients no longer suffer pain. Pain management relies largely on the use of opioid analgesics together with regional anaesthetic techniques and other adjuncts.

Many patients present to the ICU with painful conditions or undergo painful procedures during their stay. Patients commonly report pain from routine ICU procedures like arterial and central venous cannulation, endotracheal suctioning, insertion of an indwelling urinary catheter or nasogastric tubes and even turning in bed.[47] In addition, other adverse symptoms commonly reported include unsatisfied thirst, difficult sleeping, anxiety, unsatisfied hunger, depression and shortness of breath.[47]

Pain has multiple adverse consequences, such as:

- provoking anxiety
- contributing to lack of sleep
- worsening delirium
- increasing the stress response
- causing respiratory embarrassment due to atelectasis and sputum retention
- causing immobility with venous and gut stasis.

Pain management comprises many modalities in addition to pharmacological methods, including:

- a caring and supportive ICU team, whom the patient can trust
- warm and comfortable surroundings
- attention to pressure areas
- bowel and bladder care
- adequate hydration and amelioration of thirst (e.g. moistening the mouth)

- early tracheostomy where indicated to reduce the discomfort of endotracheal intubation
- supplemental treatments such as acupuncture, acupressure, massage and transcutaneous electrical nerve stimulation (TENS).

Accurate and structured pain assessment is an important part of ICU patient management. For the patient who can communicate, self-reporting remains the gold standard. For those unable to self-report, a variety of pain assessment tools is available, some tailored specifically to critically ill patients. The Behavioural Pain Scale (BPS) (Table 91.3) and Critical-Care Pain Observation Tool (CPOT) (Table 91.4) are well validated in adult ICU patients.[48–52] The use of vital signs and physiological markers alone to assess pain, and response to analgesic administration are unreliable.

OPIOIDS

Opioids remain the mainstay of analgesia in the ICU. The most commonly used agents in the ICU used worldwide include:

- morphine and its analogues (e.g. diamorphine, codeine)

Table 91.3 Behavioural pain scale

ITEM	DESCRIPTION	SCORE
Facial expression	Relaxed	1
	Partially tightened (e.g. brow lowering)	2
	Fully tightened (e.g. eyelid closing)	3
	Grimacing	4
Upper limbs	No movement	1
	Partially bent	2
	Fully bent with finger flexion	3
	Permanently retracted	4
Compliance with mechanical ventilation	Tolerating movement	1
	Coughing but tolerating ventilation most of the time	2
	Fighting ventilator	3
	Unable to control ventilation	4

- semisynthetic and synthetic agents:
  - phenylpiperidine derivatives (e.g. pethidine, fentanyl, sufentanil, remifentanil)
  - methadone
  - thebaine derivatives (e.g. buprenorphine, oxycodone).

The effects of opioids are mediated via the four opioid receptor subtypes; mu, kappa, delta and nociceptin. These are G protein–coupled receptors that inhibit adenyl cyclase to reduce cyclic adenosine monophosphate (cAMP). This results in analgesia mediated at supraspinal, spinal and peripheral nerve endings.[53] The side effects of opioids are well described.

Opioids are titrated to effect by intermittent IV injection, or by continuous infusion. This may be controlled by the nurse (nurse-controlled analgesia [NCA]) or by the patient (patient-controlled analgesia [PCA]). Suitable regimens are 1 mg/mL of morphine, 20 µg/mL of fentanyl or 200 µg/mL of hydromorphone titrated to effect.

NCA is often combined with a BZA such as midazolam to produce a 'sedative/analgesic' infusion for patients on mechanical ventilation (see Sedation section). Opioids can also be administered via the subarachnoid, epidural, transdermal, oral, sublingual and intranasal routes.

In the critically ill, the use of opioids may be complicated by:

- wide interindividual response to similar dosages, especially in debilitated and elderly patients.
- severe hypotension following rapid administration, particularly in hypovolaemic patients
- prolonged duration of action, due to accumulation of parent compound and metabolites (e.g. morphine and its major metabolites morphine-3-glucuronide and morphine-6-glucuronide) in the elderly and in patients with renal and hepatic dysfunction. Use of drugs with shorter half-lives (e.g. fentanyl or sufentanil) or those with organ-independent metabolism (e.g. remifentanil) can reduce this problem
- constipation, often requiring concomitant administration of aperients to promote regular evacuation and prokinetics to prevent gastrostasis and allow enteral feeding
- the development of tolerance
- withdrawal symptoms on cessation or reduction of opioid medication.

Recognition of withdrawal symptoms is not always simple in ICU patients because they may mimic sepsis or delirium. Treatment is by reinstitution of and then slow withdrawal of the opioid. Alternatively, symptoms may be controlled by substitution for a long-acting opioid (e.g. methadone), BZAs or α_2-agonists.

The specific opioid antagonist naloxone has little role to play in the ICU, except for the treatment of severe hypotension, unwanted sedation or respiratory depression following opioid use or overdose. Rapid reversal of opioid effect to facilitate neurological assessment may be another valid use.

REMIFENTANIL

This is a synthetic, selective mu receptor agonist. It undergoes organ-independent hydrolysis by plasma, red blood cell and tissue esterases. It has a reliable context-sensitive half-time of 4 minutes, which makes it particularly attractive for critically ill patients.

Although an analgesic, it is gaining favour as a sedative agent in intensive care because it causes sedation, tube tolerance and a slowed respiratory rate. In addition, its pharmacokinetic profile makes it ideal for rapid neurological assessment. Studies show reduced extubation times and ICU length of stay when compared with traditional opioids.[21,22]

The loading dose is usually 1 µg/kg; however, this should be avoided or attenuated in critically ill patients. Continuous infusion rates of 0.05–0.5 µg/kg/min are usually required, and a starting rate of 0.1 µg/kg/min is recommended. Dosage alterations are usually in increments of 0.025–0.1 µg/kg/min. Due to the short half-life, adequacy of response can be assessed within 20 minutes.

Weaning should also be done by incremental dose reductions due to the risks of rebound hyperalgesia. Adding ketamine during the weaning process may modulate this risk.[54]

SIMPLE ANALGESICS

Paracetamol and other simple analgesics (e.g. salicylates) are particularly effective for:

- musculoskeletal pain
- perioperative pain
- inflammatory conditions
- multimodal analgesia, to reduce opioid requirements.

These drugs are given PO, per rectum (PR) or IV to supplement analgesia in the critically ill (e.g. paracetamol 1 g 4–6-hourly). Paracetamol use is limited by the risk of hepatic dysfunction if used in high dose or for prolonged periods.

NON-STEROIDAL ANTI-INFLAMMATORY DRUGS

The commonly used non-steroidal anti-inflammatory drugs (NSAIDs) are carboxylic acids (e.g. indometacin [indomethacin], ibuprofen, mefenamic acid) or enolic acids (e.g. piroxicam). NSAIDs are useful for supplemental/multimodal analgesia in the ICU for the conditions listed previously for simple analgesics. They are given PO, PR or by IM injection (e.g. indomethicin 100 mg twice daily PR). Patient selection is paramount in the critically ill due to their serious side effects, including:

- renal dysfunction
- gastrointestinal haemorrhage

- increased bleeding tendency due to platelet inhibition.

The newer cyclooxygenase-2 specific (COX-2) inhibitors, such as valdecoxib and its injectable precursor parecoxib, have a much lower side-effect profile than traditional NSAIDs. This group of drugs should be used for only short periods due to an increased cardiovascular morbidity associated with long-term use.[55] COX-2 inhibitors should be avoided in postoperative cardiac surgical patients due to an increased incidence of thromboembolic complications and sternal wound infection.[56,57]

TRAMADOL

Tramadol is a synthetic, racemic preparation with multiple analgesic actions. The (+) enantiomer is a mu receptor agonist and serotonin reuptake inhibitor, whereas the (–) enantiomer is a norepinephrine reuptake inhibitor.[58] In addition to mu receptor action, which accounts for approximately 30% of its analgesic effect, it also enhances the descending inhibitory pathways involved in pain modulation.[59] It is useful for moderate to severe pain in the postoperative patient in doses of 50–100 mg IV, PO or IM 4-hourly to a maximum of 600 mg/day. Patients are at risk of developing serotonin syndrome while taking tramadol in combination with other proserotonergic agents.[60]

TAPENTADOL

Tapentadol is a centrally acting, synthetic analgesic with mu receptor agonism and norepinephrine reuptake inhibition. It is not a serotonin reuptake inhibitor, does not require metabolic activation and has no active metabolites. It is predominately conjugated by the liver and undergoes minimal cytochrome P450 enzymatic metabolism, thus reducing potential drug interactions.[61,62] It is useful for moderate to severe pain in doses of 50–100 mg IV or PO 4-6 hourly. Despite the relative lack of serotonergic activity compared with tramadol, case reports of serotonin syndrome involving tapentadol in combination with other proserotonergic agents have been reported.[62]

KETAMINE

(See 'NMDA receptor antagonist' earlier.) Ketamine is commonly used as part of multimodal analgesic regimens in surgical patients with severe pain, or if tolerant to opioids. Continuous infusion in a dosage range of 0.1–0.2 mg/kg per hour is recommended.

NITROUS OXIDE

Short-term administration of Entonox (50% nitrous oxide in oxygen) is still useful for analgesia during painful procedures (e.g. burns dressings). This may be given by demand valve (controlled by the patient) or be administered by the medical staff.

LOCAL ANAESTHETICS – REGIONAL ANALGESIA

The use of local anaesthetic techniques in the critically ill patient is limited by:

- pain often emanating from multiple sources and therefore not amenable to a single regional technique
- the requirement for IV sedation/analgesia (for reasons previously outlined), making a regional technique for pain superfluous
- the need to treat pain over a prolonged period, mandating either repetition of the regional block or the placement of an indwelling catheter (e.g. epidural catheter). Indwelling catheters have a defined duration of insertion (usually 3–4 days) due to increasing infection risk
- coagulopathy and thrombocytopenia, frequently seen in this group of patients, making procedures such as epidural injection less safe.

When a regional technique is considered viable, then the following need to be considered:

- the procedure should be carried out by adequately trained personnel
- regional techniques may be time consuming and require additional staff to properly position the patient and assist the proceduralist
- regional techniques carry serious complications (e.g. subarachnoid injection of local anaesthetic or epidural haematoma during placement of epidural catheters), as well as the risk of local anaesthetic toxicity
- good preparation is paramount:
  - informed consent from patient or legal surrogate
  - recent normal coagulation profile or correction of abnormal profile. Platelet counts greater than 75,000/μL are recommended and antiplatelet agents (other than aspirin) should be ceased at an appropriate time interval beforehand
  - the knowledge of and ability to deal with complications
  - experience and knowledge of the drugs being used. Typically ropivacaine 0.2% is used for regional infusions and can be combined with an opioid, such as fentanyl 2–4 μg/mL, for epidural infusion. Recommended maximum bolus doses and continuous infusion rates must be known. For ropivacaine, a single bolus of up to 3 mg/kg is allowed (to a maximum of 300 mg), whereas continuous infusion rates should not exceed 400 μg/kg/h
- adequate training of nursing staff to monitor the level of block in neuraxial techniques, haemodynamic parameters and for possible complications.

Within the previous context, the following blocks may be useful in patients:

- femoral nerve block for hip and femur injuries; 20–40 mL of 0.2% ropivacaine injected intermittently 8–12-hourly into the region of the femoral nerve immediately inferior to the inguinal ligament
- intercostal or paravertebral nerve blocks or catheters for thoracic and upper abdominal injuries or wounds; 20 mL of 0.2% ropivacaine injected into the region of appropriate intercostal nerve – a single injection site has been shown to cover multiple nerve root levels[63]
- brachial plexus or IV regional anaesthesia for isolated upper limb injuries or procedures (e.g. fracture manipulation)
- epidural analgesia for thoracic and abdominal pain (e.g. flail chest, pancreatitis)
- intrapleural analgesia/anaesthesia, applied either via a catheter placed for this purpose or via previously placed intercostal drains.

SLEEP

Although, outwardly, sedated patients resemble the sleep state, there are notable neurophysiological differences. Typically, critically ill patients have shorter periods of sleep, with a distinct reduction of slow-wave 'deep' sleep and rapid eye movement (REM) sleep.[64] Critically ill patients have poor sleep patterns due not only to their primary illness but a host of other factors, including:

- loss of the sleep–wake cycle after prolonged sedation
- pain
- invasive devices and monitoring
- the ICU environment
- nursing duties.

The importance of sleep disturbance in the critically ill on outcome is unknown, but there is concern over its contribution to delirium.[65]

Much of the focus on improving sleep in critically ill patients relies on non-pharmacological measures, addressing the sleep environment and sleep hygiene of the patient. Pharmacological agents such as BZAs may help patients to get to sleep quicker and wake less often but do not seem to improve the quality of physiological sleep.[65]

THE FUTURE

Research into sedation and analgesia in critically ill patients is intensifying. Areas in which future study is focusing include:

- patient-controlled sedation
- target-controlled infusions in intensive care
- automated/semiautomated sedation delivery systems[66]
- melatonergic agents for nocturnal sleep (e.g. ramelteon, valdoxane, melatonin).

Inotropes and vasopressors

John A Myburgh

INTRODUCTION

The pharmacological support of the failing circulation is a fundamental component of acute medicine with broad applications to patients undergoing resuscitation in the Emergency Department, major surgery under general anaesthesia or in the intensive care unit (ICU).

The principal aim of these drugs is to restore inadequate systemic and regional perfusion to physiological levels.

DEFINITIONS

Inotropic agents are defined as drugs that act on the heart by increasing the velocity and force of myocardial fibre shortening. The consequent increase in contractility results in increased cardiac output and systemic blood pressure.

Vasopressors are broadly considered to be drugs that have a predominantly constrictive action on the peripheral vasculature, both arterial and venous. These drugs are used primarily to increase mean arterial pressure.

The distinction between these two groups of drugs is redundant, despite reference to these in iterations of clinical practice guidelines.

The most commonly used drugs, the catecholamines noradrenaline (norepinephrine) and adrenaline (epinephrine), have both inotropic and protean effects on the venous and arteriolar vasculature.

Given the overlap of pharmacodynamic effects of these drugs, the term 'vasoactive therapy' is a more appropriate description.

Characteristics of the ideal vasoactive drug are shown in Box 92.1.

THE FAILING CIRCULATION

PHYSIOLOGY

Traditionally, cardiac output is discussed in terms of factors that govern cardiac function. These include heart rate and rhythm, preload, myocardial contractility and afterload. Although this perspective is helpful in managing patients whose circulatory function is limited by intrinsic cardiac disease, it is incomplete.

Cardiac output is controlled by venous return to the heart from the peripheral vasculature at an equal rate to that ejected during each cardiac cycle (Fig. 92.1).[1,2]

Blood is pumped from the heart down the aorta by a pressure gradient that is determined by the force of myocardial ejection (contractility) and the impedance to ventricular ejection (afterload). The resultant mean arterial pressure is the major 'afferent' determinant of regional perfusion pressure. Twenty per cent of the blood volume is contained in the arterial ('conducting') vessels.

There is a marked drop in perfusion pressure and flow across the capillary beds to facilitate diffusion of substrates and oxygen. The difference between mean arterial pressure and the pressure in end-capillaries ('efferent' perfusion pressure) determines regional, or organ-specific, perfusion pressure.

Blood enters the venous system and is returned to the heart by a pressure gradient between mean systemic pressure and right atrial pressure. The amount of blood returned to the heart determines the degree of ventricular filling prior to systole (preload) that subsequently determines stroke volume and cardiac output.

Under physiological conditions, the venous ('capacitance') system contains approximately 70% of the total blood volume that acts as a physiological reservoir – the 'unstressed' volume. Under conditions where circulatory demands increase, increased sympathetic tone will cause contraction of this reservoir.[3] The resultant auto-transfusion – the 'stressed' volume – may increase venous return by approximately 30% with consequent increased cardiac output.[4]

Both the arterial and venous systems are integrated under complex neurohormonal influences. These include the adrenergic, renin–angiotensin–aldosterone, vasopressinergic and glucocorticoid systems in addition to local mediators such as nitric oxide, endothelin, endorphins and the eicosanoids.[5]

PATHOPHYSIOLOGY

Circulatory dysfunction or failure may be considered in terms of the major determinants of cardiac output,

ABSTRACT

The pharmacological support of the failing circulation in critically ill patients is directed at restoring and maintaining vital organ perfusion. This is primarily achieved by the administration of intravenous fluids in hypovolaemic patients and augmented by the early and concomitant use of infusions of catecholamines, noradrenaline or adrenaline. These drugs should be used to augment inadequate endogenous responses and are effective at increasing mean arterial pressure, cardiac output and venous return. Current evidence supports the use of these drugs as first-line agents for all forms of shock, although the evidence base is limited. There is little evidence to support the use of synthetic catecholamines or other drugs such as phosphodiesterase inhibitors. Drugs should be titrated to a patient-specific mean arterial pressure and at clinical indices of vital organ function.

although there is marked interdependence between these factors.

HEART RATE

Severe bradycardia may reduce both cardiac output and mean arterial pressure if sympathetic tone is compromised. Vasoactive drugs with a positive chronotropic effect increase both the rate and speed of conduction, thereby restoring cardiac output and mean arterial pressure.

Tachycardia is associated with decreased left coronary artery perfusion, due to a reduction of diastolic time when coronary perfusion occurs. This may exacerbate myocardial ischaemia in patients with coronary artery disease, particularly if mean arterial pressure, specifically diastolic blood pressure, is compromised. Drugs that shorten diastolic time or compromise coronary perfusion should be used with caution in susceptible patients.

Box 92.1 The ideal inotrope

- Increases contractility
  - Increases mean arterial pressure
  - Increases cardiac output
  - Improves regional perfusion
- No increase in myocardial oxygen consumption
  - Avoidance of tachycardia
  - Non-arrhythmogenic
  - Maintenance of diastolic blood pressure
- Does not develop tolerance
- Titratable
  - Rapid onset
  - Rapid termination of action
- Compatible with other drugs
- Non-toxic
- Cost effective

PRELOAD

Loss of intravascular blood volume or extracellular fluid is the most common cause of inadequate ventricular preload. This is corrected judiciously with intravenous fluids to maintain and restore normovolaemia. Hypovolaemia must be recognised and treated as soon as possible, preferably before vasoactive therapy is used, although the early use and concomitant use of vasoactive therapy is recommended.[6]

There are other determinants of ventricular preload and venous return. Factors such as loss of muscle tone, positive intrathoracic pressure, loss of atrial contraction (atrial fibrillation) and ablation of sympathetic tone will compromise preload by reducing venous return. Under these circumstances, volume replacement alone

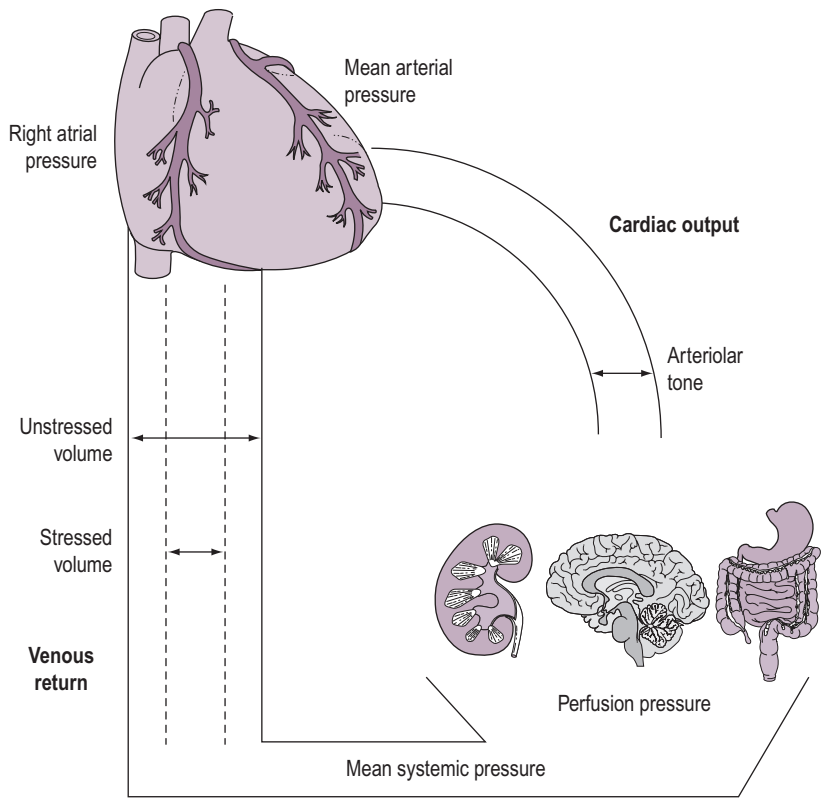

Figure 92.1 Schematic relationship of the determinants of cardiac output and venous return.

may be insufficient to maintain adequate preload, and early, concomitant vasoactive therapy is recommended to augment venous return.

MYOCARDIAL FUNCTION

Myocardial or 'pump' failure may be divided into disorders of systolic ejection (systolic dysfunction) and diastolic filling (diastolic dysfunction).

Systolic dysfunction occurs as a result of reduced effective myocardial contractility. This may be due to primary myocardial factors such as ischaemia, infarction or cardiomyopathy. Myocardial depression of both right and left ventricular function may occur in severe sepsis ('septic cardiomyopathy') or following prolonged infusions of catecholamines ('down-regulation').[7] Increased impedance to ventricular ejection (e.g. hypertensive states) or structural abnormalities (e.g. aortic stenosis or hypertrophic obstructive cardiomyopathy) may cause systolic dysfunction.[8]

Diastolic dysfunction is characterised by reduced ventricular compliance or increased resistance to ventricular filling during diastole. It may be due to mechanical factors, such as structural abnormalities of the ventricle (e.g. restrictive cardiomyopathy), or to impaired diastolic relaxation that occurs with myocardial ischaemia or septic cardiomyopathy. This results in elevated end-diastolic pressure and pulmonary venous congestion. Episodic or 'flash' pulmonary oedema is a common clinical sign of diastolic dysfunction. Tachycardia that shortens diastolic time may exacerbate diastolic failure. Diastolic dysfunction frequently accompanies systolic failure, in both acute and chronic cardiac failure, particularly in elderly patients.[9]

In the presence of systolic dysfunction, adequate stroke volume may be maintained by an increase in left ventricular end-diastolic volume (the Frank–Starling relationship), provided diastolic function is optimal. However, if the loss of effective myocardial mass is critical, the ventricle will be unable to maintain an adequate stroke volume and cardiac output will fall. In this situation, systolic dysfunction usually requires treatment with inotropic agents in order to augment stroke volume, thereby increasing cardiac output and mean arterial pressure.

AFTERLOAD/IMPEDANCE

Disruption or impairment of regulation of the peripheral vasculature may result in circulatory failure. This includes acute sympathetic denervation, such as high quadriplegia, epidural or total spinal anaesthesia ('spinal' shock); distributive failure such as anaphylaxis; or 'vasoplegia' associated with severe sepsis ('vasodilatory' shock).[7,10]

These syndromes are characterised by reduced responsiveness of the peripheral circulation to endogenous or exogenous sympathetic stimulation. This results in pooling in the venous circulation due to the inability to produce a 'stressed' volume.

Management of these conditions has traditionally focused on 'vasoconstrictor' or 'vasopressor' therapy on the arterial circulation, but the predominant vascular lesion is in the venous circulation where haemodynamic monitoring is limited.

CLASSIFICATION

The common cellular mechanism of action of vasoactive agents involves an influence on the release, utilisation or sequestration of intracellular calcium (Fig. 92.2). These agents are divided into two main groups based on whether or not their actions depend upon increases in intracellular cyclic adenosine 3,5-monophosphate (cAMP) and are outlined in Table 92.1.

CATECHOLAMINES

Sympathomimetic amines are the most frequently used vasoactive agents in the ICU and include the naturally occurring catecholamines dopamine, noradrenaline and adrenaline, and the synthetic inotropes dobutamine, isoprenaline and dopexamine.

RECEPTOR BIOLOGY

Catecholamines bind to populations of adrenergic receptors, largely divided into α and β subgroups. Further subgroups of α- (α_{1A}, α_{1B}, α_{2A}, α_{2B}, α_{2C}) and β-receptors (β_1, β_2, β_3) have been identified.[5]

Signal transduction from catecholamine–receptor occupation to the effector cell is modulated by conformational changes in G proteins associated with these receptors. Under the influence of second messengers,

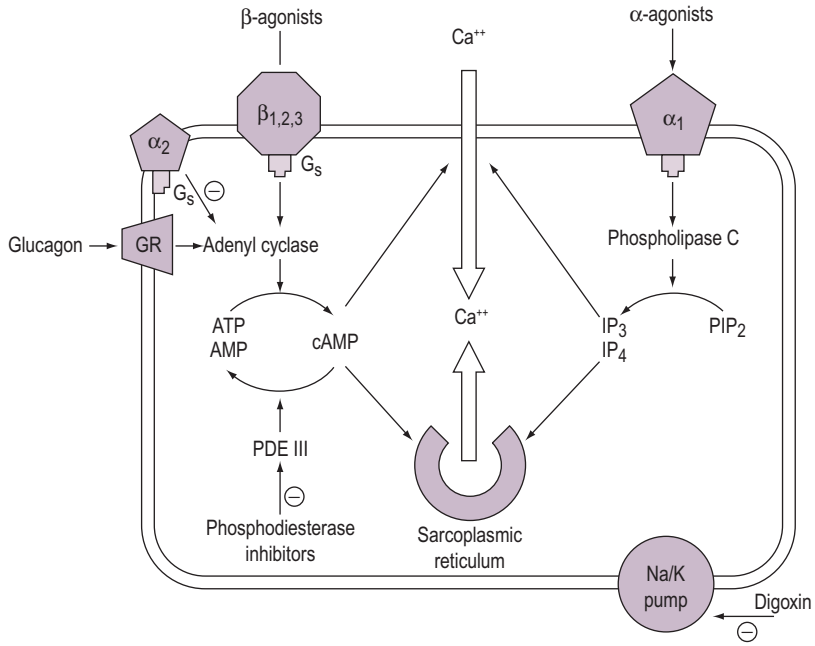

Figure 92.2 Schematic representation of the action of inotropic drugs on intracellular calcium in myocytes. *AMP*, Adenosine monophosphate; *ATP*, adenosine triphosphate; *cAMP*, cyclic AMP; *GR*, glucagon receptor; G_s, G protein complex; *IP3*, inositol phosphate 3; *PDE III*, phosphodiesterase III; *PIP2*, phosphoinositol diphosphate.

such as nitric oxide, endothelin and eicosanoids, conformational changes promote the release of calcium from intracellular stores and membrane calcium permeability. Subsequent phosphorylation of substrate proteins via protein kinases act as third messengers to trigger a cascade of events that lead to specific cardiovascular effects.

β-receptor occupancy predominantly activates adenyl cyclase to increase the conversion of adenosine triphosphate to cAMP. α-receptor occupancy acts independently of cAMP by activation of phospholipase C, which increases inositol phosphates (IP_3 and IP_4) and diacyl glycerol.

This complex agonist–receptor–effector relationship is responsible for teleological, homeostatic mechanisms, such as physiological responses to stress and autoregulation, and may be markedly influenced under pathological conditions. These states produce qualitative changes in the agonist–receptor–effector organ relationship where receptors no longer respond to physiological or pharmacological sympathetic stimulation to the same extent (desensitisation); and quantitative changes, such as reduced receptor density, receptor sequestration and enzymatic uncoupling, may also result in impaired responses (down-regulation).[11]

BIOSYNTHESIS

The biosynthesis and chemical structures of the naturally occurring catecholamines are shown in Fig. 92.3a.

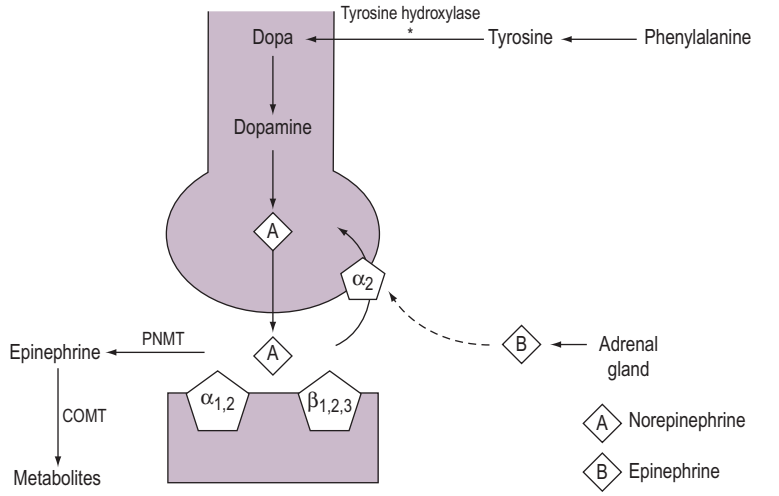
Catecholamines consist of an aromatic ring attached to a terminal amine by a carbon chain. The configuration of each drug is important for determining affinity to respective receptors.

Dopamine is hydroxylated to form noradrenaline that is the predominant peripheral sympathetic chemotransmitter in humans acting at all adrenergic receptors. The release of noradrenaline from sympathetic terminals is controlled by re-uptake mechanisms mediated via α_2-receptors and augmented by adrenaline released from the adrenal gland at times of stress. Noradrenaline is converted to form adrenaline, which is subsequently metabolised in liver and lung.

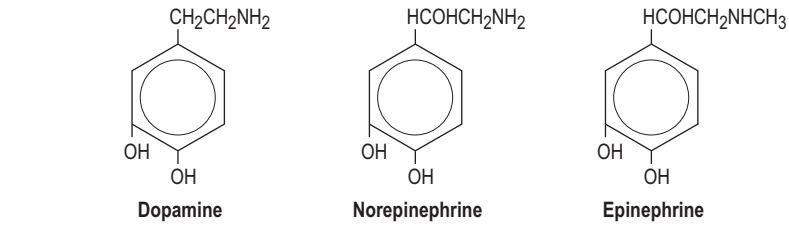
All catecholamines have short biological half-lives (1–2 minutes) and a steady state plasma concentration is achieved within 5–10 minutes after the start of a constant infusion. This allows rapid titration of drug to a clinical end-point such as mean arterial pressure.

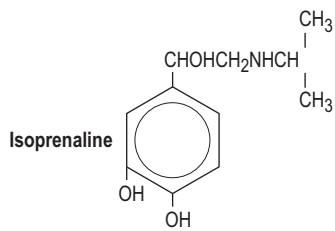
Adrenaline and noradrenaline infusions produce blood concentrations similar to those produced endogenously in shock states, whereas dopamine infusions produce much higher concentrations than those naturally encountered. Dopamine may exert much of its effect by being converted to noradrenaline, thus bypassing the rate-limiting hydroxylation step in catecholamine synthesis.

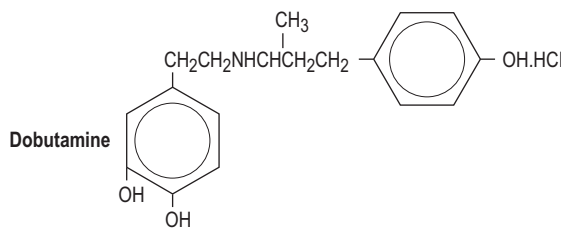
The synthetic catecholamines are primarily derivatives of dopamine (see Fig. 92.3b). These agents are characterised by increased length of the carbon chain

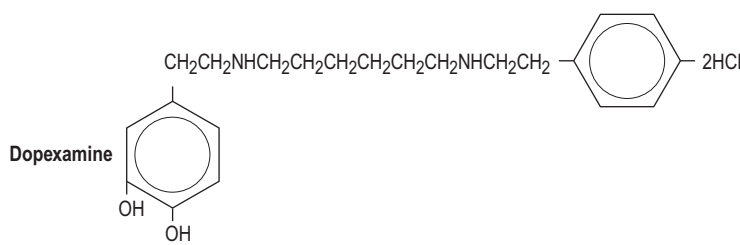


a









b

Figure 92.3 (a) Biosynthesis of catecholamines in sympathetic terminals. *, Rate-limiting step by tyrosine hydroxylase; *COMT*, catechol-*o*-methyl-transferase; *PNMT*, phenethanolamine-*N*-methyltransferase. (b) Chemical structure of endogenous and synthetic catecholamines.

that confers affinity for β-receptors. Dobutamine is a synthetic derivative of isoprenaline. These agents have relatively little affinity for α-receptors due to the configuration of the terminal amine, which differs from the endogenous catecholamines.

Adrenaline, noradrenaline and isoprenaline all have hydroxyl groups on the β-carbon atom of the side chain, and this is associated with 100-fold greater potency than dopamine or dobutamine.

SYSTEMIC EFFECTS

The systemic effects of these agents vary widely between patients and within individuals at different times. The adequacy of response is often unpredictable and depends on the aetiology of circulatory failure and systemic co-morbidities. In some patients, strong 'pressor' responses to small doses may occur characterised by a sharp increase in mean arterial pressure, whereas in others progressively increasing doses of vasoactive drugs are required to attain a targeted mean arterial pressure.

The classification of sympathomimetic agents into α- and β-agonists, based on the above structure–function relationships, is a widely used, albeit crude, predictor of systemic effects.

Adrenaline, noradrenaline and dopamine are predominantly β-agonists at low doses, with increasing α-effects becoming evident as the dose is increased.

The synthetic catecholamines are predominantly β-agonists.

CARDIOVASCULAR

The cardiovascular effects of the catecholamines under physiological conditions are shown in Table 92.2.

Noradrenaline, adrenaline and dopamine increase stroke volume, cardiac output and mean arterial pressure, with little change in heart rate. Dopamine is associated with an increased incidence of dysrhythmias.[12] The effects on the vasculature are similar, primarily increasing venous return without changes in the resistance to venous return and no demonstrable changes in calculated systemic vascular resistance.

Isoprenaline increases cardiac output predominantly by increasing heart rate and by moderate inotropy. This occurs without a significant change in blood pressure due to predominant β_2-receptor-induced venodilatation.

The profile of dobutamine is similar to isoprenaline, although increases in heart rate are not as pronounced. Both of these agents may decrease mean arterial pressure, particularly in hypovolaemic patients, due to reduced venous return caused by venodilatation. The adverse effects of dobutamine and isoprenaline on heart rate and mean arterial pressure may compromise patients with ischaemic heart disease.

In the failing myocardium, particularly in patients with cardiac failure following cardiopulmonary bypass or septic shock, endogenous stores of noradrenaline are markedly reduced.[7] There may be significant desensitisation and down-regulation of cardiac β-receptors. In these situations, α_1- and α_2-receptors have an important role in maintaining inotropy and peripheral vasoresponsiveness.[13] This may be expressed clinically as 'tolerance' or tachyphylaxis to catecholamines, particularly with β-agonists such as dobutamine. This phenomenon may explain the requirement for high doses of catecholamines in refractory shock states. Consequently, the role of β-agonists in patients with severe myocardial failure is questioned.

Catecholamines act predominantly on the venous circulation, primarily restoring and maintaining 'stressed volumes' of the capacitance vessels within teleological limits under pathological conditions. This is important in 'vasodilatory' states such as septic shock.[10]

In clinically used doses, intravenously administered catecholamines have minimal direct vasoconstrictive effects on conducting arterial vessels, including arterial conduits used in cardiac or vascular surgery.

The development of peripheral gangrene in refractory septic shock has been attributed to catecholamine-induced vasoconstriction. There is little evidence to

Table 92.2 Cardiovascular effect of catecholamines

AGENT	β_1 EFFECTS	β_2 EFFECTS	α_1 EFFECTS	α_2 EFFECTS
	+ chronotropy + dromotropy + inotropy	+ inotropy vasodilatation bronchodilatation	+ inotropy vasoconstriction	+ inotropy vasoconstriction
Noradrenaline Adrenaline Dopamine	β effects predominate at low dose; α effects predominate at high dose			
Dobutamine	+	+	(+)	–
Isoprenaline	+	(+)	–	–
Dopexamine	+	+	–	–

+, Stimulation; (+), mild effect; –, no effect.

support this association outside anecdotal reports, as the development of tissue gangrene in these situations primarily occurs as a consequence of intravascular thrombosis caused by sepsis-mediated coagulopathy.

CEREBRAL

Under physiological conditions, catecholamines do not cross the blood–brain barrier. Cerebral blood flow is maintained at a constant rate over a range of perfusion pressure by cerebral autoregulation. Under conditions where the integrity of the blood–brain barrier is altered, such as following traumatic brain injury and aneurysmal subarachnoid haemorrhage, exogenous catecholamines may directly enter the cerebral circulation.

The degree by which these agents directly affect the cerebral circulation following traumatic brain injury is unknown, although there is some evidence suggesting that dopamine has a direct effect causing increased cerebral blood flow and intracranial pressure.[14]

RENAL

The kidney is an efficient autoregulator, maintaining constant glomerular filtration and renal blood flow by neurohormonal mechanisms such as the renin–angiotensin–aldosterone system.[11] All catecholamines increase renal blood flow to a similar extent by increasing cardiac output and mean arterial pressure with a resultant natriuresis. Catecholamine-mediated increases in renal blood flow do not affect glomerular filtration rate.

A natriuresis may also result from the inhibition of cAMP in the renal tubules. This effect has previously been attributed to a specific dopaminergic effect ('low dose' dopamine: 2 μg/kg/minute), although this occurs to a similar extent with adrenaline, noradrenaline and dobutamine. The use of 'renal' dopamine has not been shown to be effective in preventing renal dysfunction in susceptible patients.[15]

METABOLIC

Catecholamine-mediated β-stimulation may result in hyperglycaemia, hypokalaemia and hypophosphataemia, which may need monitoring and correcting.

Adrenaline is associated with the development of hyperlactataemia due to the activation of pyruvate dehydrogenase. Although associated pH may fall to levels around 7.2, the metabolic acidosis is not associated with impaired tissue perfusion or cellular dysoxia. In most patients who are haemodynamically stable, this is a self-limiting phenomenon and is not associated with adverse outcomes.[16,17]

SPLANCHNIC

The splanchnic circulation is more dependent on mean arterial pressure and the duality of the mesenteric and portal systems. Concerns about catecholamine-induced splanchnic vasoconstriction with mesenteric and hepatic ischaemia have not been substantiated.[18]

All catecholamines are equally effective in increasing splanchnic perfusion by improving cardiac output and mean arterial pressure.

PHOSPHODIESTERASE INHIBITORS

Phosphodiesterase (PDE) inhibitors are compounds that cause non-receptor-mediated competitive inhibition of PDE isoenzymes, resulting in increased levels of cAMP (see Fig. 92.2). Importantly, cAMP also affects diastolic heart function through the regulation of phospholamban, the regulatory subunit of the calcium pump of the sarcoplasmic reticulum. This enhances the rate of calcium re-sequestration and associated diastolic relaxation (lusitropy).[19]

For cardiovascular tissue, inhibition of isoenzyme PDE III is responsible for the therapeutic effects. Cardiac effects are characterised by positive inotropy and lusitropy that may be beneficial in patients with reduced ventricular compliance or predominant diastolic failure.[16]

These agents also cause potent vasodilatation with reductions in preload, venous return and afterload as well as a reduction in pulmonary vascular resistance. The term 'inodilation' has been used to describe this dual haemodynamic effect.

Tolerance is not a feature. These agents may have an unsubstantiated role in the management of patients with chronic or subacute cardiac failure by sensitising the myocardium to β-agonists. Other actions include the inhibition of platelet aggregation and the reduction of post-ischaemic reperfusion injury.

The pharmacokinetics of PDE inhibitors are markedly different from catecholamines. Drug half-lives may be prolonged and excretion is predominantly renal. Hypotension may result from vasodilatation, and combined use with catecholamines (e.g. noradrenaline or adrenaline) may be necessary to maintain mean arterial pressure.

PDE inhibitors that have been used in clinical practice include the bipyridine derivatives, amrinone and milrinone; the imidazolones, enoximone and piroximone; and the calcium sensitiser, levosimendan. The cardiovascular effects are similar. Despite the increasing use of PDE inhibitors in critically ill patients, there is little high-quality evidence about the safety and efficacy of these drugs in this patient population.[20]

Milrinone is the most commonly used drug in clinical practice, with the latter exhibiting more inotropic effects than vasodilatation. Enoximone is more rapidly metabolised, but the metabolite is active and its cardiovascular effects persist for some hours.

Levosimendan is a dose-dependent selective PDE inhibitor with a unique action on myocardial calcium metabolism. By increasing myofilament calcium sensitivity throughout the cardiac cycle by binding to cardiac troponin C, associated conformational changes induce improved inotropic and lusitropic function.

Vasodilatation is also induced through adenosine-triphosphate-sensitive potassium channels. Calcium-sensitive actions predominate at low doses, whereas PDE-inhibition effects predominate at higher doses.[21] The half-life of levosimendan is shorter than that of older PDE III inhibitors (approximately 1 hour) and it may be given by infusion. There is emerging evidence that levosimendan is not associated with improved patient-centred outcomes in critically ill patients.[22,23]

HISTORICAL DRUGS

DIGOXIN

Digitalis glycosides have been used for the treatment of heart failure for 200 years and the vagotonic effects used to control the ventricular response in selected supraventricular tachyarrhythmias. Its use in the ICU has been superseded by catecholamines and antiarrhythmics such as amiodarone.

The role of digoxin in acute cardiac failure is limited. It has minimal effects as an inotrope and evaluation of its efficacy is problematic in critically ill patients. The potential for toxicity is increased by hypokalaemia, hypomagnesaemia, hypercalcaemia, hypoxia and acidosis, particularly in patients with an associated acute kidney injury. Toxicity is manifested by dysrhythmias that may assume any form including supraventricular tachyarrhythmias, bradycardia, ventricular ectopy and conduction block at any level.

THYROID HORMONE

Thyroid hormone is required for synthesis of contractile proteins and normal myocardial contraction. It is also a regulator of the synthesis of adrenergic receptors. Its use is limited in critically ill patients, but may have a limited, although unproven, role in haemodynamic support of brain-dead organ donors as a catecholamine-sparing agent.

SELECTIVE VASOPRESSORS

Vascular responsiveness is mediated via adrenergic receptors: α-mechanisms predominantly cause vasoconstriction; β-mechanisms, specifically β_2-receptors, mediate vasodilatation (see Table 92.2).

Noradrenaline, adrenaline and dopamine have variable effects on the peripheral vasculature and should not be regarded principally as vasoconstrictors or vasopressors.

There are few selective 'vasoconstrictors' that predominantly have an unsubstantiated role in vasodilated states such as regional (epidural) anaesthesia or selected patients with acute spinal injury. Their utility in critically ill patients remains limited, although they are widely used in patients undergoing general anaesthesia.

PHENYLEPHRINE AND METARAMINOL

These agents are direct-acting α_2 agonists that are selective vasoconstrictors, both venous and arterial, with minimal β-activity. They have similar pharmacokinetics to catecholamines and may be given by infusion. In patients with normal sympathetic tone, these drugs may cause reflex bradycardia, particularly following bolus administration.

EPHEDRINE

Ephedrine is a synthetic, direct- and indirect-acting, non-catecholamine sympathomimetic that acts on both α- and β-receptors. Duration of action is longer than equivalent doses of adrenaline and it is generally unsuitable as an infusion.

VASOREGULATORY AGENTS

In addition to adrenergic regulation, neurohormonal influences have a regulatory role in maintaining vasomotor tone. These are mediated through the renin–aldosterone–angiotensin axis and local mediators such as vasopressin, corticosteroids, nitric oxide and endothelin.

The response of the neurohumoral system may become blunted in conditions such as severe sepsis, where qualitative and quantitative changes may occur. In this context, failure of vasomotor responsiveness may be considered as part of the multiple organ failure.

VASOPRESSIN

Specific vasopressinergic receptors (V_1, V_2) have been identified in association with sympathetic terminals. Vasopressin is a naturally occurring peptide secreted by the posterior pituitary gland. Reduced serum levels of vasopressin have been demonstrated in septic shock and following cardiopulmonary bypass, suggesting an inflammatory-mediated mechanism. Levels are maintained during cardiogenic shock.[24]

A proportion of patients with severe septic shock requiring high levels of catecholamines to support the circulation may respond to low doses of infused vasopressin (0.04 U/h). However, although vasopressin may improve catecholamine responsiveness in patients with less-severe shock, no benefit in mortality has been demonstrated and there is uncertainty about its use in shock states.[25]

CORTICOSTEROIDS

The role of steroid supplementation in circulatory failure has been studied for over 40 years. Although immunosuppressive or anti-inflammatory doses have been shown to be ineffective, particularly in septic shock, the replacement of 'stress response' doses (approximately 200 mg hydrocortisone per day by

continuous intravenous infusion, or 50 mg 8 hourly) have been shown to improve catecholamine vasoresponsiveness in selected patients with septic shock. However, the role of steroids in shock states remains uncertain, despite two large trials, and they are not routinely recommended.[26] Studies of the potential interaction between corticosteroids and vasopressin have similarly not demonstrated improved survival in patients with septic shock and reduced serum vasopressin levels.[27] In 2017, the ADRENAL trial, conducted in 3500 ICU patients with catecholamine-dependent septic shock demonstrated no significant difference in day-90 mortality in patients who received hydrocortisone or placebo. However, the use of the continuous infusion of hydrocortisone was associated with a reduction in the duration of septic shock, duration of mechanical ventilation and ICU admission, suggesting a potentially beneficial role of hydrocortisone as modulator of vasopressor responsiveness in patients with septic shock.[28]

CLINICAL USES

Currently, there are no definitive studies comparing the efficacy of one inotrope (or combination of inotropes) over another in terms of improving survival.[29]

DRUG SELECTION

In most instances, individual experience and preference determine selection of inotrope(s).

On a pathobiological basis, exogenous catecholamines are used to augment endogenous mechanisms that may be failing at a number of levels. In this context, vasoactive therapy should be regarded as 'cardiovascular neuroendocrine augmentation therapy'.

Noradrenaline or adrenaline are considered as the first-line drug in most causes of circulatory failure. An emerging body of evidence and current clinical practice guidelines, particularly for patients with sepsis confirms this statement.[12,30]

Dopamine predominantly acts as a precursor of noradrenaline and may be used as an alternative to noradrenaline, although it is associated with an increased incidence of arrhythmias.

Prediction of the response of an individual to a catecholamine is problematic as marked inter- and intra-individual variability to the response of vasoactive agents may occur.

The haemodynamic and metabolic response of an agent must be carefully monitored and evaluated. If there is not a satisfactory response, or if undesirable effects are obtained, the dose or agent should be changed.

MONITORING

Accurate monitoring of the circulation is essential in patients with circulatory failure to assess baseline parameters and the response of vasoactive drugs.[31]

Clinical assessment of the circulation remains the cornerstone of monitoring these patients and includes frequent assessment and recording of pulse rate and rhythm, blood pressure, adequacy of peripheral perfusion, skin turgor, level of consciousness and urine output.

The majority of patients with circulatory failure managed in the ICU require haemodynamic monitoring as clinical signs may be masked or influenced by sedation, ventilation or organ failure. As a minimum, all patients receiving vasoactive drugs in all but trivial doses should have accurate monitoring of mean arterial pressure, ideally with an intra-arterial catheter referenced to the aortic root and an assessment of volume status such as central venous pressure.

In selected patients with primary myocardial failure, an assessment of cardiac output may be useful to quantify baseline function and to assess the response of the heart to drug therapy. Measurement of cardiac output may be done non-invasively using transthoracic or transoesophageal echocardiography, or invasively by using a pulmonary catheter, ideally using a continuous cardiac output display system, although the use of these catheters has decreased substantially and is superseded by the use of transthoracic echocardiography.

Derived parameters from pulmonary artery catheters include systemic vascular resistance that is used as a surrogate index of afterload, although this parameter does not reflect afterload, arteriolar tone or venous return. Consequently, systemic vascular resistance should not be used as a criterion for selection of vasoactive drug or as a titratable end-point.

Restoration of reduced tissue perfusion is a primary aim of vasoactive therapy. This may be assessed clinically by improvements in urine output, serum urea and creatinine, reversal of metabolic acidosis and reductions in serum lactate.

DOSAGES AND DRUG ADMINISTRATION

Vasoactive drugs, such as catecholamines or vasopressors, should be administered as a continuous infusion through a dedicated central venous catheter using drug delivery systems such as infusion pumps or syringe drivers.

Infusion lines should be free of injection portals and clearly marked with identifying labels.

Concentrations of infusions should be standardised in accordance with individual unit protocols. Suggested infusion concentrations are shown in Table 92.3.

These infusions in mL/h approximate μg/min. Absolute doses with regard to body weight are not relevant; however, the titrated clinical effect is.

Vasoactive drugs are usually prescribed as a titration against a targeted mean arterial pressure. While a default target mean arterial pressure of 70 mm Hg is frequently used, this should consider the patient's

Table 92.3 Infusion concentrations of commonly used vasoactive drugs

AGENT	INFUSION CONCENTRATION	DOSE
Adrenaline	6 mg/100 mL 5% dextrose	Titrate mL/h (= µg/min)
Noradrenaline	6 mg/100 mL 5% dextrose	Titrate mL/h (= µg/min)
Dopamine	400 mg/100 mL 5% dextrose	Titrate mL/h (approx. µg/kg/min)
Dobutamine	500 mg/100 mL 5% dextrose	Titrate mL/h (approx. µg/kg/min)
Isoprenaline	6 mg/100 mL 5% dextrose	Titrate mL/h (= µg/min)
Milrinone	10 mg/100 mL 5% dextrose	Loading dose: 50 µg/kg over 20 min Infusion: 0.5 µg/kg/min
Levosimendan	25 mg/100 mL 5% dextrose	Loading dose: 24 µg/kg over 10 min Infusion: 0.1 µg/kg/min
Phenylephrine	10 mg/100 mL 5% dextrose	Titrate mL/h (= 100 µg/h)
Metaraminol	100 mg/100 mL 5% dextrose	Titrate mL/h (= mg/h)
Ephedrine	300 mg/100 mL 5% dextrose	Titrate mL/h (= 3 mg/h)
Vasopressin	20 U/20 mL 5% dextrose	2.4 mL/h (0.04 U/min)
Hydrocortisone	100 mg/100 mL 5% dextrose	Loading dose: 100 mg Infusion: 0.18 mg/kg/h

pre-morbid blood pressure, associated co-morbidities and acute illness.[16] In some clinical situations, such as elderly patients with acute-on-chronic kidney injury, a higher mean arterial pressure may be targeted, while in others, such as those with acute intracranial haemorrhage or those following major surgery at risk of secondary haemorrhage, a lower mean arterial pressure may be targeted. These targets must be re-assessed frequently as dictated by the clinical context and trajectory. Increasingly, a lower default mean arterial pressure of 60–65 mm Hg is advocated.

SPECIFIC INDICATIONS

CARDIOPULMONARY RESUSCITATION

Adrenaline has been used for circulatory collapse at least since 1907. The International Liaison Committee on Resuscitation guidelines recommends adrenaline as the first-line vasoactive drug in cardiopulmonary resuscitation.[32] The dose is 1 mg intravenously every 3 minutes.

Adrenaline is recommended as first-line therapy for 'medical pacing' for severe bradyarrhythmias that do not respond to atropine. Isoprenaline has traditionally been used for this purpose; however, its use has been superseded by adrenaline due to concerns about efficacy and lack of α-adrenergic activity.

CARDIOGENIC SHOCK

Theoretically, catecholamine infusions may confer some advantages in cardiogenic shock, particularly in association with acute myocardial infarction. In patients with systolic heart failure, adrenaline, noradrenaline, dopamine and dobutamine have been shown to cause satisfactory short-term effects. This may allow the myocardium time to recover from post-ischaemic 'stunning', particularly after revascularisation. However, no increased long-term survival due to their use has been demonstrated.[29]

The role of PDE inhibitors (e.g. milrinone) and calcium sensitisers (e.g. levosimendan) in acute heart failure may have a potential role in patients with diastolic heart failure, particularly those with associated high impedance states such as aortic stenosis and pulmonary hypertension. Due to their non-adrenergic mechanism of action, these agents may be useful in patients who are 'resistant' to catecholamines. However, recent high-quality randomised, controlled trials have not shown superiority of levosimendan over dobutamine, but showed that levosimendan is associated with increased adverse outcomes, particularly tachyarrhythmias and catecholamine-dependence in patients with septic shock.[22,23]

SEPARATION FROM CARDIOPULMONARY BYPASS

Numerous combinations of catecholamines have been used successfully to wean patients from cardiopulmonary bypass. However, there are no definitive studies demonstrating significant benefits of one catecholamine over another.

Adrenaline and noradrenaline have been found to increase cardiac output with little increase in heart rate or afterload and are often regarded as first-line drugs.

Dobutamine may be associated with vasodilatation and hypotension.

There is no conclusive evidence that the catecholamines, including noradrenaline, cause vasospasm of arterial conduits in clinically used doses.

PDE inhibitors, such as milrinone and levosimendan, either as sole agents or in conjunction with adrenaline or noradrenaline, have been used with variable success driven by local preference, although there is little high-quality evidence that these drugs are superior to catecholamines. PDE inhibitors may have a beneficial role in high impedance states such as in patients with pulmonary hypertension undergoing mitral valve replacement or in those with severe preoperative diastolic heart failure.[33]

Cardiopulmonary bypass may be associated with a systemic inflammatory response syndrome characterised by a hyperdynamic, vasodilated state. Noradrenaline is frequently advocated as a 'vasopressor' agent in this context to restore mean arterial pressure, which may be reduced as a consequence. Although catecholamines may be required to achieve appropriate target mean arterial pressure and cardiac output, caution should be applied if high doses (e.g. >30 μg/min noradrenaline) are required.

RIGHT VENTRICULAR FAILURE

Right ventricular infarction and major pulmonary embolism may be associated with acute right ventricular failure. Right ventricular depression may also occur in severe sepsis. Restoration of preload is critical in these conditions, as the failing right ventricle is particularly susceptible to reductions in preload.

Inotropes, such as noradrenaline and adrenaline, are regarded as first-line drugs in these situations in order to maintain adequate mean arterial pressure so that right coronary artery perfusion, which occurs throughout the cardiac cycle, is maintained.

SEPTIC SHOCK

The cardiovascular effects of the sepsis syndrome and septic shock are complex and range from a hyperdynamic, vasodilated state to one of increasing myocardial failure and paralysis of the peripheral vasculature (vasoplegia). The latter represents inability of the venous circulation to respond to endogenous or exogenous catecholamines with resultant venous pooling.

An increasing body of literature now recommends the use of catecholamines as first-line agents in the treatment of septic shock. The Surviving Sepsis Campaign guidelines recommend that either noradrenaline or adrenaline be used as the first-line choice vasopressor.[30] However, the basis for this recommendation is limited as there is little high-quality evidence to recommend one catecholamine over another. Concerns about adverse metabolic and splanchnic side effects of adrenaline are unsubstantiated, and there is an emerging body of evidence that noradrenaline and adrenaline are equally effective in treating septic shock.[30] There is evidence that dopamine may be associated with adverse outcomes and its use is being questioned in the absence of superiority to noradrenaline or adrenaline.[12]

The efficacy of dobutamine as a sole agent or in combination with noradrenaline in septic shock is questionable and appears to add little to the efficacy of noradrenaline or adrenaline in terms of resolution of shock or mortality.

Doses required to achieve adequate mean arterial pressure in septic shock may vary: noradrenaline or adrenaline infusions (up to 40 μg/min) may be necessary. Patients who develop marked catecholamine dependency, in the absence of other acute remediable causes, such as active infection, may respond to low doses of vasopressin or 'stress response' doses of hydrocortisone, although there is marked interindividual variation in response to these drugs. However, the use of vasopressin in patients with septic shock has not been shown to improve survival apart from a subgroup of patients with less severe shock.[25,34] Similarly, the role of corticosteroids as a catecholamine-sparing agent is recognised, but whether this observation translates to improved patient-centred outcome remains unknown with current evidence.[26]

ANAPHYLAXIS

Adrenaline is the drug of choice for anaphylactic reactions and for life-threatening bronchospasm, as it blocks mediator release and specifically reverses end-organ effects (see Chapter 66).

A dose of 0.1 mg, as 1 mL of 1:10,000 solution, may be injected subcutaneously, intramuscularly or intravenously. Repeated doses or infusions of up to 100 μg/min may be required. A strong, slowing pulse indicates a systemic pressor effect and provides a useful clinical end-point for the rate of infusion. This α-agonist effect is also probably of considerable importance in anaphylaxis, as deaths are frequently due to prolonged refractory hypotension caused by acute biventricular failure. Early intravenous fluid therapy is also important.

CEREBRAL PERFUSION PRESSURE

Augmentation of cerebral perfusion pressure is an important strategy in patients with pathological reductions in cerebral blood flow, such as traumatic brain injury and subarachnoid haemorrhage. Noradrenaline is used to augment cerebral perfusion pressure in these patients, although there is no conclusive evidence to recommend any particular drug over another.[14]

Vasodilators and antihypertensives

David O'Callaghan, David Antcliffe

Vasodilators are a generic group of drugs that are primarily used in the intensive care unit (ICU) for the management of acute hypertensive states and emergencies. In addition, they have an important role in the management of myocardial ischaemia, systemic and pulmonary hypertension, and cardiac failure.[1,2]

PHYSIOLOGY

Blood pressure is controlled by a complex physiological neurohormonal system involving all components of the cardiovascular system.[3,4] Clinical practice has focused on the arterial circulation as the major regulator of systemic pressure. The importance of venous circulation in determining mean arterial pressure and cardiac output is discussed in Chapter 92.

The role of the peripheral vasculature in the regulation of blood pressure may be conceptually regarded as a balance between vasodilatation and vasoconstriction (Fig. 93.1).[4]

CALCIUM FLUX

The concentration of intracellular ionised calcium is the primary determinant of vascular smooth muscle tone: increases lead to smooth muscle contraction; decreases cause relaxation. Control of calcium influx and efflux is determined by adrenergic receptor occupation and changes in membrane potential, which is mediated through voltage-gated channels (see Chapter 92, Fig. 92.2).

ENDOTHELIAL SYSTEM

The endothelium plays a central role in blood pressure homeostasis by secreting substances such as nitric oxide (NO), prostacyclin and endothelin.[4] These substances are continuously released by the endothelium and are integral in regional autoregulation.[5]

NO is synthesised from L-arginine by NO synthases and diffuses into smooth muscle where it activates guanylate cyclase to increase cyclic guanosine monophosphate (cGMP) resulting in the relaxation of underlying smooth muscle and vasodilatation.

Prostacyclin is synthesised via the arachidonic pathway and has a minor role in the control of vascular tone.

Endothelins are endothelium-derived vasoconstrictor peptides that are associated with increases in vascular smooth muscle intracellular calcium. They bind to endothelin receptors within the vascular smooth muscle causing vasoconstriction, usually in response to shear stresses, tissue hypoxia, angiotensin II and inflammatory mediators (e.g. interleukin-6 and nuclear factor-κB [NF-κB]).

RENIN–ANGIOTENSIN–ALDOSTERONE SYSTEM

Angiotensinogen is converted by renin to form angiotensin I, which is subsequently converted to angiotensin II by the angiotensin-converting enzyme (ACE). Angiotensin II has a number of effects on blood pressure homeostasis including the release of aldosterone, direct activation of α-adrenergic receptors on vascular smooth muscle and a direct effect in the endothelium. These effects are directed at maintaining blood pressure and are integral in the stress response. ACE also inactivates bradykinins that have predominantly vasodilatory effects, coupled to arachidonic acid synthesis and the generation of prostacyclin.

ADRENERGIC SYSTEM

The sympathetic nervous system is integrally involved with all of the above systems, regulating vascular tone at central, ganglionic and local neural levels. Adrenergic stimulation of β-receptors is associated with vasodilatation; α-receptor stimulation results in vasoconstriction. The vascular effects of the catecholamines and vasopressors are discussed in Chapter 92.

Adrenergic stimulation is the predominant system regulating venous tone[6] via endothelial differences in veins resulting production of less NO and reduced responsiveness to angiotensin II.

ABSTRACT

Vasodilator and antihypertensive medications are drugs commonly used in intensive care to treat a wide variety of clinical conditions. This chapter addresses the underlying physiology of blood pressure control from the role of calcium, the endothelial system and hormonal influences to derangements in this physiology that may lead to hypertension. In this context the mechanisms of action of the most commonly used classes of vasodilators and antihypertensive drugs are also explored. Different clinical situations and pathologies call for specific treatments with the drugs detailed, and in this chapter many of these conditions are reviewed along with current recommendations for treatment.

KEYWORDS

Hypertension
calcium
beta-blockers
ACE inhibitors
alpha-antagonists
ionodilators
aortic dissection
myocardial ischaemia
phaeochromocytoma
pre-eclampsia

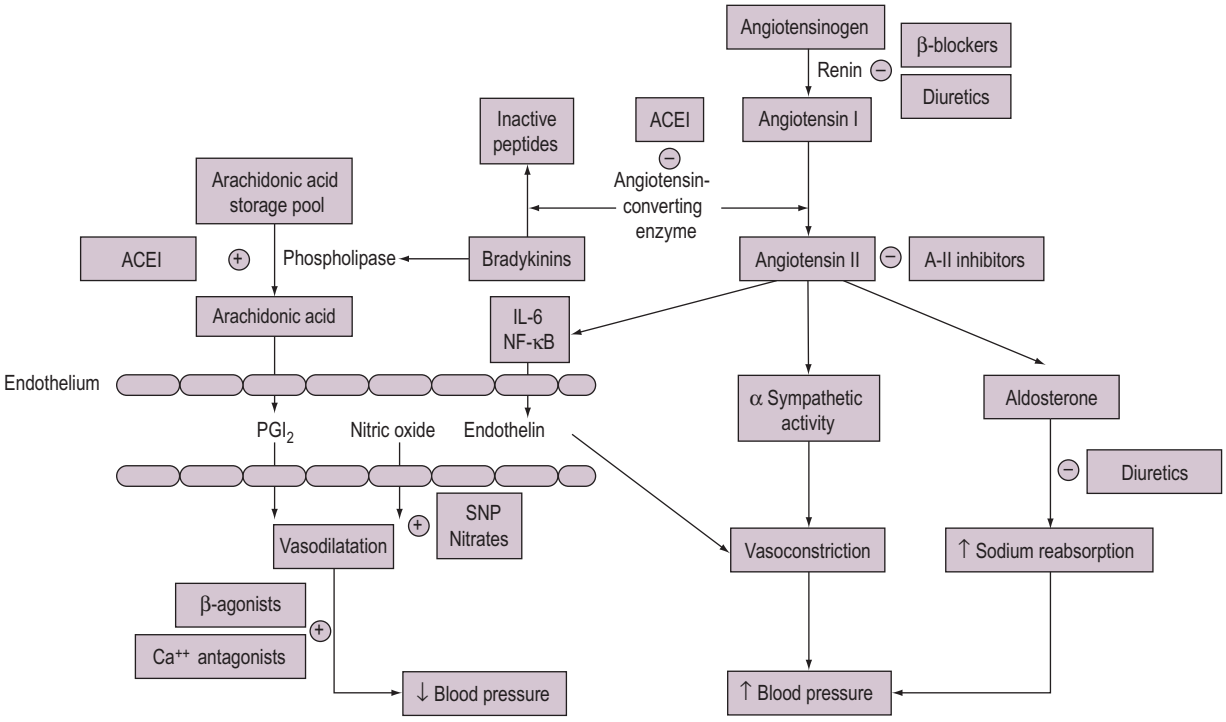

Figure 93.1 Schematic diagram of the neurohormonal factors determining vasomotor tone. Mechanism of action of vasodilators is shown by (–) for inhibition, (+) for stimulation. *A-II*, Angiotensin II; *ACEI*, angiotensin-converting enzyme inhibitors; *IL*, interleukin; *NF*, nuclear factor; *PGI_2*, prostacyclin; *SNP*, sodium nitroprusside.

PATHOPHYSIOLOGY

Hypertensive states develop as a result of impaired or abnormal homeostatic processes, causing an imbalance between vasoconstriction and vasodilation.

Essential hypertension is the most common cause of hypertension and is due to abnormal neurohormonal regulation, particularly exaggerated effects of renin–angiotensin activity.

Secondary causes of hypertension include structural abnormalities such as aortic coarctation or renal artery stenosis; endocrine conditions such as phaeochromocytoma, Cushing syndrome and pregnancy-induced hypertension; and central causes such as raised intracranial pressure.

CALCIUM CHANNEL BLOCKERS

Calcium channel blockers have numerous effects on the cardiovascular system, influencing heart rate, myocardial contractility and vasomotor tone. The entry of calcium through voltage-gated calcium channels is a major determinant of arteriolar, but not venous, tone.[7] Calcium channel blockers are recommended as a first-step treatment for hypertension in Caucasian patients greater than 55 years and Afro-Caribbean patients of any age.[8]

There are three major groups of calcium channel blockers that have different sites of action and therapeutic effects: dihydropyridines (e.g. nifedipine, nimodipine, nicardipine, amlodipine, and felodipine), phenylalkylamines (e.g. verapamil) and benzothiazepines (e.g. diltiazem).

Magnesium is a physiological calcium antagonist, and is used therapeutically as magnesium sulphate.

NIFEDIPINE

Nifedipine is a predominant arteriolar vasodilator, with minimal effect on venous capacitance vessels and no direct depressant effect on heart rate conduction.

It may be administered intravenously, orally or sublingually, and has a rapid onset of action of 2–5 minutes and a duration of action of 20–30 minutes.

Nifedipine can be used to treat angina pectoris, especially that due to coronary artery vasospasm. Peripheral vasodilatation results in decreased systemic blood pressure, often associated with sympathetic stimulation resulting in increased cardiac output and heart rate, which may counter the negative inotropic, chronotropic and dromotropic effects of nifedipine. Nevertheless, nifedipine may be associated with profound hypotension in patients with ventricular dysfunction, aortic stenosis and/or concomitant β-blockade. For this reason, the use of sublingual

nifedipine as a method of treating hypertensive emergencies is no longer recommended.[9]

Nifedipine and related drugs may cause diuretic-resistant peripheral oedema, which is due to the redistribution of extracellular fluid rather than sodium and water retention.

NIMODIPINE

Nimodipine is a highly lipid-soluble analogue of nifedipine. High lipid solubility facilitates entrance into the central nervous system where it causes selective cerebral arterial vasodilatation, which may attenuate cerebral arterial vasospasm following aneurysmal subarachnoid haemorrhage. Improved outcomes have been demonstrated in patients with Grade 1 and 2 subarachnoid haemorrhage.[10] Systemic hypotension may result from peripheral vasodilatation that may compromise cerebral blood flow in susceptible patients. Similarly, cerebral vasodilatation may increase intracranial pressure in patients with reduced intracranial elastance.

The recommended dose following aneurysmal subarachnoid haemorrhage is 60 mg orally 4-hourly, but it can be given at 30 mg 2-hourly to reduce variation in blood pressure. Intravenous nimodipine is not recommended owing to its profound effect on blood pressure.

AMLODIPINE

Amlodipine is an oral preparation that has a similar pharmacodynamic profile to nifedipine. In addition to arteriolar vasodilatory and cardiac effects, amlodipine has been shown to exert specific anti-inflammatory effects in hypertension and diabetic nephropathy, and in modulating high-density lipoprotein (HDL) in patients with hypercholesterolaemia.[11] These effects have seen amlodipine increasingly being used for the treatment of hypertension, and it may have a role in stable critically ill patients with associated comorbidities.

VERAPAMIL

Verapamil predominantly affects the atrioventricular node and is principally used as an antiarrhythmic for the treatment of supraventricular tachyarrhythmias. For this reason, concomitant therapy with β-blockers or digoxin is not recommended.

Verapamil is negatively inotropic and is not as active as nifedipine on smooth muscle; therefore it causes less pronounced decrease in systemic blood pressure. It has a limited role as a vasodilator.[12]

DILTIAZEM

Diltiazem has a similar cardiovascular profile to verapamil, although its vasodilatory properties are intermediate between nifedipine and verapamil. Diltiazem exerts minimal cardiodepressant effects and is less likely to potentiate β-blockers.

MAGNESIUM SULPHATE

Magnesium regulates intracellular calcium and potassium levels by activating membrane pumps and competing with calcium for transmembrane channels. Physiological effects are widespread, affecting cardiovascular, central and peripheral nervous systems and the musculoskeletal junction.[13]

It acts as a direct arteriolar and venous vasodilator causing reductions in blood pressure. Modulation of centrally mediated and peripheral sympathetic tone results in variable effects on cardiac output and heart rate.

Consequently, it has an established role in the treatment of pre-eclampsia and eclampsia,[14] perioperative management of phaeochromocytoma[15] and treatment of autonomic dysfunction in tetanus.[16] It has been proposed as a possible agent for the prevention of secondary ischaemia after aneurysmal subarachnoid haemorrhage; however, evidence of a benefit on outcome is still lacking.[17]

DIRECT-ACTING VASODILATORS

These drugs act directly on vascular smooth muscle and exert their effects predominantly by increasing the concentration of endothelial NO. These drugs are also known as nitrovasodilators.[18]

SODIUM NITROPRUSSIDE

Sodium nitroprusside is a non-selective vasodilator that causes relaxation of arterial and venous smooth muscle. It is comprised of a ferrous ion centre associated with five cyanide moieties and a nitrosyl group. The molecule is 44% cyanide by weight.

It is reconstituted from a powdered form. The solution is light sensitive so it requires protection from exposure to light (e.g. by wrapping administration sets in aluminium foil). Prolonged exposure to light may be associated with an increase in release of hydrogen cyanide, although this is seldom clinically significant.

When infused intravenously, sodium nitroprusside interacts with oxyhaemoglobin, dissociating immediately to form methaemoglobin while releasing free cyanide and NO. The latter is causing the vasodilation.

Dosage is from 0.5 μg/kg/min to 8 μg/kg/min, but should always start at a low infusion rate and build up slowly.

Onset of action is almost immediate with a transient duration, requiring continuous intravenous infusion to maintain a therapeutic effect. Tachyphylaxis can occur and large doses should not be used if the desired

therapeutic effect is not attained, as this may be associated with toxicity.

Sodium nitroprusside produces direct venous and arterial vasodilatation, resulting in a prompt decrease in systemic blood pressure. The effect on cardiac output is variable. Decreases in right atrial pressure reflect pooling of blood in the venous system, which may decrease cardiac output. This may result in reflex tachycardia that may oppose the overall reduction in blood pressure. In patients with left ventricular failure, the effect on cardiac output will depend on initial left ventricular end-diastolic pressure.

Sodium nitroprusside may potentially increase myocardial ischaemia in patients with coronary artery disease by causing an intracoronary steal of blood flow away from ischaemic areas by arteriolar vasodilatation. Secondary tachycardia may also exacerbate myocardial ischaemia.

Due to its non-selectivity, sodium nitroprusside has direct effects on most vascular beds. In the cerebral circulation, sodium nitroprusside is a cerebral vasodilator, leading to increases in cerebral blood flow and blood volume. This may be critical in patients with increased intracranial pressure. Rapid and profound reductions in mean arterial pressure produced by sodium nitroprusside may exceed the autoregulatory capacity of the brain to maintain adequate cerebral blood flow.

Sodium nitroprusside is a pulmonary vasodilator and may attenuate hypoxic pulmonary vasoconstriction, resulting in increased intrapulmonary shunting and decreased arterial oxygen tension. This phenomenon may be exacerbated by associated hypotension.

The prolonged use of large doses of sodium nitroprusside may be associated with toxicity related to the production of cyanide and, to a lesser extent, methaemoglobin.[19]

Free cyanide produced by the dissociation of sodium nitroprusside reacts with methaemoglobin to form cyanmethaemoglobin, or is metabolised by rhodenase in the liver and kidneys to form thiocyanate. A healthy adult can eliminate cyanide at a rate equivalent to a sodium nitroprusside infusion of 2 µg/kg/min or up to 10 µg/kg/min for 10 minutes, although there is marked interindividual variability.

Toxicity should be of concern in patients who become resistant to sodium nitroprusside despite maximum infusion rates and who develop an unexplained lactic acidosis. In high doses, cyanide may cause seizures.

Treatment of suspected cyanide toxicity is cessation of the infusion and administration of 100% oxygen. Sodium thiosulphate (150 mg/kg) converts cyanide to thiocyanate, which is excreted renally. For severe cyanide toxicity, sodium nitrite may be infused (5 mg/kg) to produce methaemoglobin and subsequently cyanmethaemoglobin. Hydroxycobalamin, which binds cyanide to produce cyanocobalamin, may also be administered (5 g over 15 minutes, which may be repeated in severe cases).

GLYCERYL TRINITRATE

Glyceryl trinitrate is an organic nitrate that generates NO through a different mechanism from sodium nitroprusside.

The pharmacokinetics allows glyceryl trinitrate to be given by infusion, with a longer onset and duration of action than sodium nitroprusside. The intravenous dosage can start at 5 µg/min and increase incrementally to 200 µg/min (maximum dose 400 µg/min). Glyceryl trinitrate may also be administered sublingually, orally or transdermally.

Tachyphylaxis is common with glyceryl trinitrate; doses should not be increased if patients no longer respond to standard doses. Glass bottles or polyethylene administration sets are required as glyceryl trinitrate is absorbed into standard polyvinylchloride sets.

The effects on the peripheral vasculature are dose dependent, acting principally on venous capacitance vessels to produce venous pooling and decreased ventricular preload.

Glyceryl trinitrate primarily dilates larger conductance vessels of the coronary circulation, resulting in increased coronary blood flow to ischaemic subendocardial areas, thereby relieving angina pectoris.

Reductions in blood pressure are more dependent on blood volume than with sodium nitroprusside. Precipitous falls in blood pressure may occur in hypovolaemic patients with small doses of glyceryl trinitrate. In euvolaemic patients, reflex tachycardia is not as pronounced as with sodium nitroprusside. At higher doses, arteriolar vasodilatation occurs without significant changes in calculated systemic vascular resistance. More recently, glyceryl trinitrate has been suggested as one approach to improve microcirculatory flow in septic shock, but only after adequate fluid resuscitation.[20]

Glyceryl trinitrate is a cerebral vasodilator and often causes headaches and should be used with caution in patients with known or suspected raised intracranial pressure.

ISOSORBIDE DINITRATE

Isosorbide dinitrate is the most commonly administered oral nitrate for the prophylaxis of angina pectoris. It has a physiological effect that lasts up to 6 hours in doses of 30–120 mg. The mechanism of action is the same as glyceryl trinitrate. Hypotension may follow acute administration, but tolerance to this develops with chronic therapy.[21]

HYDRALAZINE

Hydralazine is a potent, arterioselective, direct-acting vasodilator that acts via the stimulation of cGMP

and the inhibition of smooth muscle myosin light chain kinase.

Following intravenous administration, 5–10 mg, hydralazine has a rapid onset of action, usually within 5–10 minutes. It can alternatively be given by continuous intravenous infusion, initially 200–300 μg/min with maintenance usually 50–150 μg/min, and may be administered orally. The drug is partially metabolised by acetylation, for which there is marked inter-individual variability (35% of the population are slow acetylators). Although this does not have much clinical significance regarding the antihypertensive effects, it is important with respect to toxicity.[21]

Hydralazine causes predominantly arteriolar vasodilatation that is widespread but not uniform. It is associated with direct and reflex sympathetic activity, so that cardiac output and heart rate are increased. Prolonged use of hydralazine stimulates renin release and is associated with sodium and water retention. Consequently, hydralazine is frequently administered with β-blockers and/or diuretics.

Chronic use of hydralazine may be associated with immunological side effects including lupus syndrome, vasculitis, haemolytic anaemia and rapidly progressive glomerulonephritis.

NICORANDIL

Nicorandil has multiple actions. First, it is a potassium channel activator that leads to arteriodilation and improved coronary blood flow. Second, it has nitrate properties that cause venodilation and may also demonstrate cardioprotective effects against ischaemic injury. Third, nicorandil is currently indicated as a second-line treatment for stable angina but its use may be limited by the main side effects of headache, flushing and ulceration.

ALPHA-ADRENERGIC ANTAGONISTS

Several groups of compounds act as α-adrenergic blockers with variable affinity for populations of α-receptors. Physiology and pathophysiology may influence the responsiveness of the drug receptor–effector relationship. Receptor pathobiology is discussed in Chapter 92. Consequently, there may be marked inter- and intraindividual variability in patient response to these drugs.

There are six main groups of α-receptor antagonists: imidazolines (e.g. phentolamine), haloalkylamines (e.g. phenoxybenzamine), prazosin, β-adrenergic antagonists with α-receptor antagonism (labetalol, carvedilol), phenothiazines (chlorpromazine) and butyrophenones (haloperidol).

PHENTOLAMINE

Phentolamine is a non-selective, competitive antagonist at α_1- and α_2-receptors. At low doses, phentolamine causes prejunctional inhibition of norepinephrine (noradrenaline) release (via α_2-receptor inhibition). At higher doses, a more complete α-receptor blockade is achieved, with enhancement of effects of β-agonists due to increased local concentration of norepinephrine produced by α_2-blockade (see Chapter 92, Fig. 92.3a).

Phentolamine is administered intravenously and may be given intermittently or by infusion. Onset is rapid (within 2 minutes), with a duration of action of 10–15 minutes.

Arteriolar and venous vasodilatation reduces systemic blood pressure. Effects on cardiac output are variable, and there is modest reflex sympathetic stimulation without significant increases in heart rate.

PHENOXYBENZAMINE

Phenoxybenzamine is a non-selective, non-competitive, α_1- and α_2-receptor antagonist. Blockade is also produced on histamine, serotonin and acetylcholine muscarinic receptors. Reuptake of norepinephrine is blocked, thereby potentiating the effects of β-agonists.

Phenoxybenzamine is usually administered orally, but may also be given intravenously (taking care to avoid extravasation as it is irritant to tissues). It has a long onset of action and prolonged duration of action (3–4 days). It causes a gradual reduction in systemic blood pressure, without rapid reflex sympathetic activity.

Prolonged use is associated with increased β-adrenergic effects, predominantly increased heart rate, for which combination therapy with β-blockade is used. Phenoxybenzamine is primarily used in the management of phaeochromocytoma, either preoperatively or long term in inoperable patients. It may also be used to control autonomic hyperreflexia in patients with spinal cord transection.[22]

PRAZOSIN

Prazosin is a relatively arterioselective, competitive, α_1-receptor antagonist. It acts postjunctionally and therefore does not inhibit reuptake of norepinephrine. Consequently, it produces less tachycardia for a given reduction in systemic blood pressure.

It is administered orally and usually used for essential or renovascular (hyperreninaemia) hypertension. It is frequently used in combination with β-blockers and diuretics, particularly in patients with renal dysfunction.

LABETALOL

Labetalol is specific competitive antagonist at α_1-, β_1- and β_2-adrenergic receptors. β-blockade effects predominate, with an approximate ratio of α_1:β-receptor blockade of 1:4–7. Labetalol has partial agonist effects on β_2-receptors.

It is administered intravenously (typically 10–50 mg), has a rapid onset of action (5–10 minutes) with a duration of 2–6 hours. It may be given by infusion (usually 15–180 mg/h).

Systemic blood pressure and cardiac output are reduced by a combination of negative inotropy, arterial and venous vasodilatation. Reflex tachycardia is attenuated by β-blockade. These properties make labetalol particularly useful in controlled hypotension during anaesthesia and surgery to reduce bleeding.

Side effects, such as bronchospasm and hyperkalaemia, relate predominantly to β-blockade.

CARVEDILOL

Carvedilol is a non-selective β-blocker with α_1-antagonist activity. Most of the vasodilator activity relates to α_1-antagonism, although at high concentrations it also blocks calcium entry. The ratio of α_1:β-receptor blockade is 1:10. It is administered orally; no intravenous preparation is available.

Studies have demonstrated the slowing of progression of congestive cardiac failure and improved mortality, particularly when used in conjunction with ACE inhibitors in patients with mild to moderate cardiac failure.[23,24] It may also be used in patients who cannot be treated with ACE inhibitors.

HALOPERIDOL AND CHLORPROMAZINE

These drugs act as competitive α-receptor antagonists causing non-selective vasodilatation and blockade of norepinephrine reuptake.

These drugs are primarily used as major tranquillisers or antipsychotics; their effect on the peripheral vasculature should be regarded as a side effect, rather than a specific therapeutic action.

Reduction of systemic blood pressure is variable and may be precipitous, particularly in hypovolaemic patients with high sympathetic drive. These drugs may be useful in neurogenic hypertension, and are not regarded as first-line vasodilators.

INODILATORS

Many inotropic drugs have peripheral vascular effects and these are discussed in more detail in Chapter 92.

At low doses, epinephrine, norepinephrine and dopamine are predominantly β-agonists and can cause both arterial and venous vasodilatation. The response depends on tissue receptor predominance and density. For example, in skeletal muscle, epinephrine causes vasodilation whereas in subcutaneous tissue it is a potent vasoconstrictor; it is for this reason that intramuscular epinephrine is administered in anaphylaxis (the skeletal muscle vasodilation causing rapid systemic absorption) whereas subcutaneous administration will result in little systemic effect.

Dobutamine and isoprenaline are predominantly β-agonists and may cause decreases in mean arterial pressure, particularly in hypovolaemic patients or those with increased sympathetic drive. These agents may have a role in reducing left ventricular afterload in patients with systolic heart failure.

Milrinone is a selective type III phosphodiesterase inhibitor that prevents the breakdown of cyclic adenosine monophosphate (cAMP) within cardiac and vascular tissues. The increased cAMP levels lead to increased levels of intracellular calcium and thus increased contraction of cardiac muscle. Within vascular smooth muscle the cAMP inhibits myosin light chain kinase producing less contraction and thus vascular relaxation.

Levosimendan is a newer calcium sensitiser that leads to a greater ventricular contraction for the same intracellular calcium concentration. It also leads to vasodilatation, mediated by activation of adenosine triphosphate (ATP)-sensitive sarcolemmal and mitochondrial potassium channels. The drug itself has a relatively short half-life, but it has a long-acting active metabolite so that haemodynamic effects may be maintained for up to 7 days.

Both milrinone and levosimendan can lead to marked hypotension, particularly if a bolus dose is given. Therefore in critically ill patients a loading dose is best avoided and any excessive vasodilation may need to be balanced by a low dose of a vasoconstrictor. Usual infusion rates of milrinone are 0.375–0.75 μg/kg/min and levosimendan 0.05–0.2 μg/kg/min.

ANGIOTENSIN-CONVERTING ENZYME INHIBITORS

ACE inhibition has become a cornerstone in the management of patients with hypertension, cardiac failure and ischaemic heart disease.[25,26] They are now recommended as first-stage treatment for hypertension in Caucasian patients less than 55 years and patients with diabetic nephropathy.[8] These drugs act by non-selective, competitive, irreversible inhibition to the angiotensin I binding site thus reducing conversion to angiotensin II.

There are a very large number of ACE inhibitors on the market with very high penetration into the ambulant patient population. These drugs are administered orally; there are no routinely used parenteral preparations. Consequently, many critically ill patients admitted to the ICU may be taking ACE inhibitors. As a general rule, ACE inhibitors are stopped in most critically ill patients until vital organ (specifically renal) function is stabilised and the patient can take them enterally. Thereafter, doses are gradually increased over time with close monitoring of renal function.

PREPARATIONS

Captopril has a short half-life and therefore may be useful for initiating treatment within the ICU. It is administered orally in increasing doses and intervals to a maximum dose of 50 mg 8-hourly. It may be administered sublingually in acute hypertension (5–25 mg), with an onset of action in 20–30 minutes, and a duration of 4 hours. There are no significant differences in the cardiovascular effects between captopril and other preparations.

Enalapril is a prodrug, activated by hepatic metabolism to enalaprilat, producing a slower and more controlled action. It is administered orally in 5 mg increments to a total of 20 mg twice daily.

Lisinopril has the advantage of single daily dosing and may be useful in stable critically ill patients.

CARDIOVASCULAR EFFECTS

The cardiovascular effects of ACE inhibition are widespread, with effects that influence the peripheral vasculature, cardiac performance, and salt and water homeostasis. Consequently, ACE inhibitors are not principally regarded as vasodilators, although they have both direct and indirect effects on the peripheral vasculature.

Increased production of endothelial vasodilators, such as prostacyclin, and decreased production of endothelin by angiotensin result in generalised venous and arteriolar vasodilatation. This occurs in the absence of reflex sympathetic activity or changes in heart rate, due to the modulation of adrenergic stimulation. Systemic blood pressure is reduced without changes in cardiac output or heart rate.

ACE inhibition is associated with improved myocardial performance following acute myocardial infarction due to left ventricular remodelling and improvement in neurohumoral activation. These drugs have been shown to improve survival following myocardial infarction in patients with left ventricular dysfunction.[27]

'First-dose hypotension' is described in patients receiving ACE inhibitors for the first time. This may occur particularly in patients who are salt- and water-depleted, or those who develop sensitivity to the drug. Drug sensitivity may also present as a sudden decrease in renal function following commencement of the drug.

RENOVASCULAR EFFECTS

ACE inhibitors may cause renal failure, particularly in patients with renovascular disease, hyperreninaemic hypertension and acute kidney injury. The renal effects of ACE inhibitors may be potentiated by diuretics, non-steroidal anti-inflammatory drugs and β-blockers. ACE inhibitors are contraindicated in patients with bilateral renal artery stenosis.

As a rule in intensive care patients, ACE inhibitors are started in suitable patients once renal function has stabilised and the patient no longer requires inotropic support. Initial doses should be low and increased as tolerated.

SIDE EFFECTS AND TOXICITY

In addition to renal dysfunction, ACE inhibitors may be associated with a number of side effects. The most common of these is cough, which is due to the increased production of kinins.[28]

Severe angioneurotic oedema causing upper-airway obstruction may occur with all ACE inhibitors, although this is less common with enalapril and lisinopril. This is due to increased activation of bradykinins. ACE inhibitors are contraindicated in patients with a history of hereditary or idiopathic angioneurotic oedema.[29]

Neutropenia and agranulocytosis are uncommon but potentially lethal side effects in susceptible patients. ACE inhibitors should be avoided in pregnancy due to potential risk of foetal malformation and renal impairment.

ANGIOTENSIN RECEPTOR BLOCKERS

These are a class of antihypertensive drugs that cause irreversible, selective blockade of angiotensin II at AT_1 receptors.[30,31]

Losartan was the prototype, which has been followed by newer compounds such as irbesartan, valsartan and telmisartan. These drugs are oral preparations; there is no parenteral form.

The cardiovascular profile of angiotensin receptor blockers is similar to the ACE inhibitors, but selective blockade of angiotensin II offers several possible advantages over ACE inhibitors. These drugs are long acting and may be given once daily; onset of action is slow, thereby avoiding first-dose hypotension; and side effects, such as cough and angioneurotic oedema, are less common.[32] Angiotensin receptor blockers may be used as an alternative to ACE inhibitors but they should not be combined.[8]

CENTRALLY ACTING AGENTS

These agents modulate adrenergic stimulation at central nervous system and spinal cord level. The vasomotor centre of the medulla mainly controls sympathetic pressor influences, although other brainstem, midbrain and spinal centres have a role.

Most central responses are mediated through α_2-adrenergic receptors, which modulate the release and reuptake of norepinephrine, with subsequent effects on the peripheral vasculature and cardiac function.

CLONIDINE

Clonidine is a centrally acting α_2-agonist that stimulates inhibitory neurons in the vasomotor centre. This results in a reduction in sympathetic outflow from the central nervous system and is associated with negative inotropy and a reduction in heart rate. Systemic blood pressure is reduced by this mechanism, with associated arteriolar and venous vasodilatation. Clonidine has centrally acting analgesic properties, which make it a suitable drug in patients with postoperative hypertension.

Peripherally, it stimulates prejunctional α_2-receptors, thereby decreasing norepinephrine release, but may also have an effect at postjunctional α_1-receptors, causing vasoconstriction. This may present as rebound hypertension following an initial reduction of blood pressure as there is variable duration of the central and peripheral effects.

Clonidine can be administered orally (50–100 µg 8-hourly). It has a rapid onset of action and duration of action of 20–30 minutes.

METHYLDOPA

Methyldopa acts as a centrally acting 'false' transmitter following metabolism to methylnorepinephrine and subsequent stimulation of α_2-receptors leading to reduced sympathetic outflow, although the precise mechanism is not clear.

It has a limited role in hypertensive emergencies, but is useful in accelerated essential, renovascular and pregnancy-induced hypertension.

It is administered orally in doses of 250 mg to 3 g per day, although side effects (e.g. drowsiness and depression) may be minimised if the daily dose is less than 1 g. It may lead to a positive direct Coombs test in 10%–20% of patients.

OTHER ANTIHYPERTENSIVE AGENTS

BETA-ADRENERGIC ANTAGONISTS

β-blockers have been used for the treatment of hypertension for over 30 years and have an increasingly important role in the management of cardiac failure.[33–35] Although no longer recommended as first-step treatment of hypertension, they may be used if ACE inhibitors are poorly tolerated.[8]

In addition to decreasing heart rate and contractility, β-blockers have other neurohumoral effects that affect vascular tone. These relate to the inhibition of renin release from juxtaglomerular cells (see Fig. 93.1) and prejunctional inhibition of norepinephrine, which result in reduction in vascular tone and blood pressure. A central effect of β-blockers has also been proposed.

The mode of action has been described in terms of selectivity to blockade of β-adrenergic receptors (β_1 and/or β_2). While this is an appropriate pharmacological distinction, the clinical activity of these drugs is not as predictable due to mixed populations of β_1- and β_2-receptors in most organs and variable receptor responsiveness in physiological and pathophysiological conditions. Consequently, there is marked interindividual variability in the response to these drugs. In high-enough doses, whether intentionally or due to toxicity, all β-blockers will cause generalised antagonism with resultant therapeutic and toxic effects.

Lipid-soluble β-blockers include propranolol and metoprolol, which are predominantly excreted by the liver; atenolol and sotalol are water-soluble and predominantly renally excreted, warranting caution with these drugs in patients with renal dysfunction.

β-blockers may be given orally or intravenously. As there is significant first-pass metabolism, doses for oral and intravenous administration are markedly different.

Esmolol is an intravenous β-blocker that is rapidly metabolised by red cell esterases and is therefore not dependent on renal or hepatic function. Its rapid onset of action and short duration allow infusion of the drug, making it a useful drug in patients with acute hypertensive states associated with tachycardia. Labetalol and carvedilol are discussed above.

β-blockers are frequently used as adjuncts to vasodilators in the treatment of hypertensive emergencies and states, particularly where reflex tachycardia and sympathetic stimulation occur (e.g. hydralazine, nifedipine and prazosin).

Side effects and toxicity of β-blockers include bradycardia (which may be profound), hypotension, bronchoconstriction (caution in patients who have asthma), aggravation of peripheral vascular ischaemia, hyperkalaemia and masking of the sympathetic response to hypoglycaemia.

DIURETICS

As with β-blockers, diuretics have an established place in the management of hypertension. In addition to their effects on salt and water excretion and the inhibition of aldosterone, direct vasodilatory effects are associated with diuretics such as furosemide and the thiazides.

These drugs have a rapid venodilatory action, which may be due to inhibition of norepinephrine-activated chloride channels on veins. Reductions of blood pressure and right atrial pressure may occur following low doses, and may present before an associated diuresis.

All diuretics should be used with caution in patients with renal dysfunction and avoided if hypovolaemia is present or suspected.

PULMONARY VASODILATORS

Pulmonary vasodilators may be used in the ICU mainly to treat acute right-sided heart failure commonly after cardiac surgery/transplantation. Many of the systemic vasodilators (namely calcium channel blockers, sodium nitroprusside and nitrates) will also have vasodilatory effects within the pulmonary circulation. Specific pulmonary vasodilators may be inhaled or administered intravenously.

NITRIC OXIDE

NO is an endogenous vasodilator. When inhaled it leads to vasodilation in only the ventilated areas of the lung, and rapid combination with haemoglobin prevents systemic vasodilation. This may improve ventilation–perfusion mismatch resulting in an improved oxygenation but controlled trials have not demonstrated any beneficial effect on outcomes in severe acute lung injury and it may have an adverse effect on kidney function.[36] Its use is now mainly confined to the treatment of acute pulmonary hypertension post-cardiac surgery.

NO is oxidated to NO_2 particularly in a high-oxygen environment and therefore NO_2 levels should be carefully monitored. Similarly appropriate scavenging systems must be employed.

Rebound pulmonary hypertension may occur and so NO therapy should be slowly weaned rather than abruptly stopped.

PROSTACYCLIN

Inhaled epoprostenol or iloprost (a prostacyclin derivative) can be used as alternatives to NO, however, although some short-term benefit in oxygenation may be seen there is currently no evidence of improved outcomes with this therapy.[37] Care should be taken to avoid systemic hypotension.

SILDENAFIL

Sildenafil is a phosphodiesterase type 5 inhibitor used in the management of chronic pulmonary hypertension, as well as erectile dysfunction. There are reports of its use for acute pulmonary hypertension within the ICU where it can improve haemodynamics; however, by increasing shunt fraction it might worsen oxygenation when used in acute lung injury.[38]

BOSENTAN

Bosentan is a non-selective endothelin receptor antagonist. Its predominant use is in the treatment of type 1 pulmonary hypertension where it improves exercise capacity and delays clinical worsening. Currently, bosentan has no established role in critical care.

DRUG SELECTION

The clinical use of vasodilators in intensive care is different from their use in ambulatory patients. In the critically ill patient, these drugs are primarily used to control acute rises in mean arterial pressure associated with sympathetic stimulation, or as specific treatment of hypertensive emergencies.[39]

The ideal vasodilator is therefore one that has a rapid and predictable onset of action, allows titration to achieve a desired systemic blood pressure, does not compromise cardiac output, does not cause significant reflex tachycardia and is non-toxic.

The selection of drug to treat hypertensive states will depend on the predominant cause of hypertension and the mechanism of action in the homeostatic pathway (outlined in Fig. 93.1).

There are no large studies investigating optimum therapy in patients presenting with hypertensive emergencies. These conditions occur in a heterogeneous group of patients and drug selection is essentially determined by the underlying pathophysiology, personal preference and experience.[39]

MONITORING

The principles of haemodynamic monitoring in patients receiving vasoactive drugs are outlined in Chapter 92.

Patients with severe hypertension or those receiving infusions or doses of potent vasodilators such as sodium nitroprusside and glyceryl trinitrate must be monitored via an intra-arterial catheter. Non-invasive measurement devices are not rapid or accurate enough and are not recommended in patients with hypertensive emergencies.

As peripheral vasodilators have significant effects on both the arterial and venous systems, the assessment of volume status is important. In the majority of patients, establishing a euvolaemic state is essential before commencing a vasodilator.

DOSAGES AND DRUG ADMINISTRATION

Vasodilators administered via infusion are delivered through a dedicated central venous catheter using infusion pumps or syringe drivers, and are titrated to achieve a target mean arterial pressure. Infusion lines should be free of injection portals and clearly marked with identifying labels. Common drug doses are shown in Table 93.1.

SPECIFIC SITUATIONS

The following is a summary of the clinical uses of the above drugs in hypertensive states commonly encountered in the ICU. Specific pharmacology and physiological effects are discussed above.

Table 93.1 Dose and infusion concentrations of commonly used vasodilators and antihypertensives in intensive care

AGENT	INFUSION/DOSE	CAUTION
Sodium nitroprusside	Diluted in 5% dextrose; range 0.5–8 µg/kg/min	Cyanide toxicity (> total dose 0.5 mg/kg/24 h) Photodegradation Raised intracranial pressure Rebound hypotension Shunt and oxygen desaturation
Glyceryl trinitrate	Diluted in 5% dextrose or 0.9% sodium chloride; range 5–200 µg/min	Drug binding to polyvinylchloride Tachyphylaxis Raised intracranial pressure
Hydralazine	5–10 mg IV bolus IV infusion 50–150 µg/min	Tachycardia Myocardial ischaemia
Phentolamine	1–5 mg IV boluses	Tachycardia
Phenoxybenzamine	Oral: 10 mg/day until postural hypotension	Idiosyncratic hypotension
Prazosin	500 µg, 8-hourly up to 20 mg daily in divided doses	
Nifedipine	Dose depends on preparation	Precipitous hypotension
Amlodipine	5–10 mg oral/day	
Captopril	6.25–75 mg orally, 12-hourly	Caution in renovascular hypertension and renal failure Pregnancy Angioneurotic oedema
Enalapril	5–40 mg oral/day	Caution in renal failure and hypovolaemia
Losartan	25–100 mg oral/day	Caution in renal failure
Clonidine	50–100 µg 8-hourly	May cause rebound hypertension with chronic use
Atenolol	25–50 mg oral b.d.	Caution in poor left ventricular function and asthma Hyperkalaemia Effects potentiated in renal failure
Metoprolol	50–100 mg oral 12-hourly	As for atenolol, safe in renal failure
Esmolol	50–200 µg/kg/min infusion	
Labetalol	15–160 mg/h	

IV, Intravenous.

ACUTE HYPERTENSION

The most common cause of hypertension in intensive care patients is pain or agitation, particularly in postoperative patients. It is important that patients have adequate analgesia and sedation before antihypertensives or vasodilators are used. Other common causes of hypertension include hypothermia, urinary retention, positional discomfort and omission of preadmission antihypertensives, particularly β-blockers and ACE inhibitors. The majority of instances of acute hypertension in the ICU will respond to simple measures.[40]

Sustained hypertension may be treated acutely with incremental doses or infusions of short-acting drugs such as glyceryl trinitrate, sodium nitroprusside, labetalol, hydralazine, nicardipine or clonidine. Infusions of vasodilators may be required if hypertension persists, or if the patient is unable to take longer-acting oral agents such as prazosin or amlodipine. Hypertension associated with tachycardia may be treated with β-blockers.

A hypertensive emergency is an acute rise in blood pressure, usually greater than 180 mm Hg systolic or greater than 120 mm Hg diastolic, which is associated with signs of end-organ damage. Commonly affected organs include the brain (seizures, hypertensive encephalopathy), heart (pulmonary oedema and acute coronary syndromes), kidney, great vessels (aortic dissection) and retina (papiloedema and retinal haemorrhages). In hypertensive emergencies a priority is the rapid control of blood pressure over minutes to hours. Alternatively, a hypertensive urgency is a similar level

of elevation in blood pressure with no evidence of end-organ dysfunction. In this situation blood pressure reduction is less urgent and may be achieved over hours to days.

HYPERTENSIVE ENCEPHALOPATHY

Hypertensive encephalopathy is the presence of signs arising from cerebral oedema caused by a rapidly changed or a severely elevated blood pressure. There may be differences in the degree of hypertension that cause encephalopathy and it may be the rate of increase of blood pressure that is more important than the absolute value. It may present as confusion, visual disturbances, blindness, seizures or stroke. Uncontrolled hypertension is one of the causes of the posterior reversible encephalopathy syndrome (PRES), along with pre-eclampsia, immunosuppressant drugs and sepsis. If not adequately treated, hypertensive encephalopathy may result in intracerebral haemorrhage, coma or death.[41]

Hypertensive encephalopathy may occur in patients with untreated or undertreated hypertension or in association with other diseases such as renal disease (e.g. glomerulonephritis, renovascular disease), thrombotic thrombocytopenic purpura, immunosuppressive therapy, collagen vascular diseases or eclampsia. Consequently, drug treatment will depend on the context in which it occurs. It is also important to rule out other causes of neurological deterioration that may also present with hypertension (e.g. stroke, intracranial haemorrhage or space-occupying lesion).

There is no evidence from randomised, controlled trials to conclude that one therapy is superior to another at improving outcomes. The aim of drug therapy in these patients is to reduce blood pressure in a controlled, predictable and safe way. A blood pressure reduction of 10%–15% in the first hour may be adequate to improve symptoms,[42] and a controlled reduction of less than 25% in the first hours should be a goal.[43] Acutely, short-acting, titratable parenteral drugs are suitable in emergency situations. Assuming there are no absolute contraindications to β-blockers, labetalol and esmolol are ideal drugs to use. Sodium nitroprusside can be used, although it may increase intracranial pressure and reduce cerebral blood flow.[9]

Other agents that are useful in controlling severe hypertension include hydralazine, clonidine and ACE inhibitors (although these must be used cautiously in patients with associated renal dysfunction). Severe drops in blood pressure that might compromise end-organ perfusion have been reported after the use of nifedipine; therefore its use in the emergency setting is not recommended.[9] Combination therapy is often required, although this should be done with caution to minimise additive effects with resultant hypotension.

Patients with hypertensive emergencies are frequently hypovolaemic due to excessive sympathetic stimulation. In the absence of left ventricular failure, judicious fluid replacement may reduce blood pressure and improve renal function, thereby minimising precipitous hypotension that may result following the administration of some drugs. Diuretics are generally avoided in these conditions unless there is evidence of left ventricular failure.[42]

ACUTE STROKE

Acute stroke syndromes frequently occur in the setting of severe hypertension. The reduction of mean arterial pressure must be balanced by the maintenance of adequate cerebral perfusion pressure and cerebral blood flow. Ischaemic brain is vulnerable to critical reductions in cerebral blood flow, while excessive mean arterial pressure may increase the risk of cerebral haemorrhage.[44]

Acutely, blood pressure should be maintained in a normal range until intracranial pathology has been identified by computed tomography scan. Evidence is currently lacking regarding specific targets for blood pressure control in acute stroke. In intracranial haemorrhage intracranial pressure monitoring may be necessary to allow blood pressure to be targeted at maintaining cerebral perfusion pressure; however, if presenting systolic pressure is 150–220 mm Hg reduction to 140 mm Hg is probably safe.[45,46] In acute ischaemic stroke special attention needs to be paid to patients who may be eligible for thrombolysis. In these patients treatment is recommended to reduce systolic blood pressure to less than 185 mm Hg and diastolic pressure to less than 110 mm Hg prior to thrombolysis.[46] In those who do not meet the criteria for thrombolysis guidelines recommend blood pressure reduction only in cases where hypertension is extreme such as systolic blood pressure less than 220 mm Hg or diastolic blood pressure less than 120 mm Hg. Where acute blood pressure reduction is necessary intravenous agents are recommended and current guidelines suggest the use of labetalol or nicardipine.[47] Hypertension in patients with aneurysmal subarachnoid haemorrhage is managed with drugs outlined above.

AORTIC DISSECTION

Aortic dissection is the most dramatic and most rapidly fatal complication of severe hypertension. The aim of medical treatment is to control blood pressure and left ventricular ejection velocity to minimise propagation of the dissection. Blood pressure should be decreased as rapidly as possible to a normal or slightly hypotensive level. Titrations are usually made to achieve systolic blood pressures of 100–120 mm Hg or mean arterial pressure of 55–65 mm Hg with a heart rate

of 60 bpm.[48,49] This will depend on the patient's premorbid blood pressure and the accuracy of blood pressure measurement. It is important to maintain blood pressure at levels compatible with adequate cerebral and renal perfusion.[50]

This is best achieved initially by the use of opioid analgesia and intravenous β-blockers (e.g. esmolol, labetalol or atenolol). Verapamil or diltiazem are suitable alternatives for patients who have a contraindication to β-blockade. Second-line therapy may be with a vasodilator such as sodium nitroprusside or glyceryl trinitrate. However, the use of vasodilators alone should be avoided as this is associated with worsening aortic wall shear stresses and potential worsening of the dissection.

Aortic dissection distal to the left subclavian artery is managed conservatively with antihypertensive therapy. Proximal dissections are managed surgically after acute control of blood pressure.

ACUTE MYOCARDIAL ISCHAEMIA

Myocardial ischaemia in the absence of obstructive coronary atherosclerosis may be precipitated by severe hypertension. This occurs by increased left ventricular wall stress, reduced preload, tachycardia and increased myocardial metabolic demand. Severe ischaemia may result in acute left ventricular failure and pulmonary oedema. These patients should receive a loop diuretic in combination with a titrated vasodilator, such as intravenous glyceryl trinitrate or sodium nitroprusside, to reduce afterload.

PHAEOCHROMOCYTOMA

Tumours of the adrenal medulla secrete catecholamines that result in initial paroxysmal, then sustained, severe hypertension. They may present to the ICU as a hypertensive emergency or perioperatively for surgical ablation.[51]

Acute hypertensive crises associated with phaeochromocytoma are managed with incremental doses or infusions of phentolamine. Untreated patients may be significantly hypovolaemic and may require judicious volume replacement. β-blockers should not be used in the acute setting as these will potentiate unopposed α-adrenergic stimulation.

There is currently no universally accepted method for preparing these patients for surgery.[52] Approaches used may involve α-blockade and β-blockade, or the use of calcium channel antagonists and metyrosine.

Generally, the α-blocking agent phenoxybenzamine is commenced in 10–20 mg increments and continued until blood pressure is controlled. Excessive β-adrenergic effects are treated with β-blockers only after sufficient α-blockade to avoid unopposed α-adrenoreceptor-mediated vasoconstriction and hypertension.[22]

Calcium channel antagonists can also be utilised to facilitate α-blockade,[53,54] and nicardipine has been used in this setting. The exact role of calcium channel antagonists in this context is yet to be fully elucidated but may be to further supplement the effect of α- and β-blockers.

Metyrosine inhibits catecholamine synthesis and may be used as a short-course therapy in the days leading up to surgery. Magnesium sulphate is useful in the perioperative management of phaeochromocytoma. It is given by infusion at 2–4 g/h.[15]

RENAL FAILURE

Renal insufficiency may be a cause or consequence of a hypertensive emergency. Patients on haemodialysis (particularly those receiving erythropoietin therapy) and renal transplant patients (especially those receiving ciclosporin or corticosteroids) commonly present with severe hypertension. In patients with new-onset renal failure accompanying severe hypertension, blood pressure must be controlled without potentiating renal dysfunction. Drugs, such as calcium channel blockers, phentolamine or prazosin, may preserve renal blood flow and are appropriate in these patients. ACE inhibitors and diuretics should be used with caution until renal function has stabilised or improved.

Patients in the recovery phase of acute renal failure are usually hypertensive. This is a normal physiological response and should not be treated unless there is associated myocardial or cerebral ischaemia.[55]

PRE-ECLAMPSIA AND ECLAMPSIA

In addition to delivery of the baby and the placenta, parenteral magnesium sulphate is the treatment of choice to prevent the evolution of pre-eclampsia to eclampsia (seizures and deteriorating encephalopathy).[13] The recommended drugs for the treatment of severe hypertension in critically ill women during pregnancy or soon after birth include labetalol, hydralazine and nifedipine.[56,57]

ACE inhibitors and angiotensin receptor blockers are contraindicated in pregnancy. This is discussed in Chapter 64.

DRUG INTERACTIONS

Severe rebound hypertension may result following abrupt cessation of antihypertensive treatment. Drugs associated with this discontinuation syndrome include clonidine, methyldopa, β-blockers, guanethidine and diuretics. The degree of rebound depends on the rapidity of drug withdrawal, dosage, renovascular and cardiac function. Antihypertensives should be reintroduced according to the status of the patient,

and the degree of hypertension should be managed accordingly.

Interaction between monoamine oxidase inhibitors, other drugs (e.g. indirect sympathomimetics and narcotics) and tyramine-containing foods may result in a hypertensive emergency. This is best managed acutely with α- and/or β-blockers.

Acid–base balance and disorders

Thomas J Morgan

WATER

Water is both solvent medium and active participant in acid–base molecular transactions. At 55.5 M, its concentration dwarfs that of all other players.

WATER DISSOCIATION

Although a major oversimplification, it is useful to model water dissociation as follows:

$$H_2O \leftrightarrow H^+ + OH^-$$

By the Law of Mass Action, at equilibrium $[H^+][OH^-] = Kw\,[H_2O]$, where Kw is the temperature-dependent dissociation constant. The quantitative dominance of $[H_2O]$ allows amalgamation of Kw and $[H_2O]$ as a composite constant K'w. The equilibrium then simplifies further to:

$$[H^+][OH^-] = K'w$$

pH AND ACID–BASE NEUTRALITY

The acidity or alkalinity of aqueous solutions is represented by the pH, which is the negative logarithm of the proton concentration, or more exactly 'activity'. By the Arrhenius definition, neutrality occurs when $[H^+] = [OH^-]$, so that $K'w = ([H^+])^2$ and $pH = 0.5\ pK'w$. Neutral pH at 37°C is 6.8, approximating intracellular pH. The pH in the surrounding extracellular fluid is alkaline, usually exceeding 7.3.

CO_2 PRODUCTION AND ELIMINATION

CO_2 is generated within mitochondria at approximately 200 mL/min and flows down a series of partial pressure gradients to the atmosphere ($P_{CO_2} = 0.3$ mm Hg). The P_{CO_2} in individual tissues is determined by regional CO_2 production, regional blood flow, alveolar perfusion and alveolar ventilation. Typical cell to atmosphere driving pressures are relatively low ($\Delta P_{CO_2} \approx 50$ mm Hg) for several reasons:

- Densely invested tissue microcirculations
- Widespread distribution of carbonic anhydrase, massively accelerating dissolved CO_2/bicarbonate transitions
- Haldane and Hamburger effects, enhancing venous CO_2 transport
- A large continually refreshed interface between pulmonary capillaries and alveolar gas.

In transit to the lungs, CO_2 equilibrates with a series of aqueous environments. All pH values generated *en route* can be computed from the regional PCO_2 plus the concentrations of certain weak acids and electrolytes (see later).

The relationship between arterial P_{CO_2} ($PaCO_2$) and the pH it generates in arterial plasma is a fundamental physiological property of great interest to clinicians (Fig. 94.1). It is frequently disturbed in critical illness.

FACTORS DETERMINING THE $PaCO_2$/pH RELATIONSHIP

The six equations which underpin Peter Stewart's physical chemical analysis of acid–base (Box 94.1) are expressions of the Laws of Mass Action and Mass Conservation and the Principle of Electrical Neutrality.[1] In combination with Gibbs–Donnan effects, they dictate the shape and position of the in vivo $PaCO_2$/pH curve.

Stewart demonstrated that the pH generated by CO_2 in any body fluid can be determined from its partial pressure plus the values of two other independent variables:

1. The total concentration of 'non-volatile' weak acids (A_{tot}), whose acid characteristics arise from variable net negative molecular charges. Protein, the dominant plasma component, has an estimated titratable negative charge of 12–13 mEq/L,[2] mostly from albumin histidine moieties.[3] The normal plasma A_{tot} of approximately 15 mEq/L includes a contribution from inorganic phosphate. Erythrocytic A_{tot} is approximately 60 mEq/L. Haemoglobin is the dominant contributor, with an increment from 2,3 diphosphoglycerate.
2. The strong ion difference (SID), which is the net charge of inorganic and organic chemical entities remaining fully ionised (or quantitatively so) at pH values compatible with life. Strong ions include the cations sodium, potassium, calcium and magnesium and the anions chloride, lactate, acetoacetate and β-hydroxybutyrate. Normal plasma SID

ABSTRACT

The relationship between the partial pressure of carbon dioxide and the pH it generates in biological fluids is fundamental to acid–base diagnosis. In arterial plasma the $PaCO_2$/pH relationship provides a diagnostic framework for primary acid–base disorders and the rules of compensation. Stewart's six equations plus Gibbs–Donnan phenomena define this relationship and allow insights into the Copenhagen and Boston approaches to categorising and quantifying metabolic acid–base abnormalities. Electrical and osmotic gap calculations plus occasional specific assays are necessary adjuncts to complete diagnosis.

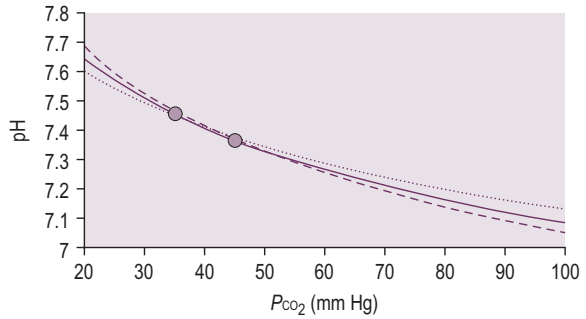

Figure 94.1 P_{CO_2}/pH relationships. The *solid line* shows the normal in vivo $PaCO_2$/pH relationship. The normal $PaCO_2$ range is between the *filled circles*. To the left of the circles there is an increasing acute respiratory alkalosis and to the right an increasing acute respiratory acidosis. The *interrupted curve* represents the normal in vitro whole blood relationship, and the *dotted curve* is the same relationship for separated plasma. A point of commonality exists at P_{CO_2} = 40 mm Hg.

Box 94.1 Stewart's six equations

$[H^+] \times [OH^-] = K'w$
$[H^+] \times [A^-] = Ka \times HA$
$[HA] + [A^-] = A_{tot}$
$[H^+] \times [HCO_3^-] = Kc \times P_{CO_2}$
$[H^+] \times [CO_3^{2-}] = Kd \times [HCO_3^-]$
$SID + [H^+] - [HCO_3^-] - [CO_3^{2-}] - [A^-] - [OH^-] = 0$

K values are known dissociation constants. See text for descriptions of SID, A_{tot} and K'w. The equations can be expressed as a single fourth order polynomial.

is +42 mEq/L. Erythrocyte SID is approximately +57 mEq/L.

ISOLATED CHANGES IN STRONG ION DIFFERENCE AND A_{tot}

A falling SID or a rising A_{tot} reduce pH, forcing equilibria towards metabolic acidosis. Conversely, a rising SID or a falling A_{tot} promote metabolic alkalosis.

SEVERAL STEWART MODEL CAVEATS

- The Stewart approach is a reductionist mathematical analysis. It is not a complete mechanistic breakdown of acid–base physical chemistry.[4] Nevertheless, its concepts provide insights into the physiological basis of Boston and Copenhagen diagnostic 'schools'[5] and serve as a research framework.[6]
- By modelling separated plasma, Stewart disregarded in vivo Gibbs–Donnan ionic traffic within the interstitium–plasma–erythrocyte (IPE) complex.[7] These phenomena cause plasma SID to vary with P_{CO_2}. Predictions of the in vivo dependence of plasma SID on P_{CO_2}[8] have been confirmed by measurements during cardiopulmonary bypass.[9] However, the SID of the overall IPE complex (SID_{IPE})[7] can still be modelled as CO_2 independent.
- The in vivo $PaCO_2$/pH relationship is thus more correctly a function of SID_{IPE} and A_{totIPE}.
- Stewart ignored the 'polyprotic' nature of individual proteins and phosphate by modelling all non-volatile weak acids in each compartment with a single anionic form (A^-), a single conjugate base form (HA) and a universal K_A value. More detailed modelling[2,3] is yet to improve on his original equations as descriptors of the ex vivo plasma P_{CO_2}/pH relationship.[10]
- Siggaard-Andersen[11] and others[12] reject the Stewart model out of hand, despite its utility. They emphasise the 'bystander' status of strong ions and regard SID as a convenient inverse quantification of the 'buffer base', defined as the total concentration of bicarbonate and non-bicarbonate 'buffers'. They assign all molecular acid–base transactions to the buffer base, with excited state water bridges providing intermolecular conduits for proton exchange.[13]

HOW ACID–BASE DISTURBANCES AFFECT THE $PaCO_2$/pH RELATIONSHIP

- Acute respiratory disturbances are primary alterations in $PaCO_2$ which move data points along the acute $PaCO_2$/pH curve without shifting it. Movement is to the left in respiratory alkalosis and to the right in respiratory acidosis (see Fig. 94.1).
- Metabolic disturbances (altered SID and/or A_{tot}) shift the entire curve. The shift is up in metabolic alkalosis and down in metabolic acidosis (Fig. 94.2).

TEMPERATURE CORRECTION OF BLOOD GAS DATA – 'ALPHA-STAT' VERSUS 'pH-STAT' APPROACHES

Blood gas analysers measure exclusively at 37°C. Temperature 'correction' is a software manipulation of plasma pH and gas tension measurements to values that correspond to the patient's core temperature. Advocates of the 'pH-stat' approach monitor these temperature-corrected pH and $PaCO_2$ values, whereas 'alpha-stat' enthusiasts track uncorrected values as measured at 37°C. Both manage patients according to normothermic reference ranges.

The pH-stat approach has similarities to the endothermic physiology of hibernating mammals, whereas the alpha-stat approach mimics the physiology of ectothermic (cold-blooded) animals. Many intensivists

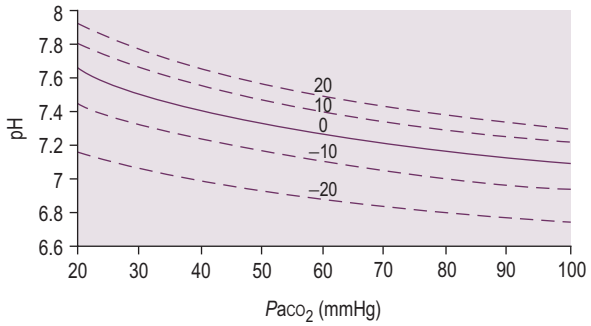

Figure 94.2 $PaCO_2$/pH curve shifts and associated standard base excess (SBE) values (mEq/L). Alterations in metabolic acid–base status shift the curve down in metabolic acidosis (SBE increasingly negative) or up in metabolic alkalosis (SBE increasingly positive).

have adopted the alpha-stat approach, the rationale of which is as follows:

- 'Alpha' is the ratio of protonated to total imidazole on histidine moieties in protein molecules. A value of 0.55 is considered best for intracellular enzyme function.
- Healthy normothermic acid–base status ($PaCO_2$ = 40 mm Hg, arterial plasma pH = 7.4) implies a neutral intracellular pH of 6.8.
- However, neutral pH varies with temperature. For example, at room temperature neutral pH = 7.0.
- Keeping intracellular pH neutral at any temperature maintains alpha at 0.55, due to temperature induced changes in imidazole dissociation. It also facilitates intracellular 'trapping' of metabolic intermediates.
- The alpha-stat goal is therefore to maintain intracellular pH neutrality at any core temperature.
- In alpha-stat theory, this goal is achieved provided $PaCO_2$ and arterial pH measured at 37°C are maintained within normothermic reference ranges.
- This is due to simultaneous alterations in K'w and CO_2 solubility as blood temperature resets to 37°C in the analyser thermostat.
- Although most commonly applied in induced hypothermia, similar arguments apply in fever, the usual intensive care unit scenario.

The main practical difference between the methods is that the pH-stat approach necessitates higher $PaCO_2$ values in hypothermia and lower values in fever. Clinical evidence for either approach is limited, with neither clearly superior.

RENAL PARTICIPATION IN ACID–BASE

Conventional descriptions of renal acid–base handling are framed in terms of filtered HCO_3^- resorption, new HCO_3^- generation and proton excretion. Proton excretion is facilitated by titration of urinary buffers at low pH, especially the $HPO_4^{2-}/H_2PO_4^-$ system (titratable acidity), and by upregulation of distal tubular NH_3 production to facilitate luminal proton 'trapping' as NH_4^+.[14]

The physical chemical explanation is simpler. $[H^+]$ and $[HCO_3^-]$ balance sheets cannot apply because these dependent variables increase and decrease according to PCO_2, SID and A_{tot}. Feedback loops acting through tubular ionophores simply modulate extracellular SID via urinary SID.[4,15,16] Upregulation or downregulation of NH_3 production ensures sufficient NH_4^+ for variable insertion as a urinary substitute for the strong cation Na^+.[17,18] Responses are rapid.[19] Unless there is proteinuria, the kidneys can modify A_{tot} only via phosphate balance, which is a different concept from that of 'titratable acidity'.

ACID–BASE ASSESSMENT

By convention acid–base disorders are categorised as respiratory ($PaCO_2$) or metabolic (non – $PaCO_2$). $PaCO_2$ is the undisputed index of respiratory acid–base status. Two 'schools', Boston and Copenhagen,[20] have formed around the identification and quantification of metabolic acid–base disturbances.

QUANTIFYING METABOLIC ACID–BASE STATUS – THE TWO 'SCHOOLS'

Standard base excess (SBE) is the Copenhagen flagship.[11] SBE integrates SID_{IPE} and A_{totIPE} effects on plasma pH while remaining independent of $PaCO_2$.[21] Boston devotees estimate metabolic acid–base status indirectly by applying empiric plasma bicarbonate-based 'rules of thumb'.[22]

BASE EXCESS, STANDARD BASE EXCESS AND 'WHOLE BODY' BASE EXCESS

In 1960 Siggaard-Andersen and colleagues introduced 'base excess' (BE), calculated by inserting pH, P_{CO_2} and haemoglobin measurements into an 'alignment nomogram' constructed from in vitro experimental data. BE was set at zero at any haemoglobin concentration when pH = 7.4, P_{CO_2} = 40 mm Hg (both at 37°C). If pH ≠ 7.4 or P_{CO_2} ≠ 40 mm Hg, BE could be defined as the concentration of titratable hydrogen ion which returns the pH of ex vivo blood to 7.4 while P_{CO_2} is maintained at 40 mm Hg.

Seventeen years later Siggaard-Andersen published the Van Slyke equation[23] to replace the empiric nomogram. The equation computes BE as $(\Delta[HCO_3^-] + \Delta[A^-])$, in other words as the deviation from the normal buffer base concentration in ex vivo whole blood. On independent evaluation, the Van Slyke equation accurately quantifies metabolic (non-respiratory) acid–base status in blood in vitro.[24] Because buffer base and SID are

quantitatively interchangeable, BE would be expressed in Stewart parlance as the offset in whole blood SID (SID_{PE} excess).

It quickly became clear that like plasma SID, BE loses independence from the partial pressure of carbon dioxide in vivo due to trans-membrane ionic shifts throughout the IPE space. By this mechanism a change in $PaCO_2$ forces BE in the opposite direction. Siggaard-Andersen's solution was to extend the whole blood model to the total IPE space by recalculating BE at a haemoglobin concentration of approximately 48 g/L.[7,11] This is SBE.

SBE is an easily grasped quantitative index of in vivo metabolic acid–base status. It is demonstrably independent of $PaCO_2$[21] and can act as a therapeutic target referenced to the IPE (extracellular plus erythrocytic) space. A useful formula is:

$$SBE = 0.93 \times ([HCO_3^-] + 14.84 \times (pH - 7.4) - 24.4),$$

with SBE and $[HCO_3^-]$ values in mEq/L.

A typical SBE reference range is −3.0 mEq/L to +3.0 mEq/L.

If SBE < −3.0 mEq/L:

- There is a metabolic acidosis, either primary or as compensation for a primary respiratory alkalosis.
- The SBE value quantifies the increase in SID_{IPE} needed to return the downshifted $PaCO_2$/pH curve to the normal position (see Fig. 94.2).
- This is approximately the required dose of sodium bicarbonate in mmol per litre of extracellular fluid (more exactly per litre of I+P+E fluid, approximately 25% of body weight).

If SBE > 3.0 mEq/L:

- There is a metabolic alkalosis, either primary or as compensation for a respiratory acidosis.
- The SBE value is the decrease in SID_{IPE} needed to return the upshifted curve to the normal position.
- Conceptually, it approximates the dose of corrective HCl required per litre of 'extracellular' (I+P+E) fluid.

With blood gas analysis, an extended electrolyte panel and off the shelf iterative software it is now possible to calculate 'whole body' BE, partitioned into 10 components including 'unknown species'.[25]

BICARBONATE-BASED APPROACH – THE BOSTON 'RULES OF THUMB'

Followers of the Boston 'school' match the plasma $[HCO_3^-]$ against the $[HCO_3^-]$ deemed appropriate for the measured $PaCO_2$, using 'rules of thumb'[22] derived from clinical and experimental data (Table 94.1). An offset denotes a metabolic acid–base disturbance.

Some drawbacks:

- The need for bedside 'mental gymnastics'.[20]
- Progressive inaccuracy above $PaCO_2$ values of 80 mm Hg. This is because the equations are linear approximations of non-linear events.
- To convert the $[HCO_3^-]$ offset to a quantitative therapeutic target, the 'apparent bicarbonate space' must first be calculated based on empiric algorithms derived from animal experiments.[26]

Table 94.1 Compensation – mechanisms and rules

DISORDER	COMPENSATION	SIMPLE RULES	BOSTON RULES
Uncompensated respiratory acidosis and alkalosis	Nil	SBE − 3.0 to + 3.0	Respiratory acidosis: $HCO_3^- = 24 + 0.1 \times (PaCO_2 - 40)$ Respiratory alkalosis: $HCO_3^- = 24 + 0.2 \times (PaCO_2 - 40)$
Compensated respiratory acidosis and alkalosis	Extracellular SID adjusted by altered urinary SID	pH is normal or $SBE = 0.4 \times (PaCO_2 - 40)$	Respiratory acidosis: $HCO_3^- = 24 + 0.35 \times (PaCO_2 - 40)$ Respiratory alkalosis: $HCO_3^- = 24 + 0.5 \times (PaCO_2 - 40)$
Metabolic acidosis	Hyperventilation reduces $PaCO_2$	$PaCO_2$ = 2 digits after pH decimal point or $PaCO_2 = 40 + SBE$ ($PaCO_2$ rarely < 10 mm Hg)	$PaCO_2 = 1.5 \times (HCO_3^-) + 8$
Metabolic alkalosis	Hypoventilation increases $PaCO_2$	$PaCO_2$ = 2 digits after pH decimal point or $PaCO_2 = 40 + SBE$ ($PaCO_2$ rarely < 60 mm Hg)	$PaCO_2 = 0.9 \times (HCO_3^-) + 9$

mm Hg, Millimeters of mercury; *SBE*, standard base excess; *SID*, strong ion difference.

ACID–BASE DISORDERS – CLASSIFICATION

PRIMARY DISORDERS

Primary acid–base disorders dictate the direction of pH disturbance. They can be respiratory ($PaCO_2$) or metabolic (non-$PaCO_2$). They are designated by the suffix 'osis', whereas the final pH abnormality has the suffix 'aemia'. In acidaemia, plasma pH is <7.35. In alkalaemia, plasma pH is >7.45. Hence we can have an acidaemia or alkalaemia due to a respiratory or metabolic acidosis or alkalosis, respectively. With opposing primary acid–base disturbances, the pH can be normal.

COMPENSATION AND ITS EFFECT ON pH

Compensation is a counterresponse to a primary disorder, reducing the severity of the pH disturbance.

METABOLIC COMPENSATION FOR RESPIRATORY DISTURBANCES

In respiratory acid–base disturbances the kidneys alter urinary SID to reset SID_{IPE} and thus SBE. By this mechanism, sustained hypocarbia and hypercarbia cause a compensatory metabolic acidosis and alkalosis, respectively. Compensation can take 5 days but is ultimately effective. Over the $PaCO_2$ range 25–80 mm Hg, which encompasses most chronic respiratory disturbances, full compensation normalises the arterial pH.[21,27,28]

RESPIRATORY COMPENSATION FOR METABOLIC DISTURBANCES

Respiratory compensation for metabolic disturbances is faster but less effective. A normal pH is never regained. Feedback loops driven by cerebrospinal fluid (CSF) and plasma pH act on central and peripheral chemoreceptors, respectively, which drive alveolar ventilation. $PaCO_2$ is forced in the direction opposing the metabolic pH perturbation.

In severe metabolic acidosis, minute ventilation can increase more than eightfold. The full response to a metabolic acid–base disturbance evolves over 12–24 hours, at first driven entirely by the peripheral chemoreceptors. Paradoxically the central chemoreceptors dampen the initial response because SID equilibration between plasma and CSF is gradual, whereas PCO_2 equilibration is immediate.

ACID–BASE 'SCANNING TOOLS'

ELECTRICAL GAPS (Table 94.2)

Accumulating strong anions reduce SID, causing metabolic acidosis. Other than chloride and L-lactate, they are not measured routinely. However, they can be injurious, especially in poisonings.[29–31] Critical care practitioners use electrical 'gaps' as early warning systems for 'unmeasured' anions. All quantify net unmeasured

plasma ionic charge in mEq/L in accordance with the Principle of Electrical Neutrality

ANION GAP

The plasma anion gap (AG) is calculated as $[Na^+] + [K^+] - [Cl^-] - HCO_3^-]$. $[K^+]$ is often omitted, reducing the typical reference range to 3–13 mEq/L. The AG quantifies [unmeasured anions] − [unmeasured cations], both strong and weak. It is increased by unmeasured anions and reduced by unmeasured cations. In health the AG largely quantifies A^-, the negative charge on albumin and phosphate.

As a scan for unmeasured strong anions, the AG signal has low sensitivity and specificity. It has zero utility when haemodilution causes coincident hypoalbuminaemia.[32]

ALBUMIN-CORRECTED ANION GAP

The albumin-corrected anion gap (AGc) allows for albumin variation by a simple correction appropriate for acidaemia.

$$AGc = AG + 0.25 \times (40 - [albumin]),$$

assuming a normal plasma [albumin] of 40 g/L.

STRONG ION GAP

Strong ion gap (SIG) further extends the AGc calculation to neutralise other 'unwanted' contributors to the gap signal, the trade-off being increased variability. Although not part of 'Stewart' theory, the SIG can be described in Stewart terms as 'apparent' SID (SIDa) minus 'effective' SID (SIDe), where SIDa = $[Na^+] + [K^+] + [Ca^{2+}] + [Mg^{2+}] - [Cl^-] -$ [L-lactate], and SIDe = $[A^-] + [HCO_3^-]$. The term 'strong ion gap' is itself a misnomer because unmeasured ions creating the 'gap' can be strong or weak.

BASE EXCESS GAP

BE is partitioned into four physical chemical components using 'Fencl Stewart' methodology.[33] The first three are calculated separately from measured plasma concentrations of sodium, chloride and albumin. The BE gap is then determined by subtracting these elements from an overall BE value, or in subsequent simplifications from SBE.

NET UNMEASURED ANIONS

The 'net unmeasured anions' quantitative approach of the late Peter Lloyd introduces 'polyprotic' modelling of plasma protein and phosphate, after the work of Constable.[2,34] It is successfully embedded in a laboratory diagnostic module in Hawkes Bay Regional Hospital, Hastings, New Zealand,[35] and there is a downloadable app (Quantitative Acid-Base Analyser for Mobile, Version 1.01, June 2014).

IPEUA AND UIX

The 'IPEua' parameter of Wolf and DeLand[7] and Anstey's 'UIX' (unmeasured ion index)[36] both quantify the unmeasured ionic species component of SBE in the corresponding 'IPE' (interstitium, plasma, erythrocyte) dimension, unlike the BE gap and its successors.

'HEAD TO HEAD' EVALUATION

Eight scanning tools were evaluated under the haemodilution stress of cardiopulmonary bypass.[32] Only the AG failed to respond significantly to a mean surge in acetate plus gluconate concentrations of greater than 10 mEq/L. IPEua and UIX performed best, with areas under receiver-operator characteristic curves of 0.88 and 0.87, respectively. Results for other tools were SIG (0.81), AGc (0.79), standard BE gap (0.77), plasma BE gap (0.71), whole blood BE gap (0.70) and AG (0.59).

OSMOLAL GAP

The osmolal gap scans for unmeasured osmotically active molecules. It is calculated as follows:

Osmolal gap
= measured osmolality − calculated osmolality.

The Bhagat formula for calculated osmolality[37] is often preferred:

Calculated osmolality (mOsmol/kg)
$= 1.89\,[Na] + 1.38\,[K] + 1.03\,[urea] + 1.08\,[glucose]$
$+ 7.45$ (all electrolyte concentrations in mmol/L)

The normal osmolal gap is less than 10 mOsmol/kg. Causes of a raised osmolal gap include:

- mannitol
- glycine (trans-urethral resection of prostate syndrome)
- poisonings with alcohols or glycols. acetone and glycerol (ketoacidosis)
- unknown solutes (hyperlactataemia and renal failure)

PRACTICAL CONSIDERATIONS

DIAGNOSTIC SEQUENCE

After taking a history and examining the patient, a set of arterial blood gases and an electrolyte panel should be evaluated. A series of questions can then be addressed:

WHAT IS THE PRIMARY PROCESS?

- The primary process determines the direction of pH change.

Table 94.3 Acid–base status – primary survey

$PaCO_2$ (mm Hg)	pH	PRIMARY PROCESS(ES)
35–45	7.35–7.45	None
>45	7.35–7.45	1. Chronic respiratory acidosis or 2. Respiratory acidosis, metabolic alkalosis
<35	7.35–7.45	1. Chronic respiratory alkalosis or 2. Respiratory alkalosis, metabolic acidosis
<35	<7.35	Metabolic acidosis
>45	<7.35	Respiratory acidosis
35–45	<7.35	Respiratory acidosis, metabolic acidosis
>45	>7.45	Metabolic alkalosis
<35	>7.45	Respiratory alkalosis
35–45	>7.45	Respiratory alkalosis, metabolic alkalosis

- Look first at the $PaCO_2$ and then at the pH it generates.
- If both are normal, a dual metabolic acid–base disturbance is still possible (metabolic alkalosis plus raised AGc acidosis) but uncommon.
- If either or both are abnormal, check whether the direction of pH change is appropriate for the $PaCO_2$:
  - Appropriate: Primary respiratory disorder.
  - Inappropriate: Primary metabolic disorder.
- Nine possible combinations of $PaCO_2$ and pH (Table 94.3) indicate specific acute, chronic or mixed primary processes.
- An abnormal $PaCO_2$ plus a normal pH means one of two things:
  - Two opposing primary acid–base disorders, one respiratory and one metabolic
  - A chronic respiratory disturbance with metabolic compensation.
- A 'normal' $PaCO_2$ combined with an abnormal pH always represents two primary acid–base disturbances (see Table 94.3).

IS THERE COMPENSATION?

- In metabolic acidosis, hypocarbia ($PaCO_2$ < 35 mm Hg) indicates compensation
- In metabolic alkalosis, hypercarbia ($PaCO_2$ > 45 mm Hg) indicates compensation
- In a respiratory acidosis, metabolic alkalosis (SBE > 3 mEq/L) indicates compensation
- In a respiratory alkalosis, metabolic acidosis (SBE < –3 mEq/L) indicates compensation

IS COMPENSATION APPROPRIATE?

- Apply 'rules of thumb' (see Table 94.1)
- Remember:
  - the pH is normal in fully compensated respiratory acid–base disturbances (though this can take days),
  - the pH is never normal in appropriately compensated metabolic acid–base disturbances.
- Identify inappropriate respiratory compensation as a separate acid–base disturbance. For example:
  - If arterial pH = 7.20 and $PaCO_2$ = 20 mm Hg, there is a metabolic acidosis with appropriate respiratory compensation (see Table 94.1).
  - If pH = 7.20 and $PaCO_2$ = 32 mm Hg, there a metabolic acidosis plus an accompanying respiratory acidosis (despite the hypocarbia).
  - If the pH = 7.20 with a $PaCO_2$ = 12 mm Hg, there is a metabolic acidosis plus an added respiratory alkalosis.

IF METABOLIC ACIDOSIS IS PRESENT, HOW SEVERE IS IT?

- Mild: SBE = –4 mEq/L to –9 mEq/L
- Moderate: SBE = –10 mEq/L to –14 mEq/L
- Severe: SBE = < –14 mEq/L

IF METABOLIC ALKALOSIS IS PRESENT, HOW SEVERE IS IT?

- Mild: SBE = +4 mEq/L to +9 mEq/L
- Moderate: SBE = +10 mEq/L to +14 mEq/L
- Severe: SBE = > +14 mEq/L

WHAT IS THE ANION GAP OR PREFERABLY THE ALBUMIN-CORRECTED ANION GAP?

- If either is elevated, look for unmeasured anions
- If the AGc is low or negative, suspect laboratory error, but consider lithium intoxication, immunoglobulin G myeloma and others (see Table 94.2).

IS ANY ALBUMIN-CORRECTED ANION GAP INCREASE ACCOMPANIED BY A SIMILAR REDUCTION IN STANDARD BASE EXCESS OR $[HCO_3^-]$?

- Yes: Single metabolic disorder
- No: Dual metabolic disorders
  - Example 1: AGc = 20 mEq/L and SBE = –15 mEq/L. There is a mixed normal AGc metabolic acidosis and raised AGc metabolic acidosis (common during resolution of diabetic ketoacidosis).
  - Example 2: AGc = 20 mEq/L and the SBE = 0 mEq/L. There is a mixed metabolic alkalosis and raised AGc metabolic acidosis (such as

Table 94.4 Types of renal tubular acidosis

	TYPE 1	TYPE 2	TYPE 4
Mechanism	Impaired distal NH_4^+ secretion	Increased proximal chloride resorption. With other proximal tubular defects = Fanconi syndrome	Reduced aldosterone secretion or sensitivity. Hyperkalaemic suppression of proximal tubular NH_4^+ production
Some causes	Idiopathic, hypercalcuric, Amphotericin B, lithium carbonate, rheumatoid arthritis, Sjögren disease, systemic lupus erythematosis, cirrhosis, renal transplant rejection, obstructive uropathy, primary hyperparathyroidism, hyperglobulinaemia	Genetic, light chain nephropathy, acetazolamide, heavy metals, aminoglycosides, valproate, chemotherapy, renal transplantation, amyloidosis, paroxysmal nocturnal haemoglobinuria	Hyporeninaemia, adrenal insufficiency, angiotensin converting enzyme-inhibitors, non-steroidal anti-inflammatory drugs, cyclosporine, heparin, amiloride, spironolactone, triamterene, pentamidine, diabetes, obstructive uropathy, interstitial nephropathies, renal transplant rejection, analgesic nephropathy
SBE	Can be <–15 mEq/L	–6 to –15 mEq/L	–6 to –8 mEq/L
Plasma $[K^+]$	Usually low	Low	High
Urine pH post frusemide	>5.5	<5.5. (Bicarbonaturia with $NaHCO_3^-$ infusion)	Usually <5.5
Urinary AG	Positive	Negative	Usually positive
Urinary NH_4^+	Reduced	Normal or high	Usually reduced

AG, Anion gap; *SBE*, standard base excess.

hyperlactataemia superimposed on a pre-existing metabolic alkalosis).

IF THE ALBUMIN-CORRECTED ANION GAP IS INCREASED, WHAT IS THE CAUSE?

- Common causes include L-lactate and the ketoanions (β-hydroxybutyrate and acetoacetate). There are several others (Table 94.4).
- If no obvious cause, a coincident raised osmolal gap suggests methanol (unmeasured anion formate) or ethylene glycol toxicity (unmeasured anions glycolate and oxalate).
- If still no obvious cause, perform specific assays (such as plasma D-lactate, salicylate or pyroglutamate and urinary organic anions).

CLINICAL ACID–BASE DISORDERS

METABOLIC ACIDOSIS

The low SID of metabolic acidosis can be due to a narrowed difference between $[Na^+]$ and $[Cl^-]$ (normal AGc, Box 94.2), or an accumulation of other strong anions (elevated AGc, Box 94.2). A normal AGc acidosis is not always hyperchloraemic because $[Cl^-]$ is only important relative to $[Na^+]$.

CLINICAL FEATURES

The adverse effects of acidaemia (Box 94.3) are more evident at low pH (<7.2). Hyperchloraemia may itself

Box 94.2 Causes of metabolic acidosis

NORMAL AGc	RAISED AGc
Saline infusions	L-lactate acidosis
Organic anion excretion	Ketoacidosis
Ketoacidosis	β-hydroxybutyrate, acetoacetate
Glue sniffing (hippurate, benzoate)	Renal failure
Loss high SID enteric fluid	Sulphate, hippurate, other organic anions
Small intestinal, pancreatic, biliary	Phosphate accumulation increases A_{tot}
Urinary/enteric diversions	Ethylene glycol poisoning
High urinary SID	Glycolate, oxalate
Renal tubular acidosis	Methanol poisoning
High urinary SID	Formate
Post hypocapnia	Salicylate overdose
High urinary SID	Salicylate, L-lactate, ketoanions
TPN and NH_4Cl administration	Pyroglutamic acidosis
	Pyroglutamate
	Toluene (glue sniffing)
	Hippurate, benzoate
	Short bowel syndrome
	D-lactate

AGc, Albumin-corrected anion gap; *SID*, strong ion difference; *TPN*, total parenteral nutrition.

Box 94.3 Adverse effects of metabolic acidosis

- Reduced myocardial contractility, tachydysrhythmia and bradydysrhythmia, systemic arteriolar dilatation, venoconstriction, centralisation of blood volume
- Pulmonary vasoconstriction, hyperventilation, respiratory muscle failure
- Reduced splanchnic and renal blood flow
- Increased metabolic rate, catabolism, reduced adenosine triphosphate synthesis, reduced 2,3-diphosphoglycerate synthesis
- Confusion, drowsiness
- Increased inducible nitric oxide synthetase expression, proinflammatory cytokine release
- Hyperglycaemia, hyperkalaemia
- Cell membrane pump dysfunction
- Bone loss, muscle wasting

cause or contribute to some low pH toxicities, such as impairment of renal blood flow, coagulation disorders, and splanchnic and cerebral dysfunction. Specific adverse effects of other strong anions include:

- blindness and cerebral oedema (formate)
- crystalluria, renal failure and ionised hypocalcaemia in ethylene glycol poisoning (oxalate)
- tinnitus, hyperventilation and fever due to uncoupling of oxidative phosphorylation (salicylate)
- artefactual plasma L-lactate elevation by blood gas analysers in ethylene glycol poisoning (glycolate).[38]

Mild acidaemia has potential benefits. For example, the Bohr effect increases tissue oxygen availability, and lowering pH is protective in hypoxic stress models. Mild normal AGc acidosis is common after infusions of low SID fluids such as 0.9% sodium chloride and certain colloids.[6] With respiratory compensation, arterial pH rarely falls to less than 7.3. Net harm is still possible, potentially from chloride itself,[39] but as yet unconfirmed.[40]

RENAL TUBULAR ACIDOSIS[14]

In renal tubular acidosis (RTA), the urinary SID setting is high relative to the SID_{IPE}, with an inadequate nadir following an acid load. The disturbance is in tubular Cl^- handling, either from reduced NH_3 production (types 1 and 4), or excessive Cl^- resorption (type 2). Causes are legion (see Table 94.4).

Apart from treating underlying causes and preventing hypercalcuria, management in types 1 and 2 RTA is based on administering sodium bicarbonate or citrate to increase extracellular SID, and managing hypokalaemia using potassium citrate (not chloride). In type 4 RTA, inciting agents are ceased and adrenal insufficiency treated with mineralocorticoid replacement. Alkali supplements and frusemide are occasionally necessary.

MANAGEMENT OF METABOLIC ACIDOSIS

Management is directed at the underlying cause. Care is required to avoid a sudden reduction in minute ventilation when instituting mechanical ventilation because this can be lethal. For example, an arterial pH of 6.9 and $PaCO_2$ of 10 mm Hg implies maximal hyperventilation. If the $PaCO_2$ is suddenly returned to 'normal' (40 mm Hg), the arterial pH will fall to 6.7. If the $PaCO_2$ rises further to 60 mm Hg, the pH will be 6.6.

ALKALINISING AGENTS – SODIUM BICARBONATE, 'CARBICARB', SODIUM LACTATE AND TRIS-HYDROMETHYL AMINOMETHANE (THAM)

The term 'alkalinising agent' is preferred to 'buffer'. True chemical buffering is a resistance to pH change on addition of an acid or base, whereas an alkalinising agent in clinical practice increases the pH at any given PCO_2. In other words, it increases the SBE (see Fig. 94.2). For example, a $NaHCO_3$ dose of 1 mmol/kg increases SBE approximately 3 mEq/L.

Administration of alkalinising agents is difficult to justify in hyperlactataemia and other organic acidoses. However, it can be appropriate to infuse $NaHCO_3$ in:

- severe normal AGc acidosis
- severe hyperkalaemia
- methanol and ethylene glycol poisoning
- tricyclic and salicylate overdose.

$NaHCO_3$ increases SBE by increasing SID. The active agent is sodium, not bicarbonate. The high CO_2 content (CO_{2tot} approximately 1028 mmol/L in a 1 M solution) creates two problems:

- The need for CO_2 impermeable containers during autoclaving and storage
- Potential for paradoxical intracellular respiratory acidosis.

Major surges in V_{CO_2} and P_{CO_2} are avoidable unless pulmonary perfusion is massively reduced, such as in cardiac arrest.[4] The key is slow administration (over the course of 30–60 minutes).

The CO_{2tot} of bicarbonate preparations can also be reduced, the tradeoff being a pH rise. In carbicarb ($CO_{2tot} = 750$ mmol/L, $P_{CO_2} = 2$ mm Hg, pH = 9.8), half the monovalent bicarbonate becomes divalent carbonate. However, complete elimination of bicarbonate as NaOH causes unacceptable alkalinity (pH of 1 M solution = 14), with local haemolysis and endothelial damage likely on peripheral administration. Sodium lactate (0.167 M, pH 6.9) is an alternative, provided lactate metabolism is efficient. Note that lactate is replaced by bicarbonate on metabolism to pyruvate. It does not 'generate' bicarbonate directly.[4]

A weak base (Btot) can offset A_{tot} to increase SBE without changing SID. THAM is tromethamine or tris buffer, a weak base with a pKa of 7.7 at 37°C. Because THAM is CO_2 'consuming', transient hypocarbia

Box 94.4 Metabolic alkalosis – causes

LOW URINARY SID	ENTERIC LOSSES OF LOW SID FLUID	GAIN OF HIGH SID FLUID
Loop or thiazide diuretics	Pyloric stenosis, vomiting/gastric outlet obstruction, nasogastric suction	$NaHCO_3$ administration
Post hypercapnia	Villous adenoma	Sodium citrate (plasma exchange, stored blood)
Corticosteroids	Laxative abuse	Renal replacement fluids with high SID (>35 mEq/L)
Cushing syndrome		Milk alkali syndrome
Primary mineralocorticoid excess		
Carbenoxolone, Glycyrrhetinic acid (licorice)		
Hypercalcaemia		
Milk alkali syndrome		
Magnesium deficiency		
Bartter and Gitelman syndromes		

SID, Strong ion difference.

coupled with the immediate SBE increase can precipitate sudden apnoea. THAM accumulates in renal impairment and can cause hypoglycaemia, hyperosmolality, coagulation abnormalities and potassium disturbances.

Potential adverse effects of all alkalinising agents include:

- sudden increases in haemoglobin–oxygen affinity
- hyperosmolar states
- reduced $[Ca^{2+}]$ and $[Mg^{2+}]$
- rebound alkalosis following resolution of an organic acidosis.

METABOLIC ALKALOSIS

Metabolic alkalosis has been described as the most common acid–base disturbance in hospital patients. With modern definitions it is often part of a 'mixed' disorder.

CAUSES OF METABOLIC ALKALOSIS (Box 94.4)

Metabolic alkalosis can be precipitated by:

- Low urinary SID (e.g. diuretics).
- Loss of low SID enteric fluid (e.g. small gut fistulae).
- Gain of high SID fluid (e.g. $NaHCO_3$ administration).

CLINICAL FEATURES

A high plasma pH has several adverse effects (Box 94.5). Mortality escalates as the pH rises to greater than 7.55, although how much is causation versus association is unclear.

TREATMENT

Remove the cause. Additional measures to accelerate extracellular SID reduction include:

- Volume repletion with saline or low SID colloid preparations.
- Administering KCl (SID zero) to correct potassium depletion.

Box 94.5 Severe metabolic alkalosis – multisystem effects

Central nervous system
Vasospasm
Seizures
Confusion, drowsiness
Neuromuscular
Weakness, tetany, muscle cramps
Cardiovascular
Arrhythmias – supraventricular and ventricular
Decreased contractility
Respiratory
Decreased alveolar ventilation
Atelectasis, hypoxaemia
Metabolic
Hyperlactataemia
Low [Pi], $[Ca^{++}]$, $[Mg^{++}]$ and $[K^+]$
Hemoglobin–oxygen affinity
Initially increased (until counteracted by increased 2,3-diphosphoglycerate)

- Acetazolamide administration to increase urinary SID.[41]
- HCl via slow administration through a central venous catheter, or indirectly as NH_4Cl, arginine hydrochloride or lysine hydrochloride.
- Renal replacement therapy.

As with metabolic acidosis, care is required when instituting mechanical ventilation. Minute volume settings should be adjusted to prevent extreme alkalaemia.

RESPIRATORY ACIDOSIS

CAUSES (Table 94.5)

The risk is increased when CO_2 production is high and when ventilation is inefficient (large alveolar or apparatus dead space, respiratory muscle disadvantage due to hyperinflation or increased work of breathing).

Table 94.5 Some causes of respiratory acidosis

MECHANISM/AFFECTED SITE	ACUTE	CHRONIC
Respiratory centre suppression	Sedative and narcotic drugs, central nervous system injury and infection brainstem vasculitis or infarction	Obesity hypoventilation syndrome
Airway obstruction	Inhalational injury, Ludwig angina, laryngeal trauma	Obstructive sleep apnoea, vocal cord paresis, subglottic and tracheal stenosis
Mechanical ventilation	'Permissive' hypercarbia	
Neural/neuromuscular	Spinal cord injury, Guillain-Barré syndrome, myaesthenia gravis, muscle relaxants, envenomation, acute poliomyelitis, critical illness myoneuropathy	Phrenic nerve damage, paraneoplastic syndromes, post-polio syndrome
Muscle	Myopathy, low $[K^+]$, high $[Mg^{2+}]$, low [Pi], diaphragmatic injury, shock	Muscular dystrophies, motor neuron disease
Decreased chest wall compliance	Abdominal distension, burns, pneumothorax, large pleural effusions	Obesity, kyphoscoliosis, ankylosing spondylitis
Loss of chest wall integrity/geometry	Flail segment	Thoracoplasty
Increased small airways resistance	Asthma, bronchiolitis	Chronic obstructive pulmonary disease
Deceased lung compliance	Acute lung injury, pneumonia, pulmonary oedema, vasculitis, and haemorrhage	Pulmonary fibrosis

CLINICAL FEATURES

These include:

- The effects of acidaemia (see Box 94.3).
- Central nervous system dysfunction, including asterixis, confusion, drowsiness, fitting and raised intracranial pressure.
- Renal dysfunction. Sympathoadrenal and renin–angiotensin activation reduce renal perfusion, glomerular filtration rate and urine output.

TREATMENT

Management is directed at the underlying cause. Mechanical ventilation, either non-invasive or invasive, may be required.

RESPIRATORY ALKALOSIS

CAUSES

Respiratory alkalosis arises in a number of clinical scenarios (Box 94.6).

Box 94.6 Conditions predisposing to respiratory alkalosis

ACUTE	CHRONIC
Hypoxaemia	Pregnancy
Hepatic failure	High altitude
Sepsis	Chronic lung disease
Asthma	Neurotrauma
Pulmonary embolism	Chronic liver dysfunction
Pneumonia, acute lung injury	
Central nervous system disorders – stroke, infection, trauma	
Drugs – salicylates, selective serotonin reuptake inhibitors	
Opiate and benzodiazepine withdrawal	
Mechanical hyperventilation – intentional or inadvertent	
Pain, anxiety, psychosis	

CLINICAL FEATURES

The multisystem effects of alkalaemia apply, plus the complications of hypoventilation.

TREATMENT

Management should be directed towards the underlying cause.

Fluid and electrolyte therapy

Anthony Delaney, Simon Finfer

The management of patients' fluid and electrolyte status requires an understanding of body fluid compartments as well as an understanding of water and electrolyte metabolism. These principles will be considered along with the commonly encountered fluid and electrolyte disturbances. Recent evidence for the use of fluid therapy in a number of common clinical scenarios will also be presented.

FLUID COMPARTMENTS (Table 95.1; Fig. 95.1)

TOTAL BODY WATER

In humans, water contributes approximately 60% of body weight, with organs varying in water content (Table 95.2). The variation of the percentage of total body weight as water, between individuals, is largely governed by the amount of adipose tissue. The average water content as a percentage of total body weight is 60% for males and 50% for females. Total body water as a percentage of total body weight decreases with age, due to a progressive loss of muscle mass, causing bone and connective tissue to assume a greater percentage of total body weight (Table 95.3).[1–3]

Total body water is commonly divided into two volumes: the extracellular fluid (ECF) volume and the intracellular fluid (ICF) volume.[2] Sodium balance regulates the ECF volume, whereas water balance regulates the ICF volume. Sodium excretion is normally regulated by various hormonal and physical ECF volume sensors, whereas water balance is normally regulated by hypothalamic osmolar sensors.[4]

EXTRACELLULAR FLUID

ECF is defined as all body water external to the cell, and is commonly subdivided into plasma and interstitial fluid volumes. The ECF is normally 40% of total body water and 25% of total body weight. With acute or chronic illness, ICF volume is reduced, and ECF volume is increased and may even exceed the ICF volume. The ECF volume can be divided into the plasma volume, the ECF volume, and the interstitial volume.

INTRACELLULAR FLUID

ICF is defined as all the body water within cells and, unlike the ECF compartment, is an inhomogeneous, multicompartmental entity, with different pH and ionic compositions depending upon the organ or tissue being considered. The ICF volume is often determined by inference from the difference in measurements of the total body water and ECF spaces. This estimation suffers from the inaccuracies inherent in both ECF and total body water measurements. In general, the ICF is considered to be 60% of total body water and 35% of total body weight.

TRANSCELLULAR FLUID

Fluids in this compartment have a common characteristic of being formed by transport activity of cells. The fluid is extracellular in nature and will be considered as part of the interstitial volume. It may vary from 1 L to 10 L, with larger volumes occurring in diseased states (e.g. bowel obstruction or cirrhosis with ascites), and is formed at the expense of the remaining interstitial and plasma volumes.

WATER METABOLISM

Water balance is maintained by altering the intake and excretion of water. In the healthy state, intake is controlled by thirst. Excretion is controlled by the renal action of antidiuretic hormone (ADH). In health, plasma osmolalities of about 280 mOsm/kg suppress plasma ADH to concentrations low enough to permit maximum urinary dilution.[5] Above this value, an increase in ECF tonicity of about 1%–2% or a decrease in total body water of 1–2 L causes the posterior pituitary to release ADH, which acts upon the distal nephron to increase water reabsorption. Maximum plasma ADH concentrations are reached at an osmolality of 295 mOsm/kg.[5] The osmotic stimulation also changes thirst sensation and, in the conscious ambulant individual, initiates water repletion (drinking), which is more important in preventing dehydration

ABSTRACT

The management of patients' fluid and electrolyte status requires an understanding of body fluid compartments and of water and electrolyte metabolism. Water balance is governed by the thirst mechanism and the secretion of antidiuretic hormone (ADH). Disorders of sodium balance, while they may be due to excess sodium intake or losses, are more commonly due to retention of excess water (due to inappropriate fluid therapy or the syndrome of inappropriate ADH leading to hyponatraemia) or dehydration. Clinicians need to consider the causes of electrolyte disorders, such as hyperkalaemia, after attending to the more life-threatening manifestations of these conditions. There is an emerging body of evidence from high quality randomised clinical trials to guide clinicians prescribing fluid therapy to critically ill patients.

than ADH secretion and action. Thus, in health, the upper limit of the body osmolality (and therefore serum sodium) is determined by the osmotic threshold for thirst, whereas the lower limit is determined by the osmotic threshold for ADH release.[6]

Increase in osmolality caused by permeant solutes (e.g. urea) does not stimulate ADH release. ADH may also be released in response to hypovolaemia and hypotension, via the stimulation of low- and high-pressure baroreceptors. ADH release is extremely marked when more than 30% of the intravascular volume is lost. ADH may also be stimulated by pain and nausea, which are thought to act through the baroreceptor pathways.[4] ADH release may also be stimulated by a variety of pharmacological agents (Table 95.4). Renal response to ADH depends upon an intact distal nephron and collecting duct, and a hypertonic medullary interstitium. The capacity to conserve or excrete water also depends upon the osmolar load presented to the distal nephron.[4]

WATER REQUIREMENTS

Water is needed to eliminate the daily solute load, and to replace daily insensible fluid loss (Table 95.5). With a normal daily excretion of 600 mOsm solute, maximal and minimal secretions of ADH will cause urine osmolality to vary from 1200 to 30 mOsm/kg, respectively, and the urine output to vary from 500 mL to 20 L/day, respectively. Skin and lung water losses vary, and may range from 500 mL to 8 L/day depending on physical activity, ambient temperature and humidity.

DISORDERS OF OSMOLALITY

TONICITY

Osmolality is a measure of the number of osmoles per kilogram (Osm/kg) of water. Tonicity is a measure of the effective osmotic pressure gradient when two fluid compartments are separated by a semi-permeable membrane. Tonicity is influenced only by solutes that cannot cross the membrane. The osmolality of the ECF is due largely to sodium salts. Clinical effects of hyperosmolality, due to excess solute, depend upon whether the solute distributes evenly throughout the total body water (e.g. permeant solutes of alcohol or urea) or distributes in the ECF only (e.g. impermeant solutes of mannitol or glucose). With impermeant solutes, hyperosmolality is associated with a shift of fluid from the ICF to the ECF compartment. Hyperosmolality due to increased impermeant solutes is known as hypertonicity. This condition may also be associated with a reduction in the serum sodium concentration (see below).

WATER EXCESS

In a 70-kg man, for every 1 L of excess pure water, ECF increases by 400 mL and ICF increases by 600 mL, on average. The osmolality also decreases by 6–7 mOsm/kg and the serum sodium falls by 3.0–3.5 mmol/L.

WATER DEFICIENCY

In a 70-kg man, for every 1 L of pure water loss, 600 mL is lost from the ICF and 400 mL from the ECF. The osmolality also increases by 7–8 mOsm/kg and the serum sodium rises by 3.5–4.0 mmol/L.

ELECTROLYTES

Chemical compounds in solution may either:

- remain intact (i.e. undissociated), in which case they are called non-electrolytes (e.g. glucose, urea)
- dissociate to form ions, in which case they are called electrolytes. Ions carry an electrical charge (e.g. Na^+, Cl^-). Ions with a positive charge are attracted to a negative electrode or cathode, and hence are called 'cations'. Conversely, ions with a negative charge travel towards a positive electrode or anode and are called 'anions'. Each body water compartment contains electrolytes with different composition and concentration (Table 95.6).

Exchangeable bone sodium	150	2

SODIUM

Sodium is the principal cation of the ECF and accounts for 86% of the ECF osmolality. In a 70-kg man, total body sodium content is 4000 mmol (58 mmol/kg) and is divided into a number of compartments (Table 95.7). Normal ECF concentration of sodium varies between

134 and 146 mmol/L. The intracellular sodium concentration varies between different tissues, and normally ranges from 3 to 20 mmol/L.

The standard Western society dietary sodium intake is about 150 mmol/day, but the daily intake of sodium varies widely, with urinary losses ranging from less than 1 to greater than 240 mmol/day.[7] Sodium balance is influenced by renal hormonal and ECF physical characteristics. The complete renal adjustment to an altered sodium load usually requires 3–4 days before balance is restored.

HYPONATRAEMIA

Hyponatraemia is defined as serum sodium less than 135 mmol/L and may be classified as isotonic, hypertonic or hypotonic, depending upon the measured serum osmolality (Box 95.1).

Isotonic hyponatraemia

Plasma normally contains 94% water and 7% solids (5.5% proteins, 1% salts and 0.5% lipids). If the solid phase is elevated significantly (e.g. in hyperlipidaemia or hyperproteinaemia), any device that dilutes a specific amount of plasma for analysis will give falsely lower values for all measured compounds. This effect produces 'factitious or pseudo-hyponatraemia' and is associated with a normal measured serum osmolality.[8] The measurement of plasma sodium by an ion-selective electrode is not affected by the volume of plasma 'solids' and therefore 'pseudohyponatraemia' will not occur with this method.[8]

Hypertonic hyponatraemia

In patients who have hypertonicity due to increased amounts of impermeant solutes (e.g. glucose, mannitol, glycerol or sorbitol), a shift of water from the ICF to the ECF occurs to provide osmotic equilibration, thus diluting the ECF sodium. Such resultant hyponatraemia is often associated with an increased measured osmolality. For example, in the presence of hyperglycaemia, for every 3 mmol/L rise in glucose the serum sodium decreases by 1 mmol/L.[9]

Hypotonic hyponatraemia

Hyponatraemia is almost always caused by an excess of total body water, due to excessive hypotonic or water-generating intravenous (IV) fluids (e.g. 1.5% glycine, 0.45% saline or 5% glucose) or to excessive ingestion of water, particularly in the presence of high circulating ADH concentrations. It may rarely be caused by loss of exchangeable sodium or potassium. In the latter circumstances, a loss of approximately 40 mmol of sodium or potassium, without a change in total body water content, is required to lower the serum sodium by 1 mmol/L. As hyponatraemia may be associated with an alteration in both total body water and total body sodium, the ECF may be increased (hypervolaemia), decreased (hypovolaemia) or exhibit no change (isovolaemia).[5]

In health, a fluid intake up to 15–20 L may be tolerated before water is retained and hyponatraemia occurs. In psychogenic polydipsia, if the water intake exceeds the renal capacity to form dilute urine, water retention and hyponatraemia will occur. With this disorder, the plasma osmolality exceeds urine osmolality. In circumstances where ADH is increased (e.g. hypovolaemia, hypotension, pain or nausea), or where renal response to ADH is altered (i.e. in renal, hepatic, pituitary, adrenal or thyroid failure), water retention occurs with lower intakes of fluid.

SPECIFIC CAUSES OF HYPONATRAEMIA

Transurethral resection of prostate syndrome

Clinical features The transurethral resection of prostate (TURP) syndrome consists of hyponatraemia, cardiovascular disturbances (hypertension, hypotension, bradycardia), an altered state of consciousness (agitation, confusion, nausea, vomiting, myoclonic and generalised seizures) and, when using glycine solutions, transient visual disturbances of blurred vision, blindness and fixed dilated pupils, following TURP. It has also been described following endometrial ablation.[10] It may occur within 15 minutes or be delayed for up to 24 hours after surgery,[11] and is usually caused by an excess absorption of the irrigating fluid, which contains 1.5% glycine with an osmolality of 200 mOsm/kg. Hyponatraemic syndromes have also been described when surgical irrigating solutions containing 3% mannitol or 3% sorbitol have been used.

Symptoms usually occur when greater than 1 L of 1.5% glycine or greater than 2–3 L of 3% mannitol or sorbitol have been absorbed.[12]

The excess absorption of irrigating fluid causes an increase in total body water (which is often associated with only a small decrease in plasma osmolality), hyponatraemia (as glycine, sorbitol or mannitol reduces the sodium component of ECF osmolality) and an increase in the osmolar gap.[12,13] When glycine is used, other features include hyperglycinaemia (up to 20 mmol/L; normal plasma glycine concentrations range from 0.15 to 0.3 mmol/L), hyperserinaemia (as serine is a major metabolite of glycine), hyperammonaemia (following deamination of glycine and serine) and metabolic acidosis and hypocalcaemia (due to the glycine metabolites glyoxylic acid and oxalate). Because glycine is an inhibitory neurotransmitter, and as it passes freely into the intracellular compartment when glycine solutions are used, hyperglycinaemia may be more important in the pathophysiology of this disorder than a reduction in body fluid osmolality and cerebral oedema.[14]

Treatment Treatment is largely supportive with the management of any reduction in plasma osmolality being based on the measured plasma osmolality and not the plasma sodium. If the measured osmolality is greater than 260 mOsm/kg and mild neurological abnormalities exist, and if the patient is haemodynamically stable with normal renal function, close observation and reassurance (e.g. the visual disturbances are reversible and will last for less than 24 hours) are usually all that is needed. If the patient exhibits haemodynamic instability or severe and unresolving neurological abnormalities, haemodialysis may be warranted. Hypertonic saline is indicated only if the measured osmolality is less than 260 mOsm/kg and severe non-visual neurological abnormalities exist.[15]

Syndrome of inappropriate antidiuretic hormone secretion

This syndrome is a form of hyponatraemia in which there is an increased concentration of ADH inappropriate to any osmotic or volume stimulus that normally affects ADH secretion.[16] Diagnostic criteria and common causes are listed in Boxes 95.2 and 95.3, respectively.

Clinical features Whereas cerebral manifestations are usually absent when the sodium concentration exceeds 125 mmol/L, progressive symptoms of headache, nausea, confusion, disorientation, coma and seizures may be observed when plasma sodium is below 120 mmol/L, particularly if the decrease in serum sodium concentration occurs rapidly.[17]

Treatment Initial treatment should be fluid restriction with close monitoring of serum sodium. If serum sodium concentration is not increasing with fluid restriction, judicious administration of sodium as IV normal or hypertonic saline may be required. As the true duration and rapidity of onset of hyponatraemia are often unclear, the presence and severity of symptoms may be used as the trigger for active correction of hyponatraemia.[17] The evidence base available to guide therapy is limited and there is consequently no consensus on the optimum rate at which to correct the serum sodium concentration. The major concern is to avoid neurological damage from untreated seizures, cerebral oedema or myelinolysis.[17] In the absence of good evidence, recommended rates at which to increase the sodium concentration vary from 0.5 to 2 mmol/L/h. Unless the treating clinician feels that more rapid correction is indicated, it seems prudent to correct the serum sodium concentration at a slower rather than a faster rate.

Box 95.2 Criteria for the diagnosis of syndrome of inappropriate antidiuretic hormone

- Hypotonic hyponatraemia
- Urine osmolality greater than plasma osmolality
- Urine sodium excretion greater than 20 mmol/L
- Normal renal, hepatic, cardiac, pituitary, adrenal and thyroid function
- Absence of hypotension, hypovolaemia, oedema and drugs affecting ADH secretion
- Correction by water restriction

ADH, Antidiuretic hormone.

Box 95.3 Aetiology of syndrome of inappropriate antidiuretic hormone

Ectopic antidiuretic hormone production by tumours
- Small cell bronchogenic carcinoma
- Adenocarcinoma of the pancreas or duodenum
- Leukaemia
- Lymphoma
- Thymoma

Central nervous system disorders
- Cerebral trauma
- Brain tumour (primary or secondary)
- Meningitis or encephalitis
- Brain abscess
- Subarachnoid haemorrhage
- Acute intermittent porphyria
- Guillain–Barré syndrome
- Systemic lupus erythematosus

Pulmonary diseases
- Viral, fungal and bacterial pneumonias
- Tuberculosis
- Lung abscess

Cerebral salt wasting

Cerebral salt wasting (CSW) is a syndrome occurring in patients with a cerebral lesion and excess renal loss of sodium and chloride.[18] The exact aetiology of the syndrome remains unclear. Although hyponatraemia is not necessary for the diagnosis, the syndrome is commonly associated with hyponatraemia.[19] The diagnosis of CSW is suspected in patients with a cerebral lesion, such as subarachnoid haemorrhage, traumatic brain injury or a cerebral tumour, when there is an elevated urine output, with elevated urinary sodium in the absence of a physiological cause for increased sodium excretion.[19] The syndrome can be differentiated from the syndrome of inappropriate antidiuretic hormone (SIADH), as patients with CSW will have evidence of ECF depletion (e.g. negative fluid balance, tachycardia, increased haematocrit, increased urea, low central venous pressure) as opposed to the SIADH where ECF volume will be normal or slightly expanded.[20] The treatment of patients involves exclusion of other causes of hyponatraemia and increased urine output, replacement of sodium and fluid losses, and possibly fludrocortisone.[21]

SPECIFIC TREATMENTS USED FOR HYPONATRAEMIA

Hypertonic saline

Hypertonic saline, most commonly as 3% saline, is used as a therapy for patients with symptomatic hyponatraemia. Due to the osmolarity (1000 mOsm/L) of 3% saline, it should be given through a central line, and care must be taken to avoid the known complications of its use, including chronic heart failure and central pontine and extrapontine myelinolysis (osmotic demyelination syndrome).[22,23] Careful haemodynamic and electrolyte monitoring throughout saline administration is required.

Although hypertonic saline has been proposed as a therapy for raised intracranial pressure in a number of clinical settings,[24] its use remains controversial.[25] In a recent methodologically sound, randomised, clinical trial, which included 229 patients with severe traumatic brain injury, resuscitation with 250 mL of 7.5% saline was not associated with improved mortality or functional outcomes compared with Hartmann's solution.[26]

Vasopressin receptor antagonists

V_2 receptor antagonists, such as lixivaptan, tolvaptan and OPC-31260, have recently been developed. These agents come from a novel class of non-peptide agents that bind to V_2 receptors in the distal tubule of the kidney and prevent vasopressin-mediated aquaporin mobilisation, and thus promote aquaresis.[27] These agents have been trialled as therapeutic options for the treatment of hyponatraemia in a number of clinical settings, including hyponatraemia associated with heart failure, cirrhosis and SIADH.[27,28] At present the role of V_2 receptor antagonists in the management of hyponatraemia in critically ill patients remains uncertain.

HYPERNATRAEMIA

Hypernatraemia, defined as a serum sodium greater than 145 mmol/L, is always associated with hyperosmolality and may be caused by excessive administration of sodium salts (bicarbonate or chloride), water depletion or excess sodium with loss of water (Box 95.4).

Excessive ingestion of sodium salts is rare, but intravenous infusion of large volumes of sodium-containing fluids is common in the management of hospitalised patients. Hypernatraemia often occurs in the recovery phase of acute illness when spontaneous diuresis or diuretic therapy results in more rapid clearance of free water than sodium. Pure water depletion is uncommon, unless water restriction is applied to a patient who is unconscious or unable to obtain or ingest water, as the thirst response normally corrects water depletion. If it occurs, the serum sodium concentration increases, in association with the loss of both ECF and ICF.

Box 95.4 Causes of hypernatraemia

- Water depletion
  - Extrarenal loss
    - Exposure
    - GIT losses (often with excess saline replacement)
  - Renal loss
    - Osmotic diuresis – urea, mannitol, glycosuria
    - Diabetes insipidus
      - Neurogenic
        - Post-traumatic, fat embolism
        - Metastatic tumours, craniopharyngioma, pinealoma, cysts
        - Meningitis, encephalitis
        - Granulomas (tuberculosis, sarcoid)
        - Guillain–Barré syndrome
        - Idiopathic
      - Nephrogenic
        - Congenital
        - Hypercalcaemia, hypokalaemia
        - Lithium
        - Pyelonephritis
        - Medullary sponge kidney
        - Polycystic kidney
        - Post-obstructive uropathy
        - Multiple myeloma, amyloid, sarcoid
- Salt gain
  - Administration of hypertonic saline, 0.9% saline or sodium bicarbonate

GIT, Gastrointestinal tract.

Clinical features

Hypernatraemia usually produces symptoms if the serum sodium exceeds 155–160 mmol/L (i.e. osmolality >330 mOsm/kg). The clinical features include increased temperature, restlessness, irritability, drowsiness, lethargy, confusion and coma.[29] Convulsions are uncommon. The diminished ECF volume may reduce cardiac output, thereby reducing renal perfusion, leading to pre-renal renal failure.

Treatment

For pure water depletion, this consists of water administration. If IV fluid is required, 5% glucose or hypotonic saline solution (0.45% saline) can be used, as sterile water infusion causes haemolysis. In rare cases, IV sterile water may be used by administering through a central venous catheter.[30] Since rapid rehydration may give rise to cerebral oedema, the change in serum sodium should be no greater than 0.5 mmol/L/h.[29]

POTASSIUM

Potassium is the principal intracellular cation and accordingly (along with its anion) fulfils the role of the ICF osmotic provider. It also plays a major role in the functioning of excitable tissues (e.g. muscle and nerve). As the cell membrane is 20-fold more permeable to potassium than to sodium ions, potassium is largely responsible for the resting membrane potential. Potassium also influences carbohydrate metabolism and glycogen and protein synthesis.

Total body potassium is 45–50 mmol/kg in the male (3500 mmol/70 kg) and 35–40 mmol/kg (2500 mmol/65 kg) in the female; 95% of the total body potassium is exchangeable. As ECF potassium ranges from 3.1 to 4.2 mmol/L, the total ECF potassium ranges from 55 to 70 mmol. About 90% of the total body potassium is intracellular: 8% resides in bone, 2% in ECF water and 70% in skeletal muscle. With increasing age (and decreasing muscle mass), total body potassium decreases.

FACTORS AFFECTING POTASSIUM METABOLISM

The potassium content of cells is regulated by a cell wall pump-leak mechanism. Cellular uptake is by the Na^+/K^+ pump, which is driven by Na^+/K^+ ATPase. Movement of potassium out of the cell is governed by passive forces (i.e. cell membrane permeability and chemical and electrical gradients to the potassium ion).

Acidosis promotes a shift of potassium from the ICF to the ECF, whereas alkalosis promotes the reverse shift. Hyperkalaemia stimulates insulin release, which promotes a shift of potassium from the ECF to the ICF, an effect independent of the movement of glucose. β_2-adrenergic agonists promote cellular uptake of potassium by a cyclic adenine monophosphate (AMP)-dependent activation of the Na^+/K^+ pump, whereas α-adrenergic agonists cause a shift of potassium from the ICF to the ECF.[31] Aldosterone increases the renal excretion of potassium; glucocorticoids are also kaliuretic, an effect that may be independent of the mineralocorticoid receptor.

Normally, mechanisms to reduce the ECF potassium concentration (by increasing renal excretion and shifting potassium from the ECF to the ICF) are very effective. However, mechanisms to retain potassium in the presence of potassium depletion are less efficient, particularly when compared with those of sodium conservation. Even with severe potassium depletion, urinary loss of potassium continues at a rate of 10–20 mmol/day. Metabolic alkalosis also enhances renal potassium loss, by encouraging distal nephron Na^+/K^+, rather than Na^+/K^+ exchange.

HYPOKALAEMIA

Hypokalaemia is defined as a serum potassium of less than 3.5 mmol/L (or plasma potassium less than 3.0 mmol/L). It may be due to decreased oral intake, increased renal or gastrointestinal loss, or movement of potassium from the ECF to the ICF (Box 95.5).

Clinical features

These include weakness, hypotonicity, depression, constipation, paralytic ileus, ventilatory failure, ventricular tachycardias (characteristically Torsades de pointes), atrial tachycardias and even coma.[32] With prolonged and severe potassium deficiency, rhabdomyolysis, thirst and polyuria, due to the development of renal diabetes insipidus, may occur. The electrocardiograph (ECG) changes are relatively non-specific, and include prolongation of the PR interval, T-wave inversion and prominent U-waves.

Treatment

IV or oral potassium chloride will correct hypokalaemia, particularly if it is associated with metabolic alkalosis. If the patient has renal tubular acidosis and hypokalaemia, potassium acetate or citrate may be preferred to potassium chloride. IV administration of potassium should normally not exceed 40 mmol/h, and plasma potassium should be monitored at 1- to 4-hourly intervals.[33] In patients with acute myocardial infarction and hypokalaemia, traditional recommendations were to maintain the serum potassium at ≥4.0 mmol/L,[34] but more recently the need to administer supplemental potassium when the serum potassium is greater than 3.5 mmol/L has been questioned.[35]

HYPERKALAEMIA

Hyperkalaemia is defined as a serum potassium greater than 5.0 mmol/L or plasma potassium greater than 4.5 mmol/L. It may be artefactual (from sampling errors such as in vitro haemolysis); true hyperkalaemia may be due to excessive intake, severe tissue damage, decreased excretion or body fluid compartment shift (Box 95.6).

Box 95.5 Causes of hypokalaemia

Inadequate dietary intake (urine K^+ <20 mmol/L)
Abnormal body losses
- Gastrointestinal (urine K^+ <20 mmol/L)
  - Vomiting, nasogastric aspiration
  - Diarrhoea, fistula loss
  - Villous adenoma of the colon
  - Laxative abuse
- Renal (urine K^+ >20 mmol/L)
  - Conn syndrome
  - Cushing syndrome
  - Bartter syndrome
  - Ectopic ACTH syndrome
    - Small-cell carcinoma of the lung
    - Pancreatic carcinoma
    - Carcinoma of the thymus
- Drugs
  - Diuretics
  - Corticosteroids
  - Carbapenems, amphotericin B, gentamicin
  - Cisplatin
- Renal tubular acidosis
- Magnesium deficiency

Compartmental shift
- Alkalosis
- Insulin
- Na^+/K^+ ATPase stimulation
  - Sympathomimetic agents with β2 effect
  - Methylxanthines
- Barium poisoning
- Hypothermia
- Toluene intoxication
- Hypokalaemic periodic paralysis
- Delayed following blood transfusion (see Chapter 97)

ACTH, Adrenocorticotropic hormone.

Box 95.6 Causes of hyperkalaemia

Collection abnormalities
- Delay in separating RBC
- Specimen haemolysis
- Thrombocythaemia

Excessive intake
- Transiently following blood transfusion (see Chapter 97)
- Exogenous (i.e. IV or oral KCl, massive blood transfusion)
- Endogenous (i.e. tissue damage)
  - Burns, trauma
  - Rhabdomyolysis
  - Tumour lysis

Decrease in renal excretion
- Drugs
  - Spironolactone, triamterene, amiloride
  - Indomethacin
  - Captopril, enalapril
- Renal failure
- Addison disease
- Hyporeninaemic hypoaldosteronism

Compartmental shift
- Acidosis
- Insulin deficiency
- Digoxin overdosage
- Succinylcholine
- Arginine hydrochloride
- Hyperkalaemic periodic paralysis
- Fluoride poisoning

IV, Intravenous; *RBC*, red blood cells.

Clinical features

These include tingling, paraesthesia, weakness, flaccid paralysis, hypotension and bradycardia. The characteristic ECG effects include peaking of the T-waves, flattening of the P-wave, prolongation of the PR interval (until sinus arrest with nodal rhythm occurs), widening of the QRS complex, and the development of a deep S-wave. Finally, a sine wave ECG pattern that deteriorates to asystole may occur at serum potassium levels of 7 mmol/L or greater.

Treatment

This is directed at the underlying cause, and may include dialysis. Rapid management of life-threatening hyperkalaemia may be achieved by[36]:

- Calcium chloride 5–10 mL IV of 10% (3.4–6.8 mmol, which is used to reduce the cardiac effects of hyperkalaemia)
- Sodium bicarbonate, 50–100 mmol IV
- Glucose, 50 g IV with 10–15 units of soluble insulin
- Oral and rectal resonium A, 50 g
- Diuresis with frusemide, 40–80 mg IV
- β-agonists; for example, salbutamol 5–10 mg nebulised.

CALCIUM

Almost all (99%) of the body calcium (30 mmol or 1000 g or 1.5% body weight) is present in bone. A small but significant quantity of ionised calcium exists in the ECF, and is important for many cellular activities including secretion, neuromuscular impulse formation, contractile functions and clotting. Normal daily intake of calcium is 15–20 mmol, although only 40% is absorbed. The average daily urinary loss is 2.5–7.5 mmol. The total ECF calcium of 40 mmol (2.20–2.55 mmol/L) exists in three forms: 40% (1.0 mmol/L) is bound to protein (largely albumin), 47% is ionised (1.15 mmol/L) and 13% is complexed (0.3 mmol/L) with citrate, sulphate and phosphate. The ionised form is the physiologically important form, and may be acutely reduced in alkalosis, which

causes a greater amount of the serum calcium to be bound to protein.[37] The total serum calcium can vary with the serum albumin concentrations. A correction factor can be used to offset the effect of serum albumin on serum calcium: this is 0.02 mmol/L for every 1 g/L increase in serum albumin (up to a value of 40 g/L), added to the measured calcium concentration. For example, if measured serum calcium is 1.82 mmol/L, and serum albumin is 25 g/L, corrected serum calcium = 1.82 + [(40 − 25) × 0.02] mmol/L = 2.12 mmol/L. It has been suggested that ionised calcium, where available, is a better indicator of calcium status in the critically ill.[38]

HYPOCALCAEMIA

Common causes of hypocalcaemia include hypoparathyroidism and pseudohypoparathyroidism, septic shock, acute pancreatitis and rhabdomyolysis.[39] Clinical features of reduced serum ionised calcium include tetany, cramps, mental changes and decrease in cardiac output. Symptomatic hypocalcaemia should be treated with IV calcium, as either calcium chloride or calcium gluconate. It should be remembered that 1 mL of calcium chloride has three times as much elemental calcium as 1 mL of calcium gluconate, and so the former is the preferred formulation in acute situations. Calcium should be administered via a central vein when practical, owing to the risk of tissue damage if extravasated.[39]

HYPERCALCAEMIA

The clinical features of hypercalcaemia include nausea, vomiting, pancreatitis, polyuria, polydipsia, muscular weakness, mental disturbance and ectopic calcification. Some of the common causes of hypercalcaemia include endocrine diseases, such as hyperparathyroidism and thyrotoxicosis, renal failure, malignancy, thiazide diuretics and prolonged immobilisation.[39]

Severe hypercalcaemia (>3.3 mmol/L) or more moderate symptomatic hypercalcaemia will require specific therapy. A cause for the elevated calcium concentration should be sought, and specific treatment may be warranted. General measures include restoration of intravascular volume, followed by the use of a loop diuretic, such as frusemide, to promote calcium excretion. The use of bisphosphonates, such as pamidronate, is recommended for severe hypercalcaemia.[40] Other therapies to consider include corticosteroids, calcitonin and mithramycin.

MAGNESIUM

Magnesium is primarily an intracellular ion that acts as a metallo-coenzyme in numerous phosphate transfer reactions. It has a critical role in the transfer, storage and use of energy.

In humans, the total body magnesium content is 1000 mmol, and plasma concentrations range from 0.70 to 0.95 mmol/L. The daily oral intake is 8–20 mmol (40% of which is absorbed) and the urinary loss, which is the major source of excretion of magnesium, varies from 2.5 to 8 mmol/day.[41]

Box 95.7 Causes of magnesium deficiency

- Gastrointestinal disorders
  - Malabsorption syndromes
  - GIT fistulas
  - Short-bowel syndrome
  - Prolonged nasogastric suction
  - Diarrhoea
  - Pancreatitis
  - Parenteral nutrition
- Alcoholism
- Endocrine disorders
  - Hyperparathyroidism
  - Hyperthyroidism
  - Conn syndrome
  - Diabetes mellitus
  - Hyperaldosteronism
- Renal diseases
  - Renal tubular acidosis
  - Diuretic phase of acute tubular necrosis
- Drugs
  - Aminoglycosides
  - Carbenicillin, ticarcillin
  - Amphotericin B
  - Diuretics
  - Cis-platinum
  - Ciclosporin

GIT, Gastrointestinal tract.

HYPOMAGNESAEMIA

Hypomagnesaemia is caused by decreased intake or increased loss (Box 95.7). Clinical features include neurological signs of confusion, irritability, delirium tremors, convulsions and tachyarrhythmias. Hypomagnesaemia is often associated with resistant hypokalaemia and hypocalcaemia. Treatment consists of IV magnesium sulphate as a bolus of 10 mmol administered over 5 minutes, followed by 20–60 mmol/day.

HYPERMAGNESAEMIA

Hypermagnesaemia is often caused by excessive administration of magnesium salts or conventional doses of magnesium in the presence of renal failure. Clinical features include drowsiness, hyporeflexia and coma, vasodilatation and hypotension, and conduction defects of sinoatrial and atrioventricular nodal block and asystole may occur. Treatment is directed towards increasing excretion of the ion, which may require dialysis. IV calcium chloride may be used for rapidly treating the cardiac conduction defects.[41]

Box 95.8 Causes of hypophosphataemia

Hyperparathyroidism
Vitamin D deficiency
Vitamin-D-resistant rickets
Renal tubular acidosis
Alkalosis
Parenteral nutrition
Alcoholism
Refeeding syndrome

Box 95.9 Causes of hyperphosphataemia

Rhabdomyolysis
Renal failure (acute or chronic)
Vitamin D toxicity
Acidosis
Tumour lysis
Hypoparathyroidism
Pseudohypoparathyroidism
Diphosphonate (bisphosphonate) therapy
Excess intravenous administration

MAGNESIUM THERAPY

There are increasing reports of the use of magnesium as a therapy for a variety of conditions. A randomised, controlled trial of over 10,000 women with pre-eclampsia demonstrated the efficacy of magnesium in the prevention of eclampsia[42]; it is also a recommended treatment for established eclampsia. It has been used to treat atrial fibrillation, to achieve both rate control and reversion to sinus rhythm in a number of settings, including post-cardiac surgery, and in the emergency department.[43,44] Magnesium, given either intravenously or nebulised, may be beneficial for patients with acute severe asthma.[45,46] Magnesium has been investigated for preventing delayed cerebral ischaemia and improving functional outcomes in patients with subarachnoid haemorrhage, but current evidence does not support its routine use for this indication.[47]

PHOSPHATE

While most of the body phosphate exists in bone, 15% is found in the soft tissues as ATP, red blood cell 2,3-DPG, and other cellular structural proteins, including phospholipids, nucleic acids and phosphoproteins. Phosphate also acts as a cellular and urinary buffer.[41]

HYPOPHOSPHATAEMIA

Hypophosphataemia may be caused by a decreased intake, increased excretion or intracellular redistribution (Box 95.8). Although hypophosphataemia is generally symptom-free, clinical features have been described that include paraesthesia, muscle weakness, seizures, coma, rhabdomyolysis and cardiac failure. Hypophosphataemia may be a prominent feature of the refeeding syndrome when it may be accompanied by other electrolyte disturbances such as hypokalaemia and hypomagnesaemia. Treatment consists of close monitoring and replacement as oral or IV sodium or potassium phosphate, 50–100 mmol/24 h.

HYPERPHOSPHATAEMIA

Hyperphosphataemia is usually caused by an increased intake or decreased excretion and is common in both acute and chronic renal failure (Box 95.9). Clinical features include ectopic calcification of nephrocalcinosis, nephrolithiasis and band keratopathy. Treatment may require haemodialysis; otherwise oral aluminium hydroxide and even hypertonic glucose solutions to shift ECF phosphate into the ICF can be used.

FLUID AND ELECTROLYTE REPLACEMENT THERAPY

GENERAL PRINCIPLES

In critical illness many of the body's normal homeostatic mechanisms are deranged and basic life-preserving senses, such as hunger and thirst, may be abolished by disease processes or by treatments such as the use of sedation. As a result, the survival of critically ill patients depends on the administration of appropriate volumes of fluids, and appropriate quantities of electrolytes and nutrition by their medical and nursing attendants. In addition to basal requirements, many critically ill patients have abnormal fluid and electrolyte losses that must be replaced; examples are discussed below.

GASTROINTESTINAL LOSSES

The daily volumes and composition of gastrointestinal tract (GIT) secretions in mmol/L are shown in Table 95.8. Clinical effects of fluid loss from the GIT are largely determined by the volume and composition of the fluid, and therapy is usually directed at replacing the losses. Gastric fluid loss (e.g. from vomiting and nasogastric suction) results in water, sodium, hydrogen ion, potassium and chloride depletion. Hence metabolic alkalosis, hypokalaemia, hypotension and dehydration develop if the saline and potassium chloride losses are not correctly replaced.

Pancreatic and biliary fluid losses (e.g. pancreatic or biliary fistula)

These may result in hyperchloraemic acidosis with hypokalaemia, hypotension and dehydration if the losses of bicarbonate, potassium and saline are not replaced.

Table 95.8 Daily volume and electrolyte composition of gastrointestinal tract secretions

ELECTROLYTES (mmol/L)	VOL. (L)	H^+	Na^+	K^-	CL^-	HCO_3^-
Saliva	0.5–1.0	0	30	20	10–35	0–15
Stomach	1.0–2.5	0–120	60	10	100–120	0
Bile	0.5	0	140	5–10	100	40–70
Pancreatic	0.75	0	140	5–10	70	40–70
Small and large gut	2.0–4.0	0	110	5–10	100	25

Intestinal losses (e.g. fistula or ileostomy losses, diarrhoea and ileus)

These result in hypokalaemia, hypotension and dehydration if the saline and potassium losses are not replaced.

RESUSCITATION FLUIDS

Systemic hypotension is a common feature of acute illness and first-line treatment is usually the administration of intravenous resuscitation fluid. The fluids available to clinicians to maintain or expand intravascular volume include crystalloids, colloid solutions and blood products; the properties of the latter two are discussed in Chapters 97 and 98.

Whether the choice of resuscitation fluid influences patients' outcomes has been the subject of long-running debate. This debate has been fuelled by the conflicting and inconclusive results of a number of meta-analyses.[48,49] Data from clinical trials may help guide clinicians with the choice of resuscitation fluids. The Saline versus Albumin Fluid Evaluation Study, found that saline and albumin produced comparable outcomes in a heterogeneous population of critically ill adult patients,[50] but in patients with traumatic brain injury resuscitation with albumin was associated with a significant increase in mortality.[51] The Crystalloid versus Hydrioxyethyl Starch Trial study demonstrated no advantage to the use of hydroxyethyl starch (HES) compared to saline in a similar population of patients, with a greater proportion of those assigned to HES being treated with renal replacement therapy.[52] The choice of fluid for resuscitation also may be important in patients with severe sepsis. In a trial led by the Scandinavian Critical Care Trials Group[53] patients with severe sepsis who were resuscitated with hydroxylethyl starch 130/0.42 in Ringer's acetate had an increased risk of death compared with those resuscitated only with Ringer's acetate. Although rapid fluid resuscitation remains a strongly recommended treatment for adults with severe sepsis in the developed world, a trial in African children with severe infections has challenged the assumption that this is the correct strategy in all situations. In the Fluid Expansion as Supportive Therapy study, children with severe infections who received 20–40 mL/kg of either normal saline or 5% albumin as fluid boluses had an increased risk of death compared with those who received only maintenance fluids.[54] The relevance of these findings for adult patients and developed world medicine is unclear. Further investigator-initiated trials are currently underway (such as the PLUS study, NCT02721654) and their results may further assist clinicians in developing evidence-based fluid resuscitation strategies.

Enteral and parenteral nutrition

Richard Leonard

It is standard practice to provide nutritional support to critically ill patients in order to treat pre-existing malnutrition and minimise muscle wasting. However, despite the universality of this practice, the evidence underlying it has often been conflicting and of disappointingly poor quality.[1] These failings lead to the familiar trap of preferring opinion based on an appealing mechanistic theory to objective evidence, exemplified by the apparently ineradicable belief that the enteral route of nutrition offers significant clinical benefits.[2]

The problem persists with the publication of numerous clinical practice guidelines,[3–10] which differ significantly in important areas.[11] Fortunately, both the quantity and the quality of available evidence are improving, offering hope that our present uncertainties may be resolved in the future.

NUTRITIONAL ASSESSMENT

Objective assessment of nutritional status is difficult in the intensive care unit (ICU) because disease processes confound methods used in the general population. Anthropometric measures such as triceps skin-fold thickness and midarm circumference may be obscured by oedema. Voluntary handgrip strength is impractical in unconscious patients. Laboratory measures, including transferrin, pre-albumin and albumin levels, lymphocyte counts, and skin-prick test reactivity, are abnormal in critical illness. Subjective clinical evaluation is better than objective measurement at predicting morbidity.[12] Historical features of malnutrition include weight loss, poor diet, gastrointestinal symptoms, reduced functional capacity and a diagnosis associated with poor intake. Physical signs include loss of subcutaneous fat, muscle wasting, peripheral oedema and ascites.

The problem of subjectivity in nutritional assessment in intensive care has led to attempts to define a group of patients at greater nutritional risk, to whom optimal support may be of most benefit. The observation that an increase in caloric intake was associated with reduced mortality only in patients with a body mass index (BMI) below 25 or above 35[13] led to the development of scoring systems to identify patients at high nutritional risk.[14] The NUTRIC score[15] comprised age, APACHE II and SOFA scores, number of comorbidities, number of days in hospital before admission to the ICU, and interleukin 6 (happily, the modified version[16] dispenses with the need to measure the latter) and has been validated in a general ICU population as identifying a group with worse outcomes. Although the use of nutritional scoring systems is advocated in guidelines, a clinical benefit offered above subjective assessment remains to be demonstrated.

PATIENT SELECTION AND TIMING OF SUPPORT

There are reasonable grounds to believe that it is better to provide nutritional support to critically ill patients than not to do so. This belief is based on the close association between malnutrition, negative nitrogen and calorie balance and poor outcome,[13] and the inevitability of death if starvation continues for long enough. In otherwise healthy humans, this takes several weeks to occur. There is also some direct evidence from one study of jejunal feeding in patients operated on for severe pancreatitis,[17] in which the control group received only intravenous fluids until normal diet resumed. Mortality decreased markedly in the group receiving nutritional support.

Two questions arise from this, relating to the important problem of when nutritional support should start:

- How long is it safe to leave a critically ill patient without nutrition? In other words, which patients need to be fed artificially because they would otherwise be starved for too long, and which can safely wait until they are able to eat?
- If the patient will clearly exceed whatever period is deemed reasonable, is it better to begin feeding immediately? In other words, if we are going to feed, when should we start?

Quite good evidence now supports the early institution of nutritional support, and the trend is both to tolerate much shorter periods without nutrition and to begin feeding more rapidly after initial resuscitation.

ABSTRACT

The evidence base for nutritional support of critically ill patients is at long last improving, although an excess of differing guidelines persists. Feeding should be introduced early, once initial resuscitation is complete, and within 24–48 hours of admission to the intensive care unit (ICU). The route of feeding is largely unimportant, but the enteral route is cheaper and easier to use. The energy and protein requirements of critically ill patients are not known with certainty, and probably vary with the patient's prior nutritional status, and the nature, severity and time-course of the underlying illness. Identification of patients at high nutritional risk, and applying protocolised methods to optimise their nutritional support may improve outcomes. Despite the popularity of research into nutritional adjuncts and techniques, such as intentional underfeeding, aimed at modifying generic disease processes, there is no basis presently for their routine use in unselected intensive care patients.

KEYWORDS

Malnutrition
energy and protein requirements
enteral nutrition
parenteral nutrition
nutritional adjuncts

In 1997, recommendations from a conference sponsored by the US National Institutes of Health, the American Society for Parenteral and Enteral Nutrition and the American Society for Clinical Nutrition suggested that nutritional support be started in any critically ill patient unlikely to regain oral intake within 7–10 days.[18] The basis for this was that, at a typical nitrogen loss of 20–40 g/day, dangerous depletion of lean tissue may occur after 14 days of starvation. Others have suggested a maximum acceptable delay of 3–7 days. Small studies comparing earlier with delayed institution of nutritional support have had conflicting results. A meta-analysis comparing early (first 48 hours after admission to the ICU) with late enteral feeding revealed a reduction in infectious complications.[19] Two subsequent meta-analyses comparing early and delayed enteral feeding both found a reduction in mortality with early support,[20,21] although the authors commented that the total number of patients and the methodological quality of the studies included were both low. Early institution of enteral feeding within 24 hours of ICU admission in patients unlikely to feed orally in that time was an important component of the ACCEPT study guideline (Fig. 96.1).[4] The weight of evidence is presently in favour of this more aggressive approach, and recently issued guidelines endorse this,[9,10] but it cannot be regarded as conclusively proven.[22,23] There have been suggestions that patients with low disease severity and nutrition risk, and those with sepsis, may be adversely affected by aggressive early feeding. The former are unlikely to be significantly represented in the ICU population outside North America, while concerns about the latter were somewhat assuaged by large-scale observational data.[24] The most recent sepsis guidelines reflect this reduced concern.[25]

NUTRITIONAL REQUIREMENTS OF THE CRITICALLY ILL

The optimal doses of energy and protein in critical illness have yet to be determined. A great deal of research effort is currently being directed at this area. Earlier research has been hampered by the linkage between protein and energy provision imposed by the composition of commercially available feeds, and by the fact that in practice the target intake is frequently not achieved.[13,26] Optimal intakes may also vary depending on the nutritional status of the patient, and the nature, severity and stage of the underlying illness. These factors have probably confounded past attempts to define a single best dose in unselected patients.

Some muscle wasting and nitrogen loss are unavoidable in critical illness, despite adequate energy and protein provision.[27] This fact, coupled with a realisation that caloric requirements had previously been overestimated, has led to a historical downward revision of intake, a process which may be continuing.

ENERGY

In 1997, the American College of Chest Physicians published guidelines recommending a daily energy intake of 25 kcal/kg,[3] and this has remained a commonly adopted (although commonly not achieved) target energy intake for critically ill patients.

More recently, concerns have been raised that this standard intake may be excessive. An observational study found lower mortality in those patients who received 9–18 kcal/kg/day than in those with higher and lower intakes.[28] Serendipitously, this is the range within which the actual intake delivered seems to fall. Various mechanisms have been postulated to explain potential harm from higher intake, including suppression of autophagy (an important element of defence against intracellular organisms). There are two main strategies of intentional under-feeding – 'trophic' feeding, whereby a very small volume of feed is provided with the aim of preserving gut mucosal integrity, and 'hypocaloric' feeding, in which around 50% of the standard target is provided. Several studies showed little overall effect, a finding replicated by two recent meta-analyses.[29,30] At present, unequivocal benefits of hypocaloric feeding have yet to be demonstrated in large prospective trials. It remains extremely important to realise that enterally fed patients frequently fail to achieve their target intake, and that significant prolonged under-feeding, with a mounting cumulative caloric deficit, is closely associated with worse outcomes.[13,28,31,32] Very recent observational data continue to demonstrate an association between higher caloric intake and lower mortality in critically ill patients with high NUTRIC scores.[33] Intentional under-feeding, if it has a place at all, may be a strategy more suited to less sick, better nourished patients.

Attempts have also been made to tailor the energy provided to critically ill patients to their individual needs. Two methods are commonly used: indirect calorimetry and predictive equations. Indirect calorimetry is the rather burdensome gold standard; its use may become easier in future with the availability of devices designed for ICU patients. It permits measurement of the resting energy expenditure (REE). This value excludes the energy cost of physical activity, which increases later in the course of an ICU admission.[34] Calorimetry reveals deviations from values predicted by equations,[35] such that two-thirds of patients in one study were being either under- or overfed.[36] Previously, it could not be shown that outcomes are improved by the use of calorimetry,[37] but a more recent study showed a trend towards reduced hospital mortality in the group whose feeding was calorimetrically guided (and who received in consequence a higher caloric intake).[38] Moreover, there are no clear data to relate measured REE to total energy expenditure in the individual patient. Presently, few ICUs use calorimetry.

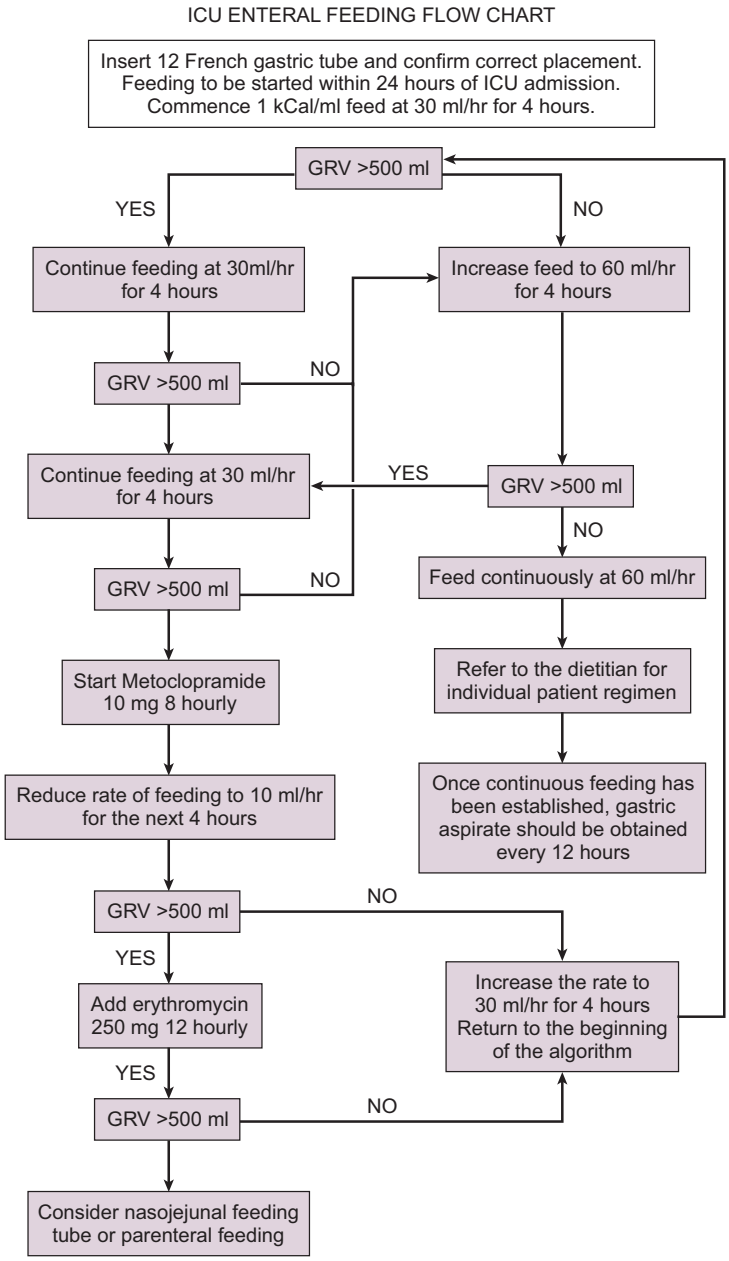

Figure 96.1 Algorithm for intensive care unit (ICU) enteral feeding. *GRV*, Gastric residual volume. *Courtesy of Ella Terblanche, Liesl Wandrag and Jacqui O'Flynn.*

In the absence of a reliable measurement of REE, there exist several equations converting basal metabolic rate predicted from anthropometric data into an estimate of energy expenditure. These rely on correction factors to adjust for variables such as diagnosis, pyrexia and activity. Accepting the general inaccuracy of equations compared with measured energy expenditure, the Penn State formula[39] appears to perform most accurately, except in obese patients.[35]

Despite the popularity of measurements or estimates of energy expenditure, it is not yet clear that their routine use improves outcome. Many ICUs dispense with both and simply aim to deliver 25 kcal/kg/day, in the hope – if not the firm belief – that achieving

somewhat less than this represents an appropriate intake. Increasing the target intake towards 30 kcal/kg/day as the patient recovers and activity increases might then be rational. Nonetheless, the difficulties in interpreting the presently available evidence mean considerable uncertainty attaches to this practice. It may well be that the use of nutritional risk assessment tools to target sicker, more nutritionally compromised individuals with more aggressive regimes tailored to measured REE would represent an improvement on current practice, but this remains to be demonstrated.

PROTEIN

Assessment of nitrogen balance by measuring urinary urea nitrogen is too variable to be useful in estimating protein requirements in the ICU.[40] As there is an upper limit to the amount of dietary protein that can be used for synthesis,[41] there is no benefit from replacing nitrogen lost in excess of this, although mild overprovision appears not to be harmful.[42] The dietary protein requirement for healthy humans is around 0.8 g/kg/day, and for many years the standard recommendation in critical illness was 1 g/kg/day. On the basis of observational studies suggesting reduced mortality and muscle wasting with higher protein intake,[43] recommendations have now been increased to at least 1.2 g/kg/day. Some patients may require up to 2–2.5 g/kg/day, especially those with burns and elderly trauma patients.[9,42] Delivering high-protein intake without also risking excessive energy provision may require use of specialised feed formulae.

MICRONUTRIENTS

Critical illness increases the requirements for vitamins A, E, K, thiamine (B1), B3, B6, vitamin C and pantothenic and folic acids.[44] Thiamine, folic acid and vitamin K are particularly vulnerable to deficiency during total parenteral nutrition (TPN). Renal replacement therapy can cause loss of water-soluble vitamins and trace elements. Deficiencies of selenium, zinc, manganese and copper have been described in critical illness, in addition to the more familiar iron-deficient state. Subclinical deficiencies in critically ill patients are thought to cause immune deficiency and reduced resistance to oxidative stress. Suggested requirements for micronutrients in critically ill patients vary between authors and depending on route of administration; the most comprehensive guidance[44] is reproduced in Tables 96.1 and 96.2. More recent but broadly similar recommendations for some compounds are also available.[45,46]

Commercial preparations of both enteral and parenteral feeding solutions provide standard amounts of micronutrients. Supplementation of intake of certain antioxidant vitamins and trace elements above these levels is discussed below.

Table 96.1 Daily vitamin requirements in critical illness[44]

VITAMIN	FUNCTION	AMOUNT
Vitamin A	Cell growth, night vision	10,000–25,000 IU
Vitamin D	Calcium metabolism	400–1000 IU
Vitamin E	Membrane antioxidant	400–1000 IU
Beta carotene*	Antioxidant	50 mg
Vitamin K	Activation of clotting factors	1.5 µg/kg/day
Thiamine (vitamin B1)	Oxidative decarboxylation	10 mg
Riboflavin (vitamin B2)	Oxidative phosphorylation	10 mg
Niacin (vitamin B3)	Part of NAD, redox reactions	200 mg
Pantothenic acid	Part of coenzyme A	100 mg
Biotin	Carboxylase activity	5 mg
Pyridoxine (vitamin B6)	Decarboxylase activity	20 mg
Folic acid	Haematopoiesis	2 mg
Vitamin B12	Haematopoiesis	20 µg
Vitamin C	Antioxidant, collagen synthesis	2000 mg

*Not strictly a vitamin.

Table 96.2 Daily trace element requirements in critical illness[44]

ELEMENT	FUNCTION	AMOUNT
Selenium	Antioxidant, fat metabolism	100 µg
Zinc	Energy metabolism, protein synthesis, epithelial growth	50 mg
Copper	Collagen cross-linking, ceruloplasmin	2–3 mg
Manganese	Neural function, fatty acid synthesis	25–50 mg
Chromium	Insulin activity	200 mg
Cobalt	B12 synthesis	
Iodine	Thyroid hormones	
Iron	Haematopoiesis, oxidative phosphorylation	10 mg
Molybdenum	Purine and pyridine metabolism	0.2–0.5 mg

Table 96.3 Water and electrolyte requirements per kilogram per day

Water	30 mL
Sodium	1–2 mmol
Potassium	0.7–1 mmol
Magnesium	0.1 mmol
Calcium	0.1 mmol
Phosphorus	0.4 mmol

WATER AND ELECTROLYTES

Water and electrolyte requirements vary widely depending on the patient's condition; typical basal intakes are shown in Table 96.3.

ROUTE OF NUTRITION

When possible, patients should be fed enterally. The advantages over the parenteral route are, however, simply that it is cheaper and easier. Despite the persistent widespread belief that the enteral route offers non-metabolic benefits such as improved gut mucosal integrity and enhanced immune responsiveness, this does not appear to translate into meaningful benefit to patients.

Two hypotheses are commonly advanced in support of the putative superiority of enteral feeding. First, it appears that the lipid contained within TPN is immunosuppressive. Intravenous lipid is known to suppress neutrophil and reticulo-endothelial system function, and a comparison of TPN with and without lipid in critically ill trauma patients showed a lower complication rate in those not receiving lipid.[47] Second, enteral feeding is believed by some to protect against infective complications by improving gut mucosal barrier function and the immune function of gut-associated lymphoid tissue, reducing bacterial translocation and consequent multiple organ failure. However, these theories are based mainly on studies in mice; none of the causal relations they rely upon have been established in humans.

Despite a range of early, small, often poorly designed studies suggesting reductions in infection rates in patients fed enterally, the large recent CALORIES trial demonstrated clearly the absence of any effect of route.[26] While meta-analyses continue to report a reduction in infections with enteral feeding, this effect seems to be based purely on the excessive caloric intake previously associated with parenteral nutrition, rather than the route itself.[8,48] The value of contaminating high quality data from CALORIES with those from earlier, less rigorous studies is far from apparent, and an effect of route alone on clinically significant outcomes is now highly unlikely.

One related area of controversy remains the practice of supplementing partially successful but inadequate enteral intake with intravenous feeding relatively early in the course of an ICU admission. A large multicentre study compared early parenteral supplementation of inadequate enteral intake (within 48 hours of ICU admission) with supplementation delayed until day 8.[49] There was no mortality difference, but patients in the delayed-supplementation group left the ICU earlier and suffered fewer infectious complications. However, interpretation of this study is complicated by the fact that the early-supplementation group received 25–30 kcal/kg/day, raising the possibility that high intake, rather than the route of feeding, was responsible for the increase in infections. The study also used tight glycaemic control. These differences from common practice make it difficult to generalise the findings. It is presently uncertain whether, when and at what dose parenteral feeding should be used to supplement inadequate enteral intake, but very early, aggressive intravenous supplementation does not seem warranted.

ENTERAL NUTRITION

ACCESS

Nasal tubes are preferred to oral, except in patients with a basal skull fracture, in whom there is a risk of cranial penetration. A large-bore (12–14 Fr) nasogastric tube is usually used at first, to provide gastric drainage and permit measurement of gastric residual volumes (see below). Once feeding is established, this can be replaced with a more comfortable fine-bore tube. A stylet is needed to assist in passage of fine-bore tubes. The position of all tubes must be checked before feeding is started, as misplacement is not uncommon and intrapulmonary delivery of feed is potentially fatal. In the United Kingdom, the National Patient Safety Agency has issued guidance recommending daily pH testing of tube aspirate, with X-ray confirmation of correct placement reserved for cases in which pH testing is equivocal or impossible.

Nasojejunal tubes may be beneficial if impaired gastric emptying is refractory to prokinetic agents (see below); their unselective use is not indicated even in patients with mildly elevated gastric residual volumes.[50,51] Spontaneous passage through the pylorus following blind placement is not reliable, but may be increased by the administration of a single dose of erythromycin.[52] Endoscopic or fluoroscopic assistance is needed for truly reliable transpyloric tube placement, although use of electromagnetic guidance systems may obviate the logistic difficulties these traditional methods entail.[53] There are conflicting data on the question of whether nasojejunal feeding reduces the risk of aspiration or ventilator-associated pneumonia,[51,54,55] although a meta-analysis concludes that

it probably does.[8] The tenuous evidence of a clear benefit, coupled with the cost and logistic difficulty of placing them, precludes the routine use of nasojejunal tubes for all patients.

An alternative method of access in those needing long-term enteral feeding is percutaneous gastrostomy, which can be performed endoscopically or radiologically. Percutaneous jejunal access can be obtained either via a gastrostomy or by direct placement during incidental laparotomy.

REGIMEN

Slowly building up the rate of feeding is not proven to avoid symptoms of feed intolerance, such as diarrhoea or high gastric residual volumes. Head-injured patients fed with target intake from the outset have fewer infective complications,[56] and the practice has subsequently been shown to be safe in unselected ICU patients.[57] Nevertheless, it is presently common practice to start delivering around 30 mL/h and build up to the target intake depending on tolerance, as judged by gastric residual volumes. A more aggressive strategy of so-called 'volume-based feeding' (delivering the target volume over 24 hours and catching up for any period of feeding interruption with an increased rate), together with acceptance of higher gastric residual volumes (up to 300 mL) and routine use of prokinetics, results in an increase in the proportion of target intake delivered.[58]

Traditionally, gastric residual volumes are assessed by aspiration of the tube every 4 hours. Values over 150 mL on two successive occasions have been associated with an increased incidence of ventilator-associated pneumonia in one study[59]; in contrast, others have found no link between high residual volumes and the risk of aspiration.[60] Nevertheless, if the residual volume is consistently greater than 200 mL, treatment with prokinetic agents (metoclopramide 10 mg q8h or erythromycin 250 mg q12h intravenously) appears to increase tolerance of feeding, though there is no discernible effect on mortality or morbidity.[52] This is unsurprising in light of two studies showing that it is safe to tolerate gastric residual volumes up to 500 mL[61] or even not to check the volume at all.[62] In refractory cases, a nasojejunal tube often permits successful enteral feeding because small bowel function is resumed quicker than gastric emptying. A nasogastric tube is still needed to drain the stomach. Diarrhoea, abdominal distension, nausea and vomiting may suggest intolerance, even if gastric volumes are low. Absence of bowel sounds is common in ventilated patients and should not be taken to indicate ileus.

Fine-bore tubes should not be aspirated, as this causes them to block. Various folk remedies have been tried for unblocking tubes, including instillation of Coca-Cola, fruit juice and pancreatic enzyme supplements. The instillates should be left in situ for an hour or more.

COMPOSITION

Commercially available enteral feeding solutions vary widely in composition. Polymeric feeds contain intact proteins (derived from whey, meat, soy isolates and caseinates) and carbohydrates in the form of oligo- and polysaccharides. These require pancreatic enzymes for absorption.

Elemental feeds with defined nitrogen sources (amino acids or peptides) are not of benefit when used routinely, but may enable feeding when small bowel absorption is impaired, for instance in pancreatic insufficiency or following prolonged starvation. Lipids are usually provided by vegetable oils consisting mostly of long-chain triglycerides, but some also contain more easily absorbed medium-chain triglycerides. The proportion of non-protein calories provided as carbohydrate is usually two-thirds.

Electrolyte composition varies widely, with sodium- and potassium-restricted formulations available. Vitamins and trace elements are usually added by the manufacturers so that daily requirements are present in a volume containing roughly 2000 kcal. The possible benefits of providing additional doses of some of these substances to critically ill patients are considered below.

COMPLICATIONS

Enteral feeding is an independent risk factor for ventilator-associated pneumonia.[63] Sinusitis due to nasogastric intubation may necessitate changing to an orogastric tube. Fine-bore tubes are vulnerable to misplacement in the trachea or to perforation of the pharynx, oesophagus, stomach or bowel. Percutaneous endoscopic gastrostomy is associated with a high 30-day all-cause mortality in acutely ill patients, in whom it may be best avoided.[64] Other complications include insertion site infection, serious abdominal wall infection and peritonitis. Surgically placed jejunostomies can cause similar problems, and may also obstruct the bowel.

Diarrhoea is common in ICU patients, particularly those being fed enterally. It is often multifactorial and causes considerable distress and morbidity, particularly when the patient is repeatedly soiled with watery stool. Common causes include antibiotic therapy, *Clostridium difficile* infection, faecal impaction and a non-specific effect of critical illness. Malabsorption, lactose intolerance, prokinetic agents, magnesium, aminophylline, quinidine and medications containing sorbitol (for instance, paracetamol syrup and cimetidine) are occasional culprits. Rate of administration of enteral feed also plays a role. Faecal impaction, medication-induced diarrhoea and *C. difficile* infection

must be excluded or treated, while malabsorption may respond to elemental diet. Slowing the rate of feeding sometimes helps; diluting the formula does not. It is unclear whether addition of probiotics or fibre to enteral feed is of benefit in preventing or treating diarrhoea.[8,9]

Metabolic complications include electrolyte abnormalities and hyperglycaemia. Severely malnourished patients are at risk of refeeding syndrome (see below) if nutritional support is begun too rapidly.

PARENTERAL NUTRITION

Parenteral nutritional support is indicated when adequate enteral intake cannot be established within an acceptable time. In some cases, absolute gastrointestinal failure is obvious, whereas in others it becomes apparent only after considerable efforts to feed enterally have failed. As discussed above, there is ample evidence that if enteral feeding cannot be established early, then the parenteral route can safely be used until it can. Nevertheless, the aim in all patients fed intravenously should be to revert to enteral feeding as circumstances permit.

Parenteral feeding solutions may be prepared from their component parts under sterile conditions. Ready-made solutions also exist, but any necessary additions must be made similarly.

In ICU patients, the daily requirements are infused continuously over 24 hours. Careful biochemical and clinical monitoring is important, particularly at the outset (Box 96.1).

Box 96.1 Minimum monitoring during total parenteral nutrition – less stable patients may require more intensive surveillance

Nursing
1. Temperature
2. Pulse
3. Blood pressure
4. Respiratory rate
5. Fluid balance
6. Blood sugar (4-hourly when commencing feed)

Daily (at least)
1. Review of fluid balance
2. Review of nutrient intake

2. Uric acid

ACCESS

The major concern with central venous access for TPN is prevention of infection. The following considerations apply.[65]

- *Insertion site:* subclavian lines have lower infection rates than internal jugular or femoral lines. Peripherally inserted central catheters (PICC) also provide safe, convenient access for TPN with low infection rates, and are increasingly used worldwide.
- *Tunnelling* may reduce infection rates in internal jugular lines but apparently not in short-term subclavian lines. It is not recommended for routine use.
- *Expertise* of operator and adequacy of ICU *nurse staffing levels* affect infection rate.
- *Skin preparation:* 2% chlorhexidine in alcohol is the most effective.
- *Sterile technique:* maximal sterile barrier procedures (mask, cap, gown, gloves and large drape) are known to reduce catheter-related bacteraemia rates sixfold. There is a bewildering resistance to use of these precautions outside ICUs.
- *Dressings:* permeable polyurethane transparent dressings are superior to impermeable.
- *Antimicrobial catheters:* catheters coated with either chlorhexidine and silver sulfadiazine or rifampicin and minocycline are several times less likely to cause bacteraemia than standard polyurethane catheters. The duration of the anti-infective effect appears to be longer with the antibiotic-coated catheters (2 weeks vs 1).
- *Scheduled exchange* has not been proven to reduce catheter-related sepsis.
- *Guide-wire exchange* is associated with increased bacteraemia rates, which in routine use outweigh the reduced mechanical complications.

In practice, pre-existing central access is used in the first instance. If a multilumen catheter is used, one lumen should be dedicated to administration of TPN and not used for any other purpose. Three-way taps should be avoided and infusion set changes carried out daily under sterile conditions. For long-term TPN (more than 2 months), specialised catheters with a tunnelled cuff or a subcutaneous port are recommended, although PICC access provides a convenient bridge if already in use.

COMPOSITION

ENERGY

Energy is provided by a combination of carbohydrate and lipid. The optimal balance between the two is unknown; often 30%–40% of non-protein energy is

given as lipid. Alternatively, glucose may be relied upon for almost all the energy, with lipid being infused once or twice a week to provide essential fatty acids.

Glucose is the preferred carbohydrate and is infused as a concentrated solution. Exceeding the body's capacity to metabolise glucose (4 mg/kg/min in the septic patient) can lead to hyperglycaemia, lipogenesis and excess CO_2 production. Endogenous insulin secretion increases to control blood sugar levels. However, many patients require additional insulin, particularly diabetics. This may be infused separately, but when requirements are stable it is more safely added to the TPN solution. Persistent hyperglycaemia is better addressed by reducing the glucose infusion rate than by large doses of insulin.

Lipid provides essential fatty acids (linoleic and linolenic acids) and is a more concentrated energy source than glucose. It may thus avoid the complications of excess glucose administration. However, there are concerns of immunosuppression from lipid infusion, as discussed above. Traditionally, lipid preparations consist of soybean oil emulsified with glycerol and egg phosphatides. Replacement of some or all of the soybean oil with olive-oil- or fish-oil-based lipids or with medium-chain triglycerides has been proposed to offer immunological benefits; however, clear evidence of this has so far been elusive.[66]

NITROGEN

Nitrogen is supplied as crystalline solutions of L-amino acids. Commercially available preparations vary in their provision of conditionally essential amino acids. Glutamine, tyrosine and cysteine are absent from many because of instability.

MICRONUTRIENTS

Vitamin and trace element preparations are added to TPN solutions in appropriate amounts. Thiamine, folic acid and vitamin K are particularly vulnerable to depletion and additional doses may be necessary.

ELECTROLYTES

Amino acid preparations contain varying quantities of electrolytes; additional amounts may need to be added to the solution.

COMPLICATIONS

Parenteral nutrition has the potential for severe complications.

- *Catheter-related sepsis* is addressed above. Other complications of central venous cannulation are discussed elsewhere.
- *Electrolyte abnormalities* include hypophosphataemia, hypokalaemia and hypomagnesaemia, especially in the first 24–48 hours.
- *Hyperchloraemic metabolic acidosis* may result from amino acid solutions with a high chloride content. Replacing some chloride with acetate in the TPN solution will resolve this where necessary.
- *Rebound hypoglycaemia* may occur when TPN is discontinued suddenly. TPN should be weaned over a minimum of 12 hours. If it cannot be continued, an infusion of 10% dextrose should be started and blood sugars closely monitored.
- *Refeeding syndrome* may occur when normal intake is resumed after a period of starvation. It is associated with profound hypophosphataemia, and possibly hypokalaemia and hypomagnesaemia. With the restoration of glucose as a substrate, insulin levels rise and cause cellular uptake of these ions. Depletion of adenosine triphosphate (ATP) and 2,3-diphosphoglyceric acid (2,3-DPG) results in tissue hypoxia and failure of cellular energy metabolism. This may manifest as cardiac and respiratory failure, with paraesthesiae and seizures also reported. Thiamine deficiency may also play a part.
- *Liver dysfunction* is common during TPN. Causes include hepatic steatosis, intrahepatic cholestasis and biliary sludging from gallbladder inactivity. The problems necessitating TPN in the first place may also cause liver dysfunction.
- *Deficiencies* of trace elements and vitamins (especially thiamine, folic acid and vitamin K) may occur.

NUTRITION AND SPECIFIC DISEASES

ACUTE RENAL FAILURE

The advent of continuous renal replacement therapy means that dietary fluid and protein restriction is unnecessary in the ICU. Use of specialised lipid or amino acid formulations in TPN is not supported by evidence, and in general normal nutritional support is appropriate in acute renal failure.

LIVER DISEASE[67]

Energy requirements in ICU patients are not altered by the presence of chronic liver disease. Protein restriction has previously been advocated in patients with chronic hepatic encephalopathy; however, modern practice is to provide a normal protein intake. Hepatic encephalopathy may in part be due to depletion of branched-chain amino acids (BCAAs) permitting increased cerebral uptake of aromatic amino acids, which produce inhibitory neurotransmitters. Neither the routine use of feeds enriched with BCAAs nor intravenous supplementation with BCAAs is indicated.[8,9,22] Thiamine and fat-soluble vitamin deficiencies are common in patients with chronic liver disease.

Acute liver failure reduces gluconeogenesis; hypoglycaemia is a common problem necessitating glucose infusion. Energy and protein requirements are unaltered. BCAAs have not been shown to be superior to standard amino-acid solutions. In patients with

cerebral oedema and severely elevated ammonia levels, brief protein restriction may help.

RESPIRATORY FAILURE

Oxidation of fat produces less carbon dioxide than glucose. There have been attempts to use this to assist in weaning from mechanical ventilation by providing 50% of energy intake as lipid, with mixed results. Avoidance of overfeeding is more important. The supplementation of omega-3 fatty acids in patients with acute respiratory distress syndrome (ARDS) is discussed below.

ACUTE PANCREATITIS

Formerly, TPN was a cornerstone of the management of severe acute pancreatitis to minimise pancreatic stimulation. This has changed with the publication of studies showing both gastric and jejunal feeding to be safe, effective and associated with reductions in infective complications compared with TPN.[68] Elemental feeds and pancreatic enzyme supplements are logical if malabsorption is a problem. Despite the shift towards enteral feeding of patients with pancreatitis, some only can be fed intravenously.

OBESITY

In the absence of calorimetry, the modified Penn State equations specific for the obese[69] are recommended for estimation of energy requirements.[9,70] Although the most recent US clinical practice guideline recommends hypocaloric, high-protein feeding for obese patients, the recommendation is based only on expert consensus, and the supporting evidence is tenuous. If this approach is adopted, the suggested caloric requirement is 11–14 kcal/kg actual body weight/day in patients with a BMI of 30–50, and 22–25 kcal/kg ideal body weight/day in patients with a BMI over 50. High protein intake is emphasised, at 1.2 g/kg actual body weight/day, or 2–2.5 g/kg ideal body weight/day. The benefits of hypocaloric, high-protein feeding in obesity remain to be proven, though, and at present there is insufficient evidence to justify feeding obese patients differently from others.

It is important to note that patients who have undergone some forms of bariatric surgery (especially sleeve gastrectomy and gastric bypass) are at increased risk for micronutrient deficiency, including iron, selenium, copper, zinc, thiamine, folate and vitamins B12 and D.

ADJUNCTIVE NUTRITION

Certain substances have been used as adjuncts to feeding solutions, in attempts to modulate the metabolic and immune responses to critical illness. In general, no conclusive benefit has yet been shown in unselected critically ill patients.

GLUTAMINE

Glutamine serves as an oxidative fuel and nucleotide precursor for enterocytes and immune cells, mainly lymphocytes, neutrophils and macrophages. It also regulates the expression of many genes related to signal transduction and to cellular metabolism and repair. During catabolic illness, glutamine is released in large quantities from skeletal muscle in order to supply these needs. It may then become 'conditionally essential' and hence depleted, particularly given its absence from many parenteral feeding solutions, with potentially adverse effects on gut barrier and immune function. Both enteral and parenteral glutamine supplements have been extensively investigated. Overall, evidence of benefit has remained weak, and comes from old, small, singlecentre studies, which lacked power to inform as to safety.[71] On the other hand, two large, recent, multicentre studies (the REDOXS[72] and MetaPlus[73] studies) found that glutamine supplementation (in the case of MetaPlus combined with antioxidants and fish oils) may be harmful in some groups. Its use is not justified.

SELENIUM

Selenium is necessary in the regulation of glutathione peroxidase, the major scavenging system for oxygen free radicals. Low plasma selenium levels are common in ICU patients, and a number of small studies have shown potential benefits, but these could not be reproduced in well-powered trials.[74,75] Selenium supplementation is not justified.

ANTIOXIDANT VITAMINS

Vitamins A, C and E are also involved in systemic defence against oxidant stress, and have been studied in various doses and combinations with selenium or omega-3 fatty acids. Of the trials not using other adjuncts, only one has shown a reduction in deaths using large enteral doses of vitamins C and E; numbers were relatively small, however, and the control group had a very high mortality rate.[76] In light of the safety concerns arising from the MetaPlus study, routine supplementation with antioxidant vitamins cannot be justified on present evidence.

ARGININE AND IMMUNONUTRITION

Arginine is a non-essential amino acid that acts as a precursor of nitric oxide, polyamines (important in lymphocyte maturation) and nucleotides. Animal studies suggest enhanced cell-mediated immunity and survival when arginine is supplemented. Several

commercially available enteral feeding solutions combine omega-3 fatty acids, arginine, nucleotides and in one case glutamine to produce so-called immune-enhancing diets. There is evidence to support their use following major surgery, but little in general ICU patients. Meta-analysis suggested an increase in mortality when arginine supplementation was given to septic patients,[77] and interim safety assessment of a trial led to its early cessation when this finding was replicated in the subgroup of patients with sepsis.[78]

There has been continued interest in using feeds enhanced with omega-3 fatty acids, often in combination with antioxidant vitamins and borage oil. Some studies have found benefits in patients with ARDS or sepsis. However, these results could not be repeated by other more recent trials,[79–81] and current knowledge does not warrant supplementation with omega-3 fatty acids, alone or in combination with other compounds.

Blood transfusion and patient blood management

James P Isbister, Craig French

Blood component therapy has a central therapeutic role in clinical medicine; however, blood banking and transfusion medicine have tended to focus on the blood component supply rather than the demand/patient perspective. The clinical focus is 'what is best for the patient?' and not, 'what is best for the blood supply?' This shift from blood product focus to problem-based focus is now referred to as patient blood management (PBM).[1–3] PBM is an evidence-based approach, which, by clinically managing and preserving a patient's blood, aims to optimise patient outcomes.[4] The demand for blood components continues to increase consequent to the greater burden of chronic disease due to ageing of the population, increasing severity of illness, and both a widening range of clinical indications for blood components and newer blood-intensive surgical procedures. This is being tempered by greater focus on clinically appropriate use.

When prescribing blood component therapy, the clinical problem and patient's needs must be accurately identified and clearly understood. Blood component therapy is often required while the basic disease process is corrected (e.g. surgical control for acute haemorrhage, or support for bone marrow suppression until the marrow recovers). Therapy is aimed at controlling the effects of a deficiency (e.g. anaemia, thrombocytopaenia) or preventing secondary complications. Alternatively, the indication is passive immunotherapy (e.g. Rhesus prophylaxis) or high-dosage intravenous immunoglobulin as immunomodulatory therapy.

The role of blood transfusion in a wide range of clinical settings has been critically reassessed, especially in relationship to the labile blood components (red cells, platelet concentrates, fresh frozen plasma, cryoprecipitate). Careful risk assessment and the use of blood conservation techniques have made 'bloodless' surgery possible in most uncomplicated elective surgical settings. Added to the uncertainty about the indications and benefits of allogeneic blood transfusion is the accumulating evidence that blood transfusion is an independent risk factor for poorer clinical outcomes. While transfusions may be lifesaving it is appropriate that there is greater focus on techniques to minimise exposure, transfusion alternatives, and closer attention to the quality and immediate efficacy of blood components.

Traditionally, transfusion has been regarded as the 'default' decision when there is clinical uncertainty. The benefits of transfusion were assumed with little or no evidence to support this assumption and patients were unnecessarily exposed to potential harm.[5,6] Given that the decision-making process for using blood component therapy can be challenging, that indications may be controversial, and that particularly in hemodynamically stable patients the evidence of benefit is uncertain, there are both common sense and scientifically evidence-based reasons to adopt a non-transfusion default position.[7,8] If allogeneic blood component therapy can be avoided, the potential hazards cease to be an issue.

Both evidence-based transfusion medicine and the fact that blood is altruistically donated require that blood is seen as a valuable and unique natural resource that should be conserved and managed appropriately. Blood components should be used as therapy only when there is evidence for potential benefit, when alternatives have been considered, and the potential for harm has been minimised. Potential hazards must be balanced against benefits and wherever possible the benefits and risks should be explained to the patient/relatives.

In considering the use of allogeneic blood transfusion the following questions need to be addressed:

- What is the timeframe of the decision-making process?
- Is it an elective decision?
- What is the most appropriate therapy for the patient?
- Are there alternatives to allogeneic transfusion?
- What component is indicated and where should it be obtained?
- Except for serological compatibility are there any other patient-specific requirements (e.g. irradiated, cytomegalovirus [CMV]-negative)
- How should the component be administered and monitored?
- What are the potential hazards of the blood component therapy?
- Can the risk of adverse effects be avoided or minimised?

ABSTRACT

The administration of blood products to critically ill patients can be lifesaving; however, like all medical interventions the potential risks must be considered together with the benefits. To address this patient blood management (PBM) has been introduced into clinical practice. This chapter provides an overview of PBM as it applies to the critically ill patient: in particular the application of evidence-based clinical practice guidelines, including to those patients with critical bleeding and massive transfusion, is emphasised. Transfusion-related immunomodulation and storage lesion have been associated with adverse patient outcomes. The clinical relevance of recent research in these areas is discussed. Red cell serology (blood type and cross matching) is a highly specialised area: a basic overview for the critical care physician is provided.

KEYWORDS

Blood component therapy
blood transfusion
patient blood management
critical haemorrhage
massive blood transfusion
coagulopathy
hazards of blood transfusion
acute lung injury
blood storage lesion

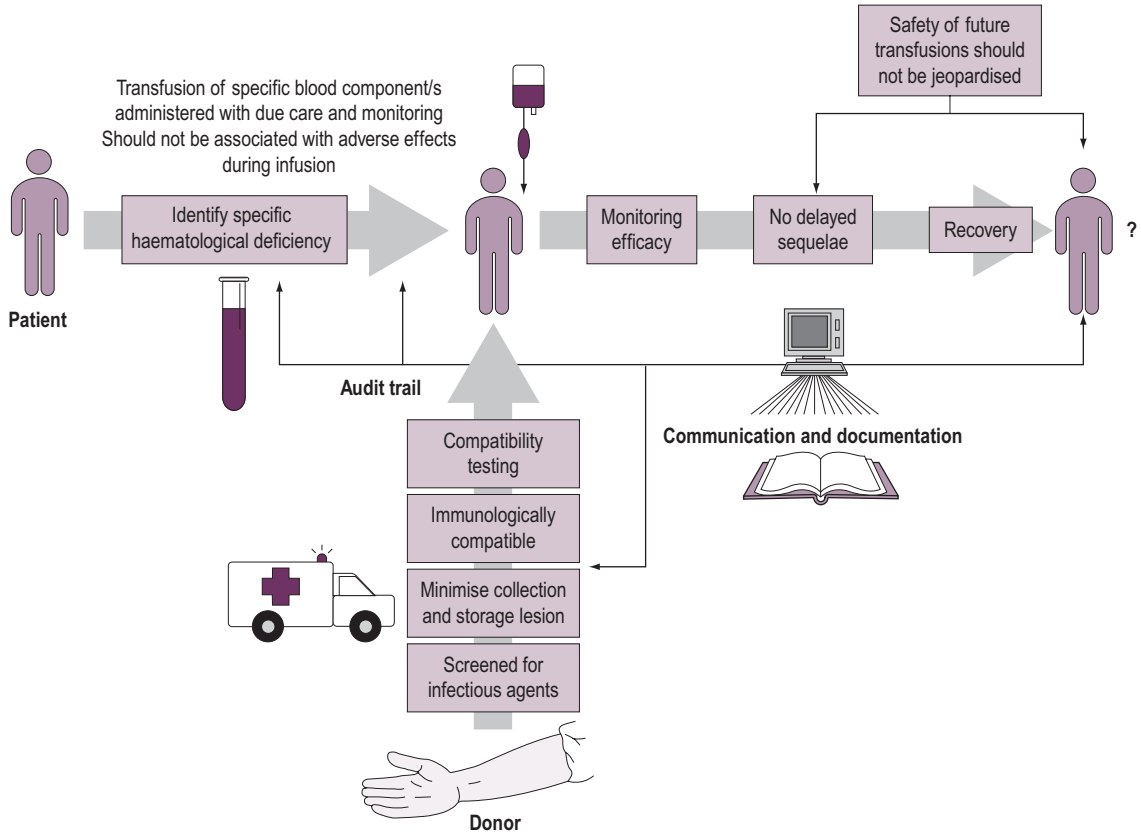

Figure 97.1 What is a safe transfusion?

- Is the patient fully informed of the medical decisions?
- What is the cost of the transfusion therapy?

Safe and effective transfusion requires attention to the following details (Fig. 97.1):

- clearly defined indication and benefits of blood components
- accurate patient identification for blood group compatibility
- identification and careful management of high-risk patients
- appropriate handling, administration and monitoring
- provision of adequate amounts and quality of component(s)
- communication of benefits and risk to the patient/relatives
- the infusion should not be associated with preventable ill effects
- awareness of possible transfusion-related complications
- early diagnosis and prompt action in relation to adverse events of transfusion
- accurate documentation
- input into quality-assurance programmes.

BLOOD STORAGE AND THE STORAGE LESIONS

Blood is altered from the moment of collection and the 'lesions' of collection – anticoagulation, separation, cooling, preservation and storage – compound and progressively increase until the date of expiry.[9] The extent of these changes is determined by collection technique, the specific blood component, the preservative medium, the container, storage time and storage conditions. The threshold storage time for blood components has generally been arbitrarily determined by in vitro studies and assessment of in vivo survival. In the case of red cell concentrates, regulatory standards specify that greater than 75% of transfused cells should survive post-transfusion.

Storage results in quantitative and/or qualitative deficiencies in blood components, which may reduce the immediate efficacy of a transfusion. In parallel with these storage changes is an accumulation of degenerate material (e.g. microaggregates, microparticles and procoagulant material), release of vasoactive agents, cytokine generation and haemolysis.[5] Some are related to the presence of leucocytes and can be minimised by pre-storage leucoreduction.[10] Red cells undergo a change from their biconcave disc shape to spiky

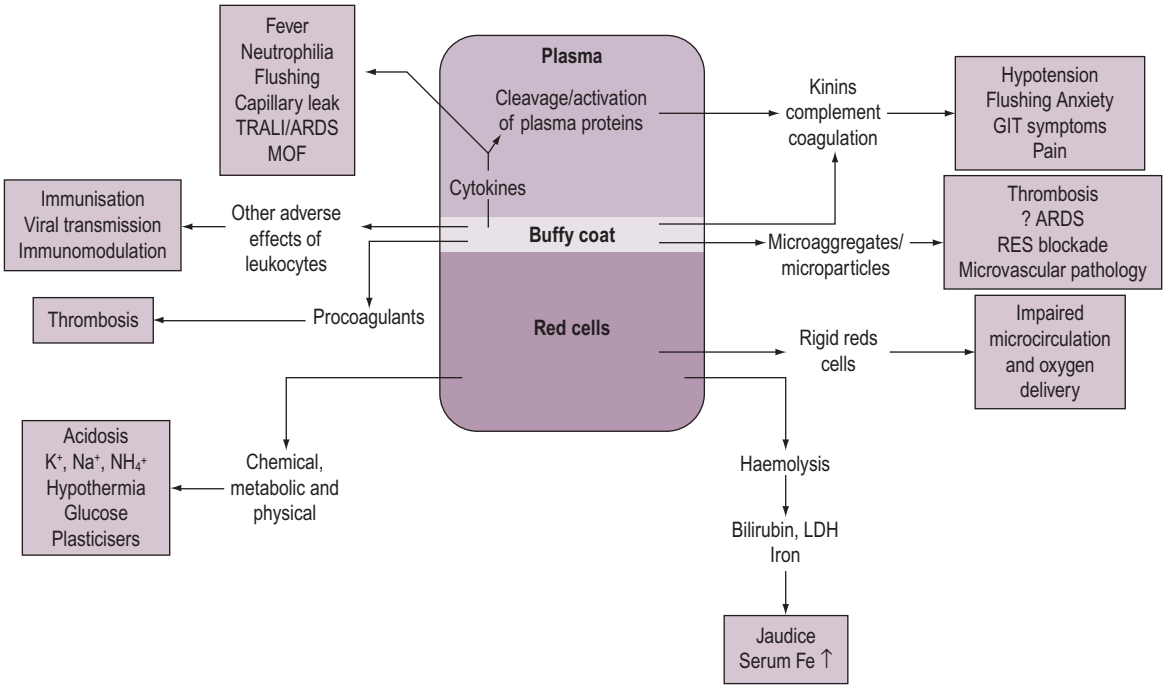

Figure 97.2 The storage lesions. *ARDS*, Adult respiratory distress syndrome; *GIT*, gastrointestinal tract; *LDH*, lactic dehydrogenase; *MOF*, multiorgan failure; *RES*, reticulo-endothelial system; *TRALI*, transfusion-related acute lung injury.

spherocytes (echinocytes) and in so doing lose their flexibility. There are also changes in the red cell membrane resulting in an increased tendency to adhere to endothelial cell surfaces in the microcirculation, especially if there is activation of endothelial cells, for example, in the presence of the systemic inflammatory response (e.g. with shock or sepsis).[11] There is evidence that the immediate post-transfusion function of stored red cells and haemoglobin in delivering oxygen to the microcirculation and unloading is questionable, and several hours are required for red cell oxygen carriage and delivery to return to normal.[12–14] It is important to differentiate between the storage lesion being responsible for failure to achieve clinical/laboratory end-points due to reduced survival and/or qualitative defects in cellular function and the 'toxic' effects of blood storage (Fig. 97.2).

The use of blood filters has been an acknowledgement of the existence of the blood storage lesion and its possible clinical significance. The 170 µm blood-giving filters were first introduced into transfusion medicine to stop the occlusion of blood-giving sets; however, the use of pre-storage leucoreduction filters, and to mitigate the development of the storage lesion in both blood and platelets from its inception, is more logical and scientific. Universal pre-storage leucoreduction is now standard practice in many countries, although it was primarily introduced as a precautionary measure against the possible transmission of variant Creutzfeldt–Jakob disease (vCJD) and not to address the numerous other indications for the removal of leucocytes.[15]

The clinical significance of blood storage lesions remains uncertain. A large body of observational evidence suggest poorer outcome following the administration of older blood.[16–21] Two large, randomised, controlled trials have not demonstrated effect on mortality of the age of transfused red blood cells (RBCs)[22,23]; however, further studies with increased power are required to exclude a clinically significant difference. It is assumed that blood components have been appropriately collected, processed, stored, transported and transfused but, despite much greater attention to standard operating procedures and regulation generally, the quality of the final product cannot be guaranteed.[24] The 'assumed' quality of labile cellular blood products is based on research data and monitoring of standard operating procedures. There is rarely detailed individual product assessment prior to transfusion. It is accepted that the adverse effects of storage increase with time and an arbitrary 'cut-off' is mandated on the basis of research studies. It is reasonable to state, that as a result of improved blood collection, processing, preservation, storage and cold chain management that the clinical use of the labile allogeneic blood components is considerably safer than in the past. However,

questions remain as to efficacy and indications for use.

In relation to the possible clinical significance of the storage lesion, the following should be considered:

- quantitative and qualitative deficiency of blood component
  - failure to achieve anticipated end-points due to reduced quantity and/or quality of the blood product
  - exposure to excessive numbers of donors in achieving efficacy
- physical characteristics
  - hypothermia
  - chemical characteristics
  - citrate toxicity
  - acid–base imbalance
  - glucose
- contamination
  - bacterial resulting in endotoxaemia or septicaemia
  - plasticisers
- accumulation of 'toxic' or degenerate products
  - role of the storage lesion in transfusion-related immunomodulation
  - role of cytokines
  - role of reticuloendothelial system blockade
  - accentuation of free radical pathophysiology due to free iron
- effects of transfusion on laboratory parameters (e.g. elevations in bilirubin, neutrophils, serum iron and lactic dehydrogenase), which may lead to incorrect interpretation
- large-volume transfusions (proportional to storage age) as a risk factor for multiorgan failure (MOF) and adult respiratory distress syndrome (ARDS)
- early hyperkalaemia, late hypokalaemia
- activation and consumption of the haemostatic factors with possible contribution to disseminated intravascular coagulation (DIC) and venous thromboembolism
- non-haemolytic, non-febrile transfusion reactions
- hypotension and circulatory instability due to vasoactive substance (kinins, histamine).

THE ROLE OF LEUCOCYTES AS A 'CONTAMINANT' IN LABILE STORED BLOOD AND THE ROLE OF PRE-STORAGE LEUCOREDUCTION

Leucocytes may be responsible for a wide range of blood component quality and safety issues, but there are difficulties in assessing potential adverse effects.[15] Specific adverse outcomes in some patients have been shown to be due to the presence of leucocytes (e.g. non-haemolytic febrile transfusion reaction, platelet refractoriness and transfusion-associated graft-versus-host disease [TAGVHD]), but this is the minority. In the broader context the overall available evidence – in the absence of adequate large, randomised, clinical trials – suggests that universal pre-storage leucoreduction may reduce transfusion-related morbidity.[25] Leucoreduction of red cell and platelet concentrates potentially minimises the clinical consequences of the immunomodulatory effects of allogeneic transfusion. Hence it may decrease the incidence of recurrence of some cancers, of postoperative infections and of bloodstream infections. In many patients transfusion-related acute lung injury (TRALI) is a multifactorial disorder and in 'at-risk' patients non-leucoreduced blood may be a risk factor. Patients at particular risk include those with trauma, burns, critical bleeding, shock, sepsis and those undergoing cardiopulmonary bypass.[26–29] The quality and function of pre-storage leucoreduced red cell concentrates is better maintained on storage, ensuring better post-transfusion efficacy and survival.[30]

CLINICAL GUIDELINES FOR BLOOD COMPONENT THERAPY

The following is a brief summary of the clinical guidelines for the use of commonly used blood components. The use of specific concentrates or recombinant products is beyond the scope of this book. As alluded to, there is a shift in the current development of clinical practice guidelines from focusing on specific indications for blood components to problem-oriented understanding of the clinical issues (i.e. PBM).[31,32]

RED CELL TRANSFUSIONS

What constitutes the appropriate use of red cell transfusions in acute medicine is contentious because of the difficulties in identifying the benefits of red cell transfusion in many circumstances. Pursuit of the lowest safe haematocrit continues to receive considerable attention, but pushing any aspect of a system to its limits risks 'sailing too close to the wind', which may be appropriate in some situations but potentially hazardous in others.[33,34]

In critically ill patients who are not actively bleeding, a restrictive transfusion strategy should be employed. Guidelines recommend that for most patients red cell transfusion is generally unnecessary when the haemoglobin concentration is greater than 90 g/L.[32] When haemoglobin concentration is in the range 70–90 g/L RBC transfusion is not associated with improved survival. The decision to transfuse should be based on the patient's clinical condition. The transfusion of red cell concentrates is likely to be appropriate when haemoglobin is less than 70 g/L and the anaemia is not reversible with specific therapy; however, lower levels may be acceptable in well-compensated patients, especially in the younger age group.[6] When transfusion is indicated a single unit followed by clinical reassessment is advised.[32]

PLATELET TRANSFUSIONS

Platelet transfusion therapy may benefit patients with platelet deficiency or dysfunction. The following are the indications for platelet transfusions[32]:

PROPHYLAXIS

- In a critically ill patient without bleeding when the platelet count is $<20 \times 10^9$/L
- To maintain the platelet count at $>50 \times 10^9$/L in patients undergoing surgery or invasive procedures
- In qualitative platelet function disorders, depending on clinical features and setting (platelet count is not a reliable indicator for transfusion).

BLEEDING PATIENTS

- In any haemorrhaging patient in whom thrombocytopenia secondary to marrow failure is considered a contributory factor[35]
- When the platelet count is $<50 \times 10^9$/L in the context of massive haemorrhage/transfusion and $<100 \times 10^9$/L in the presence of diffuse microvascular bleeding.

The transfusion of platelet concentrates is not generally considered appropriate:

- when thrombocytopenia is due to immune-mediated destruction
- in thrombotic thrombocytopenic purpura and haemolytic uraemic syndrome
- in uncomplicated cardiac bypass surgery.

FRESH FROZEN PLASMA

There are few specific indications for fresh frozen plasma.[32,36] Its use may be appropriate:

- for the replacement of single-factor deficiencies where a specific or combined factor concentrate is not available
- for treatment of the multiple coagulation deficiencies associated with acute systemic coagulopathies:
  - DIC
  - massive blood transfusion
  - trauma-induced coagulopathy
  - cardiac bypass surgery
  - liver disease
  - peripartum coagulopathies
  - venom-induced coagulopathies.
- for treatment of inherited deficiencies of coagulation inhibitors in patients undergoing high-risk procedures where a specific factor concentrate is unavailable
- for immediate reversal of warfarin-induced anticoagulation in the presence of potentially life-threatening bleeding when prothrombin complex concentrates (PCC) are not available.[37]

The use of fresh frozen plasma is generally not considered appropriate in cases of:

- hypovolaemia
- plasma exchange procedures unless post-exchange invasive procedures are planned or there is a specific indication for replacement
- treatment of immunodeficiency states.

CRYOPRECIPITATE

Cryoprecipitate is prepared from freshly collected plasma and contains factor VIII, fibrinogen, von Willebrand factor, factor XIII and fibronectin. Cryoprecipitate was originally developed for treatment of haemophilia due to factor VIII deficiency, but is now prescribed to treat congenital or acquired hypofibrinogenaemia, usually in the context of liver disease, trauma, DIC, hyperfibrinolysis or massive transfusion.

FIBRINOGEN CONCENTRATE

Fibrinogen concentrate is a freeze-dried preparation derived from human plasma. It is administered intravenously after reconstitution with water for injections. In Australia and New Zealand each vial contains 1 g of human fibrinogen and is approved for use for the treatment of acute bleeding episodes in patients with congenital fibrinogen deficiency, including afibrinogenaemia and hypofibrinogenaemia. In critically ill patients the routine use of fibrinogen concentrate is not advised; however, it may be indicated in critical bleeding where hypofibrinogenaemia exists.[32] Research to define the role of fibrinogen concentrate in the bleeding patient is ongoing.

IMMUNOGLOBULIN

Normal human immunoglobulin is available in intramuscular and intravenous forms for the treatment or prevention of infection in patients with proven hypogammaglobulinaemia.[38,39] Intravenous immunoglobulin G is recommended as adjunctive therapy for toxic shock syndrome caused by group A streptococci or *Staphylococcus aureus*[40]; however, the routine use of immunoglobulin therapy in septic shock is not advised. Intravenous immunoglobulin therapy also has a role in therapy of some autoimmune disorders, such as idiopathic thrombocytopenic purpura, autoimmune polyneuropathy and others.

FACTOR CONCENTRATES

There is an increasing number of plasma protein concentrates available for clinical use. Some are prepared from donor plasma and some by recombinant technology. Factor VIII and factor IX concentrates have an established role in the management of haemophilia, but others are in the process of establishing their clinical efficacy and indications. Antithrombin III (ATIII) concentrates are available for thrombophilia due to ATIII

deficiency and have been recommended in other disorders where ATIII may be depleted (e.g. DIC, MOF) but evidence for efficacy is sparse.[41,42] Recombinant human activated protein C has antithrombotic, anti-inflammatory and profibrinolytic properties. Clinical trials of activated protein C in severe sepsis did not demonstrate a consistent beneficial effect.[43] Accordingly its use is no longer recommended.[42]

Recombinant activated factor VII (rFVIIa) was developed for the management of haemophilic patients with coagulation factor inhibitors; rFVIIa has been used 'off label' for controlling haemorrhage in the non-haemophilic setting and there is considerable controversy as to its benefits and risks.[44,45] Patients with uncontrolled critical bleeding and coagulopathy, despite large transfusions and surgical intervention, have significant mortality rates and rFVIIa in these clinical situations has been administered as salvage therapy. While there are a number of case reports and series reporting on the use of rFVIIa in critical life-threatening haemorrhage, controlled studies have not demonstrated evidence for efficacy, and concern exists regarding thrombotic complications. Its routine use is not recommended.[35]

POTENTIAL ADVERSE EFFECTS OF ALLOGENEIC TRANSFUSION

The pathophysiology of blood transfusion reactions can broadly be divided into five categories (Fig. 97.3):

- Reactions may occur due to *immunological differences* between the donor and recipient, resulting in varying degrees of blood component incompatibility. In general, in order for a reaction to occur, the recipient needs to have been previously immunised to a cellular or plasma antigen.[46]
- A wide range of *infectious agents* may be transmitted by allogeneic blood component therapy.
- *Alterations in blood products due to preservation and storage* may result in quantitative and/or qualitative deficiencies in the blood components, which will reduce transfusion efficacy and expose the patient to potentially adverse consequences from storage accumulants in the component.
- *Technical or clerical errors* may result in adverse events in all the above categories.
- *Psychological* – this includes informed consent issues and patient anxiety about compatibility and infectivity.

In terms of causation of an adverse clinical event, the possible role of blood transfusion can be classified into three categories on the basis of probability (Fig. 97.4):

- *Definite – unifactorial – transfusion caused*: the well-understood and reported hazards of transfusion (i.e. immunological, technical, infectious) are generally unifactorial with a 1:1 causal relationship between the blood component transfused (usually a specific individual unit) and the adverse consequence for the patient. ABO blood group incompatibility, transfusion-related infection transmission, TAGVHD and TRALI due to donor leucoagglutinins are examples in this category.
- *Probable – oligofactorial – transfusion related*: some adverse consequences of transfusion result from interaction with other insults, pathophysiology or host factors, but the contribution of the transfusion can usually be specifically identified. Fever, allergic reactions, hypotensive reactions, pulmonary oedema, some cases of TRALI, hyperbilirubinaemia and CMV transmission are examples in this category.

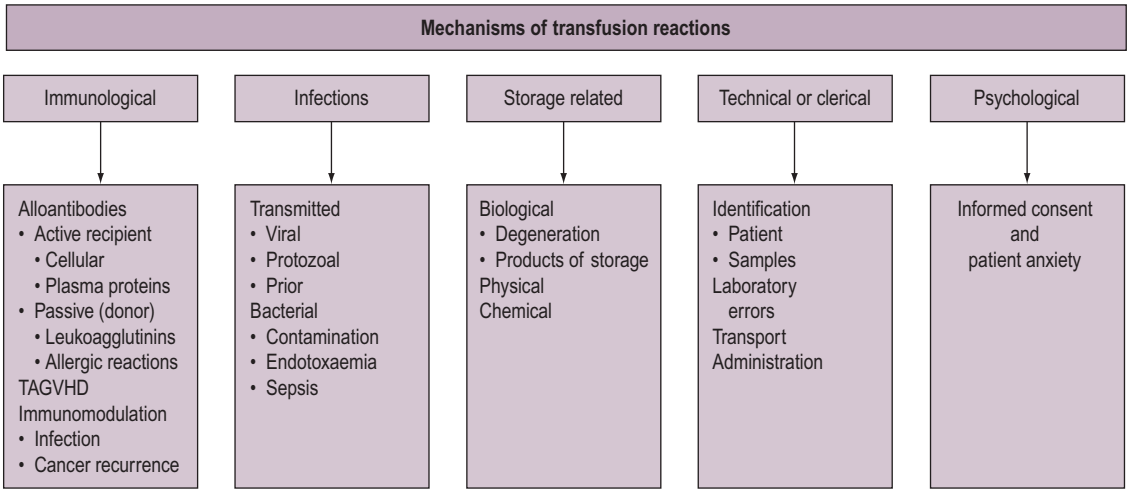

Figure 97.3 Possible mechanisms of adverse effects to blood transfusion. *TAGVHD*, Transfusion-associated graft-versus-host disease.

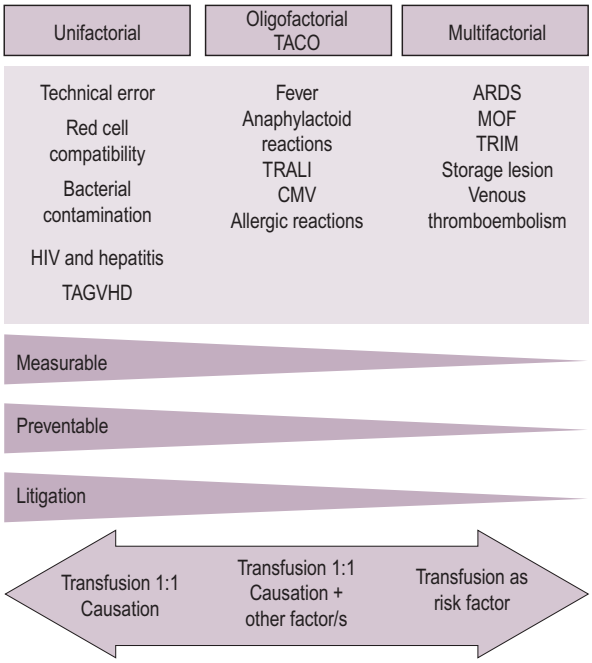

Figure 97.4 Algorithm for analysis for the possibility of a transfusion reaction. *ARDS*, adult respiratory distress syndrome; *CMV*, cytomegalovirus; *HIV*, human immunodeficiency virus; *MOF*, multiorgan failure; *TACO*, transfusion-associated circulatory overload; *TAGVHD*, transfusion-associated graft-versus-host disease; *TRALI*, transfusion-related acute lung injury; *TRIM*, transfusion-induced immunomodulation.

- *Possible – multifactorial – transfusion associated*: transfusion may be a contributor to a complication or poor clinical outcome. In these circumstances it is difficult to implicate transfusion directly in an individual case, nor is it necessarily the major factor. Transfusion-induced immunomodulation (TRIM) and the clinical consequences of storage lesions fall into this category. The role of transfusion being associated with adverse consequences has been established in observational studies, but causation cannot be confidently concluded. Accumulating evidence, in the absence of randomised clinical trials, supports causation, thus demanding a more precautionary approach to allogeneic blood transfusion, examination of alternatives to transfusion and implementation of methods to improve the quality of transfused blood components (especially red cell and platelet concentrates). Universal pre-storage leucoreduction is currently the most important and effective strategy for minimising the clinical impact of TRIM and the blood storage lesions.

Adverse reactions to blood component therapy may present in a wide range of 'guises' and transfusion must always be considered in the differential diagnosis of any unexpected clinical presentation or indeed as a contributory factor to a clinical picture that may have several contributory factors (Fig. 97.5).[47]

PYREXIA

Mild febrile reactions are not usually a matter of concern. The majority of febrile reactions are now considered to be an immunological reaction against one or more of the transfused cellular or plasma components, usually leucocytes.

TRANSFUSION-RELATED INFECTIONS

HEPATITIS

Post-transfusion hepatitis is a potential complication of allogeneic transfusion; donor selection, serological and nucleic acid tests ensure exclusion of infective donors. Hepatitis B and C are now almost totally preventable transfusion-transmitted diseases.

HUMAN IMMUNODEFICIENCY VIRUS

Donor selection, antibody screening and nucleic acid testing of blood donors have almost eliminated transfusion-associated human immunodeficiency virus (HIV) infection.

MONONUCLEOSIS SYNDROMES

The development of swinging pyrexia with varying degrees of peripheral blood atypical mononucleosis, 7–10 days following transfusion, can cause diagnostic confusion. Abnormalities in liver function are common. CMV infection is the commonest cause of this syndrome. When correctly diagnosed CMV is not a serious infection assuming the patient does not have immune compromise.

OTHER TRANSFUSION-TRANSMISSIBLE INFECTIONS

There is an increasing range of agents that have the potential to be transmitted by blood transfusion. The reader is referred to reviews for further information.[47-49]

BACTERIAL CONTAMINATION

Bacterial contamination of stored blood has always been recognised as a potential cause of fulminant endotoxic shock. Although a rare complication, continuing reports of its occurrence, especially in relation to platelet concentrate transfusion, have increased awareness.[50,51] The clinical features of transfusion-related bacterial sepsis in the non-anaesthetised patient include rigors, fever, tachycardia and vascular collapse, with prominent nausea, vomiting and diarrhoea. Anaesthetised patients may have a delayed onset of symptoms (fever, tachycardia, hypotension and cyanosis), followed by DIC, renal failure and sometimes acute lung

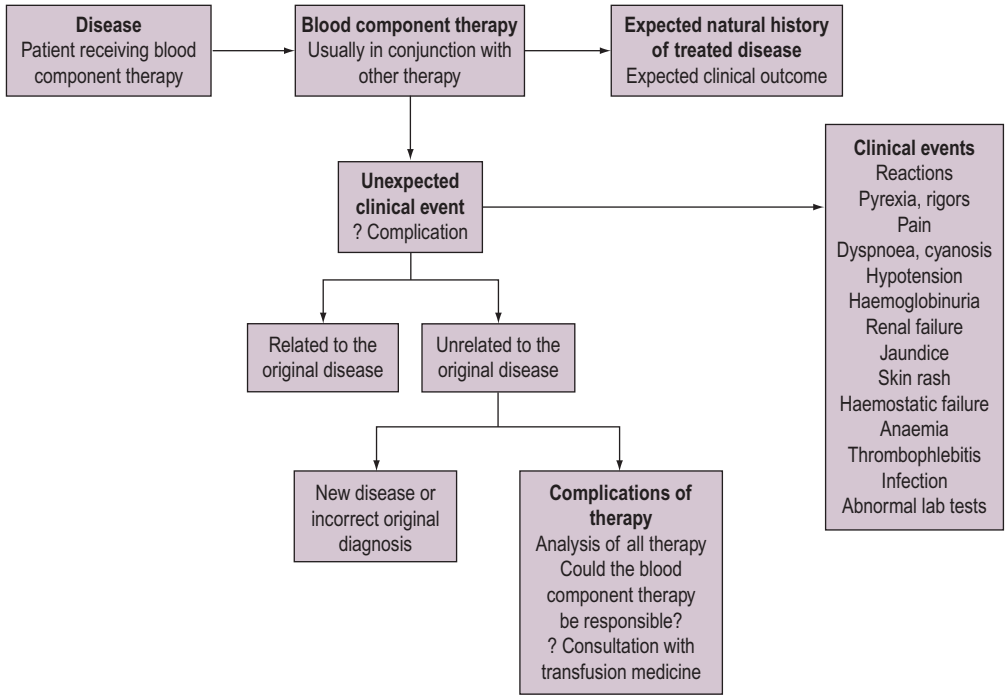

Figure 97.5 Adverse reactions to blood component therapy may be just one of the contributory factors in the differential diagnosis of any unexpected clinical presentation.

injury. The requirement to store platelet concentrates at room temperature increases the risks of bacterial contamination. Pre-release bacterial testing is being more widely advocated as a measure to minimise the problem.

HAEMOLYTIC TRANSFUSION REACTIONS

The most severe acute haemolytic transfusion reactions are due to ABO incompatibility, have an identifiable cause and are avoidable, in contrast to delayed haemolytic reactions that are immune in nature and are difficult to prevent.

INITIAL SYMPTOMS AND SIGNS

The classic symptoms and signs of an acute haemolytic transfusion reaction, typical of ABO incompatibility, include apprehension, flushing, pain (e.g. at infusion site, headache, chest, lumbosacral and abdominal), nausea, vomiting, rigors, hypotension and circulatory collapse.

HAEMOSTATIC FAILURE

Haemorrhagic diathesis due to DIC may be a feature, resulting in severe generalised haemostatic failure, with haemorrhage and oozing from multiple sites.[52] As the responsible transfusion is likely to have been administered for haemorrhage, increasing severity of local bleeding may be the first clue to an incompatible transfusion, especially if the patient is unconscious or anaesthetised in the operating room.

OLIGURIA AND RENAL IMPAIRMENT

Renal impairment may complicate a haemolytic transfusion reaction and its prevention or the appropriate management of established renal failure is important. If circulating volume and urinary output are rapidly restored, established renal failure is unlikely to occur. Death from acute renal failure directly caused by an incompatible blood transfusion is preventable, unless there are other poor prognostic factors.

ANAEMIA AND JAUNDICE

A severe haemolytic transfusion reaction may be suspected from the development of jaundice or anaemia.

ALLERGIC AND ANAPHYLACTOID REACTIONS

Non-cellular blood (plasma and plasma derivatives) components are rarely considered to be a major cause for adverse reactions to transfusion therapy. However, the complexity of plasma and its various components and the effects from component processing results in a broader spectrum of potential adverse effects than is frequently recognised. The antigenic heterogeneity of plasma proteins and the presence of antibodies make the non-cellular components of blood responsible for a range of adverse effects, many of which remain poorly

understood and commonly pass unrecognised in clinical practice.[53]

There has been debate over the years as to the classification of allergic reactions to blood components. Clinical severity may range from minor urticarial reactions or flushing through to fulminant cardiorespiratory collapse and death. Some of these reactions are probably true anaphylaxis, but in others the mechanisms have been less clear and the term 'anaphylactoid' has been used. To avoid implying the mechanism of the reaction, the term 'immediate generalised reaction' has also been used.

The clinical syndromes of immediate reactions have been classified as follows:

- Grade I:
  - skin manifestations
- Grade II:
  - mild to moderate hypotension
  - gastrointestinal disturbances (nausea)
  - respiratory distress
- Grade III:
  - severe hypotension, shock
  - bronchospasm
- Grade IV:
  - cardiac and/or respiratory arrest.

PLASMA AND PLASMA COMPONENTS MAY CAUSE ADVERSE EFFECTS BY SEVERAL PATHOPHYSIOLOGICAL MECHANISMS

Immunological reactions to normal components of plasma may occur in two ways:

- plasma proteins being antigenic to the recipient; they may contain epitopes on their molecules that are different from those on the recipient's functionally identical plasma proteins (e.g. anti-IgA antibodies)
- antibodies in the donor plasma reacting with cellular components of the recipient's blood cells or plasma proteins.

Physicochemical characteristics and contaminants of donor plasma, such as temperature, chemical additives, medications and microorganisms, may be responsible for recipient reactions.

The preparation techniques and storage conditions of blood and blood products may potentially cause adverse reaction through:

- *accumulation of metabolites* or cellular release products
- *plasma activation* (i.e. activation of some of the proteolytic systems). Importantly, the complement and kinin/kininogen systems may generate vasoactive substances and anaphylatoxins that may be responsible for reactions. Some apparently allergic reactions to blood products may be due to vasoactive substances in the infusion. Subjective sensations may be missed in an unconscious patient. Hypotension occurring during rapid infusion of a hypovolaemic patient is likely to be interpreted as further volume loss, particularly with some plasma protein fractions that have been reported as producing a transient fall in blood pressure, and a situation fraught with risk of overload can be produced
- *histamine generation*: histamine levels increase in some stored blood components and levels may be correlated with non-febrile, non-haemolytic transfusion reactions. Histamine release may be stimulated in the patient by plasma components, synthetic colloids and various medications
- *generation of cytokines* during storage may be responsible for non-haemolytic transfusion reactions
- *chemical additives*: there are various chemical additives (ethylene oxide, formaldehyde, drugs, latex) that may be responsible for immunological or non-immunological recipient reactions.

TRANSFUSION-ASSOCIATED GRAFT-VERSUS-HOST DISEASE

Graft-versus-host disease, classically observed in relationship to allogeneic bone marrow transplantation, may occur following a blood transfusion owing to the infusion of immunocompetent lymphocytes precipitating an immunological reaction against the host tissues of the recipient.[54] It is most commonly observed in immunocompromised patients, but may also be seen in recipients of directed blood donation from first-degree relatives, and occasionally where donor and recipient are not related, owing to homozygosity for human leucocyte antigen haplotypes for which the recipient is heterozygous. The syndrome usually occurs 3–30 days post-allogeneic transfusion with fever, liver function test abnormalities, profuse watery diarrhoea, erythematous skin rash and progressive pancytopenia. TAGVHD has be minimised by prestorage leucoreduction but gamma irradiation of blood products is currently the standard of care for the prevention of TAGVHD.[55]

TRANSFUSION-RELATED ACUTE LUNG INJURY

TRALI is a serious complication of blood transfusion and the leading cause of transfusion-related mortality in the United States in FY2015.[56] In the classic plasma neutrophil antibody-mediated form of the disease, symptoms usually arise within hours of a blood transfusion.[57] In contrast to patients with ARDS, recovery usually occurs within 48 hours. The underlying pathophysiology of 'classic' TRALI is due to the presence of leucoagglutinins in donor plasma. When complement is activated, C5a promotes neutrophil aggregation and sequestration in the microcirculation of the lung, causing endothelial damage leading to an interstitial oedema and acute respiratory failure. This classic form of TRALI has been recognised for over five decades, but was thought to be a rare complication of allogeneic plasma transfusion. As leucoagglutinins occur

typically in plasma from multiparous females, male-donor-only fresh frozen plasma is recommended and provided by most blood supply agencies.

It is now accepted that there has been under-recognition and under-diagnosis of TRALI, partly due to a lack of clinical awareness, but also due to a broader understanding of mechanisms by which blood transfusion may cause or be a contributory factor to lung injury.[58] There is also recent experimental evidence supporting a 'two-hit' hypothesis in which patients may be 'primed' by shock, sepsis or extracorporeal circulation making them more susceptible to acute lung injury from blood transfusion.[59]

TRANSFUSION-ASSOCIATED CIRCULATORY OVERLOAD

Transfusion-associated circulatory overload (TACO) is receiving more attention in recent years as many cases of difficult to explain dyspnoea following blood transfusion are caused by circulatory overload.[60] This may be confidently established in some cases, but in others there may be contributing factors, such as pulmonary capillary leak syndromes. Indeed, when there is no identifiable cause for dyspnoea and a definitive transfusion-associated cause of dyspnoea cannot be identified, but suspected, the term transfusion associated dyspnoea (TAD) is used.

TRANSFUSION-RELATED IMMUNOMODULATION

Allogeneic blood transfusion is immunosuppressive having implications in relation to resistance to infection and the likelihood of cancer recurrence.[61–65] Donor leucocytes probably play the most important role in this immunomodulation. TRIM, may be the mechanism by which allogeneic blood transfusion is responsible for poorer clinical outcomes discussed in the next section.

ALLOGENEIC TRANSFUSION AS AN INDEPENDENT RISK FACTOR FOR POORER CLINICAL OUTCOMES

Over the last two decades experimental and clinical studies have identified blood transfusion as an independent risk factor for morbidity and mortality.[66–69] This has been a surprise to many clinicians, health administrators and patients, as it was assumed that blood transfusion can only be of benefit to the bleeding or anaemic patient. This long-standing belief is now being effectively challenged, and debate has moved significantly from a paradigm with a focus on transfusion to one in which the urgent control of critical bleeding, with the avoidance and/or minimisation of blood transfusion.

TRIM is associated with poorer clinical outcomes in a range of clinical settings; however, it is not possible to categorically conclude causation or that pre-storage leucoreduction will eliminate all risk. Accordingly, a precautionary approach should be adopted that is consistent with PBM guidelines, with the modus operandi being to minimise or avoid allogeneic transfusion.[32,70,71]

CRITICAL BLEEDING AND MASSIVE BLOOD TRANSFUSION

For the purpose of this discussion critical bleeding refers to major haemorrhage that is life threatening and is likely to result in massive transfusion. Major haemorrhage is defined as the loss of one blood volume over 24 hours.[72] There is a reappraisal of clinical practice guidelines for the use of blood components in the bleeding patient. The guidelines no longer focus solely on the management of massive blood transfusion, but also stress the importance of the management of critical bleeding and avoiding getting into the massive transfusion coagulopathy quagmire in which the patient can spiral down into the 'triad of death'–coagulopathy, acidosis and hypothermia.[35] Contemporary management of patients with acute haemorrhage challenges some long-standing dogmas. In most patients permissive hypotension and minimal volume resuscitation are considered preferable to aggressive fluid resuscitation until haemorrhage is controlled; however, the optimal blood pressure level remains unknown. Early control of bleeding by compression, tourniquet, packing or surgical control is paramount.

In previously healthy patients who have suffered an acute blood loss of less than 25% of their blood volume, restoring that volume is more important than replacing oxygen-carrying capacity. Intravenous fluid administration may preclude the necessity for allogeneic transfusion, especially when bleeding can be controlled. Intravenous fluids also allow time for transfusion compatibility testing. In the context of acute bleeding and hypovolaemic shock, the haemoglobin level is not the primary indicator for determining the need for allogeneic red cell transfusion. A normal human may survive a 30% deficit in blood volume without fluid replacement, in contrast to an 80% loss of red cell mass if normovolaemia is maintained. Minimisation of allogeneic blood transfusion is important and haemodilution with tolerance of anaemia is now accepted clinical practice. However, there are limits to haemodilution, and not just from the perspective of oxygen-carrying capacity. Marked reduction in blood viscosity is counterproductive as reactive peripheral vasoconstriction to maintain total peripheral resistance results in reduction in functional capillary density in the microcirculation.

In critical bleeding, specific component blood therapy is often required; while lifesaving in this setting transfusion is increasingly being recognised as a two-edged sword and probably a contributory factor to microcirculatory dysfunction and impaired tissue

cellular metabolism. While the evidence base is limited, it is suggested that institutions develop a massive transfusion procedure to guide the initial response to critical bleeding that includes advice regarding the dose, timing and ratio of blood component therapy.[35] Massive transfusion procedures should also include advice regarding their activation; emphasise the importance of early control of bleeding; and facilitate communication and coordination between clinicians, laboratory staff and transfusion service providers. The issue of the optimal ratio of plasma, platelets, and red cells remains controversial. There appears to be a survival advantage associated with decreasing ratios. Data from battlefield studies generated enthusiasm for a 1:1:1 ratio; however, when tested in a multicentre, randomised trial a ratio of 1:1:1 was not superior to a ratio of 1:1:2.[73] This trial provides the best available evidence for the optimal ratio of blood component therapy in the initial response to severe life-threatening bleeding. Failure of haemostasis is common in critically bleeding patients, and is complex and multifactorial in pathogenesis. The importance of avoiding acidosis and hypothermia cannot be overemphasised as the triad of coagulopathy, acidosis and hypothermia has an extremely poor prognosis. Coagulopathy associated with critical bleeding is also related to other aspects of the pathophysiology of the clinical setting. The assumption that there is a 'generic coagulopathy' vaguely referred to as DIC is incorrect and can result in inappropriate therapeutic decisions. DIC refers to a systemic process leading to a consumptive coagulopathy with diffuse microvascular thrombosis. While it is seen following critical bleeding, other causes of coagulopathy are more common. Resuscitation-associated (dilutional) coagulopathy is related to large-volume intravenous fluid (usually crystalloid) administration during the management of haemorrhagic shock.[74] There is also increasing recognition of acute traumatic coagulopathy[75] (ATC) which is driven by the combination of tissue injury, vascular damage and shock. ATC may occur independently of acidosis, hypothermia or haemodilution. Excessive activation of the protein C system and hypofibrinogenaemia secondary to secondary hyperfibrinolysis appears important in its pathogenesis; however, a detailed discussion of ATC is beyond the scope of this chapter and the reader is referred to recent reviews.[75,76] In all circumstances there is activation or inhibition of some aspect of the haemostatic system, and therapy is better informed if the varied mechanisms are understood.

Except for severe abnormalities, haemostatic laboratory parameters correlate poorly with clinical evidence of haemostatic failure. In the massively transfused patient, thrombocytopenia and impaired platelet function are the most consistent significant haematological abnormalities, the correction of which may be associated with control of microvascular bleeding. Coagulation deficiency from massive blood loss is initially confined to factors V and VIII. Activated partial thromboplastin time (APTT), prothrombin time (PT) and fibrinogen assay should be performed, but the urgency of the situation does not usually allow for other specific factor assays. Fibrinogen, the bulk protein of the haemostatic system and essential for effective fibrin clot formation, is receiving greater attention with wider recommendations for replacement using concentrates or cryoprecipitate. Fibrinogen levels less than 1 g/L have generally been the trigger for replacement, but this is being reassessed, especially in the peripartum setting.[77,78]

Frequently, complex tests are required for definitive diagnosis, but the urgency of the situation cannot always await the results, and therapy may be initiated on clinical evidence with minimal laboratory information. A problem with the standard screening tests of coagulation function is that they do not give information about the actual formation of the haemostatic plug, its size, structure or stability. Point-of-care viscoelastic testing assesses clot formation in fresh or citrated whole blood in real time. It appears well suited to the clinical setting of critical bleeding and its use has been advocated to guide blood component therapy.[79]

In ongoing bleeding with associated microvascular oozing, various approaches may be taken. The use of fresh unrefrigerated whole blood (FUWB) is not routinely recommended. It is an 'emotive' subject and has been advocated in some military settings. The provision of fresh whole blood presents logistical, ethical and safety problems. Unscreened blood carries and increased risk of transfusion-transmitted infections and ABO haemolysis. Its use is best limited to clinical trials and situations of life-threatening bleeding where blood component therapy is unavailable or ineffective. As discussed earlier, the routine use of rFVIIa in patients with critical bleeding is not recommended.[35,80] Specialist haematologist advice should be sought prior to its off-label use.

SPECIFIC HAZARDS OF MASSIVE BLOOD TRANSFUSION

Massive blood transfusion may be defined in several ways:

- replacement of the circulating volume in 24 hours
- >4 units of blood in 1 hour with continuing blood loss
- loss of 50% of circulating blood volume within 3–4 hours.

Any patient receiving massive blood component therapy is likely to be seriously ill and have multiple problems. Many adverse effects must be considered in conjunction with the injuries and multiorgan dysfunction. It is not always possible to define the complications caused or aggravated by massive blood transfusion.

CITRATE TOXICITY

A patient responds to citrate infusion by the removal of citrate and the mobilisation of ionised calcium. Citrate is metabolised by the Krebs cycle in all nucleated cells, especially the liver. A marked elevation in the citrate concentration is seen with transfusion exceeding 500 mL in 5 minutes; the level rapidly falls when the infusion is slowed. Citrate metabolism is impaired by hypotension, hypovolaemia, hypothermia and liver disease. Toxicity may also be potentiated by alkalosis, hyperkalaemia, hypothermia and cardiac disease. The clinical significance of a minor depression of ionised calcium remains ill defined, and it is accepted that a warm, well-perfused adult patient with normal liver function can tolerate a unit of blood each 5 minutes without requiring calcium. The rate of transfusion is more significant than the total volume transfused. Common practice is to administer 10% calcium gluconate 1.0 g intravenously following each five units of blood or fresh frozen plasma. Such a practice remains controversial as there is concern regarding calcium homeostasis and cell function in acutely ill patients.

ACID–BASE AND ELECTROLYTE DISTURBANCES

Acid–base

Stored bank blood contains an appreciable acid load and is often used in a situation of pre-existing or continuing metabolic acidosis. The acidity of stored blood is mainly due to the citric acid of the anticoagulant and the lactic acid generated during storage. Their intermediary metabolites are rapidly metabolised with adequate tissue perfusion, resulting in a metabolic alkalosis. Hence the routine use of sodium bicarbonate is unnecessary and is contraindicated. Alkali further shifts the oxygen dissociation curve to the left, provides a large additional sodium load and depresses the return of ionised calcium to normal following citrate infusion. Acid–base estimations should be performed and corrected in the context of the clinical situation. With continuing hypoperfusion, however, metabolism of citrate and lactate will be depressed. In this situation, intravenous bicarbonate and calcium to correct acidosis and low ionised calcium may be considered.

Serum potassium

It is unlikely that the high potassium levels in stored blood have pathological effects in adults. However, hypokalaemia may be a problem 24 hours after transfusion as the transfused cells correct their electrolyte composition and potassium returns into the cells. Thus, although initial acidosis and hyperkalaemia may be an immediate problem with massive blood transfusion, the net result of successful resuscitation is likely to be delayed hypokalaemia and alkalosis. With CPD (citrate–phosphate–dextrose) blood, the acid load and red cell storage lesion are less. Constant monitoring of the acid–base and electrolyte status is essential in such fluctuating clinical situations.

Serum sodium

The sodium content of whole blood and fresh frozen plasma is higher than the normal blood level due to the sodium citrate. This should be remembered when large volumes of plasma are being infused into patients who have disordered salt and water handling (e.g. in renal, liver or cardiac disease).

HYPOTHERMIA

Blood warmed from 4°C to 37°C requires 1255 kJ (300 kcal) – the equivalent heat produced by 1 hour of muscular work – with an oxygen requirement of 62 L. Hypothermia impairs the metabolism of citrate and lactate, shifts the oxygen dissociation curve to the left, increases intracellular potassium release, impairs red cell deformability, delays drug metabolism, masks clinical signs, increases the incidence of arrhythmias, reduces cardiac output and impairs haemostatic function. Thus a thermostatically controlled blood-warming device should be routinely used when any transfusion episode requires the rapid infusion of more than two units of blood.

HYPERBILIRUBINAEMIA

Jaundice is common following massive blood transfusion as a significant amount of transfused stored blood may not survive, resulting in varying degrees of hyperbilirubinaemia. During hypovolaemia and shock, liver function may be impaired, particularly in the presence of sepsis or MOF. An important rate-limiting step in bilirubin transport is the energy-requiring process of transporting conjugated bilirubin from the hepatocyte to the biliary canaliculus. Thus, although an increased load of bilirubin from destroyed transfused red cells may be conjugated, there may be delayed excretion leading to a conjugated hyperbilirubinaemia. This ‘paradoxical’ conjugated hyperbilirubinaemia may be misinterpreted, leading to unnecessary investigations. The effect of resorbing haematoma and the possibility of an occult haemolytic transfusion reaction should also be considered.

BASIC IMMUNOHAEMATOLOGY

Red cell serology is a highly specialised area of knowledge and it is not possible to expect clinicians to have more than a basic working knowledge essential for patient safety. The following is a summary of core knowledge for the clinician.

SALINE AGGLUTINATION

Safe red cell transfusion has revolved around this traditional serological technique. A saline suspension of red cells is mixed with serum and observed for agglutination. Saline agglutination is used for ABO blood grouping and is one of the techniques for compatibility testing of donor blood.

THE DIRECT AND INDIRECT ANTIGLOBULIN TEST

In red cell serology, the antiglobulin test (Coombs test) is used to detect IgG immunoglobulins or complement components. The direct antiglobulin test (DAT) detects immunoglobulin or complement components present on the surface of the red cells circulating in the patient. The result is positive in autoimmune haemolytic anaemia and haemolytic disease of the newborn and during a haemolytic transfusion reaction. The indirect antiglobulin test (IAT) detects the presence of non-agglutinating antibodies in the patient's plasma, usually the IgG type. Antibody screening for atypical antibodies and pre-transfusion compatibility testing are the main applications of the IAT.

REGULAR AND IRREGULAR (ATYPICAL) ANTIBODIES

The regular alloantibodies (isoagglutinins) of the ABO system are naturally occurring agglutinins present in all ABO types (except AB), depending on the ABO group. Group O people have anti-A and anti-B isoagglutinins; group A have anti-B; and Group B have anti-A. Group A cells are the cause of the most common and most dangerous ABO-incompatible haemolytic reactions. Atypical antibodies are not normally present in the plasma, but may be found in some people as naturally occurring antibodies or as immune antibodies. Immune antibodies result from previous exposure due to blood transfusion or pregnancy. Naturally occurring antibodies more frequently react by saline agglutination and, although they may be stimulated by transfusion, are usually of minimal clinical significance. In contrast, many of the immune atypical antibodies are of major clinical significance and their recognition is the raison d'être for pre-transfusion compatibility testing and antenatal antibody screening. Most of the clinically significant immune atypical antibodies are detected by the IAT.

Blood group antigens vary widely in their frequency and immunogenicity. The D antigen of the Rhesus blood group system is common and highly immunogenic. Thus, when a Rh-negative (i.e. D-negative) patient is exposed to D-positive blood there is a high likelihood of forming an anti-D antibody. It is for this reason that the D antigen is taken into account when providing blood for transfusion, in contrast to the numerous other red cell antigens that are less common or less immunogenic. Beyond the Rh (D), and sometimes the Kell (K) blood group antigens, it is not practical, or necessary, to take notice of other blood group antigens unless an atypical antibody is detected during antibody-screening procedures.

THE ANTIBODY SCREEN

On receipt of a blood sample by the transfusion service, the red cells are ABO and Rh D typed, and the serum is screened for atypical antibodies. This screen consists of testing the patient's serum with group O screening cells. The screening panel consists of red cells obtained usually from two group O donors containing all common red cell antigens occurring with a frequency of greater than approximately 2% in the community. If an atypical antibody is detected on the antibody screen, further serological investigations are carried out to identify the specificity of the antibody. These investigations are time-consuming and when possible should be carried out electively.

THE CROSSMATCH (COMPATIBILITY TEST)

The crossmatch is the final compatibility test between the donor cells and the patient's serum. This test tends to be overemphasised, to the detriment of the antibody screen. With sophisticated knowledge of serology the emphasis in the supply of compatible blood is now concentrated on the steps prior to the final compatibility crossmatch.

THE TYPE AND SCREEN SYSTEM

As pre-compatibility testing has assumed the major role in the selection of blood for transfusion, there has been a rethinking of policies relating to the supply of blood for elective transfusions. Whenever elective surgery is planned for a patient who is likely to require blood transfusion, the transfusion service must receive a clotted blood sample well before the anticipated time of surgery. The pre-compatibility testing should be carried out during the routine working hours when facilities are geared for large workloads and enough staff is available to handle all contingencies.

THE PROVISION OF BLOOD IN EMERGENCIES

When quick clinical and laboratory decisions are made under conditions of stress it is frequently difficult for all involved personnel to appreciate the difficulties of others. The decision to give uncrossmatched, partially crossmatched, or to wait for crossmatched compatible blood is not easy, and certain basic serological considerations may clarify for the clinician some of the problems faced by the serologist. Depending upon the degree of urgency and the extent of previous knowledge about the patient's red cell serology, blood can be provided with varying degrees of safety. However, it should be emphasised that when a patient is exsanguinating and likely to die, the giving of ABO-compatible uncrossmatched blood, especially if the antibody screen is negative, is a safe and appropriate therapy.

UNIVERSAL DONOR GROUP O BLOOD

Group O blood under normal circumstances will be ABO compatible with all recipients. The transfusions

should be given as red cell concentrates screened for high-titre A or B haemolysins and used only in extreme emergencies. If the recipient is of childbearing age, every attempt should be made to give Rh-D-negative blood until the patient's blood group is known.

ABO-GROUP-SPECIFIC BLOOD

Transfusion of blood of the correct ABO type circumvents the isoagglutinin problems alluded to above. Simple as this approach may seem, its safety is dependent on meticulous attention to grouping. Previous blood group information, such as a 'bracelet' group or 'unofficial' group written in the patient's records, may be incorrect and there may be considerable risk if blood is administered on the basis of this information.

SALINE-COMPATIBLE BLOOD

The administration of saline-compatible blood is, for practical purposes, the administration of ABO-group-specific blood.

Colloids and blood products

Andrew Lewington, Luke McMenamin

A colloid fluid contains microscopic particles which may be synthetic (e.g. gelatin or starch) or natural (e.g. albumin) suspended in a crystalloid solution, with isotonic saline being most commonly used. The colloidal particles are sufficiently large such that they are retained within the circulation and therefore exert an oncotic pressure across the capillary membrane. In health, the volume-expanding effect of a colloid is superior to that of a crystalloid. Colloids have therefore been used for fluid resuscitation and the expansion of the intravascular volume to restore haemodynamic stability and organ perfusion. However, in critically ill patients or following major surgery the volume-expanding effect of a colloid is reduced (described below) and there has been much debate with respect to the efficacy of colloid fluids versus crystalloid fluids in intravenous fluid resuscitation in theses settings.

The Starling equation has traditionally been used to explain the movement of fluid between the different body compartments, which is determined by the hydrostatic and osmotic forces exerted across semipermeable membranes. The osmotic pressure generated by a solute is proportional to the number of molecules or ions and independent of molecular size. Colloid osmotic pressure (COP) is that exerted by macromolecules and the ultramicroscopic particles (proteins and colloids).[1,2] It can be measured using a membrane transducer system in which the membrane is freely permeable to small ions and water but largely impermeable to the colloid molecules.[3] The membrane pore size and the molecular size distribution of the colloid being studied will dictate the measured value (Figs 98.1 and 98.2).[2,4] The intact vascular barrier is freely permeable to electrolytes and other small osmolytes (glucose, mannitol), but relatively impermeable to macromolecules (see Fig. 98.2). An iso-oncotic colloid or protein preparation has an oncotic pressure equal to that of the human plasma.

More recent experimental findings have challenged the Starling equation and demonstrated that transvascular fluid exchange in humans is not completely explained by this theory. The discovery of the glycocalyx on the surface of the luminal side of all vascular endothelial cells has helped to further our understanding of transvascular fluid exchange.[3] The glycocalyx consists of membrane-bound proteoglycans and glycosaminoglycans (e.g. heparin sulphate and hyaluronic acid), with negatively charged side chains binding plasma proteins. An intact and functional endothelial surface layer (ESL), including the glycocalyx together with the bound plasma proteins (mainly albumin), constitutes the endothelial barrier whose role it is to retain plasma constituents (Fig. 98.3). With new evidence, it is now accepted that the pressure gradient across the anatomical vessel wall appears to be of less importance than previously thought.

In health, the ESL provides an intact barrier with the intravascular osmotic pressure acting as an important determinant of the overall intravascular volume and therefore adequate cardiac preload. During episodes of critical illness, trauma, sepsis, volume overload and major surgery, the ESL is vulnerable to injury from inflammation and/or ischaemia-reperfusion injury, which damages the glycocalyx and impairs the competence of the vascular barrier. In this setting colloidal fluids will pass through the ESL more easily and distribute throughout the interstitial compartment, resulting in a larger volume of distribution and reduced efficacy. This phenomenon helps to explain the clinical challenge of providing adequate intravenous fluid resuscitation to maintain intravascular volume and cardiac preload during critical illness at a time when the ESL is damaged.

Theoretically, an infusion of colloids should expand the pre-existing blood volume by the volume infused, having a volume effect of 100%.[4,5] However, this is not always the case and the volume effect of a colloid is very much context specific.[6] Human studies have demonstrated that nearly 100% of an infused iso-oncotic preparation of human albumin or hydroxyethyl starch remains within the circulatory compartment to maintain normovolaemia during acute blood loss. Whereas when the same fluid is infused into a normovolaemic patient, the volume effect is reduced to 40%, with the remaining fluid directly shifting towards the interstitial space secondary to a marked alteration of the integrity of the ESL.[7] In this scenario it has been proposed that the release of atrial natriuretic peptide-activating metalloproteases may digest the endothelial glycocalyx. This helps to explain the pathophysiological

ABSTRACT

Colloids contain natural or synthetic particles, which are sufficiently large to be retained within the circulation and when infused into a healthy subject have a volume-expanding effect that is superior to that of a crystalloid. However, a greater understanding of the physiology of the endothelial surface layer and how this is disrupted in critical illness in addition to the publication of several studies demonstrating an increased risk of acute kidney injury associated with synthetic colloids (e.g. hydroxyethyl starches) has seen the pendulum swing in favour of crystalloids as first-line resuscitation fluids. Natural colloids such as human albumin 5% may be used for the treatment of hypovolaemia in a wide variety of clinical conditions, but there is currently no evidence that it offers any advantages over less expensive synthetic colloids or crystalloids. Other blood products or plasma derivatives include fresh frozen plasma (FFP), cryoprecipitate, recombinant factor VII, factor IX and immunoglobulin solutions.

process that underlies the risks associated with the excessive administration of perioperative intravenous fluids during major surgery and the consequences on the ESL.[8]

In comparison to colloids, crystalloids have larger volumes of distribution depending on their composition (Fig. 98.4).[9] With respect to fluid resuscitation, isotonic crystalloids target the whole extracellular compartment, whereas hypotonic crystalloids easily distribute across all body fluid compartments. Colloids or plasma substitutes initially target the intravascular

compartment. The ideal properties of a colloid would include:

- stable with a long shelf life
- pyrogen, antigen and toxin free
- free from risk of disease transmission
- intravascular volume effect lasts for several hours
- metabolism and excretion do not adversely affect the recipient
- no tissue accumulation
- no direct adverse effects (e.g. acute kidney injury [AKI], coagulopathy).

GELATINS

Gelatin was one of the first synthetic colloids used for intravenous fluid resuscitation. It is produced from the hydrolysis of bovine collagen.[10] The more commonly available preparations are succinylated gelatin (Gelofusine) and urea-linked gelatin–polygeline (Haemaccel) which are suspended in balanced solutions, making them more physiological.[1,2] Gelatins are relatively inexpensive and stable, with long shelf lives. The gelatins' plasma-volume-expanding effect lasts only about 90–120 minutes followed by elimination through the kidneys.[5]

Gelatins have frequently been used as volume expanders in critically ill patients in the intensive care unit (ICU). It is important to note that Haemaccel has a significant calcium content which makes it incompatible with citrated blood if infused through a giving set that has been previously used for this product; however, this does not apply to SAGM (saline–adenine–glucose–mannitol) blood. The reported incidence of reactions to gelatins is low (<0.5%) and range from mild skin rash and pyrexia to life-threatening anaphylaxis. The gelatins appear to have the least impact on haemostasis and it is not clear whether they have any impact over and above simple haemodilution of clotting factors. However, safety evidence from large randomised controlled trials is lacking.

HYDROXYETHYL STARCHES

Hydroxyethyl starches (HES) are produced by hydroxyethyl substitution of amylopectin, a D-glucose polymer obtained from potato or waxy maize.[1,2] The pattern of hydroxyethyl substitution on glucose moieties influences the susceptibility to hydrolysis by non-specific amylases in the blood. The different products are commonly described by their weight-averaged molecular weight (MWw: the number of molecules at each weight times the particle weight divided by the total weight of all the molecules) and their degree of substitution,[1-5] distinguishing hetastarches (0.6–0.7), pentastarches (≈0.5) and tetrastarches (≈0.4). Starch preparations are stable at room temperature and have long shelf lives. The duration of intravascular retention is proportional to MW[2,4,11,12] but is greater than 6 hours even for the 130-kDa tetrastarches. The initial volume effect of iso-oncotic HES preparations (6%) when infused to substitute actual intravascular deficits is close to 100%, irrespective of the generation.[11-13] HES products are associated with an acceptable incidence of adverse events including anaphylactoid reactions. Tissue deposition may result in intractable itching if large volumes of HES are infused over several days.[14] HES products can cause a coagulopathy.[15] In particular, factor VIII (FVIII) levels are reduced and platelet function is impaired, causing a von Willebrand-like syndrome. It is likely that in new-generation HES products some of the side effects are attenuated.[16] However, their safety still needs to be proven.[17-23]

Over recent years there has been much debate regarding the safety of HES in volume resuscitation in the ICU.[24] Numerous trials have investigated the role of HES, in particular in the management of sepsis as summarised in Table 98.1. The Efficacy of Volume

AKI, Acute kidney injury; *CON*, control; *HES*, hydroxyethyl starch; *NR*, not reported; *NS*, normal saline; *RCT*, randomised clinical trial; *RRT*, renal replacement therapy.

Substitution and Insulin Therapy in Severe Sepsis (VISEP) trial suggested hyperoncotic preparations of older generations in high dosage should be avoided in haemodynamically stable septic patients due to an increased incidence of AKI.[17] The Scandinavian Starch for Severe Sepsis/Septic Shock (6S) study demonstrated a significantly increased 90-day mortality after HES use, but included 800 septic patients only *after* initial stabilisation.[16] The CHEST study found no difference in mortality and an unaltered renal state (RIFLE) after HES in 7000 ICU patients despite an increase in the use of renal replacement therapy.[17] In 2013 the Cochrane review stated that the use of all HES products increases the risk of AKI and renal replacement therapy in all patient populations and a safe volume of any HES solution has yet to be determined. The report concluded that in most clinical situations it is likely that these risks outweigh any benefits and alternate volume replacement therapies should be used in place of HES products.[18] In the same year the National Institute for Health and Care Excellence (NICE) clinical practice guideline made the recommendation not to use the tetrastarch HES for fluid resuscitation.[19] These recommendations have resulted in the European Health Agency and US Food and Drug Administration restricting the use of HES in patients with critical illness. More clinical studies will be required in the future to address these concerns.

DEXTRANS

Dextrans are polysaccharides biosynthesised commercially from sucrose by the bacterium *Leuconostoc mesenteroides* using the enzyme dextran sucrase.[1,2] This produces a high-molecular-weight dextran that is then cleaved by acid hydrolysis and separated by repeated ethanol fractionation to produce a final product with a relatively narrow MW range. The products are described by their MW – Dextran 40 and Dextran 70 having MWs of 40,000 and 70,000 Da, respectively.

Dextran preparations are stable at room temperature and have long shelf lives. Dextran 70 is used as a plasma substitute for the treatment of hypovolaemia and has an intravascular volume-expanding effect that lasts at least 6 hours. Dextran 40 is used for its effects on microcirculatory flow and blood coagulation in some types of surgery (e.g. vascular, neuro and plastic surgery). The beneficial effects on outcome when Dextran 40 is used as an 'anti-sludging agent' remain controversial. Dextran 40 should not be used as a plasma substitute for the treatment of hypovolaemia as, although it produces an immediate plasma volume expansion as a result of its low MW, it may obstruct kidney tubules and cause AKI.

Dextrans can precipitate true anaphylactic reactions, as antidextran antibodies may be present due to synthesis of dextrans by lactobacilli that occur naturally as gut commensals. Dextran infusion, particularly of the high-molecular-weight products, can also precipitate anaphylactoid reactions. The risk of true anaphylactic reactions can be decreased about 10-fold by pre-treatment with monovalent hapten–dextran. The dextrans are also associated with significant haemostatic derangements which include:

- haemodilution of clotting factors
- reduction in FVIII activity
- increase in plasminogen activation
- increase in fibrinolysis
- reduction in clot strength
- impairment of platelet function.

Red cell aggregation is also reduced with the lower-molecular-weight dextrans. In patients whose haemostatic function is normal prior to infusion, a maximum dose of 1.5 g/kg is often recommended to avoid risk of bleeding complications. The anticoagulant effects of dextrans can be utilised perioperatively

as a prophylaxis against thromboembolism.[1,2] Currently, due to the adverse side-effect profile and the requirement to pretreat with the hapten, dextrans are not commonly used in Europe.

HUMAN ALBUMIN SOLUTION

Naturally occurring human albumin is thought of as an ideal colloid and is commonly the reference solution against which other colloids are judged. Albumin represents the main protein responsible for colloid oncotic pressure and also possesses anti-inflammatory properties by scavenging reactive oxygen species and acts as a buffer for acid-base balance. Human albumin solution is a natural colloid and contains more than 95% albumin with a uniform molecular size (monodispersity), whereas all of the semisynthetic colloids have a distribution of molecular sizes (polydispersity).[2,4] The size–weight relationship is relatively constant, although some colloids can have equivalent MW with different molecular size – succinylated and urea-linked gelatins have almost identical molecular weights but the succinylated product undergoes conformational change due to an increase in negative charge and is physically larger.[4,5]

Human albumin solutions are prepared from human plasma and heat treated to ensure that neither hepatitis nor HIV can be transmitted. It has a relatively short (~1 year) shelf life at room temperature, but a 5-year shelf life at 2°C–8°C. Human albumin 5% (the 4% version is a cost-free by-product of the production of packed red cells, exclusively used in Australia) is used for the treatment of hypovolaemia in a wide variety of clinical conditions. Concentrated salt-poor 20% human albumin is used for the treatment of hypoalbuminaemia in the presence of salt and water overload (e.g. liver failure with ascites). Albumin has putative advantages that include limiting free radical-mediated damage but the importance of a normal serum albumin level remains uncertain.[25-27]

Human-derived colloid has a number of disadvantages. It is an expensive product and concerns have been raised about transmission of infectious agents – such as new-variant Creutzfeldt–Jakob disease (nvCJD) associated with bovine spongiform encephalopathy (BSE) – that are not removed by currently available techniques. Concerns have also been raised by the conclusions of a highly controversial meta-analysis suggesting that the use of human albumin solution may be associated with increased mortality in the critically ill.[27-29] These conclusions were probably unjustified for most collectives except for traumatic brain injury,[30] but there is currently no evidence that the use of human albumin has any advantages over less expensive semisynthetic alternatives[30,31] or indeed crystalloids. However, the latter still applies to all colloids.[30,33,34] The volume effect of 5% human albumin is approximately 90% when used to maintain blood volume during acute blood loss.[32]

FRESH FROZEN PLASMA

Fresh frozen plasma (FFP) contains normal plasma levels of all the clotting factors, albumin and immunoglobulin. A unit is typically 200–250 mL and has a FVIII level of at least 0.7 IU/mL (i.e. 70% of normal levels) and about 0.5 g of fibrinogen. It is kept at a temperature of –18°C or less in order to preserve coagulant levels. FFP is used for the replacement of multiple clotting factor deficiencies (e.g. liver disease, coumarin anticoagulant overdose and coagulopathy associated with massive blood transfusion).[24,35,36] An initial dose of at least 15 mL/kg (four packs for a 70-kg adult) is considered to be appropriate. Physiologically, in a normovolaemic patient, it might be better to correct any clotting factor deficit using a concentrate and then maintain the appropriate level using FFP instead of colloids in the face of ongoing bleeding or other volume deficit. This might decrease the risk of intravascular hypervolaemia, but currently there are no data to support using FFP in this way. FFP should not be used as a plasma volume expander, solely for the treatment of hypovolaemia.

CRYOPRECIPITATE

Cryoprecipitate is prepared by freeze-thaw of FFP, collection of the precipitate and then its resuspension in human plasma. It is a concentrate of FVIII, von Willebrand factor and fibrinogen and contains about 50% of the coagulant factor activity of the original unit (e.g. fibrinogen 250 mg, FVIII 100 IU). Cryoprecipitate is stored at –18°C and remains stable for up to a year.[35] It is indicated in the treatment of coagulation defects, including massive haemorrhage and disseminated intravascular dissemination (DIC), if there is microvascular bleeding associated with a fibrinogen level less than 0.5 g/L. Also, it is, in principle, an alternative to the preferable FVIII or von Willebrand factor concentrates in the treatment of inherited deficiencies of those proteins.[24,36]

FACTOR VIII

Recombinant FVIII is available but concentrates are also still prepared from pools of donor plasma and heat or chemically treated to inactivate HIV-1. It has a shelf life of 2–3 years. Chromatographic concentration results in high-purity FVIII, and the relative merits of high- and intermediate-purity products are being investigated.

Indications are the treatment of haemophilia A.[37] The dosage should carefully follow the recommendations of the respective manufacturers, targeting at plasma activities between 30% and 100%, depending

on the clinical situation. Preferably, the strategy should be planned together with a specialist and will usually lead to a bolus of 25–50 U/kg, which can be repeated, for example, 12-hourly.

FACTOR IX COMPLEX

Factor IX complex (prothrombin complex concentrate, also called 'PPSB') contains the vitamin-K-dependent factors II, VII, IX and X in varying amounts, and is prepared from pools of plasma.[35] It is a freeze-dried preparation reconstituted with water immediately before use. Factor IX complex is mainly used to correct bleeding disorders due to an overdose of the vitamin K antagonistic coumarin anticoagulants in patients who cannot tolerate large volumes of FFP.[35] Purified factor IX concentrates are now available and appear preferable in haemophilia B.

IMMUNOGLOBULINS (GAMMA GLOBULINS)

Human immunoglobulin preparations are pooled from plasma from normal blood donors. It contains antibodies to hepatitis A, measles, mumps, varicella, polio and prevalent bacteria, reflecting the plasma of the donors.[35] Immunoglobulins are indicated in the prevention or treatment of patients with hypogammaglobulinaemia, and may have a role in the treatment of autoimmune diseases, such as thrombocytopenic purpura and myasthenia gravis. Specific immunoglobulins are available for a range of infectious agents including tetanus, hepatitis B, rubella, measles, rabies and varicella zoster. They are made from donor plasma known to contain high levels of the specific IgG antibodies and are used for prophylaxis and treatment in patients who have not been actively immunised. Rhesus-D immunoglobulin is prepared from plasma containing high levels of anti Rh-D antibodies and it prevents sensitisation of Rh-negative mothers to Rh-D positive cells that may enter their circulation. The principal use of Rh-D immunoglobulin is in the prevention of haemolytic disease of the newborn.[38]

Plasmapheresis, therapeutic plasma exchange and intravenous immunoglobulin therapy

Ian Kerridge, David Collins

Blood-letting to remove 'evil humours' has been practiced for over 2000 years. However, although the restoration of 'balance' and the removal of 'noxious' agents from the blood remains the rationale for apheresis, contemporary practice is now based upon an extensive scientific understanding of the pathophysiology of the diseases treated by plasmapheresis and plasma exchange.[1] Exchange transfusions revolutionised the management of haemolytic disease in the newborn, and paved the way for therapeutic plasmapheresis and plasma exchange – the removal of plasma, with replacement by albumin–electrolyte solutions or fresh frozen plasma (FFP). Initially used in the management of hyperviscosity associated with malignant paraproteinaemia, it is now also used in the treatment of more than 100 autoimmune disorders. It is, however, expensive, is not without risk, and its use in many diseases remains a matter of ongoing debate.

Intravenous immunoglobulin (IVIG) – once used purely as replacement therapy for patients with primary humoral immune deficiency – has also become increasingly used as an immunomodulatory agent. Its relevance in this chapter is that it is now being used in many disorders in which plasma exchange is effective, but the convenience and safety of IVIG therapy is preferred as an alternative. The underlying principles in managing autoimmune diseases with IVIG are similar to those of therapeutic plasmapheresis and plasma exchange. The immunomodulatory mechanism of action of IVIG remains controversial and it is likely, as with plasma exchange, that there is more than one mechanism in play. Therapeutic efficacy of IVIG has been established in controlled trials for a range of diseases including idiopathic thrombocytopenic purpura, Kawasaki disease, Guillain–Barré syndrome (GBS), dermatomyositis and others. There is compelling evidence that IVIG can modulate immune reactions of T cells, B cells and macrophages, thus interfering with antibody production and degradation, but also modulating the complement cascade and cytokine networks.

RATIONALE FOR PLASMA EXCHANGE

Theoretically, plasma exchange should be effective to treat any disorder in which there is a pathogenic circulating factor responsible for disease. However, it is increasingly clear that this premise is too simplistic as many other mechanisms contribute to its beneficial effects (Box 99.1). Plasma exchange brings about numerous alterations in the plasma's *milieu interieur* – which may be clinically beneficial or detrimental.

PATHOPHYSIOLOGY OF AUTOIMMUNE DISEASE

Autoimmune disease originates from the breakdown of immunoregulation (i.e. immune tolerance), allowing the immune system to become autoaggressive. Autoimmune diseases with underlying humoral mechanisms result from either a circulating autoantibody against a self-antigen (alone or in combination with an environmental antigen), or circulating immune complexes (which may be deposited in the microcirculation of various organs, resulting in end-organ damage). Cellular and tissue damage are affected by the autoantibody or immune complexes activating the cellular and humoral components of the inflammatory response. The circulating proteolytic systems involved include the complement, coagulation, fibrinolytic and kinin systems. On the cellular side, neutrophils and macrophages are involved, with eosinophils and basophils also playing a part.

Therapy in acute and chronic autoimmune disease aims to minimise irreparable end-organ damage and support patients during the acute illness. This therapy may include:

- non-specific therapy to suppress the effector mechanisms (e.g. corticosteroids, antiplatelet therapy, non-steroidal anti-inflammatory drugs, anticoagulation and depletion of humoral effector mechanisms by plasma exchange or defibrination)

ABSTRACT

Plasmapheresis and therapeutic plasma exchange (TPE) provide effective treatment for over 100 diseases, including those resulting from immunoproliferation with aberrant antibody production, autoimmune disease, immune complex disease and other immune disorders and for the treatment of disease resulting from poisoning, accumulation of toxins or depletion of coagulation factors. Intravenous immunoglobulin (IVIG) – once used purely as replacement therapy for patients with humoral immune deficiency – has also become increasingly used as an immunomodulatory agent. An understanding of the rationale for plasmapheresis, TPE and IVIG, the indications for their use and the adverse consequences that may arise is essential for those working in high acuity care and for those responsible for the care of patients with immune disease.

KEYWORDS

Plasmapheresis
plasma exchange
intravenous immunoglobulin (IVIG)
immune complex disease
autoimmunity

- therapy to reduce the circulating levels of a humoral factor, which is achieved with plasma exchange or an immunoabsorption technique
- specific or broad-spectrum immunosuppressive agents to suppress or block the immune response (e.g. corticosteroids, cytotoxic agents, anti-lymphocyte globulin, high-dose intravenous gamma-globulin therapy)
- therapy directed at altering reticuloendothelial function, which may then have effects on autoantibody and immune complex clearance, or clearance of circulating damaged cells
- IVIG immunomodulatory therapy.

Box 99.1 Rationale for plasma exchange

Removal of circulating toxic factor antibodies
- Monoclonal antibodies
- Autoantibodies
- Alloantibodies

Immune complexes
Chemical drugs
Depletion of mediators of inflammation
Replacement of deficient plasma factor(s)
Potentiation of drug action
Enhanced reticuloendothelial function
Altered immunoregulation
Potentiating effect of plasma exchange on other modes of therapy (e.g. glucocorticoids)

As most disorders are multifactorial, it is unlikely that a single form of therapy will be successful, so a multipronged approach to therapy needs to be based upon analysis of the underlying pathophysiology. The stage of the disease is also important (Fig. 99.1). Clearly, plasma exchange will have a different response when autoantibody production is rising rapidly, compared with a stage when autoantibody has ceased production. Also, immunoregulation is a complex process and therapies may interfere at different points in the immune mechanisms.

In some circumstances, specific and directed therapy may attack the most relevant link in the pathophysiological chain, but overall multiple approaches to

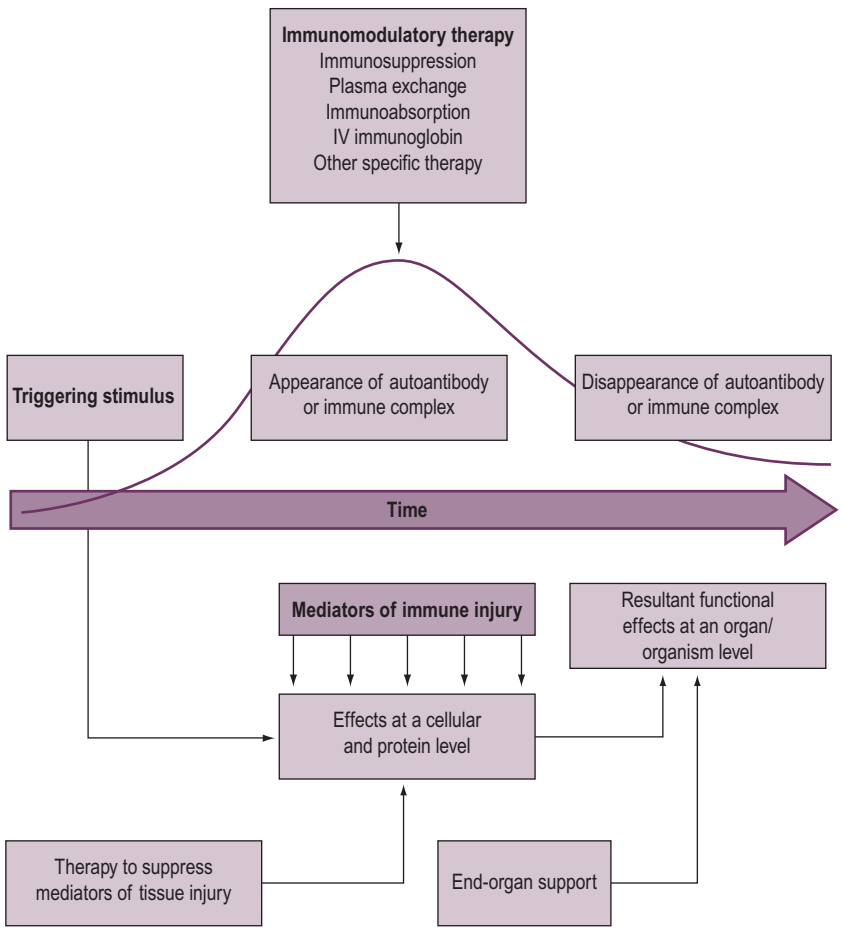

Figure 99.1 The therapy of 'one-hit' autoimmune disease. *IV*, Intravenous.

therapy may be required. In general, plasma exchange is a temporising procedure and concomitant immunosuppressive therapy is required to maintain control. Plasma exchange should generally be regarded as a first step in immunomodulatory therapy, and be restricted to acute or fulminant situations in which autoantibodies or immune complexes are responsible for life-threatening or end-organ-damaging complications. If the humoral factor is only transient ('a one antigen hit' disorder), then no follow-up immunosuppression is required (e.g. acute post-infectious polyneuritis). Increasingly, monoclonal antibody therapy with rituximab (an anti-CD20 antibody) is finding a role in the longer-term management of autoimmune diseases.[2,3]

The recognition of the immunomodulatory effects of IVIG has resulted in an exponential increase in its use in immune and inflammatory disorders – with availability being one of the main drivers of the supply of human-derived plasma products. Indeed, in most of the immune and inflammatory disorders in which plasma exchange has been used, IVIG has been used – often with equal efficacy.[4]

TECHNICAL CONSIDERATIONS

Therapeutic plasmapheresis and plasma exchange are based upon the principle of separation – which can be done by filtration, centrifugation or a combination of both, depending on the equipment available. There are a number of apheresis machines on the market. Filtration plasma exchange is found on a number of dialysis machines and uses a semipermeable membrane with small holes or pores up to 0.2 μm in diameter; this is approximately 30 times the diameter of the pores found in conventional high-flux haemofilter membranes.[5] Blood is pumped into this chamber and the plasma passes through the membrane; this membrane will allow the passage of substances up to 3×10^6 Da, separating substances, such as immunoglobulins, immune complexes and complement factors, from the cellular part of the blood.[5] The plasma is then diverted to a waste bag and the remaining cellular product mixed with replacement fluid and returned to the patient.

Apheresis machines using centrifugation use continuous or intermittent blood flow. The continuous flow machines pump blood through a band centrifuge; applied G-force separates out the blood according to its molecular weight, and the particular product (in this case the plasma) is removed and pumped to the waste bag, with the remaining cellular material being mixed with the replacement fluid and returned to the patient.[6] Intermittent centrifugation uses a Latham bowl, which fills with blood, is centrifuged; the plasma is separated to a waste bag and the cellular products returned to the patient with replacement fluid. This procedure can be carried out through one vein; however, it is a longer procedure than the continuous-flow machines.[6]

The extracorporeal blood is anywhere between 150 mL and 250 mL depending on the machine being used. There is cooling in the extracorporeal circuit, and the replacement fluids will be cool so consideration should be given to maintain body temperature, with a blood warmer and warming blankets.[7]

Good venous access is required for an efficient procedure. Stopping and starting of the machine due to inadequate flow exposes the patient to larger doses of anticoagulant. Peripheral access can be achieved using 18 g or 16 g cannula; however, many patients' veins cannot cope with multiple punctures when a high number of procedures are required, and therefore consideration should be given to a central venous access device (CVAD). There are a number of CVADs available on the market, ranging from semipermanent to the more permanent. A Vas-Cath can be inserted either into the jugular or femoral veins but will have a limited lifespan dependent on the chosen vein, whereas a perma-cath or apheresis Hickman, which are tunnelled after insertion via a central neck vein, will have a longer life and a lower infection risk.

Depending on the reason for plasma exchange, a risk assessment of which access to use should be undertaken to ascertain a suitable device for the patient and the length of treatment. It may, as in the case of thrombotic thrombocytopenic purpura (TTP), be better to start off with peripheral veins for the first couple of treatments until the platelets rise and a more permanent line can be inserted safely and without the use of transfused platelets.[8]

To ensure that the extracorporeal circuit does not clot during plasmapheresis anticoagulation is required. Most apheresis machines use regional anticoagulation, with citrate added as blood enters the apheresis circuit. Pooled plasma also contains citrate so, if used, the amount of citrate returned to the patient is further increased. It should be noted, however, that citrate toxicity can also occur when albumin is used, as this is a calcium-free and calcium avid-binding solution.[7] Although citrate is plasma-bound and relatively short-acting, there will still be some returned to the patient where it is metabolised. Patients with abnormal liver functions will take longer to metabolise the citrate and therefore have an increased risk of citrate toxicity. Citrate toxicity produces hypocalcaemia with symptoms including oral or extremity paraesthesia, light-headedness, tetany, nausea, vomiting and cardiac arrhythmias.[9] The drop in calcium levels occurs within the first 15 minutes of the procedure,[7] therefore attention should be paid to the patient's serum calcium and, if required, supplementation commenced prior to the start of the procedure. Calcium gluconate 10% at a dose of 2 mL per 250 mL of replacement fluid has been recommended; this can be added to the albumin or run as a concurrent infusion.[10,11] Other electrolytes can also become depleted, and should therefore be monitored and replaced as required.[7] Magnesium also binds to

citrate and there can be up to a 60% fall in the blood levels of patients; however, concurrent supplementation is not recommended as routine.[7]

As plasma exchange requires the removal of plasma, this necessitates the use of replacement fluid – which can be 'fresh' plasma (FFP), plasma fractions, albumin, crystalloid or some combination of these. The choice of replacement fluid is made on the basis of the underlying pathology. In TTP, for example, the absence or inhibition of an enzyme, ADAMTS-13 protease and the resultant accumulation of ultra-large von-Willebrand factor leads to the formation of microthrombi and causes the clinical features of the disease, so the replacement fluid should contain ADAMTS-13 enzyme and functional VWF. In contrast, in hyperviscosity states, replacement with colloid alone will be more beneficial.

Occasionally the apheresis circuit is secondary to heart bypass, extracorporeal membrane oxygenation (ECMO) or renal dialysis. The literature is limited but it has been reported as safe.[7] For ECMO and heart bypass, the apheresis practitioner must work closely with the medical staff and perfusionist to ensure the patient's safety. At times the procedure can be managed by undertaking a tandem procedure. This is where an additional device is fitted to the return line of the primary circuit. This line has two ports placed approximately 12 cm apart and allows for the apheresis draw and return lines to be connected. Blood is drawn into the apheresis circuit, processed, plasma drawn off and replacement added. The whole blood is then returned to the patient. The beauty of this procedure is that the ECMO or dialysis needs only to be stopped for the brief time it takes to connect or disconnect the apheresis machine. Consideration is given to the management of the patient's blood pressure and fluid status during the procedure, and these should be corrected as dictated by the patient's condition. Therefore, it is essential that there is good communication between all members of the team and an assessment of the patient's ability to cope with two extracorporeal circuits is made.[12] The majority of apheresis machines will have the capacity to undertake a blood prime of the equipment this will help support the patient's blood volume. Depending on the anticoagulant being used for the primary circuit, the amount of anticoagulant in the apheresis circuit can be reduced. The patient should receive appropriate electrolyte replacement.[13]

INDICATIONS (Box 99.2)

Plasma exchange is most beneficial for immunoproliferative and autoimmune diseases. In some conditions with unclear pathophysiology, the beneficial effects of plasma exchange may be due to infusion of a deficient component in the replacement plasma, rather than removal of a circulating factor.

Box 99.2 Acute diseases in which plasma exchange may be beneficial*

Immunoproliferative diseases with monoclonal immunoglobulins
Hyperviscosity syndrome
Cryoglobulinaemia
Renal failure in multiple myeloma
Autoimmune diseases due to autoantibodies or immune complexes
Goodpasture syndrome
Myasthenia gravis
Guillain–Barré syndrome
Chronic inflammatory demyelinating polyneuropathy (CIDP)
Stiff-man syndrome
Systemic lupus erythematosus
Fulminant antiphospholipid syndrome
Thrombotic thrombocytopenic purpura
Haemolytic uraemic syndrome (HUS)
Rapidly progressive glomerulonephritis
Coagulation inhibitors
Autoimmune haemolytic anaemia
Pemphigus
Paraneoplastic syndromes
Conditions in which replacement of plasma may be beneficial +/– removal of toxins
Disseminated intravascular coagulation
Multiorgan dysfunction syndrome
Overwhelming sepsis syndromes (e.g. meningococcaemia)
Conditions in which the mechanisms are unknown
Reye syndrome
Removal of protein-bound or large-molecular-weight toxins
Paraquat poisoning
Envenomation

*This is an incomplete list and includes only disorders that are relatively common or in which plasma exchange has a definitive role to play.

The American Society for Apheresis (ASFA) has published comprehensive 'Guidelines on the Use of Therapeutic Apheresis in Clinical Practice: Evidence-based approach from the Apheresis Applications Committee of the American Society for Apheresis'.[14] The ASFA guidelines describe four categories of disorder on the basis of a review of the available literature on the efficacy of therapeutic plasma exchange (TPE). These are as follows:

- *Category I*: 'Disorder for which apheresis is accepted as first-line therapy, either as a standalone treatment or in conjunction with other modes of treatment'.
- *Category II*: 'Disorders for which apheresis is accepted as second-line therapy, either as a standalone treatment or in conjunction with other modes of treatment'.
- *Category III*: 'Optimum role of apheresis therapy is not established. Decision-making should be individualised'.

- *Category IV*: 'Disorders in which published evidence demonstrates or suggests apheresis to be ineffective or harmful. Internal Review Board approval is desirable if apheresis treatment is undertaken in these circumstances'.

Category I disorders include: myasthenia gravis, GBS, Goodpasture syndrome (anti-glomerular basement membrane [GBM] antibody disease), cryoglobulinaemia, chronic inflammatory demyelinating polyradiculoneuropathy (CIDP), sickle cell disease (acute stroke) and Wegener's granulomatosis.

Category II disorders include: multiple sclerosis, neuromyelitis optica, acute disseminated encephalomyelitis, ABO-incompatible solid organ transplantation and catastrophic antiphospholipid syndrome (CAPS).

Category III disorders include: aplastic anaemia, autoimmune haemolytic anaemia, paraneoplastic neurological syndromes, erythrocytosis, acute liver failure, immune complex rapidly progressive glomerulonephritis (RPGN) and sepsis, and multiorgan failure.

Category IV disorders include: dermatomyositis or polymyositis, idiopathic (autoimmune) thrombocytopenia purpura (ITP), rheumatoid arthritis, chronic progressive multiple sclerosis, scleroderma, amyloidosis and inflammatory bowel disease.

MONOCLONAL ANTIBODIES ASSOCIATED WITH IMMUNOPROLIFERATIVE DISEASES

Monoclonal immunoglobulins are a classical feature of multiple myeloma and Waldenström's macroglobulinaemia, but may also be associated with other lymphoproliferative disorders. These monoclonal proteins may be associated with numerous clinical effects, many of which may be reversed by plasma exchange:

- *Hyperviscosity syndrome:* characteristic clinical features of hyperviscosity in association with monoclonal proteins include visual disturbance, neurological dysfunction and hypervolaemia. All are rapidly relieved by plasma exchange.[15]
- *Haemostatic disturbances:* monoclonal proteins may impair haemostasis by adversely affecting platelet function or by inhibitory effects on coagulation factors. Plasma exchange is usually effective in controlling haemorrhage and may be helpful in preparing patients for surgery.
- *Renal failure:* the development of renal failure in the course of multiple myeloma is generally regarded as a sign of poor prognosis. The renal failure is often multifactorial in origin, but some of these factors may be reversible by plasma exchange. Patients presenting acutely with hyperviscosity, dehydration and hypercalcaemia may show recovery of renal function following adequate hydration, alkaline diuresis and plasma exchange.

IMMUNOLOGICAL DISEASES

DISEASES MEDIATED BY SPECIFIC AUTOANTIBODIES

Goodpasture syndrome

In Goodpasture syndrome circulating anti-GBM antibodies can often be demonstrated. The disease classically has a fulminant presentation with rapidly progressive renal failure and life-threatening pulmonary haemorrhage. Early diagnosis and intensive plasma exchange may be necessary to preserve renal function and control pulmonary haemorrhage. Patients who are already in anuric renal failure rarely show improvement in renal function.[16]

Myasthenia gravis

Removal of the acetylcholine receptor autoantibody is often associated with clinical improvement, but the beneficial effects of plasma exchange are usually transient, so the procedure should be used in conjunction with other forms of therapy (see Chapter 58). The major role of plasma exchange is in myasthenic crisis in patients whose condition is resistant to other forms of therapy, and prior to surgery. Therapy can be monitored by acetylcholine receptor autoantibody assays and respiratory function tests. During the procedure patients may transiently deteriorate, owing to a combination of the physical exertion and removal of medication from the circulation. Adequate ventilatory support should be available. IVIG may also be used in myasthenia gravis.[17–19]

Stiff-man syndrome

Stiff-man syndrome is a rare neurological disorder characterised by involuntary axial and proximal limb rigidity and continuous motor unit activity on electromyography. Autoantibodies to glutamic acid decarboxylase are usually demonstrable and plasma exchange is often successful in those in whom autoantibody can be demonstrated, but if negative they are less likely to respond.[20,21]

Autoimmune haematological disorders

Haemostatic failure due to autoantibodies directed against coagulation factors may present a major management problem. Antibodies directed against factor VIII are the commonest, occurring spontaneously or in association with replacement therapy in haemophiliacs. First-line therapy in patients with coagulation factor inhibitors usually requires activated factor VII therapy with recombinant VIIa or appropriate prothrombin concentrates, but plasmapheresis may also be useful in patients who are refractory to first-line therapy or as an adjunct to first-line therapy.[22]

Plasmapheresis may also provide an important part of treatment for patients with CAPS. Although the exact mechanism(s) by which plasmapheresis may assist in the management of CAPS is unknown, including

removal of antiphospholipid antibodies, complement, tumour necrosis factor and cytokines, and restoration of normal levels of antithrombin, protein C and protein S, when used in combination with anticoagulants and steroids it appears to provide the highest likelihood of resolution of thromboses and survival.

IMMUNE COMPLEX DISEASE

Rapidly progressive glomerulonephritis

Immune-complex-induced RPGN may occur by itself or be associated with several systemic disorders (e.g. systemic lupus erythematosus [SLE], polyarteritis nodosa, IgA nephropathy, post-streptococcal infection and Wegener's granulomatosis).[23–25] Plasma exchange may result in improvement in renal function even in patients who present with anuria. The decomplementing and defibrinating effects of plasma exchange may be partly responsible for clinical improvement. The therapeutic role of plasma exchange in RPGN is difficult to assess, but most experienced physicians feel that the procedure leads to a more rapid and complete recovery of renal function in fulminant, rapidly deteriorating cases. However, the ultimate prognosis of the disease depends on adequate immunosuppression to inhibit immune complex formation, or spontaneous disappearance of the inciting antigen.

Systemic lupus erythematosus

In acute life-threatening or organ-damaging relapses of SLE, plasma exchange should be considered if there is rapid deterioration in renal function, cerebritis or acute fulminant lupus pneumonitis.[26]

Cryoglobulinaemia

The various forms of cryoglobulinaemia may be associated with vasculitis or hyperviscosity. If there is an acute fulminant presentation with cutaneous vasculitis, renal failure, and neurological impairment then plasma exchange should be considered an urgent definitive form of therapy.

OTHER IMMUNE-MEDIATED DISEASES

Renal transplant rejection

Humoral mechanisms appear to play a part in hyperacute renal allograft rejection. Plasma exchange +/− IVIG may be useful in tiding patients over episodes of acute graft rejection. However, results of clinical trials have been conflicting.[27,28] General opinion is that plasma exchange helps in a limited number of patients who cannot be currently pre-selected by any clinical or laboratory criteria.

Thrombotic microangiopathies (see also Chapter 100)

The thrombotic microangiopathies describe a number of syndromes characterised by endothelial damage to capillaries and arterioles, leading to disseminated microvascular thrombosis, thrombocytopenia and (often) haemolytic anaemia. They include TTP, haemolytic uraemic syndrome (HUS), atypical HUS, disseminated intravascular coagulation (DIC), CAPS and paediatric thrombocytopenia-associated multiorgan failure (TAMOF).

Thrombotic thrombocytopenic purpura

TTP is a potentially fulminant and life-threatening disorder characterised by platelet microthrombi in small vessels, resulting in microangiopathy. TTP has been linked to a severe deficiency in ADAMTS13 with metalloprotease activity with its target cleavage sequence in vWF. The deficiency of ADAMTS13 may be due either to the presence of an IgG autoantibody inhibitor to this vWF-reducing metalloproteinase or to inherited mutations in ADAMTS13. The clinical syndrome of TTP is manifest by the pentad of thrombocytopenia, microangiopathic haemolytic anaemia, fever, renal dysfunction and neurological abnormalities. Abdominal symptoms, hepatic dysfunction and pulmonary abnormalities may also occur.

TTP used to be a fatal disease in 90% of patients, but dramatic improvement in its outcome has occurred over the past two decades. Plasma exchange has become the cornerstone of the treatment with cryoprecipitate-poor plasma (depleted in vWF).[29,30] It is now possible to achieve remissions in the majority of patients and cures are now common, although unfortunately relapse may occur. The clinical course at relapse is usually milder than the disease at presentation and less-aggressive therapy may be needed.

Haemolytic uraemic syndrome

This syndrome has many similarities to TTP, but in contrast to cerebral TTP, renal involvement is the hallmark of microangiopathy and thrombocytopenia.[31] HUS is commonly categorised into 'typical' and 'atypical' HUS.

Typical HUS, the majority of cases, is commonly associated with infection and diarrhoea (see Chapter 100). Less often, HUS may present insidiously and the cause, which may include chemotherapy, radiotherapy or other medications, may be unclear. TPE is generally not recommended for typical HUS associated with infection – which is often self-limiting and has a mortality of less than 5%. Although it is often tried in adult patients with HUS and in patients with typical HUS of more indeterminate cause – the results are often disappointing.

Atypical HUS is thought to result from genetic mutations in the complement pathway or from acquired autoantibodies against factor H, which result in uncontrolled activation of the alternative complement pathway and direct injury to the microvasculature. In contrast to typical HUS, plasma exchange may be beneficial in patients with atypical HUS, although the optimal therapy for atypical-HUS is now thought

to be eculizumab – a monoclonal antibody that binds with high-affinity to C5 and blocks terminal complement C5a and C5b-9 activity.

Because it is often difficult to distinguish atypical HUS from typical HUS and HUS from TTP, particularly in the acute setting, plasma exchange is often initiated until the results of genetic studies and biomarkers can assist in clarifying the diagnosis.

Inflammatory demyelinating neuropathies and Guillain–Barré syndrome

This acute self-limiting disease in which an acute demyelinating neuropathy occurs (usually following a viral infection) commonly results in admission to the intensive care unit (see Chapter 58). The demyelination is due to post-infectious autoimmunity, with both the cellular and the humoral arms of the immune system attacking myelin. There is now wide experience in the use of plasma exchange and IVIG therapy in GBS, with controlled trials substantiating its benefits of shortening of the illness, and complications. Therapy should be instituted early.[19,32] As GBS also responds to high-dose IVIG, there is debate as to which should be the first line of therapy; as the therapies have comparable efficacy and safety, decisions are usually made on the basis of local logistics and economics.[33] In some cases the onset of recovery after therapy may be delayed, probably due to time for remyelination to occur. Some patients show rapid improvement after plasma exchange, suggesting the presence of neuronal blocking factors. CIDP neuropathy is related to GBS, and plasma exchange and/or IVIG have important roles in treatment, in many cases requiring long-term therapy.

COMPLICATIONS

Plasma exchange is a relatively safe procedure, with a case fatality rate of 3–5 per 10,000 procedures – mainly as a consequence of cardiac arrest, cardiac failure and transfusion-associated acute lung injury (TRALI). Minor complications due to fluid shifts, electrolyte abnormalities and exposure to blood products are common, and for these reasons close supervision by experienced physicians and apheresis operators with a sound understanding of the haemodynamic, biochemical, haematological and immunological effects of plasma exchange is of paramount importance.[34,35]

Assessment prior to commencing the procedure should include vascular access, haemodynamic stability, transfusion history, relevant co-morbidities and concomitant medications.

Potential complications of plasma exchange include: fluid imbalance, reactions to replacement fluids, vasovagal reactions, pyrogenic reactions, hypothermia, embolism (air or microaggregates), hypocalcaemia, anaemia, thrombocytopenia, haemostatic disturbances, hepatitis, hypogammaglobulinaemia and altered pharmacokinetics of drugs.

Plasma exchange can be used for the removal of some drugs in overdose; therefore it will also remove drugs that are being given for therapeutic reasons. Drugs that are likely to be removed are those with a low volume of distribution or high protein binding.[36,37] Consideration should be paid to the timing of drug administration and commencement of the plasma exchange. Other considerations should be the duration of the procedure, the number of procedures and the timing of them, as well as the total volume of plasma removed. Where the level of a particular drug can be measured, this may be required more often to ensure the maintenance of therapeutic levels.

Where patients are receiving continuous infusions affecting sedation or blood pressure, continuous monitoring must occur, and if there are any increases in dose during the apheresis procedure attention should be paid at the end of the procedure to ensure the patient does not receive an excessive dose. The use of the pharmacist in planning apheresis and medication should be considered.[38] If there is any concern that a drug may be removed during the procedure then it should be withheld until completion, or the effects monitored during the procedure and additional doses given as required.[39] Where possible, angiotensin-converting enzyme (ACE) inhibitors and angiotensin receptor blockers should be stopped 24 hours prior to plasma exchange.[40] This is because these drugs will decrease the patient's ability to activate bradykinin, which, in turn, can lead to flushing, hypotension and respiratory distress.[37]

CIRCULATORY EFFECTS

Any extracorporeal procedure is likely to lead to problems of circulatory instability. Intravascular volume changes, vasovagal reactions, medications and infusion fluids may alone, or in combination, be responsible for circulatory problems. Often the patient will be able to compensate, but if there are pre-existing issues (e.g. altered blood volume, vascular disease or renal failure) then close monitoring is essential. A strict fluid and electrolyte balance should be kept at all times, both during the plasma exchange and as a daily tally.

PLASMA ONCOTIC PRESSURE

Most patients compensate for minor fluctuations in colloid osmotic pressure (COP). Patients who have oedema or local factors predisposing to interstitial fluid accumulation (e.g. raised intracranial pressure, interstitial pulmonary oedema, deep venous thrombosis, and renal impairment) need close attention.

INFECTION

Many patients who are undergoing plasma exchange are already immunosuppressed, either due to their disease or secondary to drug therapy. In patients

requiring recurrent and frequent plasma exchange, attempts should be made to maintain serum immunoglobulin levels. When FFP is not used as replacement fluid, the bacteriocidal and opsonic activities of blood are probably impaired, and it is probably advantageous to infuse at least two units of FFP at the conclusion of the procedure. At the completion of a course of plasma exchange, consideration may need to be given to a dose of intravenous gammaglobulin.

HAEMOSTASIS

Plasma exchange, particularly where albumin is used as the replacement fluid, causes perturbations in the haemostatic system, which may result in either bleeding or thrombosis. The significance of these alterations will depend largely on the volume and frequency of exchange, pre-existing defects in the system, anticoagulation, other risk factors for thrombosis, replacement fluids and invasive procedures.[34]

THE PREGNANT PATIENT

The use of plasma exchange in pregnant patients has been described as safe by many sources. However, there are several considerations to take into account. First is the patient's blood volume, which will increase by 50% from the second trimester; therefore this must be recalculated, and 50% added as the patient's pregnancy progresses, thereby increasing the exchange volume. The patient's position during the procedure needs to be left lateral decubitus, which will move the gravid uterus to take the pressure off the abdominal blood vessels.[41]

Fibrinogen levels rise by 50% in pregnancy and need to be regularly assessed. Blood should be drawn at the commencement of the procedure, and 50% of the predicted lower standard value should be added to the values, and the patient's levels assessed within this range. Because of this change in fibrinogen, an increase in anticoagulant may be required to reduce the risk of clotting within the apheresis circuit. Where a patient has albumin as the replacement therapy, it may be necessary to use FFP towards the end of the procedure to help correct any deficiencies. Assessment of the patient's ionised calcium levels will assist in determining the amount of calcium replacement required. However, the use of a concurrent infusion of calcium gluconate will negate the risk of any citrate toxicity.[42]

Evaluation of the pregnancy by the obstetric team is essential to help maintain the health of mother and child.

REACTIONS TO REPLACEMENT FLUIDS

The rapid infusion of any blood component may be associated with allergic or vasomotor reactions. Plasma exchange is a rather unique situation as blood or blood products and plasma substitutes are being infused at resuscitation rates into normovolaemic, normotensive patients.

Hypotension can occur at any point in the procedure and although plasma exchange will maintain the patient as normovolaemic, there is always the risk of reaction to the exchange fluid or fluid shifts within the patient. Fluid shifts will normally respond to slowing down or halting the procedure and giving a bolus of fluids until there is recovery of the blood pressure.[43] It is helpful to ensure adequate hydration of the patient prior to commencing the procedure as this will also help reduce the risk. It should be noted that many patients have a small drop in their systolic blood pressure within minutes of commencing the procedure. Patients with neurological disorders may also benefit from running the procedure in a positive fluid balance to help counteract a lack of peripheral venous resistance.

Reactions to plasma can be seen as the development of pruritis or urticarial, and necessitate the administration of an antihistamine. If there is chest tightness, acute dyspnoea or hypoxia, and the patient is receiving plasma as the replacement fluid, then consideration should be given to TRALI (see Chapter 97) and appropriate treatment commenced.[10]

Where albumin is the replacement fluid on consecutive days, attention should be paid to coagulation parameters as there may be dilution of clotting factors. In patients with normal liver function, it would be expected that these would return to normal within a few days of ceasing plasma exchange; however, if the patient has had a recent haemorrhage or is pre- or post-surgery then the use of donor plasma may be justified.[7]

EFFECTS OF INTRAVASCULAR PROTEINS

If plasma protein fractions or albumin are being used for replacement fluids, not only will coagulation and complement components be depleted, but various transport and binding proteins in the circulation are significantly reduced. These may have significant effects on drug activity and elimination (e.g. antithrombin III levels may have effects on heparin activity). The effects of corticosteroids may be potentiated after plasma exchange owing to a reduction in binding proteins.

INTRAVENOUS IMMUNOGLOBULIN

IVIG products were originally developed in the 1950s for the treatment of immunodeficiency states. Since then, the immunomodulatory properties of IVIG have led to much broader usage in autoimmune and inflammatory disorders – usually in much higher doses.[44] In many cases the use of IVIG is based upon very limited evidence and much of its use is prescribed

for 'off-label' indications.[45] Consequent shortages of IVIG and concerns regarding its costs have led governments worldwide to attempt to restrict its use to only those conditions in which it has an established or emerging role.

IVIG is a sterile fractionated blood product consisting of concentrated immunoglobulin derived from pooled human plasma from thousands of healthy blood donors. IVIG typically contains more than 95% unmodified IgG (which has intact Fc-dependent effector functions) and trace amounts of IgA and IgM, cytokines, soluble CD4, CD8 and HLA molecules. Because IVIG is derived from large numbers of donors this provides a rich diversity of antibody repertoires and specificities.

A range of IVIG products are available. Although all contain IgG molecules, they may differ with regard to their pH, osmolality, excipient compounds (sucrose/sodium) and, consequently, in their adverse effects. In recent years IVIG preparations have been progressively improved – with the elimination of sugars and the normalisation of salt content and pH, which has significantly reduced the incidence of adverse reactions.[46] At present there is a lack of good comparative data to suggest that one IVIG preparation is superior to another.

IVIG has multiple immunomodulatory and anti-inflammatory activities including: modulation of complement activation with inhibition of generation of membrane attack complex (C5b-9) and subsequent complement-mediated tissue damage, suppression of idiotype antibodies, neutralisation of 'super-antigens', saturation of Fc receptors on macrophages and suppression of various inflammatory mediators including cytokines (TNF-α, IL-1α, IL-6), chemokines, adhesion molecules and metalloproteinases.[47] Importantly, many of these effects extend beyond the half-life of IVIG (IVIG lasts 6–22 days in circulation), suggesting that the immunomodulatory effects of IVIG are not simply due to enhanced passive clearance of autoantibodies or interference with pathogenic autoantibodies.

Box 99.3 Diseases in which intravenous immunoglobulin has an established benefit

- Acquired hypogammaglobulinaemia secondary to haematological malignancies
- Chronic inflammatory demyelinating polyneuropathy
- Guillain–Barré syndrome
- Idiopathic (autoimmune) thrombocytopenia purpura (ITP) in adults
- Inflammatory myopathies
- Kawasaki disease
- Lambert–Eaton myasthenic syndrome
- Multifocal motor neuropathy
- Myasthenia gravis
- Neonatal haemochromatosis
- Primary immunodeficiency diseases
- Stiff-man syndrome
- Graft-versus-host disease
- Acute disseminated encephalomyelitis
- Anti-neutrophil cytoplasmic antibody (ANCA)-positive systemic necrotising vasculitis
- Autoimmune haemolytic anaemia
- Pemphigoid and pemphigus
- Evans syndrome – autoimmune haemolytic anaemia with ITP
- Fetomaternal/neonatal alloimmune thrombocytopenia
- Haemophagocytic syndrome
- ITP in children
- IgM paraproteinaemic neuropathy
- Kidney transplantation
- Multiple sclerosis
- Opsoclonus myoclonus ataxia
- Post-transfusion purpura
- Secondary hypogammaglobulinaemia (including iatrogenic immunodeficiency)
- Specific antibody deficiency (including IgG subclasses)
- Toxic epidermal necrolysis/Stevens–Johnson syndrome
- Toxic shock syndrome

INDICATIONS FOR INTRAVENOUS IMMUNOGLOBULIN (Box 99.3)

IVIG has an established role in the treatment of primary immune deficiency and in acquired humoral immunodeficiency states due to haematological malignancies (particularly chronic lymphocytic leukaemia and multiple myeloma) and organ transplantation.[47] It also has an established role in many other conditions associated with autoimmune dysregulation as an immunomodulatory therapy including GBS, idiopathic thrombocytopenic purpura, myasthenia gravis, CIDP and Kawasaki disease. IVIG is often as efficacious as plasmapheresis and so is often recommended as first-line therapy with TPE used for patients who are unresponsive to IVIG and immunosuppressive therapy (generally corticosteroids).[48,49] IVIG is considered as second- or third-line therapy in a number of other conditions in which standard therapies have been ineffective, or are contraindicated and/or where the available evidence is inconclusive. Opinion remains divided as to whether IVIG has any role in sepsis. Despite a biological rationale for its use (based largely on preclinical work demonstrating enhanced bacterial clearance, inhibitory effects on mediators of inflammation and attenuated lymphocyte apoptosis) there is inconsistent evidence regarding its therapeutic efficacy.[50–52]

ADVERSE EFFECTS OF INTRAVENOUS IMMUNOGLOBULIN

Adverse effects occur in 3%–8% of patients. Most are mild and transient, including flushing, fever,

headache, chills, fatigue, nausea, diarrhoea, malaise, myalgia, dyspnoea, back pain, tachycardia and hypotension. Immediate adverse effects can be effectively treated by slowing or temporarily discontinuing the infusion and symptomatic therapy with analgesics, antihistamines and glucocorticoids in more severe reactions. IgA deficiency-related anaphylactic reactions are rare and largely preventable by the identification of patients with IgA deficiency and the use of IgA-depleted immune globulin.

Late adverse effects, including acute renal failure, venous thromboembolism, neutropenia, haemolytic anaemia, arthritis and aseptic meningitis, are also rare. Acute renal failure is generally transient; it usually occurs in dehydrated patients and after the use of sucrose-stabilised products owing to osmotic injury. Thromboembolic complications occur as a result of hyperviscosity, especially in patients who have received a rapid infusion of high-dose IVIG and in those with risk factors including: advanced age, immobilisation, previous venous thromboembolism, hypertension, diabetes mellitus and dyslipidaemia.[53] The blood group antibodies present in IVIG may act as haemolysins and coat red cells with immunoglobulins – resulting in a positive direct antiglobulin test (DAT) and, occasionally, haemolytic anaemia.

Haemostatic failure

Chee Wee Tan, Christopher M Ward

Haemostasis is the process whereby blood fluidity and vascular integrity are maintained in the event of vascular injury. Failure of haemostasis is common in critically ill patients and may be complex and multifactorial in pathogenesis. As haemostatic failure may complicate a wide range of medical, surgical and obstetric disorders, definitive diagnosis and specific therapy can significantly impact on outcome. Therapy may need to be initiated on clinical evidence with minimal laboratory information.

NORMAL HAEMOSTASIS

The haemostatic system is tightly controlled, and its role is to initiate clot formation where and when required and in adequate, but not excessive, amounts. There has been a paradigm shift in our understanding of the haemostatic system from one of circulating clotting factors to a more complex process occurring on the surface of activated or damaged cells (Fig. 100.1).[1,2]

The triad of vascular constriction, platelet plugging and fibrin clot formation provides the framework for haemostasis (see Fig. 100.1). Fibrinogen is the bulk protein of the coagulation system and fibrin is the end-product of a cascade of proteolytic activity, whereby precursor coagulation proteins are activated to become potent proteolytic enzymes, which, with the aid of cofactors, produce further activated proteins downstream. Thrombin converts fibrinogen to fibrin soluble monomers, which subsequently polymerise to form the fibrin clot, which is then stabilised by factor XIII. Thrombin generation in small amounts initially occurs in relationship to tissue-factor-bearing cells. This is then transferred to the activated platelet surface where amplification occurs, as highlighted by the cellular model of coagulation.[2]

Following injury, vascular constriction reduces bleeding, and allows time to initiate haemostasis. This is accentuated by vasoconstrictors released in association with platelet plug formation. With large-volume haemorrhage, the consequent systemic hypotension is an important physiological mechanism to minimise blood loss and facilitate stabilisation of the haemostatic plug. Controlled or 'tolerated' hypotension is now accepted as an important aspect of managing critical haemorrhage.[3,4] Vascular endothelial cells play an active role in haemostasis by synthesising substances that act at the membrane surface and/or interact with platelets and the coagulation system (e.g. prostacyclin, antithrombin, plasminogen activator, von Willebrand factor [VWF], thrombomodulin, heparin cofactor II and nitric oxide).[5]

The coagulation system is now thought to be triggered predominantly via the extrinsic pathway in vivo. Damaged tissues expose tissue factor (TF), a membrane-bound protein present in cells surrounding the vascular bed. Factor (F) VII and VIIa (a small amount circulates normally in the blood) then bind TF, activating FX. FXa interacts with the cofactor FVa to form prothrombinase complexes, which generates a small amount of thrombin on the cell surface. FIX is also activated by the TF/VIIa complex; it does not play a significant role in the initiation phase of coagulation, but diffuses across to platelets in the vicinity that have adhered in proximity to the site of the TF-bearing cells. FIXa binds to a specific platelet surface receptor and interacts with cofactor FVIIIa, leading to activation of FX directly on the platelet surface, resulting in the amplification and propagation of coagulation.

VWF is a multimeric glycoprotein (GP) that mediates platelet adhesion to the exposed subendothelium and links the primary vascular/platelet phase to coagulation by being the carrier protein for FVIII. FVIII dissociates from VWF to form a complex on the activated platelet surface with FIXa (tenase complex) to activate FX to FXa. Platelets interact with VWF via GP Ib–IX–V complexes. This results in platelet deceleration along the subendothelium, allowing platelet receptors to bind collagen. Adhesion to collagen and subsequent platelet activation is now thought to be critical in haemostasis and is facilitated by platelet GPVI and GPIa–IIa receptors.[6,7] Recent literature suggests that GPIb–IX–V and GPVI may work in concert to mediate platelet activation, culminating in stable platelet aggregation via the activation of GPIIb–IIIa.[8,9]

Platelet adhesion results in a platelet monolayer over the injured subendothelium, forming a procoagulant surface. Activation of the coagulation cascade results in local generation of thrombin, which binds to

ABSTRACT

Haemostatic failure is encountered increasingly and with greater complexity in the critical care setting with patients with multiple co-morbidities, drug therapies and risk factors that influence the fine balance between haemostasis, thrombosis and major bleeding. This chapter outlines the physiological basis of coagulation and the common factors leading to disordered haemostasis. Clinical and laboratory assessment of primary and secondary haemostasis are discussed, in particular the emergence of point-of-care thromboelastic testing, which provides a global assessment of coagulation and can be used in goal-directed approaches to optimise blood product use and improve clinical outcomes in major bleeding. Management of important congenital and acquired haemostatic disorders are reviewed, including disseminated intravascular coagulation, thrombotic microangiopathies, and bleeding as a result of antiplatelet and anticoagulant therapy, with particular reference to newer agents. Risks and benefits of treatment strategies are discussed.

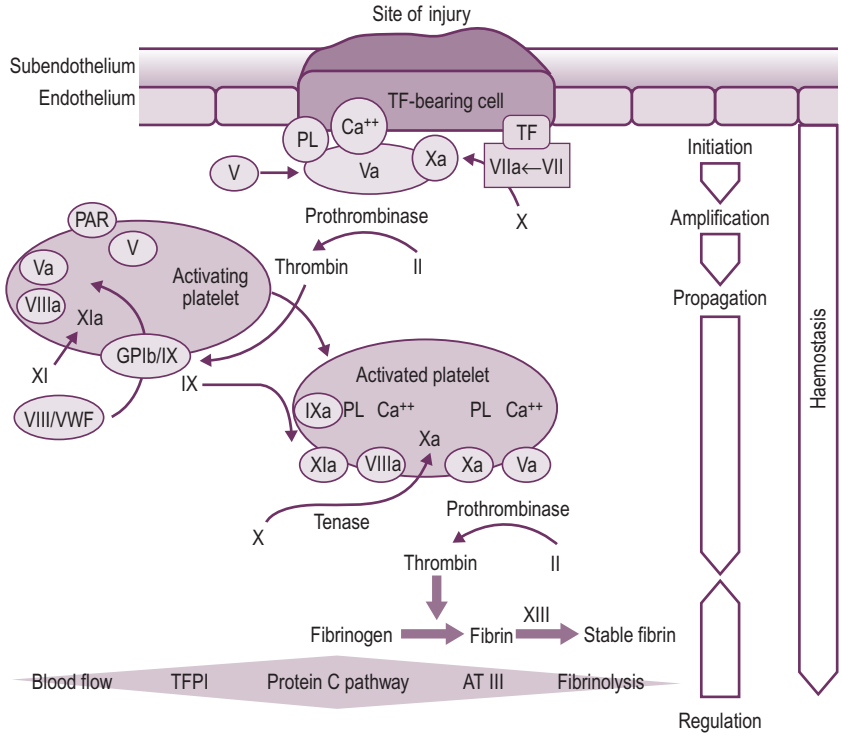

Figure 100.1 The cellular model of coagulation emphasises the interplay between the endothelium, platelets and coagulation factors in the formation of a stable fibrin clot. *AT*, Antithrombin; *PAR*, protease activated receptors; *PL*, phospholipids; *TF*, tissue factor; *TFPI*, tissue factor pathway inhibitor; *VWF*, Von Willebrand factor.

platelet protease-activated receptors (PARs), enhancing intracellular calcium mobilisation and platelet aggregation, resulting in production of a haemostatic plug and further facilitating coagulation. Further clot extension occurs due to platelet recruitment by platelet agonists, such as thrombin, adenosine 5-diphosphate (ADP) and thromboxane A_2, which are released directly from platelets. P-selectin is expressed during activation and plays a role in platelet-to-platelet and platelet-leucocyte interactions.

Parallel to and within the coagulation system are complex feedback mechanisms to guard against inappropriate and excessive activation.[10–12] Several inhibitory proteins, including antithrombin, thrombomodulin, protein C and S, TF pathway inhibitor, together with the fibrinolytic system, are important in this regard. Thrombin itself acts as either a procoagulant or anticoagulant depending on the context. Perturbations in this complex system can produce a wide range of clinical disorders from arterial or venous thrombosis to major bleeding.

SYSTEMIC HAEMOSTATIC ASSESSMENT

Clinical features may localise pathology to either coagulation factors or platelets (see Fig. 100.2). Clinical history is important, especially previous bleeding, family history, co-morbid medical conditions and medications.

Haemostatic system assessment can be broadly divided into laboratory tests of primary haemostasis, specifically platelet number and function, and tests of secondary haemostasis, which assess the integrity of the coagulation cascade (see Fig. 100.2). Point-of-care haemostatic testing is increasing, particularly in the peri-operative assessment of bleeding risk, in critical bleeding and massive blood transfusion, and in the assessment of bleeding risk attributable to anticoagulant and antiplatelet therapy.

TESTS OF PRIMARY HAEMOSTASIS

A full blood count may reveal thrombocytopenia. While a low platelet count ($<50 \times 10^9$/L) can contribute to haemostatic failure, a normal platelet count does not exclude platelet dysfunction as a cause of bleeding. Platelet function tests can be used both for the diagnosis of platelet disorders, and to monitor antiplatelet therapy at point of care.[13,14]

The platelet function analyser (PFA-100, and more recently Innovance PFA-200) has replaced the bleeding time as a commonly used screening test for primary haemostatic defects. In the PFA-100, citrated whole blood

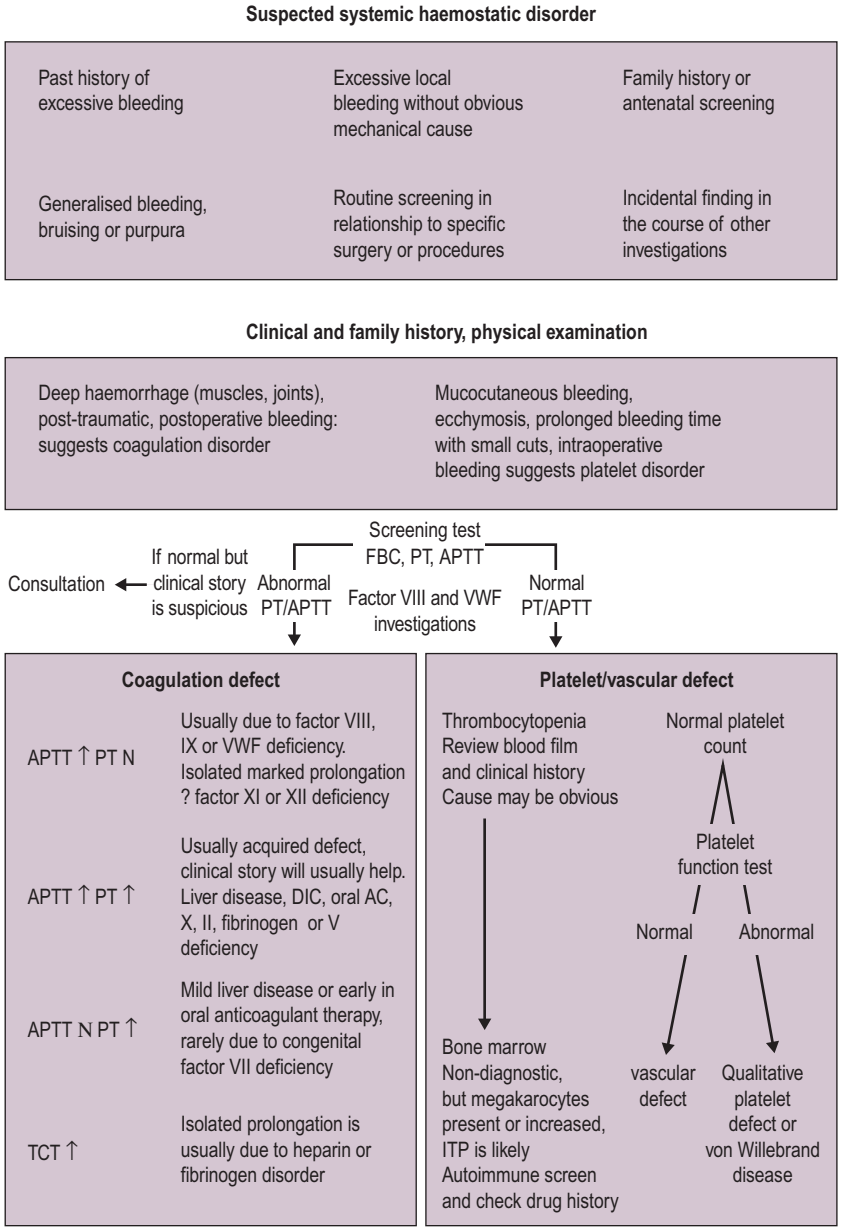

Figure 100.2 Key features of history, examination and laboratory testing involved in the work-up of a patient suspected of a systemic haemostatic disorder. *AC*, Anticoagulants; *APTT*, activated partial thromboplastin time; *DIC*, disseminated intravascular coagulation; *FBC*, full blood count; *ITP*, idiopathic thrombocytopenic purpura; *PT*, prothrombin time; *TCT*, thrombin clotting time; *VWF*, Von Willebrand factor.

is subjected to high shear through a membrane coated with platelet agonists, collagen/epinephrine (adrenaline) or collagen/ADP, resulting in platelet adhesion, aggregation and closure of a membrane aperture.[15] The time to occlude the aperture is the test end-point and is referred to as the closure time. The technique is simple and rapid to perform, but results may be influenced by the platelet count, haematocrit, and ABO blood group. A normal result has a high negative predictive value, and the test is also sensitive to major bleeding disorders such as von Willebrand disease (vWD), Glanzmann thrombasthenia (deficiency in GP IIb/IIIa) and aspirin use. The assay is less sensitive to milder bleeding defects such as platelet storage pool disease, variably prolonged by GP IIb/IIIa antagonists and not affected by clopidogrel.[16] Standard light transmission

aggregometry (LTA) is the gold standard method for diagnosing platelet function defects, but requires technical expertise and hence is less useful in the critical care setting. The recent development of whole blood multiple electrode platelet aggregometry (WBA), such as the Multiplate (Roche), to measure platelet function is promising, as it is a simple and rapid assay with reduced risk of artefactual platelet activation.[17] The use of WBA in assessing platelet response to aspirin and clopidogrel has been published, with results correlating well with LTA.[18,19]

The VerifyNow (Accumetrics) is a point-of-care test that measures platelet aggregation in whole blood, and has been used to gauge response to aspirin, clopidogrel and GP IIb/IIIa antagonists in the setting of percutaneous coronary intervention.[20] Flow cytometry has the advantages of low sample volume and whole blood testing, reflecting physiological conditions.[21,22] The phosphorylation of vasodilator-stimulated phosphoprotein (VASP) is a flow cytometry application used to assess response to clopidogrel.[23]

TESTS OF SECONDARY HAEMOSTASIS

A full blood count, prothrombin time (PT), activated partial thromboplastin time (APTT), fibrinogen level, D-dimer and thrombin time (TT) provide a broad screen for most clinically significant haemostatic disorders (see Fig. 100.2).[24–26] Based on these results, further specific tests of haemostasis may be performed (e.g. mixing studies, factor assays, platelet function tests and tests of fibrinolytic function).

PROTHROMBIN TIME

The PT is a test of the extrinsic coagulation system. Prolongation may be caused by FVII deficiency, liver disease, vitamin K deficiency or oral anticoagulant therapy. The PT is also expressed as the international normalised ratio (INR), and is used to monitor warfarin use.

ACTIVATED PARTIAL THROMBOPLASTIN TIME

The APTT is a test of the intrinsic coagulation system, and there may be significant variation in test sensitivity and specificity between laboratories. In unselected patients there is poor correlation between the APTT prolongation and bleeding risk. A lupus anticoagulant may prolong the APTT and represent a prothrombotic state, rather than a bleeding tendency. In a patient with a suspected systemic haemostatic defect, an isolated prolongation of the APTT may represent:

- deficiency or inhibitor of FVIII, FIX or FXI
- deficiency in the contact phase of coagulation; that is, FXII and prekallikrein, which importantly does not result in clinically significant bleeding
- prolongation of both APTT and PT may be due to deficiencies of factors X, V, prothrombin or fibrinogen.

THROMBIN CLOTTING TIME

This is a test of the final conversion of fibrinogen to fibrin. Prolongation of thrombin clotting time (TCT) is due to hypofibrinogenaemia, dysfibrinogenaemia, heparin or the generation of fibrin degradation products.

D-DIMER

The D-dimer assay measures cleavage fragments resulting from the proteolytic action of plasmin on fibrin, so is specific for fibrinolysis and a marker of fibrin generation. Apart from venous thrombosis, raised D-dimer can be seen in the postoperative state, trauma, renal impairment, sepsis and importantly, in disseminated intravascular coagulation (DIC) with hyperfibrinolysis.

SPECIFIC COAGULATION FACTOR ASSAYS

Fibrinogen is commonly measured in patients suspected of systemic haemostatic failure, using clottable protein methods, end-point detection techniques or immunochemical tests. The Clauss method is the most common fibrinogen assay used.

Specific factor assays can be performed as secondary tests, after initial screening tests, such as APTT, reveal abnormalities. With an isolated prolonged APTT, a mixing test, in which plasma from normal donors is added to patient sample plasma, can be performed. It will correct APTT prolongation secondary to factor deficiencies, but not due to coagulation factor inhibitors. These include thrombin inhibitors, such as heparin and dabigatran, and acquired FVIII inhibitors. An APTT corrected by a mixing test is further investigated with specific assays for FVIII, FIX and FXI. An isolated PT is investigated in a similar fashion, with FVII deficiency/inhibitor a possible cause.

GLOBAL COAGULATION ASSAYS

The PT and APTT, although useful in detecting coagulation factor deficiencies, have drawbacks. Haemostasis does not just involve coagulation factors, but also cellular components including platelets and endothelial cells, so there is inevitably a limited assessment of coagulation profile via these tests. Global coagulation assays can assess the haemostatic system as a whole, extending coagulation monitoring beyond initial fibrin polymerisation.[27] Point-of-care testing with global coagulation assays offers significant advantages in the critical care setting, including significantly faster turnaround time compared to PT/APTT and assessment of fibrinolytic activity. Global coagulation testing includes whole blood thromboelastography (TEG) (i.e. TEG and ROTEM assays), and thrombin generation tests (TGT). TEG has become more widely used in view of its capacity for real-time coagulation assessment, more so than TGT.

TGTs measure the final step of the coagulation pathway. It informs on both the bleeding risk and

hypercoagulability of a patient, as thrombin has both prothrombotic and fibrinolytic roles. The calibrated automated thrombogram (CAT) assesses thrombin generation by using fluorogenic substrates. As thrombin generation continues beyond fibrin clot formation, it can provide further information on haemostatic capacity. Studies have demonstrated the value of TGT in predicting bleeding in cardiac surgery.[28] TGT parameters responded to fresh frozen plasma (FFP) and fibrinogen concentrate replacement in patients experiencing peri-operative dilutional coagulopathy.[29]

Studies also show that TGT can predict bleeding tendency in patients with mild haemophilia A and FXI deficiency, in whom FXI levels correlate poorly with extent of bleeding.[30,31] More recently, TGT has been used to assess the response to rivaroxaban in patients with anti-phospholipid syndrome.[32] While the use of TGTs are restricted to specialised centres, applications of TGTs are likely to increase in future, particularly with the development of whole blood TGTs.[33]

TEG enables ongoing evaluation of a clot as it forms. In both methods, a sample is placed in a cup, with a pin present in the centre of the cup as the device is operating. In TEG the cup is spinning, whereas in ROTEM it is the pin that rotates. Clot formation results in reduced pin movement, with the information translated into computer tracings, such as that depicted in Fig. 100.3.[34]

Fig. 100.3 illustrates the utility of TEG to provide information on all stages of haemostasis, including fibrinolysis. Measurement of clot strength is gauged by the use of platelet inhibitors, such as abciximab (TEG) or cytochalasin D (ROTEM), hence representing a surrogate marker of fibrinogen levels. TEG has been widely used in cardiac surgery and liver transplantation, and as part of massive transfusion protocols and in trauma settings. Goal-directed approaches towards best-practice use of blood products while optimising clinical outcomes have been recommended by consensus guidelines.[35,36] TEG can play an important role here, establishing initial coagulation status of critically ill patients, triggering early use of appropriate products (including tranexamic acid, fibrinogen, platelets and FXIII), with the resultant changes in haemostatic factors reflected by serial TEG, guiding further blood product administration to improve patient status.[37,38] TEG-platelet mapping assesses clot strength and enables quantification of the extent of inhibition of platelet function by aspirin and ADP antagonists, and has been used to assess bleeding risk prior to surgery.[39]

However, high-quality evidence of global coagulation assays impacting significantly on key clinical outcomes is lacking.[35,40] The greatest benefit has been seen in cardiac surgery.[41] In this area, while use of TEG has resulted in reduction in blood product usage, including red blood cells (RBCs), platelets and especially FFP, benefits, such as reduced mortality and surgical re-exploration rates, have not been consistently demonstrated. Assay standardisation remains an issue.

One of the major benefits of TEG is the capacity to assess fibrinolysis more rapidly, leading to early use of antifibrinolytic therapy. However, critical care physicians should be aware that in major studies, such as the CRASH-2 study, benefits of tranexamic acid extended to all trauma patients who are bleeding or at risk of bleeding.[42,43] Hence therapy should not be delayed while waiting for TEG results nor should it be limited only to patients with hyperfibrinolysis demonstrated on TEG.

While there are limitations with TEG, it provides a more comprehensive assessment of coagulation status when compared to PT/APTT, and its ability to detect and monitor changes in coagulation status at the bedside can lead to the rationalisation of blood product use and early use of therapies shown to improve clinical outcome, such as fibrinogen and tranexamic acid.

CONGENITAL HAEMOSTATIC DEFECTS

Congenital bleeding disorders are rare, but should be suspected in the clinical setting with discrepant or unexpected major bleeding or with abnormal laboratory results (i.e. an isolated prolonged APTT). It is important to identify the defect so that specific replacement therapy can be administered, with dosage guided by regular coagulation factor level monitoring. Congenital bleeding disorders include haemophilia A (FVIII deficiency), haemophilia B (FIX deficiency) and vWD. Haemophilia A and B are characterised by musculoskeletal and soft-tissue bleeding. Apart from specific factor concentrates, antifibrinolytics such as tranexamic acid are useful adjunctive therapy, with desmopressin also effective therapy in mild haemophilia A and certain types of vWD by stimulating endogenous release of FVIII and VWF.

Congenital platelet disorders are also rare, the commonest severe disorder being Glanzmann thrombasthenia, which is a deficiency or dysfunction of GP IIb/IIIa. A history of repeated mucocutaneous bleeding with an abnormal aggregometry result is suggestive of such disorders. Platelet transfusions may be required for acute severe bleeds or in the peri-operative period; recombinant factor VIIa (rFVIIa) is important in cases of platelet transfusion refractoriness. Desmopressin (DDAVP) and antifibrinolytic therapy may also have a role.

ACQUIRED HAEMOSTATIC DISORDERS

Acquired haemostatic disorders also can be broadly divided into platelet defects and coagulation factor abnormalities.

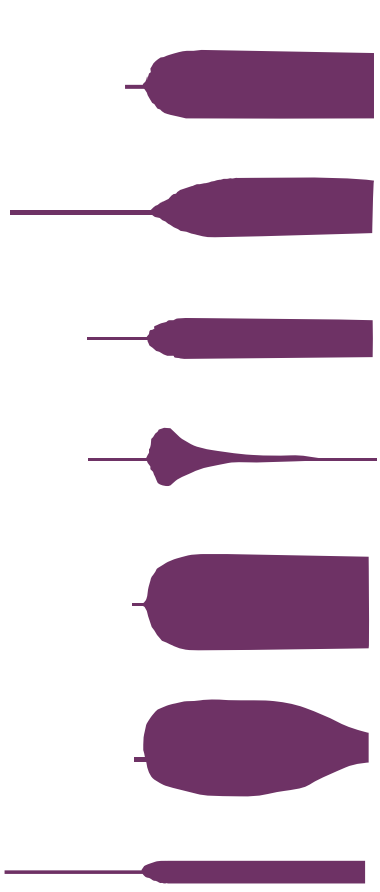

Figure 100.3 Comparative thromboelastograph tracings in normal and pathological states, with measured parameters assessing different aspects of haemostasis. These include: R time, which is the time elapsed until initial fibrin formation; K time gauges the dynamics of clot formation, α-angle assesses the kinetics of fibrin accumulation and cross-linkage, maximum amplitude *(MA)* assesses the effectiveness of platelet–fibrin interactions, while lysis time assesses fibrinolysis. *Modified from Srinivasa V, Gilbertson L, Bhavani-Chankar K. Thromboelastography: where is it and where is it heading?* Int Anesthesiol Clin. *2001;39:35–49.*

QUANTITATIVE PLATELET DEFECTS

DRUG-INDUCED THROMBOCYTOPENIA

The clinical presentation of drug-induced thrombocytopenia ranges from mild to life-threatening bleeding. Drugs with a predilection for inducing thrombocytopenia include quinine, antituberculous drugs, heparin, thiazide diuretics, penicillins, sulfonamides, rifampicin and anticonvulsants.

Heparin-induced thrombocytopenia (HIT) is an important and potentially life-threatening complication of heparin therapy.[44] An immune reaction to heparin typically occurs after 7–10 days of therapy, leading to platelet aggregation and thrombocytopenia. The thrombocytopenia seen in HIT usually does not fall below 20×10^9/L, and platelet count can be normal. HIT is not associated with bleeding, but rather represents a prothrombotic state, manifesting as arterial or venous thrombosis. Medical staff must be vigilant to the possibility of HIT occurring, and to keep heparin therapy as brief as possible. The incidence is less with the use of low-molecular-weight heparin (LMWH). A strong clinical suspicion of HIT (probability of HIT based on four criteria of the 4T score: timing and nadir of thrombocytopenia, the presence of thrombosis, and the possibility of other causes accounting for thrombocytopenia – see Table 100.1) should result in the cessation of heparin, and the commencement of an alternate anticoagulant, such as danaparoid, fondaparinux or argatroban, while awaiting laboratory results.[45]

HIT can be challenging to diagnose in the critical care setting, with many potential causes of thrombocytopenia in the same clinical scenario. Screening tests

Table 100.1 4T score to assess clinical probability of heparin-induced thrombocytopenia; a score of 0–3 represents low probability, 4–5 intermediate and 6–8 high clinical probability of heparin-induced thrombocytopenia

CATEGORY	2 POINTS	1 POINT	0 POINTS
Thrombocytopenia	>50% fall, or nadir ≥20 × 10^9/L	30–50% fall, or nadir 10–19 × 10^9/L	<30% fall, or nadir <10 × 10^9/L
Timing of the decrease in platelet count	Days 5–10, or ≤day 1 with recent heparin (past 30 days)	>Day 10 or timing unclear, or <day 1 if heparin exposure within past 30–100 days	<Day 4 (no recent heparin)
Thrombosis or other sequelae	Proven thrombosis, skin necrosis, or acute systemic reaction after heparin bolus	Progressive, recurrent, or silent thrombosis; erythematous skin lesions	None
Other causes of thrombocytopenia	Non-evident	Possible	Definite

Modified from Lo GK, Juhl D, Warkentin TE, et al. Evaluation of pretest clinical score (4 T's) for the diagnosis of heparin-induced thrombocytopenia in two clinical settings. *J Thromb Haemost*. 2006;4(4):759–765.

for HIT antibodies are available, but these also detect non-pathogenic antibodies, which can commonly occur in the setting of cardiac surgery, resulting in false positive results. Functional HIT assays, such as the serotonin release assay or whole blood aggregometry, which show platelet activation in the presence of heparin and patient serum/plasma, can confirm the diagnosis but are performed only in reference laboratories.[17] A combination of clinical and laboratory criteria is required to assess for HIT.

THROMBOTIC MICROANGIOPATHIES

The thrombotic microangiopathies (TMAs) are disease entities characterised by microvascular endothelial cell injury and formation of platelet microthrombi. They are classically defined by thrombocytopenia, microangiopathic haemolytic anaemia (MAHA) and variable organ involvement. Recent advances in understanding of the pathophysiology of the TMAs have enabled classification into three primary disorders:

- Thrombotic thrombocytopenic purpura (TTP), which is triggered by deficiency of ADAMTS-13 (a disintegrin and metalloproteinase with a thrombospondin type 1 motif, member 13), a metalloproteinase that cleaves pro-thrombotic large VWF multimers.
- Shiga toxin-producing *Escherichia coli* haemolytic uraemic syndrome (STEC-HUS), more often seen in the paediatric setting and characterised by gastrointestinal involvement.
- Atypical haemolytic-uraemic syndrome (aHUS), which is driven by dysregulation and uncontrolled activation of the alternative complement pathway and often characterised by renal impairment.

The three entities can be indistinguishable on clinical grounds, and any organ can be impacted by TMAs.[46] However, the lung is almost never involved in TTP, and severe acute renal failure at presentation is unusual in TTP. In fact, a serum creatinine of >150–200 μmol/L and/or a platelet count >30 × 10^9/L makes TTP very unlikely.[47] Platelet counts can be normal or only mildly reduced in aHUS, and the greater the systemic organ involvement, the more likely the offending TMA is aHUS.

Laboratory testing is crucial in determining the precise TMA, with stool culture positivity for STEC definitive for STEC-HUS, and an ADAMTS-13 level of less than 5%–10% is associated with TTP. Hence, aHUS remains a diagnosis of exclusion in the acute setting. Analysis of complement and genetic markers for aHUS are now available and are important for prognosis, but are not required for diagnosis of aHUS acutely.[48]

It is important to determine the specific TMA, as these conditions have significant morbidity and mortality if untreated, and have different management strategies. Plasma exchange and corticosteroids are the mainstay of management for TTP, with rituximab for refractory cases, whereas eculizumab (a monoclonal antibody directed against the complement component C5) is first-line therapy for aHUS.[49,50]

Clinicians should be aware of secondary causes/triggers of TMA, including malignant hypertension, medications such as chemotherapeutic agents, clopidogrel, and calcineurin inhibitors, pregnancy, malignancy, organ transplantation and infections.

IDIOPATHIC THROMBOCYTOPENIC PURPURA

Idiopathic thrombocytopenic purpura (ITP) is an autoimmune disorder where autoantibodies (IgG) are directed against platelets, which are subsequently destroyed by the monocyte–macrophage system, predominantly in the spleen. ITP remains a diagnosis of exclusion. Corticosteroids are first-line therapy in acute episodes, particularly if the platelets are <10 × 10^9/L or with uncontrolled bleeding. High dose dexamethasone (40 mg/day for 4 days) is increasingly used

and has demonstrated efficacy in this setting.[51] Intravenous immunoglobulin is indicated in ITP with major bleeding and/or not responding to corticosteroids, and is particularly useful pre-operatively and in pregnancy. Platelet transfusions should be reserved for life-threatening bleeding and a platelet increment is more likely following a dose of intravenous immunoglobulin. Patients with refractory ITP are treated with thrombopoietin receptor agonists; that is, romiplostim and eltrombopag, splenectomy or rituximab.

THROMBOCYTOPENIA IN CRITICAL CARE SETTINGS

Platelets play an important role in the inflammatory response and a reactive thrombocytosis is usually seen in infection. However, if there is overwhelming sepsis, associated DIC or marrow suppressive influences, including medications, thrombocytopenia can also occur.

QUALITATIVE PLATELET DEFECTS

The most common cause of acquired platelet dysfunction seen in the critical care setting is the use of antiplatelet therapy, which is discussed later in the chapter. Other causes of platelet dysfunction include uraemia, hepatic cirrhosis, multiple myeloma and myeloproliferative disorders.

Platelet dysfunction can also occur in the setting of extracorporeal circulation, especially cardiopulmonary bypass. In this setting, bleeding risk is also impacted by other haemostatic disturbances, including thrombocytopenia and increased fibrinolysis, as well as time on bypass and multiple-valve replacements or re-operations. Key haemostatic measures include ensuring adequate reversal of anticoagulants such as heparin, platelet transfusions and the use of a goal-directed approach to blood product use facilitated by TEG. The use of prothrombin complex concentrate (PCCs) and fibrinogen guided by TEG results have reduced transfusion requirements and thromboembolic events, while improving outcomes, including mortality, in some studies.[52–54]

CRITICAL HAEMORRHAGE AND MASSIVE BLOOD TRANSFUSION

The nature and management of haemostatic defects secondary to acute and/or massive blood loss are explained in greater detail in Chapter 97. TEG is now widely used to facilitate a goal-directed approach in critical bleeding and massive blood transfusion as described earlier in this chapter. Fibrinogen replacement is a key component of resuscitation protocols, with low fibrinogen often occurring early in bleeding/trauma, contributing to the effects of dilutional coagulopathy, and associated with increased mortality.[55] More recent guidelines recommended that fibrinogen be replaced based on results of TEG or if plasma levels less than 1.5–2.0 g/L, with higher levels targeted in specific populations, such as cardiac surgery (3.9 g/L).[35,36] Cryoprecipitate, a source of fibrinogen, has been withdrawn in many countries of the European Union. Fibrinogen concentrates, on the other hand, are virally inactivated and carry a lower risk of transmitting infection, are not blood group specific, and can be stored at room temperature and given without delay owing to thawing. The use of fibrinogen concentrates in a wide variety of clinical settings with high bleeding risk, including aortic aneurysm graft surgery and coronary bypass graft surgery, has resulted in a significant reduction in blood product support (FFP, platelets, RBCs), correction of laboratory abnormalities in coagulation and significant reduction in peri-operative bleeding.[56–58]

FFP and platelet concentrates are often infused to correct significant coagulopathy in massive bleeding. However, the efficacy of FFP has not been established in such settings, including cardiac surgery.[57] FFP also carries the risk of infections, incompatibility reactions, transfusion-related acute lung injury (TRALI) and fluid overload.

Tranexamic acid is now recommended to be administered as early as possible (within 3 hours) in trauma patients with or at risk of major bleeding at a loading dose of 1 g intravenously over 10 minutes, followed by an intravenous infusion of 1 g over 8 hours.[42]

HAEMOSTATIC FAILURE ASSOCIATED WITH LIVER DISEASE

The liver is the production site of nearly all the coagulation factors involved, apart from FVIII and VWF. Bleeding is challenging to evaluate in patients with liver impairment, with prohaemostatic changes (including reduced levels of natural anticoagulants and plasminogen) and antihaemostatic changes (thrombocytopenia, platelet dysfunction, impaired synthesis of clotting factors, excessive fibrinolysis) likely to co-exist. Mild to moderate prolongation of PT does not correlate with bleeding risk. Guidelines have advised assessing FFP use prior to invasive procedures, based on individual patient characteristics.[59,60] FFP also carries the theoretical risk of increasing portal pressure and aggravating bleeding. PCCs are a viable alternative, particularly in patients with fluid overload. Haemostatic defects due to vitamin K deficiency in patients with predominantly cholestatic liver disease may be reversed with vitamin K therapy, without requiring FFP.

Hypofibrinogenaemia/dysfibrinogenaemia are common in patients with liver impairment. As discussed previously, cryoprecipitate or fibrinogen concentrates can be administered in patients with chronic liver disease and bleeding with fibrinogen levels less than 1.5 g/L, or in patients not responding to FFP, as dysfibrinogenaemia is likely to be present.

DISSEMINATED INTRAVASCULAR COAGULATION

DIC is a pathophysiological process characterised by excessive activation of the haemostatic process. Initially, adequate compensation results in defects being demonstrable only in the laboratory tests, but if the initiating disorder is severe the clinical syndrome of uncontrolled acute DIC can result in significant bleeding, which is usually associated with end-organ failure. Secondary fibrinolysis can occur, which may accentuate the bleeding.

PATHOPHYSIOLOGY

DIC is characterised by the initial consumption of clotting factors and platelets within the circulation, resulting in varying degrees of microvascular obstruction due to fibrin deposition (see Fig. 100.4). When significant platelet and coagulation factor consumption occurs, bleeding may become a major feature.

Mechanisms that may inappropriately activate the haemostatic system include:

- activation of the coagulation sequence by the release of tissue thromboplastins into the systemic circulation (e.g. following extensive tissue trauma, during surgery, malignancy and during acute intravascular haemolysis)
- vessel wall endothelial injury causing platelet activation followed by activation of the haemostatic system (e.g. Gram-negative sepsis from endotoxin release, viral infections, extensive burns, prolonged hypotension, hypoxia or acidosis, see Box 100.1).
- induction of platelet activation (e.g. septicaemia, antigen–antibody complexes).

CLINICAL FEATURES

The clinical presentation of DIC varies, with patients showing thrombotic, haemorrhagic, or mixed manifestations in various organ systems. The major clinical problem of acute DIC is bleeding, manifesting as generalised bruising, or bleeding at venepuncture sites and surgical wounds. DIC may occur in association with a wide range of clinical disorders (see Box 100.1).

Box 100.1 Conditions associated with disseminated intravascular coagulation

- Infection
- Bacterial sepsis
- Viral haemorrhagic fevers
- Protozoal (malaria)
- Trauma
- Extensive tissue injury
- Head injury
- Fat embolism
- Malignancy
- Carcinoma
- Leukaemia (especially promyelocytic)
- Immunological disorders
- Transplantation rejection
- Incompatible haemolytic blood transfusion reactions
- Severe allergic reaction
- Drug reactions
- Extracorporeal circulations
- Snake bite envenomation
- Vascular disorders
- Giant haemangioma
- Aortic aneurysm
- Pregnancy associated:
  - Septic abortion
  - Abruptio placentae
  - Eclampsia
  - Amniotic fluid embolism
  - Placenta praevia
- Burns
- Hyperthermia
- Liver disease and acute hepatic necrosis

LABORATORY FINDINGS

Significant DIC can be present despite normal standard coagulation tests. The key tests in diagnosis are those that provide evidence for excessive conversion of fibrinogen to fibrin and its subsequent lysis. Platelet–fibrin clots create a mesh in the microcirculation in which passing red cells may be damaged, resulting in red cell fragmentation and haemolysis. The blood film may demonstrate fragmentation of the red cells (MAHA), but this is more commonly seen in chronic DIC, especially in association with malignancy.

The diagnosis is usually based on a combination of the appropriate clinical picture and laboratory testing of the haemostatic system (Table 100.2). Thrombocytopenia, hypofibrinogenaemia, with prolongation of the APTT, PT and TCT in conjunction with an elevation of fibrin degradation products (D-dimer test), are indicative of DIC. More specialised tests, such as elevation of fibrinopeptide A and reduced levels of antithrombin, add further weight to the diagnosis. To assist in the accurate diagnosis of DIC, the International Society on Thrombosis and Haemostasis (ISTH) has developed a scoring algorithm based on laboratory results (Table 100.3).[61]

In chronic DIC the laboratory findings differ from acute DIC, with often normal or near normal haemostasis testing results. Chronic DIC is a compensated state in which there is increased turnover of each of the haemostatic components. D-dimer is elevated in this setting and red cell fragmentation is often seen on the peripheral blood film.

THERAPY

The most important measure in the management of DIC is treatment of the initiating cause in conjunction with general resuscitation. Transfusion of blood products has the theoretical risk of 'feeding the

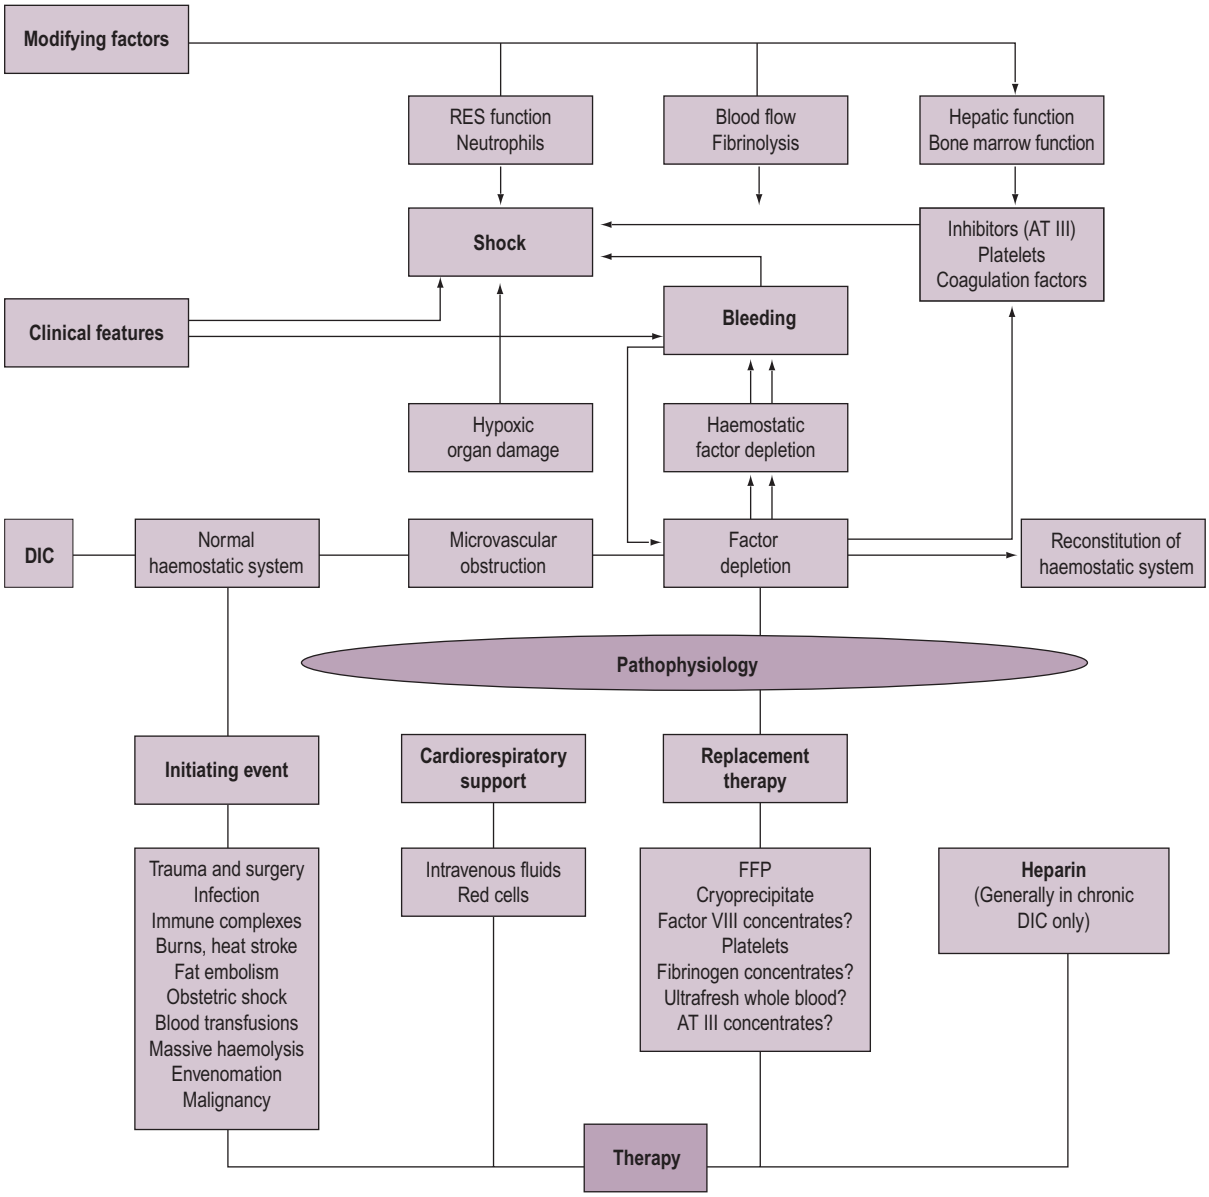

Figure 100.4 The pathophysiology and management of disseminated intravascular coagulation *(DIC)*. *AT*, Antithrombin; *FFP*, fresh frozen plasma; *RES*, reticulo-endothelial system.

fire', providing substrates for microthrombi formation. Hence, blood products should be given only in patients with bleeding/high bleeding risk or prior to major procedures. Local institutions routinely establish laboratory parameters to guide transfusion therapy, usually aiming to maintain fibrinogen levels >1–1.5 g/L and platelet counts >20–30 $\times$ 10^9/L, and PT below 1.5 times normal. Heparin should be used judiciously in the setting of DIC, and can be beneficial in settings where major thrombotic complications have occurred, rather than bleeding. Small doses of unfractionated heparin (UFH) should be used initially. There have also been reports in the literature regarding the use of antithrombin in the setting of DIC, with varying impact on patient mortality.[62]

ANTITHROMBOTIC THERAPY

The landscape of antithrombotic therapy has changed significantly in recent times with the wide availability of direct oral anticoagulants (DOACs), also known as non-vitamin K antagonists (VKA) (NOACs). Recent

consensus guidelines have suggested a preference for DOACs over VKA both in the setting of acute venous thromboembolism (VTE) and stroke prevention in the setting of atrial fibrillation (AF).[63,64] Clinicians must be aware of both the thrombotic and bleeding risks associated with continuing or withholding antithrombotic therapy, and achieve a balance between these risks in a growing number of patients with multiple co-morbidities and both prothrombotic and bleeding tendencies.

With all antithrombotic therapies, the cornerstones of management of major bleeding are investigations for a source of bleeding (i.e. endosocopy for gastrointestinal bleeding), cessation of antithrombotics, and local haemostatic and resuscitation measures. Prohaemostatic agents and reversal strategies also can be pursued depending on the antithrombotic therapy administered.

DIRECT ORAL ANTICOAGULANTS

Unlike VKAs, DOACs target specific coagulation factors, namely FXa (rivaroxaban, apixaban, edoxaban) or thrombin (dabigatran). All DOACs are renally excreted to varying extents. Efficacy and safety of DOACs in the management of VTE and stroke prevention in AF have been demonstrated in large randomised control trials, with similar findings reflected in subsequent real world studies, including the elderly and patients with renal impairment, subpopulations that are particularly at risk of bleeding due to DOACs.[65–68] DOACs offer significant advantages over VKAs, with fixed dosing, and fewer drug and dietary interactions, and they do not require routine laboratory monitoring (Table 100.4). All DOACs have shown a significant reduction in intracranial bleeding rates compared to VKA.

In patients with major bleeding or requiring emergency surgery, PT (for rivaroxaban), and APTT, TT (for dabigatran) can provide useful information on how much drug remains in the patient's circulation and hence contributes to bleeding. While not all laboratory reagents used to measure PT are sensitive to rivaroxaban, a normal PT utilising a rivaroxaban sensitive PT reagent, and a normal APTT, and in particular a normal TT (dabigatran), in this setting would suggest that DOACs are unlikely to be contributing significantly to major bleeding. Drug-specific assays, in the form of modified factor Xa assays for the factor Xa inhibitors, and dilute TT for dabigatran, are now available for DOACs to guide management. As PT and APTT are insensitive to apixaban concentrations,

Table 100.4 Pharmacological properties of new anticoagulants and antiplatelet medications

	DABIGATRAN	RIVAROXABAN	APIXABAN	EDOXABAN	PRASUGREL	TICAGRELOR

ADP, Adenosine 5-diphosphate.

an apixaban specific FXa assay is required to gauge drug levels.

Apart from major bleeding and peri-operative care, drug levels are also recommended in patients with renal impairment, in patients with recurrent thrombotic events and when non-compliance is suspected. Standard coagulation testing and drug levels are less critical in patients with normal renal function presenting with bleeding in whom the last dose of DOAC was at least 12 hours prior, as the majority of the DOAC would have been eliminated.

The key advantage of VKA therapy over DOACs was the availability of reversal strategies with vitamin K and PCCs. That is no longer the case, with idrarucizumab now available to reverse effects of dabigatran, and andexanet under development for FXa inhibitors.

Idrarucizumab is a humanised monoclonal antibody fragment with high affinity for dabigatran. It has no intrinsic procoagulant or anticoagulant activity, and is renally excreted. In a large study, idracuzimab given at two 2.5 g intravenous doses (total dose 5 g) no more than 15 minutes apart resulted in rapid and complete reversal of dabigatran activity as gauged by laboratory testing within minutes, an effect that was sustained for greater than 24 hours in nearly all patients.[69] Patients who received idrarucizumab had either life-threatening bleeding or required emergency surgery/high bleeding risk procedures. There were no major safety concerns of the drug, and a recent update of the study confirmed the safety and rapid efficacy of idrarucizumab. Idrarucizumab would now be first-line treatment in dabigatran-related critical bleeding episodes, with haemodialysis an option if the drug was not readily available. Idrarucizumab should not be used for bleeding episodes that can respond to local haemostatic measures or prior to non-emergent surgery.

Andexanet alfa is a recombinant modified human factor Xa protein, which, while catalytically inactive, binds to and sequesters FXa inhibitors, allowing endogenous factor Xa activity to be restored. It is able to reverse the activity of rivaroxaban, apixaban and enoxaparin, and is in the advanced stages of clinical trial development. Until this drug is available, for life-threatening bleeding or bleeding not responding to general haemostatic and resuscitation measures, pro-haemostatic agents such as PCCs, factor VIII inhibitor bypassing activity (FEIBA) or rFVIIa can be used. Tranexamic acid is a useful adjunctive therapy in this setting, particularly for mucosal bleeding.

The key pharmacological properties of the new anticoagulants and new antiplatelet agents are briefly described in Table 100.4.

VITAMIN K ANTAGONISTS

These agents, including warfarin, induce a functional deficiency of the vitamin-K-dependent clotting factors (II, VII, IX and X), hence causing prolongation of PT/INR. Warfarin reversal is indicated for patients with major bleeding/high risk of bleeding. Rapid reversal is achieved with infusion of PCCs (25–50 U/kg) with concurrent administration of intravenous vitamin K. Four-factor PCCs is now first-line treatment in this setting over FFP.[35,70] FFP may still have a role in countries where only three-factor PCC is available. As with bleeding in the setting of DOACs, cessation of anticoagulant and general haemostatic measures are sufficient in most instances.

Vitamin K does not act immediately, with effects seen usually within 6 hours. It accomplishes sustained

reversal, hence its use as a reversal agent needs to be carefully considered in patients at high risk of thrombotic events; that is, patients with mechanical mitral valves, AF $CHADS_2$ score of 5–6, and recent VTE or stroke (<3 months previously).[71] For most surgical interventions or invasive procedures an INR of 1.5 or less is acceptable. This can usually be achieved by temporarily ceasing warfarin. If oral vitamin K is to be given, the injectable form, which can be given both orally and intravenously, is recommended. Doses of up to 5 mg of vitamin K can reverse the INR prolongation without causing significant warfarin resistance when the drug is resumed.

HEPARINS

Heparins act by potentiating the action of antithrombin, a natural anticoagulant. UFH neutralises both thrombin and FXa, unlike the LMWHs, which predominantly neutralise FXa. The anticoagulant effect of UFH is usually measured by prolongation of the APTT. LMWHs do not prolong the APTT and are generally administered on weight basis and are not routinely monitored by a laboratory test. When monitoring is required, a drug-specific anti-Xa assay can be used.

Similar to over-anticoagulation with VKAs, cessation of heparins may be sufficient if bleeding occurs. If major bleeding has occurred, immediate reversal of UFH activity can be achieved with protamine sulphate. Protamine itself can paradoxically act as an anticoagulant in excess doses. Doses of protamine required to neutralise 80%–100% of estimated circulating UFH (e.g. 1 mg of protamine sulphate will neutralise 100 units of heparin given in the previous 2–3 hours) have been suggested.[70] Bleeding on LMWH is more difficult to manage than UFH, owing to the longer effective half-life; protamine also only partially reverses the LMWH effect (1 mg for each 1 mg enoxaparin in previous 8 hours).

ANTIPLATELET AGENTS

Antiplatelet agents are used widely for the treatment of arterial disease, and many of the non-steroidal anti-inflammatory agents (NSAIDs) are also platelet-inhibitory drugs. Aspirin has an irreversible effect on platelet function and platelet function tests may show abnormalities for up to 10 days after medication. Platelet function is usually restored within 24 hours upon cessation of NSAIDs.

$P2Y_{12}$ antagonists include clopidogrel, and newer agents such as prasugrel and ticagrelor. Prasugrel and ticagrelor have a more rapid onset of action than clopidogrel, with antiplatelet effects within 2–4 hours. These drugs inhibit the binding of ADP to its platelet receptor $P2Y_{12}$, thus suppressing ADP-mediated activation of the GP IIb/IIIa complex.

As with aspirin, platelets exposed to $P2Y_{12}$ antagonists are affected for their lifespan (5–10 days) and recovery of normal platelet function occurs as new platelets are produced. $P2Y_{12}$ antagonists are thought to be more potent than aspirin in antiplatelet effect and hence associated with higher bleeding risk.[72] Prasugrel achieves more predictable antagonism of ADP compared with clopidogrel, at the expense of increased bleeding. The bleeding risk is also high with ticagrelor.[73] The bleeding risk associated with antiplatelet agents has also increased with use of dual antiplatelet therapy of increasing duration, particularly with drug-eluting coronary stents and the risk of late in-stent thrombosis.

Clinicians are now regularly confronted with balancing the haemorrhagic risks associated with these agents against the thrombotic risks associated with their discontinuation, either during major bleeding episodes or prior to surgery. As there is no direct reversal agent, bleeding in the setting of antiplatelet therapy is managed mainly by the cessation of drug and general haemostatic measures. Desmopressin has been shown to correct aspirin-induced platelet dysfunction, although clinical outcome data are limited.[74]

Platelet transfusions are often used in acute life-threatening bleeding or prior to emergency surgery in the setting of antiplatelet therapy. However, timing and dosing remain unclear. Platelet transfusions appear to be more effective in reversing platelet dysfunction attributable to aspirin.[75] Ex-vivo studies have demonstrated that correction of clopidogrel-induced abnormal platelet aggregation responses required a higher proportion of donor platelets than aspirin. Platelet transfusions have been reported to be ineffective in reversing the effects of ticagrelor.[76] Platelet function testing with the methods described previously can guide further management. Continuing aspirin in the peri-operative period of most invasive procedures, neuroaxial anaesthesia and coronary artery bypass surgery is reasonable. If bleeding risk is deemed to be too high, clopidogrel and ticagrelor should be withheld for 5 days, and prasugrel for 7 days prior to major surgery.[71]

Normal platelet function is restored more rapidly upon cessation of GP IIb/IIIa inhibitors, more so with tirofiban and eptifibatide (4–8 hours) than abciximab (1–2 days).[70] Hence withdrawal of these drugs is usually sufficient for most bleeding episodes in the absence of thrombocytopenia. Platelet transfusions are recommended with abciximab-associated thrombocytopenia (platelet count $< 10 \times 10^9$/L).

The lack of clear efficacy of platelet transfusions in major bleeding with concurrent antiplatelet therapy was further highlighted by a landmark randomised open-labelled Phase III study (PATCH trial).[77] It showed that platelet transfusions, rather than benefiting patients, were associated with poorer outcomes in patients with stroke due to spontaneous, non-traumatic intracerebral haemorrhage. The trial concluded that platelet transfusions cannot be recommended in this setting.

ACQUIRED COAGULATION INHIBITORS

Major bleeding can be seen with rare inhibitors of coagulation factors. Autoantibodies against FVIII (commonest), IX, X, V and VWF have been reported. Bypassing agents, such as rFVIIa, activated PCCs, such as FEIBA and more recently recombinant porcine FVIII, have been shown to be efficacious in arresting bleeding in this setting, particularly high-titre inhibitors.[78] The other main aim of treatment is antibody eradication. Steroids and cyclophosphamide, as well as rituximab, have been used to achieve this aim. In acute emergencies, particularly in patients with high-titre inhibitors in whom bleeding has not responded to bypass agents, plasmapheresis with an immunoadsorption column can be used.

SUMMARY

While bleeding is complex and often multifactorial in critical care settings, there has been an appreciable advancement in diagnosis and management in the causes of haemostatic failure, both congenital and acquired. Trauma and massive transfusion management strategies are increasingly guided by TEG as part of a goal-directed approach. The increased understanding of pathogenesis of TMAs has resulted in more accurate classification of specific disease subtypes, and emergence of targeted therapies (i.e. eculizumab) for aHUS. Targeted therapies are also often available for congenital bleeding disorders, which are rare but can present for the first time after major surgery or trauma. There are now drug-specific assays for the DOACs, with effective reversal agents now available for dabigatran and emerging for factor Xa inhibitors. Less advances have been made in the management of bleeding in the setting of anti-platelet therapy, with a lack of clear benefits derived from platelet transfusions and no specific reversal agent.

Haematological malignancy

Pascale Gruber, Timothy Wigmore

INTRODUCTION

Haematological malignancies are tumours that involve the bone marrow, blood and lymphoid tissue. They account for 9% of all cancers.[1] Patients with haematological malignancies account for 1.5% of intensive care unit (ICU) admissions.[2]

CLASSIFICATION OF HAEMATOLOGICAL MALIGNANCIES

Traditional descriptive epidemiology divides haematological malignancies into four broad categories: leukaemias, Hodgkin lymphomas, non-Hodgkin lymphomas (NHL) and myelomas, with national and international organisations publishing data in this format.[3–5] The World Health Organization (WHO) subdivides haematological malignancies according to morphology, immunophenotype, and genetic and clinical features.[6–8]

LEUKAEMIA

Over 350,000 people are diagnosed with leukaemia each year worldwide.[3] Presenting features include fatigue, lymphadenopathy, hepatosplenomegaly and general symptoms of bone marrow failure, such as anaemia, bleeding and decreased resistance to infection. The diagnosis of leukaemia is based on peripheral blood and bone marrow demonstrating blast cells, immunophenotyping, cytogenetic and molecular genetic analysis. The severity of disease, the rate of progression and the treatment vary between leukaemias, so precise identification of the specific form of leukaemia is crucial to optimum management.

ACUTE MYELOID LEUKAEMIA

Acute myeloid leukaemia (AML) is characterised by uncontrolled proliferation of immature myeloid precursor cells. The WHO classifies AML into subtypes:

- *AML with characteristic genetic abnormalities:* patients with this subtype have characteristic genetic abnormalities, high rates of remission and generally a good overall prognosis. This category includes patients with translocations t(8:21), inv (16), t(16:16) and acute promyelocytic leukaemias t(15:17). Acute promyelocytic leukaemias (APML), respond well to *all*-trans-retinoic acid (ATRA).[9] In APML the promyelocytes have a classic morphology with dense cytoplasmic granules and Auer rods. The promyelocytes release thromboplastins which results in disseminated intravascular coagulation (DIC).[10]
- *AML with multi-lineage dysplasia:* patients' are often elderly with myelodysplastic syndromes (MDS) and myeloproliferative disease that progress on to developing AML. These patients tend to have a poor overall prognosis.
- *Acute leukaemias of ambiguous lineage:* this is a category of acute leukaemias where both myeloid and lymphoid cells are present or where the blast population does not allow classification in myeloid or lymphoid categories.
- *Therapy-related AML and MDS:* this is a category of patients who have received chemotherapy and/or radiotherapy who then go on to develop AML or MDS.
- *AML not categorised:* includes subtypes of AML that do not fall into the above categories.

ACUTE LYMPHOBLASTIC LEUKAEMIA

Acute lymphoblastic leukaemia (ALL) is a malignant disorder of lymphoid precursor cells, commonly seen in childhood, with a good overall prognosis. ALL induction chemotherapy typically consists of a four- or five-drug regime of prednisolone, vincristine, anthracycline, *L*-asparginase and/or cyclophosphamide.[11,12] Patients with ALL frequently have central nervous system (CNS) involvement, therefore intrathecal chemotherapy or cranio-spinal irradiation is additionally required. Remission is consolidated with further chemotherapy or haematopoietic stem cell transplant (HCT).[10] Prolonged maintenance therapy is often required to eradicate any residual leukaemic cells. A combination of daily methotrexate and 6-mercaptopurine constitutes the basis of most maintenance regimes. Five-year survival is 85%–90% for children and is less in adults.[13]

ABSTRACT

Outcomes for patients with haematological malignancies admitted to the critical care unit have improved over the last decade. This is attributable to improvements in cancer therapy with the use of less cytotoxic chemotherapy; reduced intensity conditioning regimes in patients who are elderly, have co-morbidities or are undergoing repeated transplant; more targeted therapies with the advent of precision medicine; and novel immunotherapies. In addition, advances in intensive care unit (ICU) care, the use of antimicrobial prophylaxis, improved patient selection, closer collaborative working between haematologists and intensivists, and a better understanding of the pharmacokinetics of chemotherapeutic agents in the presence of organ failure have all contributed to improvements in ICU and hospital outcome. However, a number of therapies still require evaluation, such as the impact of newer non-invasive diagnostic and therapeutic techniques, high-flow oxygen therapy, transfusion thresholds, chimeric antigen receptor T-cell therapy and further data on long-term outcomes.

KEYWORDS

Leukaemia
lymphoma
haematopoietic stem cell transplant

CHRONIC LYMPHOCYTIC LEUKAEMIA

Chronic lymphocytic leukaemia (CLL) may be classified as a form of leukaemia or low-grade lymphoma. It is most commonly found in elderly people. Clinical presentation includes fatigue, bone marrow failure, night sweats, lymphadenopathy, painful splenomegaly and autoimmune haemolytic anaemia. The natural history of CLL is variable with a median survival of 8–12 years.[10] Richter's transformation to diffuse large B cell lymphoma (DLBCL) is associated with a poor prognosis (median survival <1 year).[14] First-line treatment is fludarabine, cyclophosphamide and/or rituximab (monoclonal anti-CD20 agent).[15] Alemtuzumab (monoclonal anti-CD52 agent) is useful in refractory CLL.[16]

CHRONIC MYELOID LEUKAEMIA

Chronic myeloid leukaemia (CML) is linked to a translocation of on chromosome 22 and 9 (Philadelphia chromosome) leading to formation of BCR-ABL (a tyrosine protein kinase) causing uncontrolled proliferation in mature and immature white cells.[17] CML typically begins in the *chronic phase*, over several years progresses to an *accelerated phase* and eventually results in *blast crisis*. Patients present with weight loss, splenomegaly, fevers and night sweats. Imatinib (tyrosine kinase inhibitor), results in complete remission in approximately 80% of patients avoiding the need for HCT that was previously the only curative option for CML.[18]

LYMPHOMA

Lymphomas are tumours of B, T or NK lymphoid cells. Worldwide, over 420,000 people are diagnosed with lymphoma each year.[3] Traditionally, lymphomas are divided into Hodgkin lymphomas and NHL. Lymphomas are staged 1–4 according to lymph node spread and are designated A or B depending on the absence or presence of 'B' symptoms – night sweats, fever and weight loss.

HODGKIN LYMPHOMA

Hodgkin lymphoma is common in young people aged between 20 and 30 years. Classic presentation is of cervical lymphadenopathy, fever, night sweats, weight loss and pruritus. Reed-Sternberg cells are characteristic on histology. Choice of combination chemotherapy for Hodgkin lymphoma depends on the patients' age, sex, tumour size and the histological subtype. Radiotherapy may be given for localised or bulky disease.[19] Combination chemotherapy with or without radiotherapy is curative in 75% of newly diagnosed patients with Hodgkin disease.[10]

NON-HODGKIN LYMPHOMAS

NHL is a heterogeneous group of conditions with over 30 subtypes. NHLs are broadly divided into high and low grade. High-grade lymphomas tend to be aggressive but chemo-sensitive, whereas low-grade lymphomas are typically slow growing, indolent and incurable.[10]

Low-grade lymphomas

Low-grade lymphomas encompass follicular lymphoma (most common), mantle cell lymphoma, marginal zone lymphomas and Waldenstrom macroglobinaemia. Clinical presentation, rate of disease progression and treatment modalities vary widely. The disease may continue for years and treatment is not always indicated.

High-grade lymphomas

The most common high-grade lymphoma is DLBCL, accounting for about 30% of new cases of NHL. It typically affects elderly or middle-aged adults. First-line treatment of early-stage DLBCL includes CHOP chemotherapy (cyclophosphamide, doxorubicin, vincristine and prednisolone) with or without involved field radiotherapy.[20] Early-stage DLBCL is potentially curable with a 5-year survival of 70%–80%.[21] The anti-CD20 antibody, rituximab, has radically changed the prognosis in patients with NHL.[22] Burkitt lymphoma produces fast-growing tumours. There are three distinct variants of Burkitt lymphoma: (1) endemic (African), (2) sporadic and (3) immunodeficiency-associated. These forms differ in their clinical presentation and epidemiology but share the same aggressive nature. Childhood Burkitt lymphoma is highly responsive to combination chemotherapy with a 5-year survival greater than 90%. The risk of tumour lysis syndrome with Burkitt lymphoma is high.[23]

MULTIPLE MYELOMA

Multiple myeloma is a plasma cell malignancy that accounts for 10% of all haematological malignancies.[3] Patients present with bone pain, fractures and bone marrow failure with associated cytopenias. Renal failure is common due to light chain deposition in renal tubules, amyloidosis and hypercalcaemia from bone destruction. Multiple myeloma is not curable, but chemotherapy induces temporary remission. Typically, patients experience repeated episodes of relapse, treatment and remission over several years until the disease can no longer be controlled. Overall 5-year survival for multiple myeloma is around 35%. High-dose chemotherapy with HCT is increasingly being used as it reduces symptoms and increases survival.[24]

TREATMENT OF HAEMATOLOGICAL MALIGNANCIES

Haematological malignancies are treated using chemotherapy, radiotherapy or a combination of both with

the intent of inducing remission or cure. Recently there has been increased interest in the use of chimeric antigen receptor (CAR) T-cell therapy but it is associated with important toxicities.[25] HCT offers the only hope of cure in some conditions, but it is not without risks.

CHEMOTHERAPY

Chemotherapeutic agents, either individually or in combination, are used to induce cure or remission. Recent advances in the understanding of haematological cancers have led to an increase in the variety of chemotherapeutic agents and targeted therapies now available. Those commonly used for treatment of haematological malignancies are outlined in Table 101.1. The goal of *induction therapy* is to achieve remission by reducing the number of leukaemic cells to an undetectable level; the goal of *consolidation therapy* is to eliminate any residual undetectable disease and achieve cure. *Maintenance therapy* is used in ALL and APML to prolong remission. Chemotherapy may also be used as part of a conditioning regimen with or without total body irradiation (TBI) prior to HCT. Administration of some chemotherapeutic agents may result in life-threatening side effects.

IFOSFAMIDE NEUROTOXICITY

Ifosfamide is used in the treatment of lymphomas. It causes reversible neuropsychiatric disorders in 10%–30% of patients including visual or auditory hallucinations, confusion, personality disorders, anxiety, extra-pyramidal symptoms, seizures and coma. Symptoms occur from 2 to 48 hours after infusion, and improve 48 hours after discontinuation of the drug. Risk factors include serum albumin less than 35 mg/dL, hyponatraemia, elevated serum creatinine, previous cisplatin use and bulky abdominal disease. Treatment involves normalisation of serum electrolytes and albumin, benzodiazepines (for seizures) and methylene blue.

RETINOIC ACID SYNDROME

Patients with APML treated with ATRA are at risk of retinoic acid syndrome. Symptoms usually begin within the first 30 days of ATRA therapy and include respiratory failure, fever, weight gain, peripheral oedema, shock, acute kidney injury, cardiac failure, and pericardial and pleural effusions. The condition is potentially life threatening. Management is largely supportive and the discontinuation of ATRA is recommended.[9] There is anecdotal evidence that administration of steroids is beneficial.

IMMUNOTHERAPY

Immunotherapy, particularly with engineered T-cells (specifically CAR T-cells) is showing promising results in a variety of haematological tumours and is likely to become a mainstay of treatment. However, administration is associated with toxicities: anaphylaxis, on target/off tumour effects (such as B-cell aplasia), neurological toxicities (confusion, delirium and seizures) and cytokine release syndrome (CRS). Up to 30% of patients receiving CAR T-cell infusions experience a severe CRS with consequent multiorgan failure. This starts within hours of infusion commencement and may last for several days. Vasopressor support is usually required; invasive ventilation and renal replacement therapy may also be necessary.[25] Other patients experience mild to moderate degrees of CRS and the frequency and potential severity of response mandate administration in an environment with critical care support.

RADIOTHERAPY

Radiotherapy can be used alone or in combination with chemotherapy for lymphoma and myeloma. TBI may be instituted as part of the myeloablative regime in HCT. Side effects include gastrointestinal dysfunction, mucositis, pneumonitis, alopecia and skin irritation (Table 101.1).

HAEMATOPOIETIC STEM CELL TRANSPLANTATION

HCT is potentially curative and has now become the standard treatment for many haematological malignancies. Approximately 50,000–60,000 transplants are carried out per year.[26] ICU admission rates range from 15% to 20% with higher rates reported after allogeneic transplant.[27–29] Prior to HCT, patients must undergo myeloablative conditioning to destroy endogenous bone marrow cells. Typical myeloablative regimes include a combination of busulfan, cyclophosphamide and TBI. Reduced intensity conditioning regimes such as fludarabine and low-dose TBI are reserved for patients who are older, have multiple co-morbidities or have undergone previous transplant. They are less toxic to the bone marrow but are sufficiently immunosuppressive to permit the engraftment of donor cells.

HCT are divided according to the source of the stem cells (peripheral, bone marrow or umbilical cord) and the donor of the cells (autologous or allogeneic). Autologous transplant involves re-infusing harvested peripheral blood taken from the patient during periods of remission. With autologous transplant, patients risk the possibility of re-infusion of their own tumour cells and future disease relapse; however, treatment-related mortality is less than 5%.[30] Allogeneic transplants involve the infusion of donor stem cells (sibling or mixed unrelated donor). Immunosuppression is required to reduce the risk of graft-versus-host disease (GvHD) and graft failure. Treatment-related mortality for allogeneic transplant is much higher due to the

Table 101.1 Common chemotherapeutic agents used in haematological malignancies

CATEGORY	MODE OF ACTION	CHEMOTHERAPEUTIC AGENTS	SIDE EFFECTS
Alkylating agents	Cells directly damage DNA by forming covalent bonds	a. *Alkyl sulfonates* Busulfan	Pulmonary fibrosis Seizures Thromboembolism
		b. *Mustard gas derivatives* Chlorambucil Cyclophosphamide Ifosfamide Melphalan	Haemorrhagic cystitis Neurotoxicity Myelosuppression GI disturbance Hepatotoxicity
		c. *Triazines* Dacarbazine Procarbazine	Myelosuppression GI disturbance
Anti-metabolites	Interferes with DNA and RNA growth by acting as inhibitors of enzymes processing purine and pyrimidines	a. *Folic acid antagonist* Methotrexate	Pneumonitis Myelosuppression Hepatotoxicity
		b. *Purine antagonist* 6-mercaptopurine	Myelosuppression GI disturbance
		c. *Pyrimidine antagonist* Capecitabine Cytarabine Gemcitabine	Myelosuppression Pneumonitis Cardiac arrhythmias GI disturbance
		d. *Adenosine deaminase inhibitor* Fludarabine	Myelosuppression Autoimmune haemolytic anaemia
Antitumour antibiotics	Interfere with enzymes necessary for DNA replication	a. *Anthracyclines* Doxorubicin Daunorubicin	Cardiomyopathy
		b. *Miscellaneous* Bleomycin	Pulmonary fibrosis
Plant alkaloids	Inhibit mitosis by interfering with the assembly of microtubule structure	*Vinca alkaloids* Vinblastine Vincristine	Peripheral neuropathy Hyponatraemia Myelosuppression
Topoisomerase II inhibitors	Interferes with enzymes involved in regulating DNA coiling	Etoposide	Myelosuppression GI disturbance Rash
Tyrosine kinase inhibitors	Binds to the site of tyrosine kinase activity, preventing its activity and causing tumour cell apoptosis	Imatinib	Cardiac failure Pneumonitis Rash Fluid retention
Miscellaneous	Ribonucleotide reductase inhibitor	Hydroxyurea	Myelosuppression Hepatotoxic Nephrotoxic Mucositis
	Binds to retinoic acid receptors involved in cellular growth, proliferation and differentiation	All-trans retinoic acid (ATRA)	Retinoic acid syndrome Headache Hypertriglyceridaemia
	Depletion of cellular asparagine	Asparaginase	Pancreatitis Thromboembolism Myelosuppression

Table 101.1 Common chemotherapeutic agents used in haematological malignancies—cont'd

CATEGORY	MODE OF ACTION	CHEMOTHERAPEUTIC AGENTS	SIDE EFFECTS
Immunotherapy	Monoclonal antibodies to CD20	Rituximab	Fever Muscle and joint pain Cardiotoxicity Hepatotoxicity Nephrotoxicity
	Monoclonal antibodies to CD52	Alemtuzumab	
	Non-specific immunotherapy	Interferon alpha	
	Immunomodulatory agents	Thalidomide Lenalidomide	Thromboembolism Peripheral neuropathy Thrombocytopenia

NOMENCLATURE OF COMMONLY USED COMBINATION CHEMOTHERAPEUTIC REGIMES

CHEMOTHERAPY		HAEMATOLOGICAL MALIGNANCY
FCR	Fludarabine + Cyclophosphamide + Rituximab	CLL
ABVD	Doxorubicin + Bleomycin + Vinblastine + Dacarbazine	HL
BEACOPP	Bleomycin + Etoposide + Doxorubicin + Cyclophosphamide + Vincristine + Procarbazine + Prednisone	HL
R-CVP	Rituximab + Cyclophosphamide + Vincristine + Prednisone	NHL
R-CHOP	Rituximab + Cyclophosphamide + Doxorubicin + Vincristine + Prednisone	NHL
R-FCM	Rituximab + Fludarabine + Cyclophosphamide + Mitoxantrone	NHL
ProMACE–CytaBOM	Prednisone + Doxorubicin (Adriamycin) + Cyclophosphamide + Etoposide – Cytarabine + Bleomycin + Vincristine (Oncovin) + Methotrexate + Leucovorin	NHL
m-BACOD	Methotrexate + Leucovorin + Bleomycin + Doxorubicin (Adriamycin) + Cyclophosphamide + Vincristine (Oncovin) + Dexamethasone	NHL
MACOP-B	Methotrexate + Leucovorin + Doxorubicin (Adriamycin) + Cyclophosphamide + Vincristine (Oncovin) + Prednisone + Bleomycin	NHL
VAD	Vincristine + Doxorubicin (Adriamycin) + Dexamethasone	Multiple myeloma

Note that the above table highlights only some of the commonly used regimes.

CLL, Chronic lymphocytic leukaemia; *GI*, gastrointestinal; *HL*, Hodgkin lymphoma; *NHL*, Non-Hodgkin lymphoma.

intensive myeloablative regimens and immunosuppression required.[31]

COMPLICATIONS OF HAEMATOPOIETIC STEM CELL TRANSPLANTATION

Infection

Following HCT, the immune system takes several weeks to recover. The rapidity of recovery is dependent on the type of transplant, the source of the stem cells, the age of the recipient and donor, the myeloablative regimen, the presence of GvHD and the degree of immunosuppression.[32] Most ICU admissions are during the pre-engraftment phase. The period of engraftment is divided into three phases[33]:

1. *Pre-engraftment (<30 days)*. Recipients are neutropenic and susceptible to bacterial infections. The use of novel broad-spectrum antibiotics with excellent Gram-negative coverage has resulted in Gram-positive organisms (*Staphylococcus* spp., *Streptococcus*, *Enterococcus*) being largely responsible for bacteraemias following HCT.
2. *Early post-engraftment* (30–100 days). Cell-mediated immunity is impaired and the recipient is at risk of viral and fungal infections, such as cytomegalovirus (CMV), *Pneumocystis jirovecii* and *Aspergillus* spp.
3. *Late post-engraftment (>100 days)*. Impaired reticuloendothelial, cell-mediated and humoral functions increase recipients' risks of mycobacterial and viral infections.

Historically, CMV infection was a major cause of morbidity and mortality after HCT.[34] CMV antigen surveillance and the use of prophylactic ganciclovir in HCT recipients who are CMV-positive or have received transplants from CMV donors have led to a decrease in the number of CMV infections.[33] Similarly, *P. jirovecii*

Table 101.2 Clinical staging of acute graft-versus-host disease

STAGE	SKIN RASH	LIVER (BILIRUBIN MICROMOL PER LITRE)	GASTROINTESTINAL TRACT (DIARRHOEA IN LITRES PER DAY)
1	Maculopapular rash <25% of BSA	35–50	0.5–1
2	Maculopapular rash 25–50% of BSA	51–102	1–1.5
3	Maculopapular rash >50% of BSA	102–225	>1.5
4	Generalised erythroderma with bullae	>225	Severe abdominal pain with or without ileus

BSA, Body surface area.

Table 101.3 Grading of acute graft-versus-host disease

GRADE	CLINICAL MANIFESTATIONS
I	Stage 1–2 skin, no gut or liver involvement
II	Stage 3 skin, stage 1 gut or stage 1 liver
III	Stage 3 skin, stage 2–4 gut or stage 2–3 liver
IV	Stage 4 skin, stage 4 gut or liver

pneumonia is less common nowadays with the effective use of trimethoprim-sulphamethoxazole or pentamidine prophylaxis. Fungal infections still continue to be problematic with *Aspergillus* spp. and *Candida* spp. predominating. The routine use of azole prophylaxis has reduced the number of *Candida albican* infections but has resulted in the emergence of azole resistant *Candida* species.

Graft-versus-host disease

GvHD occurs when the donor marrow recognises the host tissue as foreign and generates an immune response. The incidence of GvHD is 30%–50% in the post-allogeneic transplant recipient and increases with HLA mismatch, advanced age of the donor and recipient, inadequate immunosuppression and the use of peripheral blood as the stem cell source. Steroids, cyclosporin and/or mycophenolate mofetil are used in the prophylaxis of GvHD. Acute GVHD classically presents 7–28 days post-transplant with a maculopapular skin rash, diarrhoea and/or intrahepatic cholestasis. Acute GvHD is staged and graded according to the number and extent of organ involvement (Tables 101.2 and 101.3).[35]

The diagnosis of acute GvHD is typically confirmed with a skin, rectal or liver biopsy. Treatment of severe acute GvHD involves high-dose pulsed methylprednisolone and/or additional immunosuppressive agents. Gastrointestinal involvement with secretory diarrhoea often necessitates the need for parenteral nutrition and octreotide. The degree of acute GvHD has shown to be predictive of 100-day survival.[36] Chronic GvHD is a multiorgan dysfunction syndrome usually occurring more than 100 days post-transplant. It can be limited or extensive with skin (itchy dry skin, scleroderma), pulmonary (bronchiolitis obliterans), ophthalmic (sicca, keratitis), salivary glands (xerostomia) and neuromuscular (polyneuropathy, polymyositis, myasthenia gravis) involvement, and liver dysfunction (hepatitis, cirrhosis). Treatment is difficult and progression can be limited by increasing the dose of immunosuppression (with a consequent risk of infection).

Graft failure

Graft failure occurs when there is a failure to establish haematological engraftment after HCT. It occurs in less than 5% of patients following allogeneic HCT. Causes of graft failure include inadequate stem cell infusion, infection and GvHD. Graft failure is associated with an increased risk of infection and transplant-related mortality. Management consists of augmentation by granulocyte-colony stimulating factor (G-CSF), stem cell re-infusion or a second HCT.

Diffuse alveolar haemorrhage

Diffuse alveolar haemorrhage (DAH) occurs in 5% of HCT patients. It occurs within 30 days of transplant and is caused by injury to the pulmonary endothelial lining from chemo- and radiotherapy. Age, acute GvHD, intensive myeloablative regimes, TBI and allogeneic transplant are risk factors. Patients typically present with pyrexia, dyspnoea, cough, anaemia and diffuse infiltrates on chest radiographs in the absence of infection. Haemoptysis is rare. Bronchoalveolar lavage (BAL) is bloody, and cytology shows haemosiderin-laden macrophages. Treatment is with high-dose steroids and the response is variable.

Idiopathic pneumonia syndrome

The incidence of idiopathic pneumonia syndrome (IPS) is approximately 7% and it is commonly seen 3 weeks after HCT. Typical presentation is of diffuse infiltrates on chest radiography or computed tomography (CT) scan in the absence of an infective aetiology. Risk factors include allogeneic transplant, GvHD and CMV-positive donor status, pre-transplant radiation, and chemotherapy (busulfan, cyclophosphamide). Treatment is mainly supportive and the mortality is over 70%.

Engraftment syndrome

Engraftment syndrome (also known as capillary leak syndrome) typically presents 4–5 days after autologous HCT with fever, erythematous rash and non-cardiogenic pulmonary oedema. Other features include abnormal liver function tests, transient encephalopathy and multiorgan failure. The underlying pathophysiology is related to the release of pro-inflammatory cytokines and neutrophils. The use of G-CSF increases the prevalence of this syndrome and should it occur, G-CSF should be discontinued immediately. The chest CT scan typically demonstrates bilateral ground-glass opacification. Management is supportive and steroids may be useful.

Veno-occlusive disease

Veno-occlusive disease (VOD) – also known as sinusoidal obstruction syndrome – presents as a triad of painful hepatomegaly, jaundice and ascites 3 weeks following HCT. Other features include weight gain, encephalopathy, bleeding and hepato-renal syndrome. The disease spectrum ranges from a mild, reversible condition to multiorgan failure. Risk factors include myeloablative conditioning regimes (busulfan, cyclophosphamide), pre-existing abnormal liver function tests, intra-abdominal radiotherapy and repeated HCT. The diagnosis is made by hepatic Dopplers showing reversed or reduced portal flow. A transjugular liver biopsy may also help establish the diagnosis. Management and prophylaxis in high-risk patients involves the use of defibrotide, a polydeoxyribonucleotide with antithrombotic, anti-inflammatory and fibrinolytic effects.[37] Severe VOD has a mortality of 85%.

Posterior reversible encephalopathy syndrome

Posterior reversible encephalopathy syndrome is a syndrome characterised by confusion, headache, visual loss and seizures commonly associated with HCT and immunosuppressive agents (e.g. ciclosporin). T2-weighted magnetic resonance imaging characteristically shows diffuse hyper-intensity involving the parieto-occipital white matter. Treatment is targeted at the underlying cause (Fig. 101.1).

Post-transplant lymphoproliferative disorder

Post-transplant lymphoproliferative disorder is a well-recognised but infrequent complication of allogeneic transplant. It is characterised by uncontrolled proliferation of Epstein-Barr virus (EBV)-infected B cells and results in the impairment of T-cell immunity. Risks include previous EBV donor or recipient exposure, aggressive immunosuppression and T-cell depleted transplants. EBV viral load should be monitored regularly. Treatment involves a gradual withdrawal of immunosuppression with the potential risk of GvHD. Intravenous immunoglobulins, anti-B cell monoclonal antibodies, rituximab and infusion of donor T-cells have all been used with variable success.

Figure 101.1 Magnetic resonance imaging scan of the brain (T2 with flair) shows high signal bilaterally involving the occipital lobes in keeping with posterior reversible encephalopathy syndrome.

Thrombotic thrombocytopenic purpura

Secondary thrombotic thrombocytopenic purpura (TTP) following HCT is due to endothelial damage from chemotherapy. The classic presentation is of renal failure, fever, thrombocytopenia, fluctuating neurological signs (confusion, mood changes, seizures and drowsiness) and microangiopathic haemolytic anaemia. The blood film typically shows red cell fragments and the haemolysis screen is positive. Treatment is supportive and involves plasmapheresis, broad-spectrum antibiotics and high dose steroids. Haemolytic uraemic syndrome is a similar entity and may be distinguished from TTP by the lack of neurological signs and fever.

PATIENTS WITH HAEMATOLOGICAL MALIGNANCY ON THE INTENSIVE CARE UNIT

Patients with haematological malignancies develop critical illness either due to their underlying cancer or cancer-related treatments such as chemotherapy, radiotherapy or HCT. Outlined below are some common reasons for ICU admission.

ACUTE ONCOLOGICAL EMERGENCIES

A small number of patients are admitted directly to ICU with complications of their haematological malignancy requiring urgent chemotherapy and/or radiotherapy. These include:

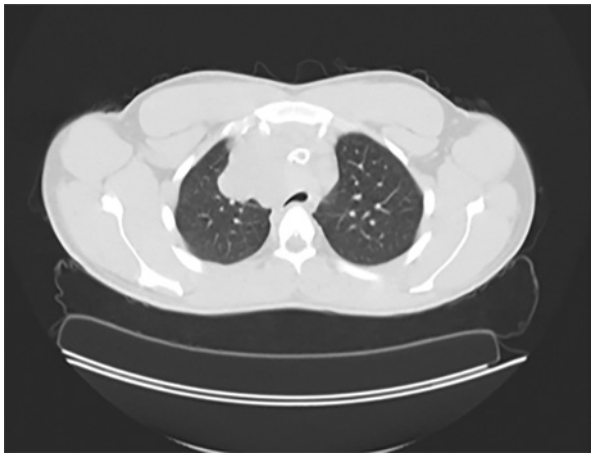

Figure 101.2 Computed tomography scan of the chest showing bulky infiltrative mass (non-Hodgkin lymphomas) extending from the anterior mediastinum to the right paratracheal space with tracheal compression.

1. *CNS involvement.* CNS involvement resulting in focal deficits, seizures, alteration of consciousness or high spinal cord compression is an indication for urgent chemotherapy and/or radiotherapy.
2. *Mediastinal masses and pericardial disease.* Bulky mediastinal masses with compression of trachea, main bronchi or major vessels are often due to NHLs and require urgent chemotherapy and/or radiotherapy to relieve the compression (Fig. 101.2).
3. *DIC.* DIC may be a presenting feature of APML. Specific chemotherapy, such as ATRA and supportive measures, is required.
4. *Hyperviscosity syndromes.* Hyperviscosity syndromes occur with multiple myeloma, leukaemia and Waldenstrom macroglobinaemia. Clinical manifestations include headaches, coma, seizures, visual impairment, retinal haemorrhages, and bleeding. Emergency management is directed at decreasing blood viscosity by plasmapheresis followed by urgent chemotherapy aimed at reducing monoclonal immunoglobulins.
5. *Macrophage activation syndrome (MAS).* MAS, also known as haemophagocytic lymphohistiocytosis, is a recognised presentation of NHL and Hodgkin lymphoma. Typical manifestations of MAS are fever, splenomegaly and at least two cytopenias (anaemia, thrombocytopenia, neutropenia). Shock, acute respiratory distress syndrome and acute kidney injury may also occur. Laboratory findings also include hypoalbuminaemia, hypertriglyceridaemia, hypofibrinogenaemia, hyperferritinaemia (>500 μg/L). Bone marrow findings show activated macrophages phagocytosing platelets, erythrocytes and leukocytes. Steroids and etoposide are the mainstays of treatment.
6. *Hyperleukocytic acute myeloid leukaemia.* Hyperleukocytosis is defined as a total leukocyte count of >100 $\times 10^9$/L. It is typically seen in patients with AML in blast crisis. White cell plugs in the vasculature cause decreased tissue perfusion and result in neurological dysfunction, ischaemia, coagulopathy and respiratory failure.[38] Leukostasis is associated with a high mortality and prompt treatment with chemotherapy and leukapheresis is indicated. Preliminary cytoreduction with hydroxycarbamide or cytarabine before the initiation of intensive chemotherapy is now recommended to prevent uncontrolled tumour lysis syndrome.

In some circumstances, starting chemotherapy in the ICU, even when infection or organ failure is present, may be appropriate to limit disease progression that results in death. Modification chemotherapeutic regimens may be required to limit organ toxicity and the duration of neutropenia. In carefully selected cases of patients given chemotherapy in the ICU, published outcomes have been reasonable with an ICU mortality of 25%–40%.[39,40] The improved outcomes have been attributed to better patient selection, more experience in the administration of chemotherapy in the ICU setting, a greater understanding of optimal chemotherapy dosing in patients with organ failure and better supportive care.[41] In fact, the administration of chemotherapy, in the ICU setting or within the last 3 weeks prior to ICU admission, does not appear to be associated with an increased risk of death.[42]

NEUTROPENIA AND NEUTROPENIC SEPSIS

Neutropenia is defined as an absolute neutrophil count (ANC) of $<1.5 \times 10^9$/L. Severe neutropenia is defined as an ANC $<0.5 \times 10^9$/L. Fever is common in patients with haematological malignancies and differentiating infectious from non-infectious causes of fever is notoriously difficult. Assessment relies on the early identification of a likely source, microbiological surveillance and surrogate information from biomarkers. Severe sepsis and septic shock in patients with haematological malignancies has a reported mortality of 36%–45%.[43,44] High-risk patients are those with significant co-morbidities and prolonged (>7 days) and severe neutropenia. Neutropenic sepsis is potentially fatal if left untreated.[45] Patients with neutropenic sepsis must have antibiotics administered within 1 hour of presentation. A minimum of two sets of blood cultures should be collected from peripheral veins and each lumen of existing central venous catheters. A chest radiograph and culture specimens from sites of suspected infection (sputum, stool, urine) should also be taken. First-line antibiotic treatment is with an anti-pseudomonal β-lactam agent, such as cefepime, a carbapenem (meropenem or imipenem-cilastatin) or piperacillin-tazobactam. Aminoglycosides, fluoroquinolones and/or vancomycin should be added

to the initial regimen in the event of septic shock or if antibiotic resistance is suspected.[46] Vancomycin (or another agent active against Gram-positive cocci) also should be added if there is a suspected catheter-related infection, soft-tissue infection or pneumonia. In ICUs where there is a high incidence of multiresistant organisms, it may be necessary to use a second-line Gram-positive agent such as linezolid. Empirical antifungal therapy should be considered for patients with persistent or recurrent fever. The need for antiviral agents or trimethoprim-sulfamethoxazole should be evaluated.

G-CSF is often used to promote neutrophil recovery in patients with profound neutropenia. Blood cell counts should be obtained daily, and the G-CSF should be discontinued when the white cell count is $>1.0 \times 10^9$/L or the ANC is $>0.5 \times 10^9$/L. Side effects of G-CSF include rash, injection site reaction, bone pain and flu-like symptoms. Finally, environmental precautions should be taken when managing neutropenic patients with meticulous hand hygiene, full barrier precautions (gloves, gowns, and in some cases overshoes and masks) and protective patient isolation. In the United Kingdom, the National Institute for Clinical Excellence has provided comprehensive guidance on the management of neutropenic sepsis following the National Confidential Enquiry into Patient Outcome and Death report (Systemic Anti-Cancer Therapy: For better, for worse? 2008).[47,48]

NEUTROPENIC ENTEROCOLITIS

Patients typically present with abdominal pain, fever and diarrhoea after chemotherapy (especially cytosine arabinoside, vinca alkaloids and doxorubicin). It is caused by a combination of chemotherapy-induced colonic mucosal wall damage, thrombocytopenia-related gastrointestinal bleeding, and colonisation of the bowel by pathogenic bacteria. Complications include bacteraemia, gastrointestinal bleeding and perforation (5%–10%). Abdominal CT scanning may demonstrate pneumoperitoneum or colonic pneumatosis indicating colonic damage with imminent perforation. Bowel-wall thickening on ultrasound scanning may also help to confirm the diagnosis. Management is conservative with bowel rest, parenteral nutrition and antibiotics that target enteric Gram-negative and anaerobic organisms, including *Clostridium difficile*. Surgery may be required in patients with uncontrolled sepsis, bowel perforation or life-threatening gastrointestinal bleeding.

RESPIRATORY FAILURE

Acute respiratory failure is the primary reason for ICU admission in patients with haematological malignancies. The aetiology is commonly infection, although other non-infectious causes including non-cardiogenic pulmonary oedema, acute respiratory distress syndrome, GvHD, DAH, IPS, chemotherapy (methotrexate, bleomycin, fludarabine, gemcitabine) and tumour infiltration of the lung should be considered (Table 101.4). Reported mortality for patients with haematological malignancies who require mechanical ventilation has improved over the last decade, but mechanical ventilation remains a poor prognostic outcome indicator.[49–51] Lung protective ventilation strategies, early use of non-invasive ventilation and high-flow nasal oxygen therapy have all contributed to improvements in

Table 101.4 Causes of respiratory failure in a patient with haematological malignancy

CAUSES	EXAMPLES	
Non-infectious	General	Acute respiratory distress syndrome Aspiration pneumonia Pulmonary leukaemic infiltration Tumour causing upper or lower airway obstruction Non-cardiogenic pulmonary oedema Chemotherapy-induced pulmonary toxicity Pulmonary interstitial fibrosis
	Specific to HCT	Diffuse alveolar haemorrhage syndrome Idiopathic pneumonia syndrome Engraftment syndrome
Infectious	Bacterial	*Pseudomonas*, *Klebsiella*, *Acinetobacter*, *Staphylococcus*, *Enterococcus*, *Streptococcus*, *Legionella*, *Mycoplasma*
	Viral	Influenza, parainfluenza, adenovirus, respiratory syncytial virus, cytomegalovirus, herpes simplex virus, varicella zoster virus
	Fungal	*Candida* spp., *Aspergillus* spp., *Pneumocystis jirovecii*
	Mycobacteria	*Mycobacterium tuberculosis*

HCT, Haematopoietic stem cell transplant.

outcome.[52,53] Routine lung biopsy is no longer recommended and diagnostic BAL is deemed useful in only a select group of patients with the risk that mechanical ventilation may be precipitated.[54]

ACUTE KIDNEY INJURY

Acute kidney injury may be a result of the underlying cancer (monoclonal light chain deposition in multiple myeloma), tumour lysis syndrome, administration of nephrotoxic agents (amphotericin B, foscarnet, aminoglycosides, methotrexate, platin derivatives, cyclophosphamide, cyclosporin), hepato-renal syndrome from VOD or sepsis. In some cases, renal replacement therapy may be required. Studies have shown that the need for renal replacement therapy is an independent predictor of mortality in patients with haematological malignancy.[55,56]

TUMOUR LYSIS SYNDROME

Tumour lysis syndrome is caused by rapid lysis of tumour cells following chemotherapy leading to the release of excessive quantities of intracellular contents into the systemic circulation. The metabolic disturbance is characterised by hyperkalaemia, hyperphosphataemia, hypocalcaemia and hyperuricaemia, which may lead to acute kidney injury and cardiac arrhythmias. It is commonly associated with the acute leukaemias and high-grade lymphomas (e.g. Burkitt lymphoma). Close monitoring of renal function, potassium, calcium, phosphate and urate levels are required in patients with high tumour burden after starting chemotherapy. Allopurinol or rasburicase (a recombinant urate oxidase enzyme) are used as prophylaxis.[57] Treatment includes aggressive fluid hydration, rasburicase and renal replacement therapy.

NEUROLOGICAL DYSFUNCTION

Neurological dysfunction may have a number of aetiologies including infection (bacterial, viral or fungal), bleeding, tumour infiltration, hyperviscosity syndromes (multiple myeloma, Waldenstrom haemoglobinaemia), cerebral infarcts and cerebral venous thrombosis. Some chemotherapy and immunosuppressive agents (methotrexate, cytarabine, 5-fluorouracil, cyclosporin) may present with CNS toxicity and cerebellar syndromes. High-dose cisplatin can cause encephalopathy and optic nerve damage.

GASTROINTESTINAL AND LIVER DYSFUNCTION

Gastrointestinal and liver dysfunction may be associated with chemotherapy (ciclosporin, methotrexate, platinum derivatives), acute GvHD, infection (CMV, EBV, hepatitis, adenovirus, rotavirus, *C. difficile*), VOD and tumour infiltration.

CARDIAC COMPLICATIONS

Cardiac complications, such as cardiac failure, arrhythmias, pericardial effusion, myocarditis or endocarditis, may be the result of the underlying cancer, chemotherapy (anthracyclines, cyclophosphamide, cisplatin) or infection.

PREDICTORS OF MORTALITY IN PATIENTS WITH HAEMATOLOGICAL CANCER

Several studies have looked at predictors of mortality to help identify those patients with haematological malignancy most likely to benefit from ICU care. Neutropenia, autologous transplant and the underlying haematological diagnosis do not seem to correlate with outcome.[58–60] However, advanced age, mechanical ventilation, vasopressor use, GvHD, elevated serum lactate on admission and allogeneic transplants are associated with poorer outcomes.[2,27,29,49,61] The number and severity of organ failures appear to be key determinants of survival.[62] Acute Physiology and Chronic Health Evaluation II scores and Simplified Acute Physiology Score II scores often underestimate mortality in patients with haematological malignancies.[28,63] Several studies have also shown a case-volume relationship demonstrating better outcomes in centres looking after higher numbers of patients with haematological cancers.[64]

OUTCOMES OF PATIENTS WITH HAEMATOLOGICAL MALIGNANCY ADMITTED TO THE INTENSIVE CARE UNIT

Previous studies have reported that patients with haematological malignancies who require intensive care often face a poor prognosis with in-hospital mortality rates of greater than 80% reported in the mid-1990s.[65] However, more recent reports have demonstrated better survival. The largest case series to date has demonstrated an in-hospital mortality of 59%.[2] This reduction in mortality is attributed to improvements in chemotherapeutic regimes, better patient selection, targeted therapies with less organ toxicity and improved ICU care.[66] A joint approach between intensivists and haematologists in the delivery of patient care, early ICU admission of patients at risk of developing organ failure, and effective triaging of patients who are unlikely to benefit from ICU care are also important contributory factors.[66,67] This trend towards lower mortality provides a strong argument against the traditionally held negative perception of patients with haematological malignancy admitted to the ICU and a trigger for change in the way we manage patients with haematological malignancies on the ICU. New recommendations encourage early ICU admission, cytoreductive therapy in patients with hyperleukocytic AML, combination therapy in patients with septic shock, early catheter withdrawal in patients with septic shock of unknown origin, the use of non-invasive diagnostic and therapeutic strategies, 'ICU trials' for appropriate

patients with clear definition of goals of care and early palliative care involvement in patients where ICU care is unlikely to be beneficial (bedridden patients, frail patients, allogenic HCT patients with uncontrolled GvHD).[68]

QUALITY OF LIFE IN CRITICALLY ILL PATIENTS WITH HAEMATOLOGICAL MALIGNANCIES

There are very few studies looking at long-term outcomes and quality of life in critically ill patients with haematological malignancies. A single-centre study followed up 85 patients with haematological malignancies and demonstrated a decline at 3 months and a slight improvement after 1 year with a failure to return to baseline function pre-ICU admission (based on the Euro-QoL-5D Medical Outcomes Study 36-item Short Form Health Survey).[69] Further studies on long-term outcomes are warranted.

Organ Donation and Transplantation

Organ donation

Stephen J Streat

Transplantation of organs and tissues is established treatment for end-stage organ failure and other conditions.[1,2] Transplant volumes are modestly increasing worldwide because of a number of strategies[3]: live (including altruistic) donors, chains of kidney exchange,[4] donation after circulatory death (DCD), admission of patients to the intensive care unit (ICU) solely for possible organ donation, accepting more organs at a higher risk of failure[1] and from extended category donors, the use of split livers for two recipients[3] and transplanting two kidneys into one recipient.[5] Improving outcomes, despite both increasing recipient co-morbidity and increasing use of organs from extended category and DCD, has led to more patients being offered transplantation. Donation from both live and deceased donors is increasing, but this is slower than the number of potential recipients on waiting lists.

Despite professional condemnation of the practice[6] desperate recipients from wealthy countries continue to take part in 'transplant tourism'[7–9] in poorer countries. Concerns have been expressed about internet-facilitated live donations being potentially vulnerable to commercial exploitation.[10,11] Slow progress continues in alternative approaches to end-stage organ failure, including artificial organs, xenotransplantation and the engineering of organs (and tissues) from stem cells, but no such organ replacement is yet available for clinical use.

The characteristics of deceased donors continue to change, with relative stability in the number of donors after brain death (DBD) in many jurisdictions[12] and ongoing increases in donors after circulatory death (DCD).[13] There are increasingly fewer donors after traumatic brain injury (TBI) and more (often extended-category) donors following (predominantly haemorrhagic) stroke, hypoxic–ischaemic encephalopathy[12] and other non-traumatic conditions. These changes result from better primary prevention of TBI, better treatment of subarachnoid and intracerebral haemorrhage and, in the United States in particular, a lethal epidemic of opioid overdose,[14] together with both changes in ICU admission criteria and end-of-life practice, and more liberal acceptance by transplant services of donors with co-morbidity or potentially reversible organ dysfunction.

Decompressive craniectomy often controls refractory intracranial hypertension[15,16] and thereby reduces the incidence of brain death but has less salutatory effects on long-term functional outcome,[15–17] which may not be acceptable to the patient.

The institution of mechanical ventilatory support in poor-prognosis patients with apparent stroke (to facilitate computed tomography [CT] scanning) has led to more such patients being admitted to ICU 'solely for possible future organ donation', sometimes – but not always – after family agreement to such a course of action. The efficacy of hypothermia,[18] and similar efficacy of targeted temperature management[19] for the amelioration of hypoxic–ischaemic encephalopathy in some populations of patients has led to its use in situations where robust evidence of efficacy is absent (e.g. prolonged asystole after asphyxia). This has contributed to more poor-prognosis patients being admitted to the ICU, including some who later donate organs either through DCD or less often after brain death.

RESPONSIBILITIES OF THE INTENSIVIST

Intensivists are located at the nexus of deceased-donor organ donation in the ICU and almost all are strongly supportive of donation.[20,21] Intensivists must accept, assert and maintain strong leadership and guardianship in deceased-donor organ donation, ensuring that medical, ethical and legal practices are done, and are seen to be done, to the highest standard.[22]

This personal view, shared by some professional societies,[22] is seldom heard in public discourse as advocates for transplant recipients and organ procurement agencies have come to define best practice in deceased-donor organ donation (and its language and metrics) in strictly utilitarian[23] and sometimes insensitive ways. Few intensive care professional societies have independently defined what constitutes best practice in organ donation, but this fact should not facilitate intensivists abrogating their professional responsibility for any aspect of the care of ICU patients and their families. In deceased-donor organ donation this involves the responsibility of caring for the dying patient and their family; identifying the potential for organ donation to occur; determining brain death; liaising with organ

ABSTRACT

Transplantation of organs from both live and deceased donors is increasing, but the number of potential recipients continues to rise. Most of the ongoing increase in deceased donation now comes from donors after circulatory death (DCD). Intensivists are located at the nexus of deceased donation in the intensive care unit and must accept responsibility for leadership and guardianship of it, ensuring that the highest medical, ethical and legal standards are maintained, despite increasingly strident and presumptive societal demands for more donors. Our responsibility includes maintaining expertise in care of the dying patient and their family; identifying of every situation with the potential for donation to occur; determining brain death; liaising with organ donation or procurement agencies; discussing organ donation with the family; maintaining physiological stability and best extracranial organ function until organ retrieval; withdrawing treatment and determining death in DCD; and caring for the family of the deceased irrespective of whether donation took place.

donation or procurement agencies and (if needed) with transplant services; discussing organ donation with the family; maintaining physiological stability and best extracranial organ function until organ retrieval; with drawing treatment and determining death in DCD; and caring for the family of the deceased irrespective of whether organ donation takes place.[22] Intensivists who do not accept these responsibilities should ensure that other colleagues are available to fulfil these roles.

CARE OF THE DYING PATIENT AND THEIR FAMILY

Intensive care staff are familiar with caring for dying patients[24] and their families, including respecting the humanity of the patient, maintaining their dignity and avoiding suffering. These values are made manifest by (inter alia) 'patient comfort care' provided by the nursing staff, continued involvement and attentiveness of the medical staff, good communication with the family and the evident compassion of all ICU staff for the patient and their family.[25]

Patient- and family-centred care requires good communication with the patient (if possible) and the family, within an atmosphere of mutual trust and respect. This is a shared responsibility of the staff and the family but the intensivist should show leadership in establishing rapport during an early meeting (e.g. the morning after admission) with the family of every intensive care patient, particularly for families of patients at high risk of death or disability, where serious issues will be addressed in subsequent meetings as the patient's situation becomes clearer. Family meetings should include an intensivist and nurse, (preferably the 'bedside nurse' looking after the patient), the self-defined family, and if the family wishes, a chaplain, social worker or cultural health worker. The intensivist should accept responsibility for leading the meeting, including being the 'bearer of bad news', and ensure that the nurse is able to be focused on being supportive of the family (while being attentive to whether the intensivist and family appear to share a common understanding). Family meetings should be held in a private room of appropriate size away from the bedside and protected from interruption. The intensivist should convey an accurate account of the sequence of events and the patient's current condition, a realistic prognosis (as far as this is possible) and the immediate treatment plan. Explicit acknowledgment of the shared responsibility of the treating team and the family to act in the best interests of the patient may help in establishing rapport. There must be enough time for family members to speak freely[26] and for their questions to be answered. Before ending the meeting the intensivist should ascertain that the family have expressed all that they want to at this time, that they understand what has been said[25] and agree with the immediate treatment plan. Ensuring that all staff give congruent messages is crucial in maintaining the trust of the family in the treating team. Ideally, one intensivist should speak with the family, but if this is not possible there must be a careful and detailed 'handover' between one intensivist and another about communication with the family. Mutual understanding and trust will help the ICU team and the family work through the most difficult and painful issues, including withdrawal of intensive therapies,[27] and the death of the patient. Discussion of organ donation in the context of such a strong therapeutic relationship becomes (comparatively) straightforward.

Many patients who develop apparent loss of brainstem function do so during a period of active surgical and medical treatment. In these circumstances, formal assessment of brain death should be undertaken after first ensuring that the necessary preconditions for brain death assessment[22] have been met. This includes stopping sedatives, opioids, neuromuscular blockers, hypothermia and other potentially confounding therapies, while maintaining extracranial physiological stability. If preconditions cannot be met for clinical determination of brain death, appropriate imaging showing absent cerebral blood flow should be performed.[22] These actions also preserve the future possibility of organ donation after brain death.

Withdrawal of intensive therapies is common practice in ICUs worldwide.[24,28] Before recommending withdrawal of therapy in the setting of severe brain damage it is essential to establish prognosis to the best possible extent. An unconfounded clinical assessment of central nervous system (CNS) function, imaging (usually CT but increasingly supplemented by magnetic resonance imaging in some conditions; e.g. diffuse axonal injury) and neurophysiology (in particular short-latency somatosensory evoked potentials) all provide important information. During the period of sedative-free CNS assessment, some patients lose apparent brainstem function. If brain death does not occur but devastating brain damage has clearly occurred, those treating the patient (e.g. intensivists, neurosurgeons and others) should achieve a consensus view of prognosis and a recommended treatment plan, which might include withdrawal of intensive treatments (e.g. artificial airway, ventilatory or inotropic support, further neurosurgery). The intensivist should then discuss the prognosis and a recommended plan with the family and facilitate a consensus. Withdrawal of treatment may subsequently occur, either because death is seen to be imminent and inevitable or because the likely survival outcome would not be in accord with the patient's previously expressed wishes or inferred best interests. It is appropriate to withdraw all intensive therapies from such patients, while continuing to provide 'comfort care' to the patient and support to the family.[29] The possibility of future organ donation must not influence the decision to limit or withdraw treatment. Some patients having intensive treatments withdrawn will die within a time frame (e.g. a 'few' hours) that makes DCD a possibility.

Prediction of death after withdrawal of therapy within a time frame that makes DCD possible is necessarily imprecise as some crucial factors (e.g. airway patency after extubation) cannot be prospectively assessed reliably. However, some combination of inadequate airway patency, ventilator-dependence, deep coma and impaired brainstem function[30,31] are strong predictors of earlier death after withdrawal of intensive therapies. Severe cardiopulmonary dysfunction is also predictive but is present in relatively few patients in whom treatment is being withdrawn because of severe brain damage. Organ donation medical specialists with intensive care expertise may assist intensivists in prediction of death within a time frame permitting DCD, and discussion with such professionals is recommended. Where there are no medical reasons why DCD seems not to be potentially feasible, it is appropriate to discuss DCD with the patient's family. However, the possibility of DCD must not be raised by the treating team before the family and the treating team have reached a consensus that treatment will be withdrawn.[22] Increasingly, families of dying patients volunteer that they (or the patient) would wish for organ donation to take place. These views are commonly expressed before the determination of brain death in patients who seem to have lost brainstem function, but can be expressed before then and even prior to a decision that intensive treatments will be withdrawn. The intensivist should sensitively acknowledge these statements and assure the family that this issue will be addressed, without further family prompting, if and when clinical circumstances are appropriate.[22]

IDENTIFICATION OF THE POTENTIAL FOR ORGAN DONATION TO OCCUR

Most ICUs admit ventilated patients with very severe brain damage whose probability of recovery is low, but this practice will identify any (small) sub-group of patients with reversible conditions and then can provide them with the necessary treatment to facilitate their recovery. There are, however, more extreme situations when the chance of acceptable recovery is so remote that neither investigation (CT scanning, usually following intubation and ventilation), active treatment (osmotherapy and emergency surgery) nor admission of the patient to the ICU[32] would usually occur. Some ICUs now routinely admit these patients, either because providing them (and their family) with good end-of-life care in an emergency department is not readily achievable, or solely for the possibility that organ donation might subsequently occur. Some patients have been admitted to the ICU after later deterioration from other wards (e.g. neurology) when possible future organ donation was not considered in the emergency department. 'Routinely' admitting all such patients to the ICU has been called for by some and could probably be expected to increase the number of organs available for transplant,[33] but various ethical, legal and clinical concerns have been raised about such practice.[34–37] Some have suggested that ICU admission should be 'automatic' (i.e. without prior family discussion) for these patients while some intensivists (including this author) admit these patients only with the informed agreement of the family – including an understanding that possible future organ donation is the only reason to admit the patient to the ICU; that organ donation might not be possible; and that the family are prepared to consider organ donation in the near future should clinical circumstances permit it. This is an area within which there is considerable clinical practice variation and no apparent professional consensus on the appropriate extent of transparency in particular.

Organ donation is possible in most situations where brain death has been confirmed or when death occurs very soon after withdrawal of treatment. The rare absolute contraindications to organ donation are when there is an unacceptably high risk of transmission of disease to the recipient (usually because of malignancy or infection), or when the long-term function of all possible donated organs is likely to be unacceptably poor.

Tissue donation (including eyes for corneas and sclera, heart valves and vascular tissue, skin and bone) is also frequently possible in most patients dying in ICUs, including from those who cannot donate organs. Because of the relative benefits and risks to recipients of donated organs and tissues, tissue donation may not be possible in some circumstances where organ donation is acceptable (e.g. low-risk possible food exposure to variant Creutzfeldt-Jakob disease).

Although current haematological or metastatic malignancy remain absolute contraindications to donation, advanced age (e.g. over 80), most treated bacterial sepsis, treated herpes simplex virus encephalitis, positive hepatitis C virus (HCV), hepatitis B virus and even HIV serology, and 'likely cured' malignancies (even some melanoma) are no longer so.[38]

Effective and non-toxic antiviral therapy for HCV has enabled transplantation of organs from HCV-infected donors to HCV-naïve recipients[39] with subsequent curative therapy, despite immunosuppression. Similarly, organs from HIV-positive donors have been transplanted into HIV-positive recipients with acceptable outcomes.[40] Finally, organ-specific relative contraindications to organ donation have reduced as the outcomes of recipients transplanted with donor organs previously considered unacceptable continues to improve. In lung transplantation, for example, some centres accept lungs with severe acute (reversible) dysfunction, and use extra-corporeal membrane oxygenation (ECMO) electively to support the recipient immediately after transplant. As transplant centres have somewhat different acceptance criteria, which themselves continue to change in a more permissive direction, intensivists should discuss possible absolute and organ-specific contraindications to donation

and subsequent transplantation with the appropriate organ donation or procurement agency (who will liaise with transplant services as required) and not decide independently that donation in general or donation of any particular organ is contraindicated on medical grounds. The intensivist should ensure that the information necessary for these decisions is provided.

INFORMATION LIKELY TO BE REQUIRED BY TRANSPLANT TEAMS

- Age, sex, weight, approximate height
- Medical and social history (including co-morbidity, surgery, medication, alcohol, smoking, illicit drug use, tattoos, body piercing, sexual history and allergies)
- Detailed clinical history of fatal illness (including cause of death, history of cardiac arrest, periods of hypotension or hypoxia, evidence of aspiration or sepsis)
- Current clinical status (including physiological parameters and the extent of ventilatory and inotropic support)
- Current investigations (including blood group, arterial blood gases, chest X-ray, electrocardiography, serum urea, creatinine, electrolytes, glucose, bilirubin, transaminases, alkaline phosphatase and γ-glutamyl transpeptidase, prothrombin ratio, activated partial thromboplastin time, haemoglobin, white cell count, platelets and all microbiology results)
- Other investigations may sometimes be required (e.g. echocardiogram, coronary arteriogram, bronchoscopy, additional CT scanning, urinary protein to creatinine ratio, lipase and/or amylase).

In most jurisdictions, an appropriate authority (e.g. a coroner or medical examiner) may legally interdict organ donation under certain circumstances (e.g. homicide) and this issue must also be clarified before donation proceeds. Additional processes may facilitate the agreement of a coroner or medical examiner, including, for example, whole-body CT scanning before organ retrieval, having a forensic pathologist attend the organ retrieval surgery and having the retrieval surgeon provide a detailed record of the organ retrieval surgical findings.

DETERMINATION OF BRAIN DEATH

This is a clinical responsibility of the intensivist and must be carried out according to appropriate codes of practice. Although there are no universal criteria for the determination of brain death, codes of practice around the world are very similar and all require[22,41,42] (at least) these three elements:

1. Establishing the presence of a condition known to produce severe and irreversible structural brain damage
2. Excluding possible confounding factors
3. Determining, by clinical examinations (usually by two independent doctors), that there is profound unresponsive coma and persistent absence of brainstem function.

The clinical examination for the determination of brain death is facilitated by a proforma,[22] which should be included in the medical record. When clinical examination is not possible (e.g. when it is confounded by medications or when brainstem reflexes cannot be examined or, rarely, when testing for apnoea cannot be performed because of very severe respiratory failure), then the absence of cerebral blood flow must instead be demonstrated by reliable imaging.[22] Clinical determination of brain death is possible in patients receiving ECMO if preconditions are fulfilled. Oxygenation can be maintained while establishing that apnoea is present despite hypercarbia by sharply reducing the sweep gas flow and measuring $PaCO_2$ at intervals until after adequate hypercarbia has occurred.[43]

The intensivist should convey the fact of brain death and its medical and legal implications to the family. It can be difficult to accept brain death as death, given the life-like appearance of the skin, the rise and fall of the chest and the warmth of the hands that are preserved by ventilatory and circulatory support. Some family members will accept an offer to view the clinical examination for brain death (with prior careful explanation of the possibility of spinal reflexes), or the cerebral blood flow study when clinical examination is confounded. This may help some to understand and accept the final awful implication of this diagnosis.[44] Intensivists should be open to offering these options. In the absence of organ donation, it is appropriate to remove ventilatory support after brain death when family needs have been met.

DONATION AFTER CIRCULATORY DEATH

DCD, previously known as non-heart-beating donation, is increasing around the world. Kootstra and colleagues from Maastricht[45] described four categories of 'non-heart-beating' donors.

CATEGORIES OF DONATION AFTER CIRCULATORY DEATH

Category I: those who are dead on arrival

Category II: those in whom cardiopulmonary resuscitation is ceased

Category III: those in whom cardiac arrest is expected to occur soon

Category IV: those who have cardiac arrest while brain dead.

In all but Category III the situation is 'uncontrolled'. DCD practice varies considerably worldwide. Almost all DCD donors in the United Kingdom, United States, Canada and Australasia are Category III donors (a

small number are Category IV). Category III donors are also most common in the Dutch experience but donation from Category I and II is increasing.[46] By contrast, in Spain, withdrawal of treatment in the ICU is less common than in Holland or the United Kingdom[47]; most DCD donors are Category I and II,[48] but Category III donors are increasing.

The legal, ethical and medical issues raised by DCD have been widely explored.[22,45,49,50] These include ensuring that there has been a consensus decision to withdraw treatment before organ donation is discussed with the family; estimating the likelihood of death within a timeframe after the withdrawal of treatment that makes donation possible; using agents (e.g. heparin) and procedures (e.g. instrumentation) prior to death that are for 'organ benefit only'; locating where the withdrawal of treatment will take place (ICU, operating room or other location); having the presence of family members there after the withdrawal of treatment; using opioids and sedatives after the withdrawal of treatment; separating clinical responsibility for end-of-life care (including opioids, sedatives and determination of death) from the responsibility for organ procurement; knowing the exact method used for the determination of death; the timing of organ removal after death; knowing the procedure to be followed if the patient does not die within a timeframe where donation is possible; ensuring that the family are fully informed and supported throughout the process; ensuring that all participating personnel are familiar with, and accepting of, DCD procedures; and ensuring that agreed protocols that explicitly address all of these issues are in place. Several national guidelines or recommendations have been produced that address these issues.[22,49,51–56] DCD should take place only after broad clinical, ethical and societal consensus has been achieved and expressed in such a document. Where such a measured process has been followed, DCD has been viewed favourably by both families and hospital staff and has modestly increased the number of organs available for transplant.

DCD after euthanasia was first reported from Belgium,[57] and more recently a combined protocol for euthanasia and DCD has been produced.[58] Demand is growing, apparently inexorably, for legislation sanctioning 'voluntary euthanasia', 'assisted suicide' and – more recently – 'physician-assisted dying' in various jurisdictions including Canada, Australia and New Zealand. Intensivists should be aware that these practices are likely to lead to calls for their involvement in facilitating DCD donation in these circumstances and should prepare a coherent and principled response.[59]

Delayed graft function is more common in recipients of DCD kidney grafts, and long-term graft and recipient outcomes – although similar[60] – may not be quite as good as after a graft from a brain-dead donor.[61] Compared to with DBD liver grafts, lower graft, patient survival and higher rates of biliary complications are commonly reported with DCD liver grafts, but these differences are probably reducing. Recipient and graft outcomes after pancreas[63] and lung transplantation[64] from DCD donors are similar to those after DBD, and similar findings seem likely in DCD heart transplantation[65] although experience remains limited. A number of strategies, in particular ex-vivo normothermic organ perfusion,[66] seem to hold promise for improving the function of many organs (particularly heart, liver and kidney) retrieved after DCD and are likely to soon become more widespread.

DISCUSSION OF ORGAN DONATION WITH THE FAMILY

Organ donation (from deceased donors) is an activity that takes place at the end of life, usually in an ICU. Organ donation is not part of transplantation, which is concerned with the care of patients with end-stage organ failure who may receive organ transplants. Appreciating this distinction allows an analysis of important issues that are not often discussed in transplant-oriented publications. Organ donation fundamentally modifies human rituals at the time of death, even of death in the ICU. Organ removal is an invasive procedure carried out in the operating room. Although done respectfully and with identical surgical processes to those used on living people, it is nevertheless viewed by some as 'mutilating'. Discussion of organ donation is an emotionally intense activity involving a family and a health professional, and requires very clear and sensitive communication. This discussion takes place in the midst of grief – when family members are experiencing the death of a family member. Awareness even of transplantation varies widely in the community and there is even less knowledge of organ donation processes. Some families may not previously have known that organ donation and transplantation occur! Similarly, discussion of and support for organ donation vary widely in the community. There is greater support of 'organ donation in principle' than either individual willingness to donate or willingness to agree to donation on behalf of a family member. Discussion of organ donation among families is promoted as a way of increasing organ donation rates and it may do so. However, some family members hold strong views against organ donation based on personal, spiritual, religious or cultural beliefs.[67] There are utilitarian views about organ donation including the notion that organ donation is the only possible 'positive' outcome that can occur in the setting of brain death[68]; that it is appropriate to refer to dead or dying persons in a utilitarian way as sources of organs for transplant[69]; that organ donation can 'help the next of kin cope with grief'[70]; and that fulfilling the previously expressed wishes of the donor should be the primary or indeed the only[71] consideration. In some jurisdictions these wishes have been deemed legally sufficient for organs

to be retrieved, and are often assumed to be a means of increasing the organ donation rate[72] by excluding the family from the opportunity to prohibit organ donation and 'returning control to the individual'. This assumption may well be erroneous.[73,74] Many countries have defined the status of an individual's wishes about organ donation after their death as constituting legally sufficient 'consent'. However, the validity of the concept of 'consent' can be questioned as the person is dead at the time that the issue is real and because current 'register-based' records of such wishes do not meet accepted standards for informed consent[75] in a personal health care context.[76] Implicit in a 'transplant-oriented' value system is the view that for a family to agree to organ donation is both desirable and of greater moral value ('the right thing to do') than the contrary decision, particularly if organ donation was the previously expressed wish of the dead person. This view, in which close family relationships[77] give no legitimacy to the family to determine what should happen to their loved one after death, is now explicitly acknowledged, practised and advocated by many organ procurement organisations including in the United States and increasingly in the United Kingdom. Similar views are increasingly expressed in Canada, Australia and New Zealand. However, even in countries that legally allow the previously expressed wishes of the deceased to determine whether organ donation may take place, usual practice continues both to involve the family and not to proceed against family objection – accepting that the impact on the deceased's family remains paramount in consent practice.[78]

In many countries, this has resulted in the evolution, exposition and advocacy of strategies to overcome 'refusal to donate'[79] and to thereby achieve 'target conversion rates'. Possible adverse effects of such strategies on family bereavement[80] are not reported by those who advocate for them and whose sole measure of 'quality', 'success' or even 'best practice' in organ donation practice is the proportion of situations in which donation occurs. Intensivists should reflect on their own views on these matters, and be aware of the views of others who might discuss organ donation with family members. Although intensivists continue to most often initiate discussion of organ donation with families in Australasia, this is becoming less common there and in other jurisdictions. Whoever undertakes this discussion should be skilled in communication with grieving people. In Australasian clinical practice, the intensivist has already established a relationship with the family, involving mutual trust and respect, in prior family meetings during the patient's final illness. This relationship naturally allows the intensivist to initiate and facilitate discussion of organ donation. Describing this encounter as 'discussing organ donation' rather than 'obtaining consent' (or 'seeking consent' or even 'persuasion')[81] is not 'organ focused' or coercive in language and enables the intensivist to provide complete and unbiased information and to support the family in their decision making, whatever they might decide about donation.

The intensivist must ensure that the fact of death (in the situation of brain death) is understood. When (Category III) DCD is a possibility, there must be prior consensus agreement by the family and the treating team that treatment must be withdrawn before the option of possible organ donation is raised by the intensivist. The patient is clearly not dead at this time, although death is certainly anticipated to be imminent. This imminent death should also be understood by the family before the option of DCD is offered. There must be sufficient time for the intensivist to inform the family about what organ donation entails (including the subsequent benefits to transplant recipients of those organs), to answer any questions and, if necessary, to facilitate decision making by the family. The discussion may take into account previously expressed wishes, previous family discussions, and the values and beliefs of the patient and family members. Some language is particularly insensitive from the perspective of grieving families and should be avoided[22] (e.g. the use of the term 'harvest'[82] rather than 'organ retrieval' to describe the process of organ retrieval, or 'the body' rather than the person's name to describe the brain-dead person). Increasingly, intensivists are being expected to facilitate the involvement of other people in this discussion – including members of organ procurement agencies and others with specific training about this discussion – with the implicit or explicit aim of 'increasing the consent rate' – to a 'target'. Various models are advocated including 'collaborative requesting', where both ICU staff and others are involved and the 'designated or trained requestor' model wherein ICU staff introduce the 'requestor' and take no part in the discussion of donation. Highly explicit strategic plans have been developed, most notably – but not exclusively – in the United States, to achieve 'target consent rates'. Although such an approach has been reported to 'increase organ donation' in non-randomised time series and other observational studies,[83-85] this was not found in the only randomised controlled trial (RCT) of 'collaborative requesting' so far conducted.[86] 'Repeated requesting' has been reported to increase the number of families who agree to donate and language that is variously persuasive or coercive (e.g. 'fulfilling the deceased's wishes', 'doing what he would have wanted', 'something good may come of this', 'many families take comfort in donation', 'there are many people dying on waiting lists, including in your community') might also achieve that objective. It is increasingly evident that 'conversion-rate'-focused approaches are beginning to dominate the discussion of donation with families, despite – and in the face of – ongoing moral distress in many intensivists, including this author.

The intensivist should facilitate the family spending time at the bedside prior to organ removal if they

wish. Some investigations (e.g. echocardiography or bronchoscopy) may be performed during this time and the family should be informed about these. The intensivist should ensure that the family is offered the opportunity to spend time with the deceased after organ removal.

MAINTENANCE OF EXTRACEREBRAL PHYSIOLOGICAL STABILITY IN BRAIN DEATH

Immediately prior to brain death there is often a limited period of hypertension, tachycardia and occasionally dysrhythmia, mediated by both autonomic activity and catecholamine secretion. Pulmonary oedema, cardiac dysfunction and myocardial injury may develop and may have implications for subsequent heart and lung graft function.[87] Treatment of this temporary sympathetic phenomenon should preferably be with short-acting agents acting only on the circulation (e.g. esmolol). Cardiac arrest rarely occurs during this phase, usually due to tachydysrhythmia, but is often reversible. Hypertension is soon followed by hypotension (which may be profound in the presence of hypovolaemia or cardiac dysfunction) and can lead to cardiac arrest or loss of donor organ viability. Blood pressure (e.g. in adults a mean arterial pressure [MAP] of ~70 mm Hg (9.31 kPa)) should be maintained with inotropic support and volume expansion. Diabetes insipidus soon occurs in most but not all brain-dead persons, which is manifest by brisk hypoosmolar polyuria, leading quickly to hyperosmolality and later to hypovolaemia if untreated.

After loss of cerebral metabolism there is a fall of around 25% in oxygen consumption and carbon dioxide production[88] so that less ventilatory minute volume is necessary for normocarbia. The fall in energy expenditure (heat production) together with the loss of vasomotor tone and loss of possible thermogenesis from shivering exacerbate the risk of hypothermia. Spontaneous movements and spinal motor reflexes commonly persist in brain death[22] and rarely include bizarre movements, which are often reproducible. Family members may be offered the opportunity to view the (perhaps second) clinical examination for brain death and should be warned about the possibility of these responses (which may not have occurred at the first examination) and given a prior explanation of them. These movements and sympathetic circulatory responses can also occur during organ retrieval in the operating room. The use of neuromuscular blockade and other agents (including opioids) is therefore recommended in the operating room.[22]

STRATEGIES FOR MAINTAINING PHYSIOLOGICAL STABILITY

The onset of brain death is usually heralded by rises in intracranial pressure (if measured), hypertension and tachycardia, and progressive loss of brainstem function (coma, pupillary dilatation). These features should initiate preparation for specific support strategies, which include ensuring that central venous access, inotropic support, intravenous access for rapid volume expansion, desmopressin and a source of external heat (e.g. a warming blanket) are all available.

VENTILATORY MANAGEMENT

The aims of ventilatory management are to maintain good oxygenation and normocarbia, to minimise circulatory depression and to maintain, if possible, sufficiently good lung function to allow for future lung donation to occur. Usual pulmonary care including changes of position and sterile endotracheal suctioning must continue. When pulmonary dysfunction is severe, high levels of positive end-expiratory pressure (PEEP) may be required to prevent airway frothing or to provide adequate oxygenation. Establishing that there is apnoea at hypercarbia in such patients may require mechanical hypoventilation prior to apnoea and continuous positive end-expiratory pressure (CPAP) during it. Compared with a conventional ventilatory strategy, the use of a lung-protective strategy (including tidal volumes of 6–8 mL/kg of predicted body weight, PEEP of 8–10 cm H_2O, testing for apnoea on CPAP rather than at zero end-expiratory pressure, and closed-circuit airway suction) has been shown in an RCT[89] to substantially increase both the number of potential lung donors meeting suitability criteria at 6 hours and the number of actual lung donors, with similar 6-month recipient survival. In a matched cohort study, oxygenation impairment remained 2 hours after an apnoea test at zero end-expiratory pressure, but a recruitment manoeuvre immediately after the apnoea test was associated with no such impairment.[90] Although a Pa_{O_2} of more than 300–350 mm Hg (40–46.5 kPa) on 100% oxygen and 5 cm H_2O PEEP was once thought essential for lung donation, more seriously impaired oxygenation (and the use of higher PEEP) have been found acceptable[91] and some transplant centres increasingly use ECMO to electively support recipients of lungs with more serious but reversible impairment with acceptable outcomes.[92]

CIRCULATORY AND METABOLIC MANAGEMENT

The aims of circulatory management are to maintain adequate organ perfusion and arterial pressure without fluid overload or harmful vasoconstriction, and without prejudicing cardiac donation where this might be possible. Reasonable initial haemodynamic goals include normotension (e.g. MAP >70 mm Hg [9.31 kPa]), heart rate of less than 100 beats/min, and central venous pressure of ~8 mm Hg (1.06 kPa). Some inotropic support is usually required. Having established normotension with an inotrope infusion, the haemodynamic response to a volume challenge should be assessed. The choice of inotrope is the subject

of more controversy than evidence. Dobutamine is not recommended. In Australasia norepinephrine (noradrenaline) is preferred and dopamine is seldom used, without apparent harm to organ function in recipients. Low-dose dopamine infusion (4 μg/kg/min) has been shown in an RCT to slightly increase urine volume without effecting serum creatinine and infusion (for ~6 hours in the donor) was associated with a slight reduction in the number of recipients receiving multiple dialyses before renal function recovered.[93] Epinephrine (adrenaline) may have a specific benefit on renal blood flow in brain death,[94] but may also increase glycaemia and thereby osmotic diuresis. Catecholamine infusion may reduce the up-regulation of organ immunogenicity that occurs in brain death and lower the incidence of acute rejection in subsequent recipients of kidney grafts.[95] Although levels of thyroid hormones fall after brain death, this is probably the 'sick euthyroid syndrome' and replacement of the thyroid hormone does not improve the circulation after brain death.[96] Importantly, and highlighting the potential for bias in non-randomised studies in organ donation, this systematic review found that benefit was shown in all 16 separate case series or retrospective audits of the use of thyroid hormones but in none of the seven RCTs.[96] Corticosteroids are often given just prior to organ removal from brain-dead donors and commonly recommended (again on the basis of retrospective analyses) to increase the number of organs, particularly thoracic organs, retrieved and transplanted. Although steroids improved the haemodynamics in an experimental model[97] and in a human RCT,[98] this did not translate into an increased number of organs procured[98] nor did an earlier RCT[99] show any benefit in kidney graft outcomes. Treatment of brain-dead liver donors with high-dose methylprednisolone (~1.6 g over ~14 hours) did not alter the use of fluids and catecholamines compared with a non-steroid group, but it was associated with lower serum levels of inflammatory cytokines in the donors, together with lower recipient transaminase levels in the early post-transplant period and a reduced incidence of acute rejection within 6 months.[100]

Two recent systematic reviews[101,102] of trials of corticosteroids did not find any evidence of benefit. Similarly, two RCTs of the combination of steroid and tri-iodothyronine (T3) did not show beneficial circulatory effects.[103,104] Vasopressin infusion can eliminate or substantially reduce the amount of catecholamine required to support arterial pressure[104,105] without apparent detriment to subsequently transplanted organs. Control of excessive polyuria will minimise the risks of developing hyperosmolality, hypovolaemia or hyperglycaemia secondary to infusion of large amounts of dextrose-containing fluids. Synthetic desmopressin (1-D amino-8 D arginine vasopressin) is commonly given to control diabetes insipidus and appears safe and effective.[106] Control of diabetes insipidus is an essential aspect of rational fluid therapy, and hypovolaemia should be corrected with resuscitation fluids.

The use of so-called 'hormonal resuscitation'[107] (combined use of T3, steroid and vasopressin) continues to increase[108] and continues to be advocated for on the basis of retrospective reports with multiple logistic regression,[109,110] despite no benefit being shown in an RCT in 80 potential cardiac donors.[104] This study did show haemodynamic improvement after brain death occurred with time in both arms of the trial, and that 14/40 hearts initially considered unsuitable for transplant were suitable 6 hours later, suggesting that a determination of unsuitability for heart donation should not be made early after brain death.

Haemoconcentration occurs early after experimental brain death. Crystalloid infusion has been reported to worsen pulmonary function in brain death and somewhat larger volumes will be required than if colloid is used.[111] At least moderate anaemia is well tolerated in brain death, but red cells may be given if needed to maintain packed cell volume at around 0.25 pending organ retrieval. Free water should be given as necessary (1–2 mL/kg/h as 5% dextrose) to maintain serum osmolality in the range of 280–310 mOsm/kg, corresponding to serum sodium below 155 mmol/L. Severe hyperosmolality (probably a marker of inadequate donor care) is associated with poor graft function in subsequent liver recipients.[112] Low-dose insulin infusion is commonly required to prevent hyperglycaemia. Failure to control diabetes insipidus will lead to increased requirements of free water to control serum osmolality, and if large amounts of 5% dextrose are used for this then hyperglycaemia and osmotic diuresis may result. Serum potassium should be kept above 3.5 mmol/L, but correction of hypophosphataemia does not improve haemodynamics in brain death.[113] Oxygen consumption, carbon dioxide production, heat production and glucose oxidation all fall in brain death owing to the loss of cerebral metabolic activity.[88] Hypothermia may readily develop in association with vasoparesis, loss of shivering, exposure to room temperature, warm polyuria and infusion of room temperature intravenous fluids. Core temperature should be kept above the 35–36.5°C required to confirm brain death.[22] Keeping the ambient temperature high (~24°C) and using infusion fluid warmers, heated humidifiers and external warming systems may be required.

AFTERCARE OF THE DONOR FAMILY

Routine aftercare is increasingly recommended[114] for all families of patients who die in ICUs. Aftercare programmes are well received[25] and have the potential to improve the care of subsequent families by revealing areas of inadequate or inappropriate communication. There may be issues specific to organ donation that

need to be addressed, sometimes by way of a family meeting with an intensivist at some later stage. Most organ donation agencies provide donor families with ongoing emotional support (which may extend over many years), provide them with limited anonymous information about the recipients, and accept and facilitate limited anonymous communication (i.e. by letter) between the recipients and the donor families by mutual consent; direct contact is not recommended.[22]

Liver transplantation

Sarah E Brown, Anish Gupta, Simon Cottam, Julia Wendon

Liver transplantation has revolutionised the care of patients, with both acute and chronic end-stage liver disease. It has become an almost routine procedure, with the majority of patients having a short post-operative intensive care unit (ICU) stay and 1-year survival greater than 90%.[1-4] Indications have widened, and contraindications decreased. As a consequence, the number of patients awaiting transplantation continues to outstrip cadaveric donor rates; waiting times lengthen, and hence patients become critically ill before receiving a transplant, increasing risk and peri-operative complications, and impairing long-term outcome.[5] Innovative strategies have evolved as possible solutions to the lack of cadaveric donor organs, including widening the donor pool to include previously unsuitable donors (so-called marginal donors), paediatric and adult living-related donation, reduced size and splitting techniques and the use of 'non-heart-beating donation'.

PATIENT SELECTION

There are currently relatively few absolute contraindications to liver transplantation and no specific age limitation. Listing requires a multidisciplinary consensus of a 50% chance of 5-year survival once all risks are considered. Donor organs are preciously scarce, and allocation principles must therefore take into account the severity of the recipient's condition and the peri-operative risk profile.

Portopulmonary and hepatopulmonary syndromes (HPS) are now an active indication for transplantation as opposed to a contraindication.[6] These patients are likely to have a more complex postoperative course, especially if graft function is borderline or they develop sepsis. Patients must have the required cardiorespiratory reserve to tolerate the procedure. Guidelines are available with regard to hepatocellular carcinoma and liver transplantation.[7,8] Such patients increasingly, if not inevitably, require disease-modifying treatments, (transarterial chemoembolisation and radio frequency ablation). Periodic imaging of the liver is mandatory to monitor disease progression whilst waiting for a suitable cadaveric donor.

Much work has gone into the development of prognostic tools to allow the accurate prediction of the need and timing for transplantation, and increasingly the system used is the model for end-stage liver disease (MELD). This was initially developed for predicting survival following transjugular intrahepatic portosystemic shunt (TIPS), but has been shown to be equally useful in predicting survival in those awaiting liver transplantation. Survival depends on the physiological reserve of the recipient and the quality of the donor organ. Cardiovascular 'fitness' should remain the key determinant for receiving high-risk donor organs, which are increasingly used in order to match demand. Peri-operative outcome scoring systems are becoming more robust (survival outcomes following liver transplantation [SOFT] and balance of risk score [BAR]), but are still limited to specific types of donor organs and are often disease non-specific.[9,10] Once multiorgan failure has developed in a debilitated patient awaiting transplantation, survival rates decrease to 20%–30% and these patients often require weeks to months of postoperative hospitalisation.[2,11]

Cardiorespiratory function requires detailed assessment prior to listing. There is not one specific test that will determine fitness for transplantation; however, a combination of routine blood tests, computed tomography (CT) imaging, electrocardiography, echocardiography, cardiopulmonary exercise testing and brain imaging – if encephalopathy is a feature – serves as a minimum. CT imaging may uncover underlying pulmonary pathology as well as any coronary calcification (a weak predictor of critical ischaemia).

Cardiopulmonary exercise testing promulgates invaluable information of the cardiac, pulmonary and skeletal muscle-mitochondrial unit. In addition to providing dynamic information on these systems, we are able to gauge the β-adrenoceptor response and the peak oxygen consumption, which has some proven prognostic value.[12] The anaerobic threshold is frequently discussed, but is subject to major limitations – anaemia, smoking, β-blocker therapy, exercise tolerance prior to illness, cirrhotic cardiomyopathy and hepatorenal disease. This test is not validated as a discriminator for accurately determining success in

ABSTRACT

With improvements in immunosuppression and organ allocation systems, liver transplantation has now become a routine procedure, with survival rates at 1 year above 90%. Adults and children with chronic liver disease or multiorgan failure secondary to acute liver failure may be listed for transplantation, with donor organs being retrieved from heart-beating and non-heart-beating donors, as well as living relatives. The management of patients with end-stage liver disease and acute liver failure mandates referral to a specialist centre, where consideration for transplantation can be assessed in a multidisciplinary setting. Increasingly complex patients are able to undergo liver transplantation today, despite the myriad of complications that frequently occur.

KEYWORDS

Liver transplantation
acute liver failure
hepatopulmonary syndrome
hepatorenal syndrome
portopulmonary hypertension
immunosuppression
reperfusion syndrome
paediatric transplantation
acute rejection
viral hepatitis

Table 103.1 Diagnostic criteria for hepatopulmonary syndrome and portopulmonary hypertension

HEPATOPULMONARY SYNDROME	PORTOPULMONARY HYPERTENSION
Chronic liver disease (± cirrhosis)	Portal hypertension
Arterial hypoxaemia	Mean pulmonary artery pressure >25 mm Hg
Pa_{O_2} < 75 mm Hg (10 kPa) or A – a O_2 gradient >20 mm Hg	Pulmonary artery occlusion pressure <15 mm Hg
Intrapulmonary vascular dilatation	Pulmonary vascular resistance >240 dynes/s per cm^{-5}

the peri-operative period, but forms an integral part of each assessment.

Cardiovascular disease is the third commonest cause of death following liver transplantation, after disease recurrence/chronic rejection and malignancy. The risk factors for coronary artery disease require scrupulous investigation prior to listing, particularly as obesity and diabetes may develop post-transplantation, further increasing cardiac risk. Angiography and carotid Doppler studies must form part of the additional work-up in those patients with multiple risk factors.

Obesity is an increasingly common feature in patients listed for transplantation, and non-alcoholic steatohepatitis is the only indication for transplantation that is rising in frequency, soon to be the leading indication. The associated co-morbidities need to be quantified, and the overall risk profile cautiously considered prior to listing. Postoperative complications including infection, wound dehiscence and ventilator dependency are more prevalent, with cardiovascular complications the main cause for mortality. Obese patients with diabetes or coronary artery disease are 40% less likely to reach 5-year survival.[13] However, even transplanted obese patients show a survival benefit over those on the waiting list despite their higher complication rate, and this provides a difficult ethical debate over resource allocation.[14] There are no thresholds in body mass index for listing. Optimisation prior to surgery should focus on controlling medical co-morbidities as well as weight loss and dietary changes.[15]

HEPATIC SYNDROMES

Changes in the cardiovascular system associated with chronic liver disease may contribute to the spectrum of cardiopulmonary disease associated with chronic liver disease and portal hypertension. A hyperdynamic state with high cardiac output, long-standing portal hypertension with the development of collateral flows, together with an imbalance of vasoactive mediators either synthesised or metabolised by the liver, may lead to characteristic changes in both flow and pressure through the pulmonary vasculature. This may be associated with hypoxia and orthodeoxia. Two ends of the spectrum are HPS and portopulmonary hypertension. The two conditions are uncommon but important, as they have vastly different impacts on risk associated with liver transplantation and long-term outcome (Table 103.1). The role of agents used in the management of primary pulmonary hypertension is yet to be examined in a controlled manner in liver disease, but data thus far suggest benefit.

HEPATOPULMONARY SYNDROME

HPS is present in approximately 20% of cirrhotic patients. It can be seen from Table 103.1 that hypoxia is a characteristic finding in this condition. It results from intrapulmonary vascular dilatation at the pre- and post-capillary level, leading to decreased ventilation/perfusion ratios; more uncommonly, anatomical shunt is present with arteriovenous communication. One of the postulated mechanisms of this vasodilatation is overactivity of pulmonary vasculature nitric oxide synthetase; pre-transplant patients have raised levels of exhaled nitric oxide that decrease post-transplant with resolution of the syndrome. Diagnosis is confirmed by contrast-enhanced echocardiography or radionuclide lung perfusion scanning. Medical treatment of the syndrome has been disappointing; indeed, most transplant centres agree that the syndrome is an indication for transplantation in itself, as resolution is reported in up to 85% after transplantation.[16] Risk stratification based on severity is important, as vastly increased peri-transplant mortality is associated with severe hypoxia and high levels of vascular shunt. Severe hypoxia qualifies for MELD exception prioritisation. Mortality overall is 16% at 90 days and 38% at 1 year. Predictors of mortality in this group are severe hypoxia (Pa_{O_2} <6.5 kPa or 50 mm Hg) and shunt fraction greater than 20%.[16] Refractory hypoxia is the indirect cause of death, which may be due to multiorgan failure, intracerebral haemorrhage and sepsis due to bile leaks. Whilst it is true that the recipient's organs are conditioned to function in the chronic preoperative hypoxic state, the liver graft must be protected from hypoxia immediately following transplantation, with a gradual weaning of oxygen levels. Resolution of the syndrome is variable and can take up to 1 year, lending support to the theory that it is vascular remodelling rather than just acute reversal of vasodilatation that reverses hypoxia.[17,18]

PORTOPULMONARY HYPERTENSION

Up to 20% of pre-transplant patients have pulmonary hypertension; this probably constitutes increased flow through the pulmonary vasculature and is not associated with increased resistance. These patients do well after transplantation. A much more ominous syndrome is the presence of pulmonary hypertension with high pulmonary vascular resistance (PVR) (seen in <4%). The aetiology of this syndrome is complex but it is characterised by a hyperdynamic high-flow state with excess central volume and non-embolic pulmonary vasoconstriction. The pathological changes associated with this syndrome match those associated with primary pulmonary hypertension except that cardiac output is high in this group.

In comparison to HPS, there are several differences in terms of response to medical treatment and outcome after transplantation. The response to epoprostenol, a prostaglandin I2 (PGI2) analogue, is encouraging. Decreases in pulmonary artery pressure – but more importantly transpulmonary gradient (TPG) – have been noted, although at least 3 months' treatment seems necessary, suggesting remodelling rather than vasodilatation is the important mechanism. A limiting factor in the treatment may also be progressive thrombocytopenia and splenomegaly. Endothelin receptor antagonists (bosentan, ambrisentan) have been shown to almost normalise PVR in selected patients by blocking the vascular reactivity of the pulmonary vascular bed. Phosphodiesterase inhibitors (sildenafil) increase the availability of nitric oxide within the pulmonary vasculature. These oral agents hold some advantage for outpatient management; however, intravenous prostacyclin remains the treatment of choice in severe cases.[19]

Another difference is the peri-operative risk and post-transplant prognosis. Resolution is not associated with transplantation and progression can be a feature. Peri-operatively, the higher the mean pulmonary artery pressure (MPAP), PVR and TPG, the greater the risk of death, usually due to acute right ventricular decompensation. Right heart pressures need to be closely monitored with pulmonary artery catheterisation preferably commenced pre-operatively to establish prostacylin infusion. Milrinone may be added to gain further control of pulmonary pressures in the peri-operative process. Trans-oesophageal echocardiography (TOE) monitoring provides invaluable assessment of right heart function, and enables more accurate volume replacement during reperfusion. If the MPAP is greater than 35 mm Hg or the PVR is greater than 250 dyne/s per centimetre, mortality reaches 40%. If MPAP is greater than 50 mm Hg some have even suggested delisting or even intraoperative cancellation as the mortality may be as high as 100%.[20] Intravenous pulmonary vasodilators are usually weaned to oral medications which about half the patients will require long term. Resolution in the remaining half occurs over several months.[19]

Table 103.2 Diagnostic criteria for hepatorenal syndrome

Cirrhosis with ascites
Serum creatinine >133 µmol/L (1.5 mg/L)
No improvement in serum creatinine (to <133 µmol/L) after 2 days of diuretic withdrawal and albumin replacement (1 g/kg per day or maximum 100 g/day)
Absence of shock
Absence of nephrotoxic drugs
Absence of renal parenchymal disease

Salerno F, Gerbes A, Gines P, Wong F, Arroyo V. Diagnosis, prevention and treatment of hepatorenal syndrome in cirrhosis. *Gut.* 2007;56: 1310–1318.

HEPATORENAL SYNDROME

Hepatorenal syndrome (HRS) is a potentially reversible cause of renal dysfunction in a small proportion of acute kidney injury (AKI) cases with cirrhosis. Two subtypes exists; type 1 results in acute renal deterioration following a precipitating event (sepsis, post-paracentesis syndrome), whereas type 2 is a progressive form occurring over weeks. It represents an advanced stage of haemodynamic dysfunction, characterised by splanchnic vasodilatation, reduced systemic vascular resistance and reduced effective arterial blood volume. This contraction in central blood volume stimulates a powerful neuroendocrine response mimicking volume depletion and pre-disposing to pre-renal failure (HRS).[21]

The diagnosis is essentially one of exclusion in a patient with cirrhosis (Table 103.2).[22] The prognosis of HRS is poor with the worst survival rates out of all the causes of AKI (3-month survival for type 1 is 20%, and type 2 is 40%). Vasoconstrictor agents, albumin, TIPS and improved antimicrobial therapy have all proven benefits in serving as a bridge to transplantation.

Transplantation is the only treatment for HRS, with normalisation of sodium excretion, serum creatinine and neurohormonal levels occurring within 1 month. The renal vasoconstrictive indices require 12 months before recovering. HRS does increase the complication rate and reduce survival following transplantation, with renal function never recovering in up to 25%. Those on renal replacement therapy for more than 8 weeks prior to transplantation should be offered combined liver–kidney transplantation. Interestingly, the risk of acute rejection for combined liver–kidney grafts is as for liver transplantation, compared to the higher rate of rejection that is seen for renal transplant alone.[22-24]

EXTRACORPOREAL HEPATIC SUPPORT

The liver has metabolic, excretory and synthetic functions; all of which need to be maintained in a patient who has liver failure until either an organ becomes

available or regeneration takes place. Two groups of devices are available; purely mechanical devices provide detoxification whilst bioartificial devices, which require an abundant source of hepatocytes, also provide synthetic and biotransformation activities. Artificial devices include plasma exchange and albumin dialysis, which may incorporate extracorporeal albumin dialysis (MARS [molecular adsorbents recirculating system, Gambro]) or fractionated plasma separation and absorption (Prometheus). Clinical trials are in progress to evaluate the place for these devices. To date, none of these artificial devices have conferred a survival benefit in liver failure in prospective randomised trials, though there has been some success with improvements in neurological status and reduced cerebral oedema.[25-27] Bioartificial devices suffer from limited hepatocyte supply and prospective clinical trials conveying survival benefits, though some early results may prove promising. In addition to efficacy, still to be elucidated is the timescale on which these devices can be used and whether they can bridge the gap to regeneration, thus sparing the patient from transplantation.

PERI-OPERATIVE ASPECTS

OPERATIVE TECHNIQUE

Orthotopic liver transplantation (OLT) involves recipient hepatectomy, revascularisation of the donor graft and biliary reconstruction.

Two main techniques are used in adult liver transplantation – those with vena cava preservation ('piggyback technique') and those using portal bypass (either internal, temporary portocaval shunt or external, veno-venous bypass). The advantages of the piggyback technique include haemodynamic stability during the anhepatic phase, without large volume fluid administration, and the negation of the need for veno-venous bypass with its associated risks and complications. Decreased transfusion requirements, shorter anhepatic time and shorter total operating time are also observed. There is no observed difference in renal function between the two techniques.[28-30] The donor hepatic artery is directly anastomosed, utilising an 'end-to-end' technique, or a conduit is constructed. Portal venous anastomosis must also be undertaken; in most patients this is an end-to-end anastomosis. Portal venous thrombosis is no longer a contraindication to transplantation and these patients may undergo a re-cannulisation procedure or require a jump graft technique. Such conduits and grafts are normally fashioned from donor vessels.

It is imperative that all those caring for the patients are aware of the surgical technique undertaken, as complications may vary. The radiologist must be aware of the technique used to allow appropriate interpretation of subsequent investigations and vascular imaging. This applies not just to the vascular anastomosis but also to the presence of a full graft, a reduced-size graft, a right or left split graft or indeed an auxiliary graft. The biliary anastomosis is normally also undertaken as an end-to-end procedure, the donor bile duct being directly joined to the recipient duct. It is no longer standard for this to be undertaken over a T-tube, but this may be required where there is marked discrepancy between donor and recipient duct size. Some conditions (e.g. extrahepatic biliary atresia, primary sclerosing cholangitis) may preclude end-to-end anastomosis, and formation of choledochojejunostomy may be required.

Split-liver grafts allow one liver to provide an organ for two recipients. Initially comprised of a child receiving the left lateral segment and an adult the remaining liver, nowadays two adults may receive grafts from one liver if the anatomy and size match allow. Such splits may be less than ideal when the recipient has a high MELD score, as is increasingly the case with the prioritisation of sick patients awaiting liver grafts. Such grafts are at increased risk of postoperative complications such as bile leaks and haematoma/collections at the cut surface.[3,31]

Auxiliary liver transplantation is a technique that involves subtotal recipient hepatectomy and implantation of a reduced-size graft. It is a technically difficult procedure, as both portal and arterial supplies have to be constructed de novo. In addition, a duplicate biliary drainage system needs to be constructed. Hepatic venous outflow is anastomosed as usual. In acute liver failure, it has significant potential, since regeneration of the native liver may obviate the need for donor function, potentially allowing withdrawal of immunosuppression. It also has application in the treatment of some hereditary metabolic disorders where adequate metabolic function may be achieved with an auxiliary graft. The major advantage is withdrawal of immunosuppressive therapy if the patient develops severe complications, or when applicable gene therapy becomes available. The disadvantage of auxiliary transplantation in the face of acute liver failure is that the postoperative course is frequently more complicated; reasons are multifactorial, and can be due to the continued presence of a regenerating native liver or due to a smaller donor graft attempting to cope with a critical illness.

Non-heart-beating transplantation (NHBD) has emerged in recent times as a potential way of increasing organs for transplantation.[32,33] The success in renal transplantation has led to exploration of its application in the fields of liver, pancreas and lung retrieval. Most retrievals are undertaken in the context of controlled NHBD (i.e. in the context of planned withdrawal of care). Warm ischaemia can be accurately assessed and cold ischaemia minimised. Early experience with NHBD was associated with inferior survival for patients and grafts, but recent experience suggests

that survival is approaching that for heart-beating donation. There are, however, continuing concerns over biliary and vascular complications. Prolonged cold ischaemia is associated with poor graft function and biliary complications, as are warm ischaemia times of greater than 30 minutes.[34] With regard to postoperative care, an understanding of the pre- and peri-operative factors is essential in anticipating potential complications, initiation of monitoring and proactive management.

Living donor-related transplantation (LDRT) is now a routine undertaking in paediatric liver transplantation. It is becoming increasingly utilised in adult liver transplantation, although its application in countries with good cadaveric donor pools is less established. Adult LDRT using right lobe grafts is an effective procedure with good survival outcomes but is associated with significant complications. From a postoperative perspective the intensive care team may be responsible for the management of both the donor and the recipient. Morbidity rates for donors are significantly higher with the use of a right lobe donation compared with a left lobe graft. Mortality for donors has been reported. Survival rates now reported for living related recipients are good, with rates of 80% at 12 months.[35,36]

Adequate function of undersized transplanted liver grafts is essential to successful outcome. Primary graft non-function is relatively rare and one of the main areas of concern is that of the so-called 'small-for-size syndrome'.[35,37] This was first recognised in the post-transplant setting but also occurs following liver resection. It is still an area under discussion but the clinical entity is that of hyperbilirubinaemia, graft dysfunction, ascites and portal hypertension with associated end-organ dysfunction/failure. There is portal hyperaemia, with portal flow passing into a small liver remnant/graft with associated pathophysiological consequences, and at a histological level there is evidence of arteriolar constriction. In some patients consideration should also be given to the potential compounder of hepatic venous outflow limitation.[38,39] Other factors that predispose to the syndrome are an inappropriate graft weight to recipient, and steatotic grafts. Most management trials have focused on optimising venous outflow and limiting/preventing portal hyperaemia and limiting portal hypertension.[35,40] Animal studies have also examined the role intrahepatic vasodilators with good effect. Management of the syndrome remains controversial but its early consideration allows the clinical team time to consider therapeutic options and interventions.

INTRAOPERATIVE MONITORING

In addition to routine monitors, invasive arterial blood pressure and central venous pressure measurements are invaluable. With modern advances in technology, it has now become routine practice to use some method of cardiac output monitoring. The trends in stroke volume variation and cardiac index can be used as a guide to fluid delivery, and to help gauge requirements for vasopressors and inotropes.

The use of TOE is often reserved for patients with known pulmonary hypertension, though this is gradually being used more frequently to assess fluid status, regional wall motion abnormalities, the presence of intracardiac thrombi and even to locate the position and patency of TIPS.[41,42]

FLUIDS, HAEMORRHAGE AND COAGULATION

There is no consensus on the amount or type of fluid that should be used during liver transplantation. The centrally deplete fluid compartment, if aggressively filled, will rapidly re-distribute to the peripheral and portal circulation, exacerbating haemorrhage.[43] Incremental volume replacement is the key, ideally guided by some form of flow monitoring. Large volumes of crystalloids must be avoided to prevent excessive interstitial oedema. The choice of colloid remains an important topic of debate and ongoing research. The following points should be remembered when deciding which colloid to infuse. Starches with a molecular weight above 200 kDa may predispose to AKI and result in pruritus. Starches may remain within the intravascular compartment for longer than gelatins; however, this effect is questionable with modern, lower molecular weight starches.[44]

OLT may be associated with massive blood loss. The causes are multifactorial and include pre-operative coagulopathy secondary to end-stage liver disease, portal hypertension, surgical technique, adhesions related to previous surgery and intraoperative changes in haemostasis. The degree of clinical coagulopathy is impossible to predict, and relies on the imbalance in anti-haemostatic and pro-haemostatic drivers.[45]

The low-grade fibrinoltyic process in advanced cirrhotics may be exacerbated during surgery, particularly during the anhepatic and re-perfusion stages. Platelet dysfunction, both quantitative and qualitative, is also common, though the impact on haemostasis is variable.[46] The consequences of massive bleeding and replacement are significant, not only in terms of postoperative morbidity and mortality, but also intraoperatively when issues such as acute hypovolaemia, reduced ionised calcium due to citrate accumulation, hyperkalaemia, acidosis and hypothermia become important. Transfusion-related acute lung injury (TRALI) is a potentially devastating complication. It is believed to result from neutrophil antibodies preformed in donor serum. The immunosuppressive effects of large volume blood transfusions are well recognised and pertinent in a group of patients who are already functionally immunosuppressed. In addition to these immediate problems is the risk of transmission of, as yet, unidentified viral infection.

Much effort has gone into reducing the amount of exogenous blood products required intraoperatively. This includes the use of cell salvage techniques with autologous transfusion and frequent testing of haemostasis, utilising both laboratory-based tests and thromboelastography or rotational thromboelastometry. The prophylactic use of tranexamic acid may attenuate the degree of fibrinolysis during the early stages of transplantation. The severe post-reperfusion fibrinolysis often resolves once the donor liver begins to function and seldom requires immediate correction. Optimisation of clot stability with fibrinogen prior to coagulation factor and platelet replacement has led to reduced transfusion requirements in major haemorrhage. Fibrinogen and prothrombin complex concentrates are gaining popularity due to reduced volume load and superior efficacy, though these products are not universally licensed or readily available. They are purified and virally inactivated by nature of the manufacture process, reducing the risks of viral transmission and TRALI.[47] There is a paucity of evidence-based thresholds for platelet transfusion, and the benefits in reducing haemorrhage and improving liver regeneration must be balanced with the adverse risks of ischaemia-reperfusion injury, TRALI and reduced survival.[46] These therapies must be judiciously employed in order to control bleeding at the potential expense of thromboembolic complications which may be as high as 4%.[41]

Although it is assumed that all patients with liver disease are subject to an increased risk of bleeding there are some subgroups that are prothrombotic, as evidenced clinically and with thromboelastography. Patients with pre-operative portal or hepatic venous thrombosis appear to carry a higher incidence of prothrombotic mutations than the general population, and patients with primary biliary cirrhosis and primary sclerosing cholangitis are frequently prothrombotic. Such patients may require anticoagulation in the early postoperative period. Other patient groups such as those with Budd–Chiari syndrome may have a recognised prothrombotic condition with a resultant early requirement for anticoagulation.

Electrolyte disorders are common in advanced liver disease, and careful monitoring of sodium, potassium and calcium levels are paramount. Hyponatraemia is associated with increased mortality in the pre-transplanted patient, and rapid changes in the peri-operative period may lead to further morbidity (although mortality appears comparable).[48] Rapid changes in sodium concentration have been linked to rare cases of central pontine myelinolysis. Calcium is required for haemostasis, and requires supplementation – especially if citrated products have been administered. Life-threatening hyperkalaemia may develop on reperfusion, and must be anticipated and managed immediately. Cell-salvage apparatus can be used to wash the packed red cells to eliminate excess citrate and potassium administration.

POST-REPERFUSION SYNDROME

The post-reperfusion syndrome is a poorly understood phenomenon that occurs after reperfusion of the portal vein through the donor graft. It is characterised by hypotension, bradycardia, vasodilatation, pulmonary hypertension, hyperkalaemia and, in some cases, cardiac arrest. The aetiology is unclear, but a sudden increase in venous return, release of vasoactive substances, and cold potassium-rich preservation fluids are potentially implicated. The syndrome usually resolves within the first 5 minutes of reperfusion with appropriate fluid loading and electrolyte management. However, in approximately 30% of patients it lasts for significantly longer, necessitating the use of inotropes and/or vasopressors. The post-reperfusion syndrome seems more common in organs with longer preservation times and may well be associated with initial poor graft function.

POSTOPERATIVE CARE

The postoperative care of the recipient depends to some extent on pre-operative co-morbidity, the presence of any of the immediate complications listed above, recipient stability during the procedure and lastly the pre-transplant cause of liver failure.

Straightforward recipients who return to the ICU in a stable condition with good graft function may be woken up and weaned immediately. The tracheal tube and some of the invasive monitoring lines should be removed as soon as no longer required to reduce the risk of infection and encourage mobility. Close monitoring of all physiological systems is important in the early postoperative period (Tables 103.3 and 103.4).

Table 103.3 Routine investigation of the post-transplant patient in the intensive care unit

	FBC	LFTs	COAGULATION	DRUG LEVELS	CULTURES	ULTRASOUND
Day 1	√	√	√		As indicated	Routine ultrasound including hepatic artery, hepatic and portal vein flow D1 and D5, and if clinically indicated at other time
Day 2	√	√	√	√	As indicated	
Day 3	√	√	√	√	As indicated	

FBC, Full blood count; *LFTs*, liver function tests.

Table 103.4 Monitoring of graft function in the intensive care unit

PARAMETER		COMMENT
General	Liver perfusion	Characteristics at surgery
	Bile production	Quality ± volume if T-tube in situ
	Haemodynamics	Stabilisation, with cessation of vasopressor requirements
Coagulation	INR/PT	8-hourly for first 24 h, thereafter daily unless indicated. Fall in PT is more important than the actual value. FFP should be withheld to assess graft function although platelets given as indicated
Biochemistry	Glucose	Hypoglycaemia is an ominous sign; 4-hourly for first 24 h Euglycaemia/hyperglycaemia requiring insulin infusion is normal
	Arterial blood gases and lactate	4- to 6-hourly depending on ventilatory requirement. Hyperlactataemia and acid-base disturbance should rapidly resolve. Other causes of base deficit, such as renal tubular acidosis and hyperchloraemia, should be excluded and managed appropriately
	AST	Should fall steadily (50% fall each day). The first measurement may reflect washout and thus the next may be higher. Daily measurements. The initial measurement reflects the degree of preservation injury
	Bilirubin	Early increases may reflect absorption of haematoma and do not reflect graft function. Haemolysis should be considered if the graft is not blood group matched, termed passenger lymphocyte syndrome
	ALP/GGT	Usually normal; increases may reflect biliary complications or cholestasis of sepsis

ALP, Alkaline phosphatase; *AST*, asparate aminotransferase; *FFP*, fresh frozen plasma; *GGT*, gamma-glutamyl transferase; *INR*, international normalised ratio; *PT*, prothrombin time.

EARLY COMPLICATIONS

As with all postoperative surgical intensive care admissions, some complications are applicable to all patients. These include haemorrhagic and pulmonary complications of any prolonged procedure in addition to specific complications pertinent to liver transplantation. These can be subdivided into technical complications, conditions and complications associated with pre-existing liver disease, and complications associated with immunosuppressive agents, graft function and massive transfusion.

CARDIOVASCULAR

End-stage liver disease is characterised by a hyperdynamic circulation, with low systemic vascular resistance, high cardiac index and a proportionately reduced central circulating volume. The majority of patients can be managed with judicious volume loading with or without vasopressors to maintain adequate perfusion pressures. However, in some patients, this state may compensate for degrees of cirrhotic cardiomyopathy, which are characterised by systolic and diastolic dysfunction, electrophysiological abnormalities and a blunted β-adrenoceptor response in the presence of an increased cardiac stress.[49-51] The massive increase in the volume of liver transplants performed in the last decade has revealed cardiac failure as an important cause of morbidity and mortality in the transplant recipient.[52] OLT can impose severe stresses on the cardiovascular system: haemorrhage, third-space loss, impaired venous return due to caval clamping, hypocalcaemia and acidosis all impair myocardial contractility. Reperfusion can also be a time of profound circulatory instability. Rapid fluctuations in filling pressures place the compromised and stressed myocardium at risk of failure. In addition, the impaired exercise tolerance of the pre-transplant recipient may have limited the clinical importance of coronary ischaemia, which becomes pertinent in the post-transplant period.

Haemodynamic changes after OLT are also common; hypertension with an increased systemic vascular resistance is frequent and may be due to the restoration of normal liver function and portal pressure, as well as the hypertensive effect of the calcineurin immunosuppressants. The increased afterload in the early post-transplant period may unmask cardiac dysfunction. Management of myocardial failure post-OLT is largely empirical; diuretics, afterload reduction and positive-pressure ventilation may all be required. In the longer term, control of cardiovascular risk factors is required and many of these patients may over the years return to the intensive care environs with other system failures and considerable burdens of hypertension, coronary ischaemia, diabetes, hyperlipidaemia and renal dysfunction.

PULMONARY

Pulmonary complications are common and occur in 40%–80% of recipients. The presence of pre-operative impairment (e.g. pleural effusions, hypoxaemia, pulmonary hypertension or the HPS) is strongly associated with postoperative complications. Specific conditions related to liver transplantation include

right hemidiaphragm palsy as a result of phrenic nerve damage, which can occur if suprahepatic caval clamping is used intraoperatively. The commonest postoperative problems are pleural effusions, ongoing shunting secondary to the HPS, atelectasis and, over subsequent days, infection. De novo acute lung injury and the acute respiratory distress syndrome are relatively uncommon at this stage. Other complications, such as TRALI and pulmonary oedema, are almost certainly under-recognised and under-reported.

Specific management of portopulmonary syndrome may be required in the postoperative period if right-sided pressures are elevated, to ensure that liver congestion and graft dysfunction do not ensue.[6,50,51] Control of pulmonary pressures may require a variety of therapeutic options, with the treatment options being similar to those utilised in primary pulmonary hypertension. Concern about potential hepatotoxicity needs to be balanced against the need to control right-sided pressures and provide optimal graft function. Similarly, HPS may take a variable time to resolve and hypoxia during this period will require recognition and management.

Respiratory complications are also seen in patients with poor muscle bulk and subsequent weakness. Similarly, the presence of osteoporosis in the pre-transplant patient is frequently associated with postoperative pain and poor cough. The role of adequate analgesia is important, as in all patients, in promoting mobilisation and adequate respiratory function. In general, the management of a protracted respiratory wean follows conventional lines.

NEUROLOGICAL

The quoted incidence of central nervous system (CNS) complications varies widely from 10% to 40% in the published series. Most neurological complications occur within the first month of transplant. The commonest causes relate to the persistence of pre-existing encephalopathy.[53,54] The causes are multiple, including hepatic, metabolic, infectious, vascular and pharmacological. A patient with acute liver failure will remain encephalopathic in the immediate post-transplant period, and is at risk of intracranial hypertension for 48 hours following transplantation, or longer in the face of graft dysfunction. De novo hepatic encephalopathy may develop in patients with severe graft dysfunction and/or primary graft non-function; again the patient is at risk of cerebral oedema. The effects of sepsis, rejection (and its treatment with high-dose steroids), drug therapy (especially the sedatives and analgesics used in the ICU setting) and the presence of renal failure may all contribute to the presence of altered conscious level. The calcineurin inhibitors (CNIs) are particularly associated with seizures and altered conscious level. All such patients will require brain imaging to further define the aetiology of their impaired neurology.

Other possible neurological complications are those of intracerebral haemorrhage. Such bleeds may relate to arteriovenous malformations, may be spontaneous or may be a complication of intracranial pressure monitoring, particularly in patients with acute liver failure. CNS infection normally presents later than the immediate postoperative period, but should always be considered, especially in those patients with a prolonged and complicated postoperative course. All possible infecting agents, including bacterial, viral, fungal and opportunistic, should be considered. Central pontine myelinolysis is a rare but potentially devastating complication associated with rapid sodium shifts. Modern technology and the use of haemofiltration techniques allow tight control of sodium shifts in the majority of patients, and this has become a rare neurological complication.

RENAL DYSFUNCTION

Despite intraoperative efforts, renal dysfunction often progresses and AKI is a relatively common complication, with an incidence of between 25% and 60% and a multifactorial aetiology.[55-58] Risk factors include the presence of pre-transplant co-morbidity (e.g. hypertension, diabetes mellitus, obesity, HRS), severity of underlying liver disease, intraoperative instability, blood product requirement, hepatic ischaemic reperfusion injury, drug toxicity, graft dysfunction and higher risk grafts. The use of higher risk, or marginal, grafts has increased due to the growing demand for organs and a desire to reduce the waiting list mortality. They include grafts from older donors, split or partial grafts, prolonged preservation time (warm and cold ischaemia times), graft steatosis, and NHBD. There is an increased risk of hepatic and extrahepatic complications following transplantation with marginal grafts, with AKI the most common complication.

Mortality in those who require renal replacement is high, graft survival is lower, and there is increased resource utilisation. In order to limit – or avoid – AKI, those with risk factors, or pre-existing renal dysfunction, should have their immunosuppression with nephrotoxic agents, such as CNIs, reduced and interleukin-2 (IL-2) blockers utilised.[59] There must be a balance between the risk of rejection and that of side effects of drug therapies. Mycophenolate mofetil (MMF), a cytotoxic immunosuppressant, may be substituted in the post-transplant course to limit or protect against renal dysfunction.

Intra-abdominal hypertension should always be considered in the post-transplant setting as a potential contributor not only to renal dysfunction but also to cardiorespiratory embarrassment. Early consideration should be given to laparostomy in patients with elevated intra-abdominal pressures and associated organ dysfunction.[60,61]

PRIMARY NON-FUNCTION

This is a spectrum occurring in 2%–23% of cases, which at worst requires urgent retransplantation. It

is characterised by poor graft function from the time of reperfusion, with hyperlactataemia, coagulopathy, metabolic acidosis, hypoglycaemia, hyperkalaemia and a rapid elevation in aminotransferase concentrations, accompanied by a systemic inflammatory response.

A major reason for the initial graft dysfunction is ischaemic injury to the graft, which depends on the type of preservation fluid used, and the duration of cold and warm ischaemia time. The aetiology of primary non-function (PNF) remains unclear.[62]

Vasodilator prostaglandins and antioxidants may have a role in 'rescue therapy', but controlled data are lacking.

SURGICAL PROBLEMS

Anastomotic thromboses are uncommon complications of liver transplantation, but can cause significant morbidity, which may require further invasive procedures and even urgent retransplantation. Hepatic artery thrombosis occurring in the early postoperative period is associated with a similar picture to PNF. Small vessel calibre is a risk factor, and is more prevalent in the paediatric recipient where it has also been associated with prothrombotic states, such as protein C deficiency. Ultrasound is the first-line screening test and is undertaken both routinely in the immediate postoperative period, and if there is a sudden rise in transaminase measurements. If the vessel is not visualised, the patient should proceed to CT angiography. If diagnosed quickly, emergency intervention can be undertaken to re-establish arterial flow; however, emergency retransplantation may be required.

Venous complications, such as portal thrombosis, are even more uncommon, and are usually associated with intraoperative technical difficulty, recurrence of pre-operative disease or undiagnosed thrombophilia. Portal thrombosis is normally associated with portal hypertension and massive ascites, but may also be associated with graft dysfunction, especially in the paediatric population. CT scanning will interrogate the vessels and also provide information on graft perfusion: regional ischemia may be identified, which may have presented as a transaminitis. Treatment is dependent on the severity of the injury but ranges from diuretics to angioplasty, surgical reconstruction or ultimately retransplantation. Regional ischaemia and areas of poor perfusion should be actively sought in patients with a transaminitis and especially in those who had received a reduced size or split-liver graft.

Biliary complications post-liver transplant are relatively common. The bile duct normally receives two-thirds of its arterial supply from the gastroduodenal artery and one-third from the hepatic artery. Post-transplant, the only supply is from the hepatic artery, making it vulnerable to ischaemic injury whether that be at the time of retrieval, reperfusion or post-operatively. The resulting complication depends on the type of biliary anastomosis and the timing of the insult. Strictures are more commonly observed than leaks. Management of biliary complications is, in the first instance, endoscopic, with stent placement and/or balloon dilatation. In patients with a T-tube in situ, cholangiography may be undertaken by that route. Open reconstruction in the early postoperative period is uncommon (Tables 103.5, 103.6 and 103.7). Bile leaks also may be seen in the postoperative period from the cut surface of a split graft. Bile leaks are associated with an increased risk of infection and, potentially, of pseudoaneurysm formation.

Table 103.5 Technical complications of orthotopic liver transplantation

COMPLICATION	COMMENT
ABDOMINAL BLEEDING	
Anastomosis	Immediate
Graft surface (if cut down)	Immediate
General ooze secondary to coagulopathy	Immediate
Pseudo-aneurysm formation	Can present early or late and is usually associated with intra-abdominal sepsis and biliary leaks
VASCULAR COMPLICATIONS	
Hepatic artery thrombosis	Early and late
Portal vein thrombosis	Early and late; there may also be a stenosis of the portal vein rather than thrombosis
Inferior vena caval obstruction	May be infra-, supra- or retrohepatic in site
BILIARY COMPLICATIONS	
Biliary leak	Usually early
Biliary stricture	Usually late
Papillary dysfunction	Late
Roux-en-Y dysfunction	Usually late

ACUTE REJECTION

Acute cellular rejection becomes a risk from approximately 5–7 days post-transplant; the clinical signs of rejection are non-specific and include fever, deterioration in graft function and a rapid rise in serum aminotransferase concentration. Liver biopsy is the only reliable diagnostic tool; however, biopsy may be relatively contraindicated due to coagulopathy. In some circumstances transjugular biopsy offers a solution to

Table 103.6 Biochemical and clinical features of technical problems

COMPLICATION	FEATURES	INVESTIGATION	MANAGEMENT
Hepatic artery thrombosis	Early: rapid rise in transaminase, coagulopathy, graft failure	Ultrasound, angiogram	Thrombectomy, retransplantation
	Differential diagnosis: hyperacute rejection, primary non/dysfunction		
	Late: biliary complications, strictures, sepsis, liver abscess	Ultrasound, angiogram	Angioplasty
Portal vein thrombosis	Early: rapid deterioration in graft function, acute liver failure, ascites, variceal bleeding	Ultrasound, CT, angiography, MRA	Thrombectomy, retransplantation, conservative management
	Late: mildly abnormal LFTs, portal hypertension, varices	Ultrasound, CT, angiography, MRA	

CT, Computed tomography; *LFTs*, liver function tests; *MRA*, magnetic resonance angiography.

Table 103.7 Differential diagnosis of graft dysfunction in intensive care unit

Primary non-function
Preservation injury
Rejection – hyperacute/acute

Biliary complications
Drug-induced liver dysfunction
Infection – viral, bacterial, fungal
Recurrent disease (normally late)

this problem. The differential diagnosis may be that of sepsis, or problems with vascular integrity; there are some data to suggest that procalcitonin may be of use in the differentiation (Table 103.8). The normal management regime for an episode of acute rejection is that of pulsed methylprednisolone (1 g for 3 days), though approximately 10% will develop steroid-resistant rejection. Antithymocyte globulin, a polyclonal lymphocyte antibody preparation, is often used in liver transplant centres to treat steroid-resistant rejection.

INFECTIOUS COMPLICATIONS

Transplant recipients are uniquely vulnerable to infection with up to 80% developing at least one infection during the first year.[63] Prolonged and technically difficult surgery, large wounds, urinary catheterisation and the need for central venous access postoperatively, combine with conditions attendant to end-stage liver disease, including neutropenia, deficits in the mucocutaneous barrier, diabetes mellitius, uraemia and protein-calorie malnutrition, to increase susceptibility.

Bacterial infections are frequent and represent the most dangerous complication in liver transplant patients. More than one-third of infections occur within the first 30 days and the risk factors include: NHBD, MELD greater than 20, albumin level greater than 2.8 g/L, high intraoperative transfusion requirement (packed red cell >6 U, fresh frozen plasma >12 U), bilioenteric anastomosis and prolonged length of stay (ICU stay >6 days and hospital >21 days).[64] However, compared with a decade ago, the overall incidence is reduced, probably due to improved and patient-tailored immunosuppressive regimens. Sepsis remains an important and life-long complication of liver transplantation, which may require readmission to intensive care.[65,66]

The epidemiology of pathogens is evolving; the incidence of Gram-positive bacterial infection (enterococci and staphylococci) is now more common than Gram-negative sepsis. More concerning is the emergence of multiple antibiotic-resistant bacteria, in particular methicillin-resistant *Staphylococcus aureus*, vancomycin-resistant enterococci and extended-spectrum β-lactamase producing Gram-negative organisms. Mortality and graft failure associated with infection caused by these multiply resistant organisms is significantly greater compared with other organisms.[67]

A decline in the incidence of both *Pneumocystis jiroveci* (formerly *P. carinii*) and cytomegalovirus (CMV) infection is probably a result of both modulating immunosuppressive regimens and more effective prophylaxis. Patients should be screened for viral infections, including herpes simplex virus (HSV) and CMV utilising polymerase chain reaction techniques.

Opportunistic fungal infections remain problematic. Candidiasis is the most frequent fungal infection and the leading cause of invasive fungal infection. The gastrointestinal tract is often colonised with *Candida* species and infection can occur secondary to overgrowth and translocation, or as the result of leaks from anastomosis within the alimentary canal. Risk factors for invasive candidiasis include: previous use of prophylactic antibiotics for spontaneous bacterial peritonitis, renal replacement therapy, retransplantation,

Table 103.8 Management of rejection in intensive care

	COMMENT	CHARACTERISTICS	LIVER BIOPSY	DIFFERENTIAL DIAGNOSIS	TREATMENT OPTIONS
Hyperacute rejection	Rare in OLT 1–10 days post-transplant	Rapid deterioration in graft function: AST >1000 Coagulopathy, acidosis	Haemorrhagic necrosis	Primary non-function/ delayed function Hepatic artery thrombosis	Retransplantation Rarely: OKT3, cyclophosphamide, plasmapheresis (unproven)
Acute rejection	30%–70% Occurs at mean of 7–9 days	Often clinically silent apart from fever and RUQ pain High AST and bilirubin Coagulation and acid-base undisturbed	Portal inflammation Endothelitis Bile duct damage	Sepsis Vascular Viral	Methylprednisolone 1 g daily for 3 days

In those who do not respond: Consider diagnosis; if correct, consider tacrolimus if induction agent is ciclosporin A, OKT3 or MMF/sirolimus if other new agents.

technically difficult surgery, intraoperative blood transfusion and prolonged ICU stay.[68] *Aspergillius* spp. are the second most common fungal infection, though diagnosis can be difficult, and often involves invasive procedures. Non-invasive serological markers, including 13-b-glucan (BDG) and aspergillus galactomannan, can be used as diagnostic indicators. The use of prophylactic antifungals is now widespread in those with risk factors, but consideration to drug-drug interactions, particularly those with CNIs, is important (Table 103.9).[69]

FEVER

In transplant recipients, 76% of febrile episodes have a documented infectious aetiology, but acute rejection needs to be considered in the differential diagnosis. In the ICU transplant recipient the aetiology is even more likely to be infectious – often nosocomial and bacterial. In one study, pneumonia, catheter-related bacteraemia and the biliary tree were the three most common sources in the ICU population (41%). Viral infections accounted for 9% of febrile episodes, fungal infections 3% and endocarditis 3%. As mentioned above, the epidemiology of pathogens is changing and it is important to have thorough knowledge of local problem pathogens on which to base meaningful antibiotic policy.

These data have implications for the threshold to investigate febrile episodes, suspect bacterial infection and commence appropriate empirical antibiotic therapy. However, it also should be appreciated that immunosuppressed recipients do not always produce a febrile response to infection.

MANAGEMENT OF CYTOMEGALOVIRUS INFECTION AFTER LIVER TRANSPLANTATION

CMV infection is rarely associated with symptomatic illness in healthy hosts, but is a major cause of morbidity and mortality in transplant recipients; it is the single

most common opportunistic infection after solid organ transplantation. In the absence of antiviral prophylaxis the overall incidence of CMV infection after OLT ranges from 23% to 85%, with approximately 50% of those developing clinical disease.

CMV infection most commonly occurs in the first 3 months after OLT, with a peak incidence in the third and fourth week. Infection may be asymptomatic or it may cause a spectrum of illness including fever, thrombocytopenia, neutropenia, pneumonia and hepatitis. The indirect effects of infection probably contribute more to the adverse effects on graft function than direct effects. CMV infection further immunosuppresses the recipient, leading to increased opportunistic fungal infection and also increased risk of Epstein–Barr virus infection which can go on to be associated with post-transplant lymphoproliferative disease. CMV infection is also implicated in increased rejection. In those patients who proceed to transplant who are already receiving immunosuppressive agents, or in those with acute liver failure, CMV disease may present earlier in the clinical course.

The risk of CMV infection post-transplant is dependent on the serological status of both the donor and recipient; the highest risk is associated with donor positive/recipient negative.[70] Proven prophylactic strategies in the high-risk groups include valganciclovir or ganciclovir for 3 months. Currently, intravenous ganciclovir remains the gold standard in the treatment of CMV disease. Therapy will be converted to oral ganciclovir to facilitate discharge from hospital and rehabilitation. There is no evidence to support specific immunoglobulin in addition, but it is frequently added in the management of CMV pneumonitis.[67]

MANAGEMENT OF VIRAL HEPATITIS

Hepatitis C (HCV)-related cirrhosis is the commonest indication for transplantation in both Europe and the United States. Post-transplant, HCV viraemia is universal. Recurrent liver disease, with a more accelerated and aggressive course, is often observed; indeed, 20% are cirrhotic at 5 years post-transplant.[71] Those with histological evidence of recurrence also have a greater incidence of acute rejection. Risk factors for progressive disease post-liver transplantation include donor characteristics (age and donor type), viral characteristics (genotype and viral load), the inflammatory grade of the explanted liver, recipient immune status and immunosuppression regimen. Immunosuppression, especially with steroids, directly increases the HCV RNA serum load. Most transplant programmes therefore convert to single- or double-agent immunosuppression regimens as soon as possible post-transplant.[72] Several strategies to prevent the complications of HCV recurrence post-liver transplant have been attempted: treatment prior to transplant, immediate or peri-operative prophylaxis, early pre-emptive therapy and treatment of established disease. Eradication of the virus prior to transplantation is the ideal approach, and the advent of interferon-free regimens with direct-acting antiviral agents has resulted in sustained virological response reported in 86%–97% of cirrhotic patients across genotypes.[73-76] There is limited evidence to suggest that peri-operative treatment may prevent reinfection of the new graft, and currently there is no established role for this, or early pre-emptive treatment. Studies have shown excellent efficacy of direct-acting antivirals, with or without ribavirin, in the treatment of HCV recurrence post-transplantation, and whilst the side-effect profile is considerably less than the previous interferon-based regimens, drug-drug interactions with CNIs are an important consideration. Retransplantation for HCV recurrence has shown to be a successful possibility should the transplanted liver begin to fail.[77]

Initial results of transplantation for hepatitis B infection were discouraging, largely due to recurrent disease with rapid and fatal progression. The introduction of oral nucleos(t)ide analogues (NA), and effective measures to prevent and treat reinfection, led to a significant improvement in outcomes. Pre-transplantation patients should be treated with NAs, preventing flares and reducing disease progression, and this combined with early post-transplant immunoprophylaxis, with hepatitis G immunoglobulin, has dramatically reduced the re-infection rate to less than 10%. Following transplantation NA therapy must be continued indefinitely. In respect of the modulation of immunosuppression regimens, the comments made with respect to HCV are similarly applicable.

IMMUNOSUPPRESSION

As the field of transplantation evolves, new immunosuppressive regimens and drugs become available. For all combinations, however, there is a balance to be struck between the optimal prevention of rejection and the toxicity and unwanted effects of the drugs. These agents affect T-cell-dependent B-cell activation, targeting different sites in the T-cell activation cascade by inhibiting T-cell activation or causing T-cell depletion. The incidence of acute rejection rises at about 1 week after OLT; it resembles a delayed-type hypersensitivity reaction, and immunosuppressive agents are highly effective at treating it. Chronic rejection occurs over months to years and is characterised by the 'vanishing bile-duct' syndrome, pathological mechanisms are poorly understood and immunosuppressant agents are largely ineffective.[59]

The introduction of CNI immunosuppression revolutionised the outcome of solid organ transplantation, leading to the 1-year survival rates we routinely see today. In most liver transplant programmes, tacrolimus, along with steroids, form the mainstay drugs after liver transplantation, certainly in the early stages.

Tacrolimus is a macrolide compound that inhibits IL-2 and interferon-gamma-production reducing T-cell activation. It is 100 times more potent than ciclosporin A and has become the first-line CNI as it is associated with fewer episodes of acute cellular rejection, steroid-resistant rejection, graft loss and postoperative death. The improvement in short-term survival following the introduction of CNIs has not translated into longer-term survival, with a loss of 7 life years when compared to the non-transplant population. The long-term side effects of CNI immunosuppression, including cardiovascular disease, chronic renal failure and malignancy, contribute significantly to the non-hepatic late deaths post-liver transplantation. Tacrolimus dosing should be individualised and drug levels monitored.

These manifestations of toxicity can be difficult in the management of post-transplant immunosuppression in patients who exhibited encephalopathy or renal dysfunction pre-transplant; the use of agents without nephrotoxic profiles, or strategies to limit the CNI dose (e.g. induction with basiliximab) may be considered in this context. It is usual to have an induction regimen beginning in the peri-operative period; this usually involves a CNI and steroids, which are administered in a high-dose taper regime. With time after transplantation, the required level of immunosuppression decreases and drug doses may be reduced further. Cytotoxic drugs, such as azathioprine or MMF, may also allow further reduction of steroids and CNIs. The long-term effects of immunosuppression have to be considered but are less pertinent in the immediate postoperative period.

Antibodies can be used in patients with pre-existing renal dysfunction, or those at high risk, as a CNI-sparing mechanism, or to minimise steroid use. Basiliximab is a humanised monoclonal antibody against the IL-2 receptor. Blockade of the IL-2 receptor prevents T-cell proliferation. In one study comparing tacrolimus plus steroids to steroid-free tacrolimus plus an IL-2 receptor blocker, graft and patient survival were comparable, but the incidence of biopsy proven acute cellular rejection, diabetes mellitus and CMV infection, were higher in the tacrolimus and steroid group.[78]

Sirolimus is a novel immunosuppressant that has been used extensively in renal transplantation and more recently in liver transplant recipients in whom the CNIs are contraindicated.[59] It resembles tacrolimus structurally, and binds to the same protein, but whereas ciclosporin and tacrolimus act by inhibiting IL-2 gene transcription, sirolimus acts by blocking post-receptor signal transduction and IL-2-dependent proliferation. In addition to its immunosuppressive actions, sirolimus is also an antifungal and antiproliferative agent. Sirolimus lacks neuro- and nephrotoxicity. However, it can raise the intracellular concentrations of ciclosporin A and tacrolimus, indirectly potentiating their toxicity. Hyperlipidaemia has also been noted, although this may be a reflection of the often higher dose steroid regimens used in combination with sirolimus. Because of its antiproliferative effects, sirolimus can also cause thrombocytopenia, neutropenia and anaemia; there have also been concerns about its effects on wound healing. Everolimus is the hydroxyethyl derivative of sirolimus. Its mechanism of action is similar to sirolimus but is secondary to the increased risk of hepatic artery thrombosis, so it should not be used until at least 30 days after liver transplantation. Sirolimus and everolimus also require therapeutic drug-level monitoring, not only because serum concentrations have a high level of intra- and interindividual variability, but also because there are significant interactions with drugs that use the cytochrome P-450 3A system.

Future strategies for limiting the long-term sequelae of immunosuppression hope to utilise the unique hepatic immunological environment, and induce tolerance so that immunosuppression could be withdrawn.

All immunosuppressive regimens should be tailored to individual patient needs and a balance struck between the side effects (short and long term) and the risk of rejection.

READMISSION TO THE INTENSIVE CARE UNIT/LATE COMPLICATIONS

The cause of readmission to the ICU after liver transplantation varies in relation to time after transplantation. Approximately 20% of recipients require readmission, and this correlates with actuarial reduced patient and graft survival. In the period immediately after transplantation, cardiorespiratory failure is the commonest reason for readmission, due to both fluid overload and infection. Indeed, an abnormal pre-discharge chest X-ray is predictive of readmission, as is high central venous pressure and tachypnoea. Other predictors of readmission are age, pre-transplant synthetic function, bilirubin, amount of intraoperative blood products and renal dysfunction. Graft dysfunction, severe sepsis and postoperative care of surgical complications are other important causes of readmission. Bleeding and biliary anastomotic leaks represent the commonest surgical causes for readmission.

LIVER TRANSPLANTATION FOR ACUTE LIVER FAILURE

Acute liver failure is a syndrome associated with an acute onset coagulopathy, jaundice and encephalopathy; the causes are many and the syndrome is notable for its high morbidity and mortality. The acceptance of emergency liver transplantation in selected cases has revolutionised the clinical course, but the outcome is sometimes disappointingly poor, often due to the rapid development of uncontrollable cerebral oedema, sepsis and multiorgan failure.

Table 103.10 King's college hospital prognostic criteria for non-survival among patients with acute liver failure

PARACETAMOL INDUCED	NON-PARACETAMOL INDUCED
pH <7.3 (irrespective of grade of encephalopathy), following volume resuscitation and >24 hours post ingestion	PT >100 s (INR >6.5) irrespective of grade of encephalopathy *or*
or	pH <7.3 following volume resuscitation *or*
PT >100 s (INR > 6.5) *and* creatinine >300 µmol/L in patients with grade III–IV encephalopathy, occurring within a 24-h timeframe	Any three of the following variables (in association with encephalopathy): Age <10 years or >40 years Aetiology: non-A, non-B or drug induced Jaundice to encephalopathy >7 days PT >50 s (INR >3.5) Serum bilirubin >300 µmol/L

INR, International normalised ratio; *PT*, prothrombin time.

There is also a short window of opportunity in listing these patients; despite the highest priority listing they may receive 'marginal' organs or even ABO blood group incompatible organs. Early determination of prognosis and appropriate listing for transplant are clearly important. The King's College Hospital prognostic criteria for non-survival among patients with acute liver failure is a tool used to identify those at high risk while sparing those in whom spontaneous recovery will otherwise occur (Table 103.10). The criteria for paracetamol-induced acute liver failure, and non-paracetamol-induced acute liver failure, were first published in 1989 and were derived from the analysis of patients managed at a single centre between 1973 and 1987.[79] It has been validated both in Europe and the United States. More recently, the advances in the non-transplantation medical management of patients with paracetamol-induced acute liver failure have led to a new novel model being devised that incorporates a dynamic component. Admission data, including age, Glasgow Coma Score, arterial pH and lactate, creatinine, INR, SOFA cardiovascular failure, are used to derive an initial predictive model, with changes to blood lactate levels and INR on day 2 to predict 30-day survival.[80] This model has yet to be prospectively validated but, as with other models in critically ill patients, sequential assessment will provide additional prognostic value.

PAEDIATRIC LIVER TRANSPLANTATION

OLT is the treatment of choice for children with end-stage liver disease. Cholestatic disorders make up the largest indication for transplantation, with extrahepatic biliary atresia plus or minus previous Kasai porto-enterostomy accounting for over 50% of paediatric transplants. Metabolic diseases and primary hepatic tumours are also common indications. As in adult recipients, multisystem effects of end-stage liver disease are common, and the occurrence of liver disease as part of a congenital syndrome (e.g. Alagille's) may warrant invasive pre-operative evaluation of extrahepatic manifestation. Scarce availability of paediatric donors has driven innovations such as reduced size grafts, split-liver techniques and living donor programmes, which have all contributed to expand the pool of available donors and reduce the mortality for those children waiting for suitable organs.

One of the biggest problems associated with paediatric transplantation is the relatively high incidence of vascular complications such as hepatic artery thrombosis, portal vein thrombosis and venous outflow obstruction. Risk factors for these conditions include fulminant hepatic failure, long operation time, donor/recipient age and weight discrepancies, young recipient age, low recipient weight and arterial reconstruction techniques. In order to minimise these often devastating complications, strategies to minimise the risk include delayed primary closure of the abdominal wall, haematocrit maintained at 22%–25% to ensure laminar flow, and the avoidance of platelets and blood components combined with considered use of anticoagulants.

Associated cardiac, pulmonary or renal abnormalities observed in some paediatric syndromes with liver disease may require particular attention and management such as the pulmonary stenosis seen in association with Alagille syndrome.

Ten-year survival rates of 74% (age 12–17 years) to 84% (age 1–5 years) has brought about a new set of challenges relating to complications and management of long-term immunosuppression. The concept of tolerance-inducing immunosuppressive regimens has spurned a number of studies investigating this phenomenon.[81]

Heart transplantation

Priya Nair, Paul C Jansz, Peter S Macdonald

INTRODUCTION

The first human to human heart transplant was performed in 1967 by Christiaan Barnard at Groote Schuur Hospital in South Africa. It was a surgical success with the donor heart functioning well immediately post-transplant; however, the patient died 18 days later from pneumonia resulting from immunosuppressive therapy. There followed an initial wave of enthusiasm with multiple centres around the world commencing heart transplant programmes. Initial results were poor, however, with high early mortality rates and few long-term survivors. Many institutions abandoned the procedure and only a handful of heart transplant programmes persisted throughout the 1970s. The discovery of cyclosporine and its introduction into clinical transplantation in the late 1970s led to renewed interest in heart transplantation with a rapid growth in transplant activity throughout the 1980s. Since then more than 100,000 heart transplants have been reported to the Registry of the International Society for Heart & Lung Transplantation (ISHLT).[1] Currently, it is estimated that approximately 5000 transplants are performed each year in over 300 countries.[2] The survival rate after heart transplantation has improved steadily over the last two decades and currently approaches 85% at 1 year, 75% at 5 years and 56% at 10 years. Median survival is 12 years. Heart transplantation is now well established as the most effective treatment available for end-stage heart failure.

Heart transplantation is limited by donor organ availability. Historically, the vast majority of deceased donors for heart transplantation were brain dead (DBD). More recently, donation after circulatory death (DCD) has re-emerged as an important source of donor lungs as well as abdominal organs, and in some cardiopulmonary transplant programmes up to one-third of lung transplants are performed from DCD donors.[3] Distant procurement and successful heart transplantation from DCD donors has now been reported by three centres using normothermic ex vivo perfusion.[4–6] Increased utilisation of hearts from DCD donors is anticipated in the years ahead.

Virtually all of the improvement in heart transplant survival over the last 20 years has been during the first few months after transplantation.[2] The improvement in survival can be explained by a number of factors including advances in immunosuppressive therapy with fewer deaths due to uncontrollable rejection or infection, and better patient selection.

THE POTENTIAL HEART DONOR

Of all organs retrieved, the heart is the one most susceptible to the multiple insults that occur during brain death and the subsequent events that occur during donor organ retrieval and transplantation. Studies involving repeated echocardiographic examination of the brain-dead donor have revealed that left ventricular systolic dysfunction is common and that it often improves together with haemodynamic status after a period of aggressive donor management.[7]

In addition to its susceptibility to the adverse consequences of brain death, the heart is the donor organ least tolerant to the obligatory ischaemia reperfusion injury (IRI) that occurs during retrieval and implantation. Data from the ISHLT Registry indicates that as the donor heart ischaemic time (the time from cross clamp of the aorta in the donor to release of the aortic cross clamp in the recipient) increases beyond 3 hours there is a progressive increase in the mortality rate at 1 year post-transplant.[2]

DONOR ELIGIBILITY CRITERIA

Donor eligibility criteria vary between jurisdictions. Those that are currently utilised in Australia and New Zealand are summarised in Table 104a.1.[8] As indicated, donors are subdivided into standard criteria and higher risk donors based on a range of donor characteristics, which, if present, are associated with an increased risk of graft failure and lower survival. Echocardiographic assessment of the donor heart is recommended in all cases. Donor heart dysfunction does not necessarily imply pre-existing disease, but is associated with an increased risk of primary graft failure (PGF).[9,10] In donors with suspected coronary artery disease, coronary angiography is recommended, if available.

ABSTRACT

Heart transplantation has emerged as the most effective treatment available for patients with end-stage heart disease. Transplantation is limited by donor numbers so that only a small percentage of patients who might benefit are able to undergo the procedure. The severe shortage of donor organs has resulted in an increased utilisation of higher risk donors with an associated risk of primary graft dysfunction or failure, which poses significant challenges during the initial intensive care unit management of these patients. Nonetheless, the large majority of heart transplant recipients make an excellent recovery following transplant surgery and return to a quality of life that is close to that of normal people of the same age. Almost two-thirds of heart transplant recipients live for more than 10 years and one-third live for more than 20 years after transplantation. Improvements in donor management and organ preservation should increase the number of cardiothoracic organs available for transplantation while ongoing refinements to post-transplant management are likely to result in further improvements in the long-term survival of these patients.

ventricular assist device

Table 104a.1 Standard versus higher risk criteria for donor hearts

DONOR PARAMETER	STANDARD CRITERIA	HIGHER RISK CRITERIA (MARGINAL)
Age	<50 years	>50 years
Donor cardiac history	Nil	Pre-existing disease
Donor co-morbidities	Absent	Hepatitis B, C
Echocardiography*	Normal	Global dysfunction (LVEF <50%) Major regional wall motion abnormality Left ventricular hypertrophy (LV wall >13 mm)
Coronary angiography*	Normal or non-occlusive disease	Occlusive coronary artery disease
Haemodynamic status	Stable	Unstable with high CVP (and/or PAoP) and low BP
Inotropic support	Low	High (>0.2 ug/kg/min of noradrenaline or equivalent)
Ischaemic time	<6 h	>6 h

*Severe abnormalities will generally result in non-use of the organ.

BP, Blood pressure; *CVP*, central venous pressure; *LV*, left ventricle; *LVEF*, left ventricular ejection fraction; *PAop*, pulmonary artery occlusion pressure.

DONOR MANAGEMENT

Management of the multiorgan donor has been discussed in detail elsewhere.

However, hormonal resuscitation is of specific relevance to cardiac transplantation. Vasopressin has been administered to the brain-dead donor often as part of a multihormonal cocktail usually with high-dose steroids and thyroid hormone, and its use results in the sparing of catecholamines, such as noradrenaline, which improves the suitability of the donor heart.[11] Use of other hormonal therapies, particularly thyroid hormone administration is controversial. In a recent systematic review, Macdonald and co-authors identified 16 case series and 7 prospective randomised controlled trials (RCTs) of thyroid hormone administration to brain-dead potential organ donors.[12] Whereas all case series reported a beneficial effect of thyroid hormone administration on a range of outcomes including donor haemodynamic stability and donor heart utilisation, none of the RCTs reported any benefit from thyroid hormone administration. Despite this controversy, thyroid hormone administration in conjunction with other hormonal therapies has been recommended as part of an aggressive management protocol for the potential cardiothoracic donor and has been incorporated into the UNOS Critical Pathway for the Organ Donor.[13]

DONOR HEART PRESERVATION

The most common method of donor heart preservation involves cardioplegia with a cold hyperkalaemic crystalloid solution then cold static storage in a preservation solution in an ice chest during transport between donor and recipient hospitals. There are multiple preservation solutions in use reflecting a lack of consensus regarding the optimal composition of these solutions.[14] All provide good preservation for up to 3 hours but beyond this there is a steady increase in the rate of PGF and mortality. This has led to a renewed interest in the use of ex vivo machine perfusion (MP) to transport hearts between donor and recipient hospitals. These provide oxygen to the donor heart and restore aerobic metabolism, thereby minimising the ischaemic insult to the donor heart. A prospective randomised trial of normothermic MP versus cold static storage of donor hearts from standard criteria donors demonstrated equivalent outcomes[15]; however, uncontrolled case series suggest that MP may yield better post-transplant outcomes when used for the preservation of higher risk donors.[16]

SELECTION OF PATIENTS FOR HEART TRANSPLANTATION

Eligibility criteria for heart transplantation have been extensively reviewed elsewhere and recently revised.[17–19] Heart transplantation is restricted to patients with end-stage heart disease who have exhausted all alternative therapies. Most patients have long-standing heart failure due either to ischaemic heart disease or some form of cardiomyopathy.[1,2] A substantial proportion of these patients require long-term mechanical circulatory support with ventricular assist devices (VADs) (so-called bridge to transplant) and currently between 30% and 50% of wait-listed patients are on such support.[1,2] There has been a dramatic evolution in the design – from large pulsatile pumps to small continuous flow devices – which have proven to be far more durable.[20,21] Two-year survival rates for persons supported on continuous flow devices are now better than 80%.[21,22] Patients on long-term

VAD support are managed as outpatients and undergo cardiac rehabilitation to optimise their physical condition prior to transplant surgery. VAD support has also been used in patients who are otherwise marginal candidates for heart transplantation due to factors such as renal impairment and pulmonary hypertension (so called 'bridge to decision'). Long-term support has been associated with reversal of these co-morbidities in several case series.[23,24]

Historically, heart transplantation has been restricted to younger patients; however, as highlighted in a recent publication of the ISHLT registry, older patients are undergoing heart transplantation.[25] Both advanced age and end-stage heart failure may be associated with physical frailty, which has been shown to be an independent predictor of mortality and is associated with increased morbidity with heart transplantation.[26] Routine frailty screening is now recommended for all patients referred for heart transplantation.[19]

Severe, irreversible pulmonary hypertension with a pulmonary vascular resistance (PVR) greater than 6–8 Wood units, which is unresponsive to pulmonary vasodilators remains one of the few contraindications. This is related to the excessive afterload placed on the donor heart and the possibility of acute right ventricular failure in the recipient. The degree of responsiveness of the pulmonary vasculature is key in patient selection. Some centres consider severe pulmonary hypertension to be a relative contraindication only and consider patients after medical therapy with pulmonary vasodilators and right ventricular inotropes in an outpatient setting and/or subject them to combined heart-lung transplantation.[27]

A small proportion of patients require consideration for transplantation present acutely in cardiogenic shock following acute myocardial infarction, cardiac surgery (post-cardiotomy) or fulminant myocarditis. Short-term survival of these patients is usually dependent on acute mechanical circulatory support, for example, with veno-arterial extracorporeal membrane oxygenation (VA-ECMO). Following the stabilisation of vital organ function and the establishment that the heart will not recover, these patients will usually be transitioned to a VAD for long-term support (so-called 'bridge to bridge').[28] Alternatively, they may be listed for urgent heart transplantation.[29]

HEART TRANSPLANT SURGERY

Heart transplantation can be performed either as an orthotopic or heterotopic procedure. The vast majority are performed orthotopically by excising the native heart and implanting the donor heart in its place. The original surgical technique described by Shumway and Lower is still widely performed. This technique involves anastomosis of the left and right donor atria to the back walls of the corresponding recipient atria containing the central connections of the vena cava and pulmonary veins. An alternative surgical technique involves bicaval anastomosis. The right atrial bicaval anastomosis can be performed alone or in conjunction with anastomosis at the level of the pulmonary veins rather than at the level of the left atrium. The proposed advantages of this technique include better preservation of atrial anatomy and function with a reduced risk of atrial thrombosis, atrial arrhythmias and atrio-ventricular (AV) valve regurgitation during long-term follow-up. Surgical series comparing these two approaches, however, suggest that long-term clinical outcomes are similar.[30]

Heterotopic heart transplantation refers to a rarely performed technique in which the native heart is retained and the donor heart is implanted 'in parallel'. The operation is achieved by anastomosing the left and right atria 'back to back' and then connecting the donor pulmonary artery and aorta to the recipient pulmonary artery and aorta with end-to-side anastomoses. The most common indication is for recipients with fixed pulmonary hypertension. In this setting, an allograft, which is used to operating against normal pulmonary pressures, would fail once transplanted into an environment of pulmonary hypertension.

Once the atrial, pulmonary artery and aortic connections are completed, vents are placed in the left ventricle (LV) and the aorta, the heart is de-aired and the cross clamp released. Temporary pacing wires are placed onto the heart and the heart is allowed a period of reperfusion while on cardiopulmonary bypass (CPB). The duration of the unloaded reperfusion varies and is related to the ischaemic time. A heart that has endured an ischaemic time (from cross clamp in the donor to reperfusion in the recipient) of 4 hours may be given up to 1 hour of reperfusion before commencing separation from CPB and allowing the heart to work. Separation from CPB and the completion of the procedure needs to proceed carefully as the transplanted heart, in particular the right ventricle (RV), is prone to acute failure.

POST-TRANSPLANT MANAGEMENT

IMMEDIATE POST-TRANSPLANT CARE AND MONITORING

In the stable uncomplicated case after transfer to the intensive care unit (ICU), the patient is extubated usually after 6–8 hours. Routine monitoring includes electrocardiogram (ECG), arterial line, pulmonary artery catheter, central venous line and urinary catheter. In some centres, separate left atrial and central venous pressure (CVP) lines have been used instead of the pulmonary artery catheter; however, the latter has the advantage of providing a calculated measure of the PVR. Pericardial, mediastinal and one or more pleural drains will be in place.

PHYSIOLOGY OF THE TRANSPLANTED HEART

The rhythm of the transplanted heart in the immediate post-transplant period is highly variable. While there may be early establishment of sinus rhythm, usually the heart is profoundly bradycardic during the first few days. Typically the sinus rate increases steadily over the first 1 to 2 weeks post-transplant and eventually stabilises at a resting rate between 90 and 100 per minute. Surgery performed with bi-atrial anastomosis may result in the appearance of dual P waves on the ECG arising from the donor and recipient atria. This is eliminated in the case of bicaval anastomosis.

As the heart is denervated, the effect of drugs is altered (Table 104a.2). Those that act by augmenting or inhibiting vagal efferent activity (e.g. digoxin, atropine) will have no effect on the transplanted heart. The transplanted heart is often 'stunned' by the IRI that occurs in the first 24 hours after transplantation. During this period the heart often demonstrates diastolic dysfunction with a restrictive filling pattern, which may persist for days. Persistent diastolic dysfunction beyond the first week post-transplant suggests the development of acute rejection.

CARDIAC RHYTHM AND PACING

AV sequential pacing with temporary pacing wires is routine in the immediate post-transplant period. Filling pressures of 10–15 mm Hg may be required to ensure adequate diastolic filling, but due to the impairment of the Frank–Starling mechanism (increased stroke volume with raised preload) from IRI, AV sequential pacing at rates up to 110 per minute may be required to maintain a normal cardiac output and stable arterial pressure. During the first week, the sinus rhythm of the transplanted heart usually increases steadily and pacing is weaned and suspended when a stable sinus rhythm above 60 per minute is established. Administration of amiodarone to the recipient prior to transplantation may delay sinus node recovery. Between 5% and 10% of transplanted hearts remain profoundly bradycardic and require implantation of a permanent pacemaker, usually after 3 weeks, which is allowed for the recovery of sinus rhythm. Oral beta agonists have been used to accelerate sinus node recovery, but it is unclear whether they are effective.

Atrial fibrillation is less common than after other forms of cardiac surgery possibly due to better preservation of atrial myocardium. Atrial flutter occurring beyond the first week post-transplant is suggestive of acute rejection and should prompt endomyocardial biopsy. If pacing wires are still present they can be used to attempt atrial overdrive pacing (AOD). Alternatively AOD pacing can be performed at the completion of the biopsy procedure. Ventricular tachyarrhythmias are very uncommon and are usually observed in the setting of severe PGF.

VASOACTIVE AGENTS

The goal in the immediate postoperative phase is to achieve an appropriate cardiac output and perfusion pressure to preserve organ function. Due to the autonomic denervation, the transplanted heart usually requires some level of chronotropic and inotropic support with catecholamines both for the right and left ventricles. At the same time, however, it is important to consider the vulnerability of the graft from IRI, and the requirement of escalating doses of catecholamines, which inevitably increase myocardial oxygen requirement, may signify the need for mechanical support in the form of intra-aortic balloon counter pulsation or VA-ECMO.

Table 104a.2 Effect of drugs on denervated heart

DRUG	EFFECT ON THE HEART	MECHANISM
Digoxin	Increased contractility; Minimal effect on AV node	Direct myocardial effect; denervation
Atropine	None	Denervation
Adrenaline	Increased contractility; increased chronotropy	Denervation hypersensitivity
Noradrenaline	Increased contractility; increased chronotropy	Denervation hypersensitivity
Isoprenaline	Normal increase in contractility; normal increase in chronotropy	No neuronal uptake
Hydralazine	No reflex tachycardia	Denervation
Beta-blockers	Increased antagonist effect	Denervation
Verapamil	Blocks AV node	Direct effect
Nifedipine	No reflex tachycardia	Denervation

AV, Atrio-ventricular.

With permission from Deng M. Cardiac transplantation. *Heart*. 2002;87:177-184.

Isoprenaline has been used traditionally in the immediate post-transplant phase based on its chronotropic, inotropic and pulmonary vasodilator properties. In the absence of large trials, it is unclear whether these properties make it any more effective than alternative inotropic agents such as dobutamine, milrinone and adrenaline. Adrenaline or noradrenaline is often co-administered if the patient is hypotensive from post CPB vasoplegia. Thyroid hormone administration to the heart transplant recipient has been advocated by some authors but as with its use in the donor, its administration to the recipient is controversial. A recent pilot RCT of levosimendan-based versus standard inotropic therapy in the early postoperative period demonstrated a lower incidence of peri-operative acute kidney injury (AKI) – albeit with a higher vasopressor requirement and longer ICU stays.[31] Usually, inotropic and vasopressor support can be weaned within the first 48–72 hours as the donor heart recovers.

Pulmonary hypertension in the postoperative phase can be damaging due to this increased afterload presented to an untrained RV. While an element of this might be 'fixed' from long-standing heart disease, most centres use inhaled nitric oxide or prostacyclin in the immediate postoperative phase to ameliorate this. Small studies in the post-transplantation phase have shown the ability of these agents to selectively dilate pulmonary vessels and thereby reduce pulmonary artery pressures and CVP, as well as increase cardiac output and mixed venous oxygen saturation.[32]

Prior to heart transplant, the recipient's arterial circulation in many cases has adapted to chronic hypotension with systolic blood pressures in the range of 80–90 mm Hg. Replacement of an end-stage failing heart with a healthy donor heart often leads to a rapid increase in blood pressure in the recipient as the donor heart regains normal function over the first few days post-transplant. This may be further exacerbated by the introduction of calcineurin inhibitors (CNIs), which can cause renal and systemic vasoconstriction. Systolic blood pressures in excess of 140 mm Hg in the first weeks after heart transplantation may result in hypertensive encephalopathy, which may manifest as headache, drowsiness and seizures. Therefore, strict control of blood pressure, initially with intravenous vasodilators, such as glyceryl trinitrate then with oral agents, may be required during this early postoperative phase.

RESPIRATORY MANAGEMENT

As mentioned, in uncomplicated cases extubation is generally achieved in the first few hours. An appreciation of cardiopulmonary interactions is especially relevant in these patients. Minimising PVR by ventilating at appropriate lung volumes (close to functional residual capacity), optimising oxygenation and minimising acidosis are important considerations. Similarly the effects of increase in systemic preload and afterload with extubation should be anticipated in patients with unstable graft function.

FLUID THERAPY AND RENAL MONITORING

Judicious attention to volume status is a key component of the early ICU management. This is due to the vulnerable state of the RV and its sensitivity to large volume boluses, which could result in a spiral of progressive RV dilatation and dysfunction. Similarly, blood and product therapy should be rationalised owing to their potential adverse effect on PVR. Patients who have had a prior left ventricular assist device are more likely to suffer bleeding due to extensive dissection and anticoagulant therapy, and use of viscoelastic tests (such as thromboelastography) to guide haemostatic therapy may be of benefit.

The incidence of AKI in heart transplant recipients varies with definitions used, but approximately 6%–10% require continuous renal replacement therapy (CRRT) in the postoperative phase. Although the majority of these patients do not require long-term renal replacement therapy (RRT), they have a higher mortality rate. Risk factors for AKI in a study of 307 consecutive recipients in Europe were previous cardiac operation, blood transfusion, troponin release and length of ischemic time.[33] Patients who are fluid overloaded may benefit from early CRRT to overcome the adverse consequences of myocardial and other organ oedema. Additionally, consideration of reduction of CNI dose or alternative immunosuppression may be required.

IMMUNOSUPPRESSION

Maintenance immunosuppression initially involves the administration of three drugs in combination – high-dose corticosteroids, an anti-metabolite (mycophenolate mofetil or azathioprine) and a CNI (cyclosporine or tacrolimus). Some transplant units also use *induction* therapy, either a T cell cytolytic agent (e.g. antithymocyte globulin) or an antibody that specifically blocks the activated IL2 receptor (e.g. basiliximab).[1,2] The T cell cytolytic agents not only are more potent immunosuppressive agents, but also are associated with more side effects related to the acute destruction of large numbers of T cells in the circulation (the so-called 'cytokine release syndrome'). Their use is associated with an increased risk of viral and fungal infections as well as later development of post-transplant lymphoproliferative disease (PTLD). The IL2R inhibitors have a much better side effect profile and their use is not associated with any increased risk of infection or PTLD.

INFECTION PROPHYLAXIS

With currently used immunosuppressive drug protocols, the risk of infection is relatively low. Prophylactic antibiotic therapy is routine. A cephalosporin administered intravenously over the first 24 hours is

routine; however, the choice of antibiotic may vary if the recipient is known to be colonised with multi-resistant organisms. Pneumocystis prophylaxis in the form of oral co-trimoxazole is commenced in the first week post-transplantation and continued indefinitely. Nystatin oral solution to prevent oropharyngeal candidiasis is also administered for the first 2 weeks post-transplant. Prophylaxis against other fungi particularly aspergillus varies and depends on local resistance patterns. Inhaled amphotericin for the first week followed by oral itraconazole for 3 months is one approach. In the event of a cytomegalovirus (CMV) mismatch (CMV-positive donor with CMV-negative recipient) oral valganciclovir is administered for the first 3–6 months. Some centres also administer valganciclovir to CMV-positive recipients.

Other routine drugs administered in the immediate post-transplant period including a typical post-transplant drug treatment protocol are listed in Table 104a.3.

Table 104a.3 Peri-operative heart transplant drug treatment protocols currently utilised in the heart transplant unit at St Vincent's Hospital, Sydney

AREA	
Pre-operative on ward	Mycophenolate mofetil 1.5 g p.o.
In anaesthetic bay	Basiliximab 20 mg IV: if creatinine >120 µmol/L on night of transplant, or previously recorded creatinine >120 µmol/L, or LVAD, BiVAD or TAH (Give second dose of 20 mg IV on day 4) Vitamin K 10 mg IV: if on warfarin Methylprednisolone 500 mg IV Ganciclovir 5 mg/kg IV: if CMV mismatch (D+/R–). Cefazolin 500 mg
In theatre off bypass	Methylprednisolone 500 mg IV Cefazolin 500 mg IV
ICU or ward	IMMUNOSUPPRESSION
	DAY 1
	Tacrolimus 0.5 mg p.o. or via nasogastric tube: if Cr <140 µmol/L: give test dose or, if unable to commence oral therapy, commence infusion at 0.015 mg/kg/day IV given as continuous infusion over 24 h If Cr >140 µmol/L: hold tacrolimus until creatinine <140 µmol/L Methylprednisolone 125 mg IV q8h × 3 doses Myocphenolate mofetil 1 g IV/p.o. b.d.
	DAY 2 ONWARDS
	Prednisolone 1.0 mg/kg/day p.o. in two divided doses until 2 weeks post-transplant then wean by 0.1 mg/kg/day each week until complete withdrawal Mycophenolate mofetil 1 g IV/p.o. b.d. Tacrolimus capsules p.o. b.d. as charted (titrate to target trough level of 8–12 µg/L by day 7) Basiliximab 20 mg IV on day *4 – if given as induction*
	BACTERIAL PROPHYLAXIS
	Cefazolin 1 g IV q8h × 3 doses
	FUNGAL PROPHYLAXIS
	Nystatin drops 1 mL p.o. q.i.d. Sulfamethoxazole 800 mg p.o. *and* Trimethoprim 160 mg (Bactrim DS), once daily on Mondays and Fridays. Itraconazole 200 mg p.o. b.d. to be given until 12 weeks post-transplant Measure itraconazole trough level on day 14 (target >500 µg/L) Tacrolimus level must be rechecked when itraconazole ceased
	VIRAL PROPHYLAXIS
	If CMV mismatch: ganciclovir 5 mg/kg/day IV on Monday, Wednesday and Friday until IV line is removed Then continue with valganciclovir 450 mg p.o. b.d. (adjusted to renal function) to be given until 12 weeks post-transplant

Continued

Table 104a.3 Peri-operative heart transplant drug treatment protocols currently utilised in the heart transplant unit at St Vincent's Hospital, Sydney—cont'd

PAIN MANAGEMENT
Morphine 1–2.5 mg IV p.r.n. Morphine 5–10 mg IM/SC p.r.n. Paracetamol 1 g p.o./IV q.i.d.
BOWEL MANAGEMENT
Docusate with sennosides (50 mg, 8 mg) p.o. 2 b.d. Movicol p.o. 1 sachet daily
GIT PROTECTION
Ranitidine 50 mg IV t.d.s., followed by Ranitidine 150 mg p.o. b.d. on ward
LIPID MANAGEMENT
Pravastatin 40 mg p.o. nocte
BONE PROTECTION
Cholecalciferol 1000 U p.o. daily Calcium citrate 2 tablets p.o. daily

BiVAD, Biventricular assist device; *CMV*, cytomegalovirus; *LVAD*, left ventricular assist device; *TAH*, total artificial heart.

Table 104a.4 Complications of heart transplantation

COMPLICATION	APPROXIMATE INCIDENCE	COMMENTS
ACUTE		
Primary graft failure	10%–20%	Requiring mechanical support with IABP, VA-ECMO or VAD
Acute rejection	25%–30%	Requiring pulse steroids in first 12 months
Bradycardia requiring pacemaker	11%	Majority sinus node dysfunction – bi-atrial technique
Acute kidney injury	15%	RIFLE score I or F, 6%–10% require RRT, very few require long-term RRT
Infection	Variable	Affected by host factors, level of immunosuppression, time after transplant.
Tricuspid regurgitation (TR)	19%–84%	Ranging from mild to severe. About 15% have long-term TR
CHRONIC		
Chronic allograft vasculopathy	11%, 22% and 45%	Angiographically detectable at year 1, 2 and 4 years
Neoplasms	2–4-fold increased risk	Predominantly skin and PTLD

IABP, Intra-aortic balloon pump; *PTLD*, post-transplant lymphoproliferative disorder; *RIFLE*, risk, injury, failure, loss, end-stage kidney disease; *RRT*, renal replacement therapy; *TR*, tricuspid regurgitation; *VAD*, ventricular assist devices; *VA-ECMO*, veno-arterial extracorporeal membrane oxygenation.

COMPLICATIONS

PRIMARY GRAFT FAILURE

PGF is a syndrome in which the transplanted heart fails to meet the circulatory requirements of the recipient in the immediate post-transplant period as a consequence of either single or biventricular dysfunction (Table 104a.4). It is manifested as hypotension and low cardiac output in the presence of adequate filling pressures.[9,10] In most instances, it is likely to result from a multifactorial process with contributing elements from the donor, the recipient and the transplant process.[9] PGF is the most feared early complication after heart transplantation and accounts for approximately 40% of all deaths within the first month.[2] The reported incidence varies widely between studies with estimates ranging between 2.3% and 26%.[9] Most of the variability can be attributed to inconsistent definitions used by different authors. When defined as the need for high dose inotropes or mechanical assist devices in the immediate post-transplant period, most investigators

Table 104a.5 International society for heart and lung transplantation diagnostic criteria and grading of primary graft dysfunction after heart transplantation

PRESENCE OF	EVIDENCED BY
Appropriate time frame	Onset <24 h post transplantation
Ventricular systolic dysfunction – left, right or biventricular dysfunction	Echocardiographic evidence of dysfunction
Cardiogenic shock lasting more than 1 h	Low systolic blood pressure <90 mm Hg and/or Low cardiac output – <2 L/min/m^2 Despite adequate intra-cardiac filling pressures – CVP >15 mm Hg and/or PAoP >20 mm Hg
Circulatory support	Mild: Low dose inotropes Moderate: High dose inotropes (Inotrope score >10) or need for IABP Severe: Need for total circulatory support: extracorporeal membrane oxygenation (ECMO) or equivalent
Exclusion of secondary causes of primary graft failure (PGF)	For example, cardiac tamponade, hyperacute rejection

CVP, Central venous pressure; *IABP*, intra-aortic balloon pump; *PAop*, pulmonary artery occlusion pressure.

Table 104a.6 Recognised risk factors for primary graft failure after heart transplantation

DONOR FACTORS	RECIPIENT FACTORS	PROCEDURAL FACTORS
Age >30 years	Age >60 years	Ischaemic time >180 min
Cardiac dysfunction on echo	Ventilator support	Donor recipient weight mismatching
High-dose inotropic support	Intravenous inotropic support, mechanical support	Female donor to male recipient
Cause of brain death	Pulmonary hypertension	Concomitant lung retrieval
Primary graft dysfunction of other organs	Overweight, diabetes mellitus	

have reported incidence rates of 10%–20% or higher. Standardised diagnostic criteria for PGF have now been developed and are listed in Table 104a.5.[10] A number of risk factors, which are donor-related, recipient-related and procedure-related, have been identified (Table 104a.6).

The management of PGF depends on the severity and the mechanism. Right ventricular failure is commonly the main contributor. The donor heart, especially when it is young and comparably small, cannot easily adapt to the often-observed pulmonary hypertension and increased PVR of the recipient. Additionally, adaptation of the donor heart may be impaired by IRI associated with organ preservation and inflammation triggered by CPB. As a result, the RV dilates and becomes ischemic which further reduces contractility. The decrease in pulmonary blood flow and the leftward shift of the interventricular septum lead to a change of the LV shape, a lower LV preload and a reduction of systemic pressure and cardiac output, which further impairs coronary perfusion. Principles of management of RV failure are listed in Table 104a.7.[34–36]

Table 104a.7 Principles of management of right ventricular failure

- Maintaining RV coronary perfusion pressure with vasopressor drugs
- Preventing RV overload by minimising excess fluid administration while monitoring the CVP closely
- Reducing (PVR) with selective pulmonary vasodilator therapy (inhaled nitric oxide or epoprostenol)
- Augmenting RV contractility by administration of inodilator drugs and using pacing as required

CVP, Central venous pressure; *PVR*, pulmonary vascular resistance; *RV*, right ventricle.

Small reports suggest that levosimendan may be a useful, adjunctive inotropic drug in the treatment of patients with primary graft dysfunction after heart transplantation.[37] In severe cases, implantation of an acute right ventricular assist device (RVAD) may be required. Longer acting agents, such as oral sildenafil, may be required to allow weaning of nitric oxide and RVAD support in such cases.[38] In severe cases

of left- or bi-ventricular failure, the early institution of total mechanical circulatory support is essential to avoid multiorgan failure.[39,40] A number of acute mechanical support options are available, but the most widely used device is VA-ECMO, which can be deployed by either peripheral or central cannulation.[39,40] Total circulatory support may be required for 7 days or longer.

INFECTIONS

Infections encountered in heart transplant recipients during the ICU phase of management are similar to those affecting routine cardiac surgical cases. Risk factors for bacterial sepsis that are of particular importance for the heart transplant recipient include pre-transplant mechanical or ventilator support and the need for high dose peri-operative immunosuppression. Other factors associated with an increased risk of sepsis in the ICU patient, such as previous colonisation with multiresistant bacteria, large volume blood loss and transfusion, acute renal failure or placement of intravenous lines, also apply to the heart transplant recipient. Classic signs of sepsis, such as high fever, may be masked or blunted by immunosuppressive therapy, so a high index of suspicion is required. Infections usually respond to conventional antibiotic therapy but choice will depend on local sensitivities. The herpes simplex virus is common in the early post-transplant period and usually responds to oral acyclovir. Clinical infections with other viruses (e.g. herpes zoster and CMV) usually have a more delayed onset after the ICU phase of treatment. Oropharyngeal candidiasis is probably the most common fungal infection and is usually preventable with oral nystatin. Occasionally, patients may present with early candidaemia, which is an important consideration in the acutely septic patient. Other fungal infections, such as aspergillus, may also occur during the immediate postoperative period but more typically occur at a later time point.

ACUTE REJECTION

Acute rejection is an adaptive immune response mounted by the recipient against the transplanted donor organ. Classical acute rejection is predominantly a T lymphocyte-mediated inflammatory response directed against the grafted organ. As the rejection response progresses, graft injury in the form of myocyte necrosis and myocardial oedema develop. In more severe rejection, other inflammatory cells, such as eosinophils and neutrophils, are recruited into the myocardium, and myocardial haemorrhage may occur. Acute cellular rejection can occur at any time but is unusual during the first week. It may be suspected on clinical grounds but is often completely asymptomatic. Symptoms are often non-specific and include fatigue, dyspnoea and fever.

Diagnosis is based on the pathological finding of a lymphocytic inflammatory infiltrate on endomyocardial biopsy, and the grading of severity is based on the extent of the inflammatory infiltrate and the presence or absence of myocyte necrosis.[41] Most transplant programmes perform regular surveillance endomyocardial biopsies commencing at about 1 week post-transplant. Biopsies are repeated weekly for the first month post-transplant, fortnightly between months 1 and 3, monthly between months 4 and 6 then less commonly thereafter, or may be performed at any time between scheduled biopsies if there is a clinical suspicion of rejection.

The overall rate of biopsy-proven acute rejection has been declining in recent years probably as a result of more effective immunosuppressive therapy.[2] Historically, most patients experienced one or more episodes of acute rejection requiring 'pulsed' steroid therapy (e.g. intravenous methylprednisolone 0.5–1.0 g daily for three doses) during the first 3 months after transplantation; however, recent registry reports indicate that only one in three heart transplant recipients will require this during the first 12 months.[2]

Antibody-mediated rejection is also now recognised as a major cause of graft injury and loss.[42] It occurs as a result of the formation of donor-specific antibodies (DSA) in the recipient that are directed usually against donor human leukocyte antigens. These may be present pre-transplant as a result of previous transfusions, organ transplants, viral infections or pregnancies. Hyperacute rejection (HAR) occurring during the first hours or days post-transplant is usually triggered by the presence of preformed DSA in high circulating titres. Fortunately, this is now a rare event as DSAs are normally detected by prospective or virtual cross-matching between the donor and recipient.[43] HAR often presents with rapid onset of severe graft dysfunction and may be difficult to distinguish from PGF. Apart from acute circulatory support, treatment involves high-dose intravenous steroids, plasmapheresis and intravenous immunoglobulin.[44] In more severe cases, monoclonal antibody treatments have been used, including rituximab and eculizumab.[44]

TRICUSPID REGURGITATION

This is the most common valvular abnormality, occurring in 19%–84% of patients, depending on the definition of significant regurgitation. In the early stages after transplantation, most tricuspid regurgitation (TR) is functional and is usually secondary to geometric distortion of the AV annular ring, and preservation of atrial and tricuspid annulus geometry may prevent the development of TR. The ISHLT guidelines recommend that patients who are identified after surgery as having moderate to severe TR should have a repeat echocardiogram in the first 24 hours after the transplantation.[45] Most patients can be managed conservatively, mainly with diuretics, and only rarely do they require surgical

intervention. Routine endomyocardial biopsies, which are required for monitoring rejection, may contribute to the TR.

LATE COMPLICATIONS

Late complications of cardiac transplant, which are sometimes encountered in the ICU patient include:

Cardiac allograft vasculopathy (CAV) – This is among the primary causes of death after the first year. This disease, which is atherosclerotic in nature and progresses rapidly, is characterised by persistent perivascular inflammation and intimal proliferation. It is sometimes considered to be a manifestation of chronic rejection. Early diagnosis of CAV is limited due to the scarcity of clinical symptoms of ischemia in the denervated graft.[46,47]

Neoplasms are among the major causes of late mortality with a two- to fourfold increase in risk compared to the general population. This elevated risk is related to the immunosuppression regimen and includes the malignant tumours related to viral infections, such as lymphoma (as a part of the PTLD) – both linked to infection by the Epstein–Barr virus, Kaposi sarcoma (related to the human herpes-virus 8), anogenital cancers (linked to the human papilloma virus) and hepatic cancer (hepatitis B and C virus).[47]

CONCLUSIONS

Heart transplantation has emerged as the most effective treatment available for patients with end-stage heart disease. Transplantation is limited by donor numbers so that only a small percentage of patients who might benefit are able to undergo the procedure. The severe shortage of donor organs has resulted in an increased utilisation of higher risk donors with an associated risk of primary graft dysfunction or failure, which poses significant challenges during the initial ICU management of these patients. Nonetheless, the large majority of heart transplant recipients make an excellent recovery following transplant surgery and return to a quality of life that is close to that of normal people of the same age. Almost two-thirds of heart transplant recipients live for more than 10 years and one-third live for more than 20 years after transplantation. Improvements in donor management and organ preservation should increase the number of cardiothoracic organs available for transplantation, while ongoing refinements to post-transplant management are likely to result in further improvements in the long-term survival of these patients.

Lung transplantation

Priya Nair, Paul C Jansz, Marshall Plit

INTRODUCTION

Lung transplantation commenced in the 1960s but, as with heart transplantation, early results were poor and the procedure was largely abandoned until the 1980s. The first successful heart–lung transplant was performed at Stanford University Medical Center in 1981. During the next decade, single and bilateral lung transplantation emerged as viable procedures for patients with end-stage lung disease. The International Society for Heart and Lung Transplantation (ISHLT) registry reports more than 55,000 lung transplants and currently, internationally, more than 4000 lung transplants are performed each year.[1] Post-transplant survival – although not as good as for other organs – has improved steadily. In the most recent ISHLT report, median post-transplant survival was 7 years with 80% survival at 1 year, 54% at 5 years and 32% at 10 years.[2] Whereas heart transplant activity has plateaued in the last decade, lung transplant activity has been increasing steadily.[2]

Historically, the vast majority of donors had undergone brain death (DBD). More recently, donation after circulatory death (DCD) has re-emerged as an important source of donor lungs and in some programmes up to one-third of lung transplants are performed from DCD donors.[3,4]

Virtually all of the improvements in survival have been during the first few months after transplantation.[5] This can be explained by advances in immunosuppressive therapy, with fewer deaths due to uncontrolled rejection or infection, and better patient selection. Nonetheless, the first few days and weeks after transplantation are still a period of high mortality risk due mainly to the complications of primary graft dysfunction (PGD) or overwhelming infection.

SELECTION OF PATIENTS FOR LUNG TRANSPLANTATION

The primary indication is the presence of advanced, non-malignant lung disease for which there is no alternative therapy. Guidelines for selection have been extensively reviewed elsewhere.[6] The major disease categories are chronic obstructive pulmonary disease (COPD)/emphysema including alpha$_1$-antitrypsin (AAT) deficiency, pulmonary fibrosis, cystic fibrosis (CF), bronchiectasis and pulmonary vascular disease.[5] Collectively, these diseases account for over 90% of cases.[6] Bilateral lung transplantation is the most commonly performed, and accounts for approximately 75% of procedures.[6] Single lung transplantation is still occasionally performed for non-AAT deficiency-associated COPD and pulmonary fibrosis, but rarely for other lung diseases. Combined heart/lung transplantation is now a relatively rare procedure.

A critical aspect of the decision making regarding suitability is the capacity of the patient to survive the stresses of surgery and postoperative recovery. For this reason, patients who are either acutely or chronically unwell are deemed unsuitable. Objective criteria for defining these characteristics are lacking and decisions have, to a large extent, been based on clinical judgement.[7] Quantitative measures of frailty may provide a more objective measure on which to base decisions; however, considerable further research is required.[7,8] The problem has been further compounded by the lack of an 'artificial lung' to bridge patients on ventilatory support and enable participation in a rehabilitation programme prior to transplant surgery. Extracorporeal membrane oxygenation (ECMO) support in ambulatory patients or the use of extracorporeal carbon dioxide removal devices may go some way towards addressing this limitation.[9,10]

In general, patients with acute respiratory failure (e.g. adult respiratory distress syndrome [ARDS], pneumonia) requiring ECMO are not considered suitable due to the uncertain recovery from the underlying illness. Proposed contraindications for transplantation in this patient group are listed in Table 104b.1.[11] Due to the lack of evidence, these are based on small case series and expert opinion.

THE POTENTIAL LUNG DONOR

The donor lung has a greater tolerability to the sequelae of brain death and subsequent insults associated with lung retrieval and transplantation than was initially

ABSTRACT

Lung transplantation has emerged as the most effective treatment available for patients with non-malignant end-stage lung disease. Transplantation is limited by donor numbers, so that only a small percentage of patients who might benefit are able to undergo the procedure. The severe shortage of donor organs has resulted in an increased utilisation of higher risk donors with an associated risk of primary graft dysfunction or failure, which poses significant challenges during the initial intensive care unit (ICU) management of these patients. Nonetheless, the large majority of lung transplant recipients make an excellent recovery following transplant surgery and return to a quality of life that is close to that of a healthy non-transplant population. Median survival following lung transplantation is 6 years with one-third of patients now living beyond 10 years. Improvements in donor management, organ preservation and the availability of donor lungs after circulatory death, in addition to brain death, should increase the number of cardiothoracic organs available for transplantation. Ongoing refinements to post-transplant management are likely to result in further improvements in the long-term survival of these patients.

Table 104b.2 Standard versus higher risk criteria for donor lungs

DONOR PARAMETER	STANDARD CRITERIA	HIGHER RISK CRITERIA (MARGINAL)
Age	<60 years	>60 years
Smoking history	<20 pack years	>20 pack years
Chest trauma	Absent	Present
Aspiration	Absent	Present
Chest X-ray	Clear	Abnormal
Arterial blood gases	Pa_{O_2} >300 mm Hg on Fi_{O_2} of 100%	Pa_{O_2} >300 mm Hg on Fi_{O_2} of 100%
Sputum	Nil or minimal	Purulent, documented infection
Bronchoscopy	Clear or minimal secretions	Purulent

considered. In particular, the tolerability to ischaemia reperfusion injury (IRI) is better than that of the heart. Donor lung function appears to be less affected by age and donors up to age 75 years are considered. DCD donors account for increasing proportions of solid-organ transplants.[3,4]

DONOR ELIGIBILITY CRITERIA

These vary between jurisdictions and categories for standard and higher risk donors (see Table 104b.2). While there have been concerns that the use of higher risk donors will lead to increased rates of PGD and death, for characteristics such as donor age, donor Pa_{O_2} or mode of death (DCD vs DBD) this has not been corroborated.[12,13] Moreover, the risk associated with donors with characteristics associated with higher mortality (e.g. smoking) needs to be balanced against the risk of death on the waiting list.[14]

Intensive care management of the donor is covered in a separate chapter.

DONOR LUNG PRESERVATION

The major method of preservation has been the administration of a cold pneumoplegic solution followed by static storage in a preservation solution. Perfadex, a normokalaemic colloid (dextran 40) solution, has emerged as the favoured solution for both DBD and DCD organs.

A major advance has been the use of ex-vivo lung preservation (EVLP) devices. This concept was first advanced by Steen[15,16] and later developed by Keshavjee,[17] who reported that EVLP could be used not only to prevent deterioration but also to restore function in lungs from extended criteria donors. A number of EVLP devices have been approved for clinical use[18] including a portable normothermic perfusion device.[19]

LUNG TRANSPLANT SURGERY

Bilateral lung transplantation was initially developed as an en-bloc technique with a single tracheal anastomosis; however, the high incidence of ischaemic anastomotic complications has led to this procedure largely being replaced by bilateral sequential single lung transplant (BSSLT) procedure. BSSLT is most commonly performed with the larger right lung transplanted first followed by the left. The surgical approach may be via a midline sternotomy, horizontal bilateral thoracosternotomy (clam-shell incision), or two smaller anterolateral thoracotomies (without division of the sternum).[20] The operation may be performed with or without cardiopulmonary bypass (CPB), depending on the ability of the native lung to sustain the cardiac output and ventilation during implantation of the first lung, and then the ability of the transplanted lung to sustain the cardiac output and ventilation during implantation of the second lung.[21] While CPB ensures the maintenance of adequate ventilation and vital organ perfusion, it requires anticoagulation and is associated with an increased risk of peri-operative bleeding and PGD.[21,22] CPB does, however, offer the advantage of better operating conditions, and importantly allows control of lung reperfusion conditions. In the absence of CPB, the newly transplanted right lung must take over ventilation in order for the left lung to be implanted. At this time the transplanted right lung will receive the entire cardiac output, which could be detrimental. A cuff of donor left atrial tissue containing the confluence of the pulmonary veins is anastomosed

to the recipient left atrium followed by the anastomosis of the donor to recipient pulmonary artery and finally the main bronchus. More recently, improved short- and long-term outcomes have been demonstrated with lung transplant surgery performed on veno-arterial ECMO as compared to conventional CPB.[23]

Single lung transplantation is performed via a thoracotomy with the order of anastomoses being bronchus, left atrium and pulmonary artery. Combined heart–lung transplantation is the most extensive cardiothoracic transplant and is restricted almost exclusively to patients with complex congenital heart disease with irreversible pulmonary vascular disease. The operation is performed on CPB as an en-bloc procedure with sequential anastomosis of the trachea, right atrium and aorta. Uncontrollable bleeding from adhesions formed during previous thoracic operations or from systemic to pulmonary arterial collaterals is a leading cause of operative death. Damage to major nerves (e.g. vagus, phrenic and recurrent laryngeal) is another potential complication and may contribute to postoperative morbidity.

ANAESTHETIC CONSIDERATIONS

Specific recipient pathology and cardiorespiratory status should be taken into consideration. When surgery is performed off CPB, single lung ventilation needs to be safely and effectively established.

In addition to standard monitoring lines listed below, intraoperative transoesophageal echocardiography is used to evaluate volume status, assess myocardial (particularly right ventricular) function, assess pulmonary pressures, rule out intracardiac shunts and evaluate vascular (particularly pulmonary venous) anastomosis after allograft implantation.[24]

POSTOPERATIVE MANAGEMENT IN THE INTENSIVE CARE UNIT

Optimal management requires an understanding of the unique pathophysiological challenges that apply to these patients.

Transplantation results in denervation below the level of the bronchial anastomosis (or below the tracheal anastomosis in the case of heart–lung transplantation). The main consequence is loss of the normal cough reflex and markedly impaired mucociliary clearance, so patients are at high risk of sputum retention during the early postoperative phase. Respiration both at rest and during exercise is unaffected by lung denervation. Pulmonary vascular resistance, airway resistance and reactivity also appear to be unaffected.

Routine monitoring includes electrocardiography, invasive arterial and central venous lines, pulmonary artery catheter and urinary catheter. Apical and basal pleural drains will be in place and are placed on continuous suction. Air leaks can occur in the first few days but are usually minor and self-limiting. Bronchoscopy is performed to check the bronchial anastomosis and to suction any secretions. Postoperative analgesia requires careful attention using opiate-sparing strategies where possible, such as thoracic epidural infusions, which promote better respiratory function.

RESPIRATORY MANAGEMENT

The goal is to wean and extubate the patient as soon as this can be safely achieved in the individual context. There is limited evidence on optimum postoperative ventilatory management; however, data from the ARDS literature have been extrapolated to this situation.[25,26] Important considerations that distinguish this cohort from other postoperative patients include recent thoracotomies, phrenic nerve dysfunction, pleural dysfunction, air leaks and donor-patient size mismatch. Additionally, as discussed below, increased capillary permeability from IRI contributes to the risk of acute lung injury.

An international survey showed that ventilation practices varied greatly between transplant centres in 18 countries.[27] Most did not consider donor characteristics in their strategy. In the absence of randomised controlled trials in this area to inform practice, recommendations for bilateral lung transplant recipients include using tidal volumes of 6 mL/kg recipient body weight, limiting peak pressures to less than 35 cm of water, using the minimum Fi_{O_2} to achieve Pa_{O_2} of 60–80 mm Hg and the use of positive end-expiratory pressure (PEEP), but limited to less than 12.5 cm due to the increased risk of air leaks.[11] Two studies[25,28] have demonstrated an association between high inflation pressures and poor outcomes, as well as higher tidal volumes with severity of PGD, respectively, adding weight to these recommendations.

Ventilation for the unilateral lung transplant patient for emphysema presents further challenges due to the risk of hyperinflation of the native lung, which is more compliant than the transplanted lung, which can result in mediastinal shift and haemodynamic instability. Additionally, the hyperinflated lung compresses the allograft, which results in atelectasis and impaired gas exchange. This situation has been reported in 15%–30% of unilateral procedures.[29] Therefore earlier extubation is particularly advantageous. Occasionally, single lung transplant recipients may require placement of a double-lumen endotracheal tube to allow differential ventilation of the native and transplanted lungs.

In case of postextubation respiratory failure, non-invasive ventilation or high-flow nasal prongs in cases of isolated hypoxaemic respiratory failure may be effective strategies to prevent re-intubation. In case of re-intubation, early tracheostomy may facilitate weaning.[11] Approximately 14% of lung transplant recipients require prolonged mechanical ventilation. In a single-centre study, this was associated with

decreased survival. However the patients who survived to hospital discharge had similar outcomes compared to those who did not require prolonged mechanical ventilation.[30]

HAEMODYNAMIC MANAGEMENT

Most patients will require vasopressors, which can generally be weaned in the first few hours.

Recipients with pulmonary hypertension or right ventricular failure require close monitoring and potentially require the use of inodilators, such as milrinone or dobutamine, in addition to selective inhaled pulmonary vasodilators, such as nitric oxide or prostacyclin, to reduce right ventricular afterload.

Arrhythmias are common in the postoperative period, particularly in older patients with an incidence of 34%–75%, and are predominantly supraventricular. These are treated with cardioversion when haemodynamically significant or with medical therapy as in other situations.[31]

Calcineurin inhibitors (CNIs) in combination with corticosteroids predispose these patients to arterial hypertension. This should be treated assiduously to reduce the risk of acute neurological complications.

FLUID BALANCE AND RENAL SYSTEM

A restrictive fluid strategy is recommended to minimise the risk of pulmonary oedema. Pilcher et al. demonstrated an increased duration of ventilation, intensive care unit (ICU) and hospital mortality in lung transplant recipients who had a central venous pressure (CVP) greater than 7 mm Hg after excluding the effect of poor myocardial function and high inotrope requirement.[32]

Diuretics should be considered to mobilise fluid retention seen in the postoperative phase, and a further consideration is the absence of lymph drainage from the transplanted lung. On the other hand, hypovolaemia in combination with CNIs may predispose to pre-renal kidney injury.

In case of kidney injury, early renal replacement therapy with fluid removal to minimise allograft oedema may be required. Both CNIs and diuretics increase urinary magnesium excretion and hence regular checks and supplementation are required to prevent arrhythmias and lower seizure threshold.[33]

BLOOD MANAGEMENT

As with other critically ill patients, the use of blood and blood products should be rationalised. A study by Weber et al. demonstrated that the transfusion of red cells was an independent factor for worse outcome in lung transplant recipients.[34] A recent study showed no effect on all-cause mortality with red cells, but higher adjusted 1-year mortality associated with platelet transfusion.[35] Nowadays, point-of-care testing with viscoelastic tests (thromboelastography and thromboelastometry) and a goal-directed transfusion algorithm are used in some centres to rationalise blood management. However, transfusion-related immunomodulation (TRIM) might ameliorate rejection risk, although sensitisation with foreign antibodies may increase it.

GASTROINTESTINAL SYSTEM AND NUTRITION

Vagal disruption and gastroparesis make reflux common and therefore proton pump inhibitors are administered routinely. In addition, prokinetic agents, such as domperidone, are used and reverse Trendelenburg position is maintained.

Patients who are not extubated early should have a nasogastric tube inserted and enteral nutrition with high protein content (along with pancreatic enzymes in the CF population) is desirable.[33]

A combination of stool softeners and stimulants (e.g. coloxyl with senna) and osmotic laxatives are used. Further measures such as Gastrografin (Diatrizoate Meglumine) may be required if the return of bowel function is delayed. Intravenous immunosuppressive drugs are switched to the enteral route only when gastrointestinal function has recovered and efficient absorption is anticipated.

IMMUNOSUPPRESSION

Induction therapy, with a move away from polyclonal antithymocyte preparations to IL2R antagonists or alemtuzumab[2] is increasingly used. ISHLT data suggest a small improvement in survival in patients receiving induction therapy.

Maintenance immunosuppression involves the administration of three drugs in combination: corticosteroids, an antimetabolite (mycophenolate mofetil [MMF] or azathioprine) and a CNI (cyclosporine or tacrolimus). Tacrolimus and MMF are the preferred CNI and antimetabolite, respectively.[2] Recipients with CF are administered their cyclosporine with a pancreatic enzyme supplement.

INFECTION PROPHYLAXIS

Lung transplant recipients are at high risk of infection – more so than other transplant recipients – as the transplanted lung uniquely is in direct contact with the external environment and any potential airborne pathogens. Often the donor has evidence of lower airway colonisation or infection prior to retrieval. In the recipient, there is impaired ciliary function and loss of the cough reflex resulting in retained secretions. In addition, a substantial proportion of recipients – those with CF or bronchiectasis – are invariably colonised with multiresistant bacteria in the upper respiratory tract at the time of transplantation. These organisms can rapidly spread to the lower respiratory tract.

Bacterial prophylaxis: Donor sputum or bronchoscopy samples are used to guide therapy. For recipients with chronic suppurative lung disease, antibiotic prophylaxis will depend on sensitivities determined from pre-transplant surveillance. Targeted antimicrobial therapy to known donor organisms appears effective in modulating infection after transplantation. Otherwise, a third-generation cephalosporin with broad spectrum against Gram-positive and negative organisms (e.g. cefotaxime) is administered. *Fungal prophylaxis*: Pneumocystis jiroveci prophylaxis in the form of oral co-trimoxazole is commenced in the first week post-transplantation and continued indefinitely. For patients who are allergic, dapsone or monthly-inhaled pentamidine are suitable alternatives. Nystatin oral solution to prevent oropharyngeal candidiasis is also administered for the first few weeks post-transplant. Aspergillus infections are less common but potentially catastrophic. Inhaled amphotericin has been shown to significantly reduce the incidence of aspergillus and other fungal infections and is administered routinely until hospital discharge.[36] An alternative approach to aspergillus prophylaxis is the use of oral azoles such as voriconazole.[37] *Viral prophylaxis:* cytomegalovirus (CMV) may cause life-threatening pneumonitis and has been associated with an increased risk of the development of bronchiolitis obliterans syndrome (BOS). Risk is highest in recipients of lungs from CMV-seropositive donors, particularly when the recipient is CMV negative (D+/R–). Although clinical infection is extremely uncommon in the first month post-transplant, it is essential to commence prophylaxis immediately. Intravenous ganciclovir is administered initially, followed by oral valganciclovir (dose adjusted for renal function). The 2013 American Society of Transplantation guidelines recommend 12 months of prophylaxis for D+/R– lung transplant recipients.[38] Valganciclovir is administered for 6 months in D+/R+ and D–/R+ recipients. CMV hyperimmune globulin is also administered for up to 1 month to D+/R– recipients. Recipients who are Epstein–Barr Virus (EBV) naïve who receive lungs from EBV-seropositive donors (D+/R–) are at high risk of developing post-transplant lymphoproliferative disorder (PTLD), which carries a very high mortality. If they are not already receiving oral valganciclovir, EBV D+/R– recipients are maintained on valaciclovir indefinitely.

Other drugs administered in the immediate post-transplant period include an insulin infusion as required to control hyperglycaemia, which is common following the administration of high-dose steroids, calcium and vitamin D supplements to prevent osteoporosis and subcutaneous unfractionated heparin for deep vein thrombosis (DVT) prophylaxis. A typical post-transplant drug treatment protocol is shown in Table 104b.3.

Table 104b.3 Peri-operative lung transplant drug treatment protocols currently utilised in the Heart and Lung Transplant Unit at St Vincent's Hospital, Sydney

AREA	
Pre-operative on ward	Azathioprine 2–3 mg/kg PO Or Mycophenolate mofetil 1.5 g PO Tacrolimus capsules 0.05 mg/kg if creatinine <120 µmol/L Omit if creatinine >120 µmol/L
In anaesthetic bay	Methylprednisolone 500 mg IV Ganciclovir 5 mg/kg IV: if CMV mismatch Cefotaxime 1–2 g IV; unless alternative antibiotic/antifungal advised by respiratory physician based on donor and recipient microbiology
In theatre off bypass	Methylprednisolone 500 mg IV Cefotaxime 1–2 g IV; unless alternative antibiotic/antifungal advised by respiratory physician based on donor and recipient microbiology
ICU or ward	IMMUNOSUPPRESSION
	IV tacrolimus 0.01 mg/kg/day given as continuous infusion over 24 h, increasing to 0.02 mg/kg depending on first steady state level. Initial target steady-state level = 12–15 mcg/L PO tacrolimus BD once extubated and recovery of gastrointestinal function; dose titrated according to levels (target 12–15 µg/L) and renal function IV/PO azathioprine 2 mg/kg nocte **OR** IV/PO mycophenolate mofetil 1500 mg BD as per respiratory physician IV methylprednisolone 125 mg q8h ×3 doses then PO prednisolone 1 mg/kg/day in 2 divided doses, tapering by 5 mg every second day to a single daily dose of 0.2 mg/kg (until first transbronchial biopsy).

Table 104b.3 Peri-operative lung transplant drug treatment protocols currently utilised in the Heart and Lung Transplant Unit at St Vincent's Hospital, Sydney—cont'd

AREA	
	BACTERIAL PROPHYLAXIS
	Cefotaxime 1 g IV t.d.s. for 5 days – (may vary according to cultures) CF patients: antipseudomonal beta-lactam, modified as required according to microbiology results IV azithromycin 500 mg daily for 3 days then PO 250 mg on Mondays, Wednesdays and Fridays
	FUNGAL PROPHYLAXIS
	Nystatin oral drops 1 mL PO q.i.d. Nebulised salbutamol 5 mg BD 30 minutes before Nebulised amphotericin (Fungizone) 10 mg BD until discharge from hospital Sulfamethoxazole 800 mg PO *and* trimethoprim 160 mg (Bactrim DS), one daily on Mondays and Fridays (If *sulphur allergy*, check with consultant: give dapsone 100 mg daily on Monday/Wednesday/Friday)
	VIRAL PROPHYLAXIS
	CMV MISMATCH
	Ganciclovir 5 mg/kg IV daily Monday/Wednesday/Friday until IV removed, then PO valganciclovir 450 mg BD (dose adjusted according to renal function) indefinitely CMV hyperimmune globulin IV: 2 vials days 1, 2, 3, 7, 14, 21
	CMV-POSITIVE RECIPIENT
	Ganciclovir 5 mg/kg IV daily Monday/Wednesday/Friday until IV removed, then valganciclovir 450 mg PO BD (dose adjusted according to renal function) for 12 months
	EBV-NEGATIVE PATIENTS (IF NOT ALREADY ON VALGANCICLOVIR)
	VALACICLOVIR 500 MG PO BD (DEPENDING ON RENAL FUNCTION) INDEFINITELY
	PAIN MANAGEMENT
	Epidural anaesthesia (max. 5 days), if appropriate Morphine 1–2.5 mg IV p.r.n. Morphine 5–10 mg IM/SC p.r.n. Paracetamol 1 g PO q6h Oxycodone 5 mg PO q6h p.r.n.
	BOWEL MANAGEMENT
	Docusate with sennosides (50 mg, 8 mg) PO 2 BD Movicol PO 1 sachet daily For CF patients check with consultant if diatrizoic acid (Gastrografin) 25–50 mL PO p.r.n. to be given
	GIT PROTECTION/REFLUX MANAGEMENT
	Pantoprazole 40 mg IV daily or Ranitidine 50 mg IV t.d.s., then Rabeprazole 20 mg PO daily when on the ward If reflux symptoms persist, consider addition of: Domperidone 10–20 mg PO q.i.d. Sucralfate 1 g PO q.i.d.
	BONE PROTECTION
	Cholecalciferol 1000 U PO daily Calcium citrate 2 tablets PO daily IF BMD <–1: zoledronic acid 4 mg IV every 12 months

BMD, Bone mineral density; *CF*, cystic fibrosis; *CMV*, cytomegalovirus; *EBV*, Epstein–Barr virus; *GIT*, gastrointestinal tract; *ICU*, intensive care unit; *IM*, intramuscular; *IV*, intravenous; *PO*, oral; *SC*, subcutaneous.

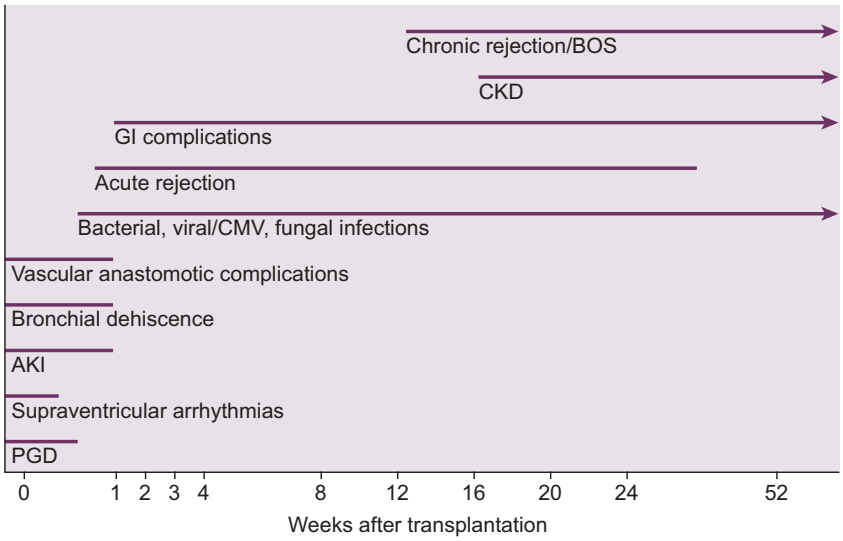

Figure 104b.1 Time course of complications following transplant. *AKI*, Acute kidney injury; *BOS*, bronchiolitis obliterans syndrome; *CKD*, chronic kidney disease; *CMV*, cytomegalovirus; *GI*, gastrointestinal; *PGD*, primary graft dysfunction.

COMPLICATIONS

In addition to immediate postoperative complications, lung transplant recipients may require ICU admission with respiratory or non-respiratory complications in the weeks or months following transplantation. Fig. 104b.1 indicates the timeline of potential complications that may require intensive care management. Recipients may be readmitted into non-transplant hospital ICUs and a basic understanding of the special complications and requirements of these patients is therefore important. However, it is strongly recommended that early communication and close cooperation between transplant centres and regional ICUs is undertaken.

PRIMARY GRAFT DYSFUNCTION

PGD is defined as a triad of worsening gas exchange, decreased lung compliance and alveolar and interstitial infiltrates, which are typically most extensive in perihilar regions, within the first 72 hours. This is multifactorial, and IRI is a major cause leading to increased capillary permeability and pulmonary oedema. The definition also requires exclusion of contributing factors, including hyperacute rejection, pulmonary venous anastomotic obstruction, cardiogenic pulmonary oedema and pneumonia.[39]

PGD is non-immune mediated, and is reported in up to 25% of recipients. The extent of the impaired oxygenation and pulmonary opacities has been used to grade severity (Table 104b.4).[40] In its most severe form, PGD3 results in fulminant ARDS. It represents the end result of multiple deleterious mechanisms provoked by donor brain death, mechanical ventilation, procurement, storage and IRI. IRI refers to sterile inflammation that occurs after substrate supply is restored following a period of ischaemia. Risk factors include prolonged graft ischemia, increasing donor age and recipient diagnosis of pulmonary hypertension (Table 104b.5).[40,41]

Table 104b.4 ISHLT grading system for primary graft dysfunction after lung transplantation

PGD GRADE	Pa_{O_2}/Fi_{O_2}	RADIOGRAPHIC INFILTRATES CONSISTENT WITH PULMONARY OEDEMA
0	>300	Absent
1	>300	Present
2	200–300	Present
3	<200	Present

PGD, Primary graft dysfunction.

Severe PGD is the major cause of early mortality, reported at up to 50%. It is also associated with increased morbidity related to the need for prolonged ventilation and ICU/hospital stay and delayed recovery of lung function. For recipients who survive an episode of severe PGD, long-term outcomes are adversely affected.

Treatment is supportive and aimed at maintaining adequate gas exchange until the syndrome resolves, using the principles of ARDS management. Inhaled nitric oxide has been shown to improve gas exchange and lower pulmonary vascular resistance acutely, but it has not been found to affect overall survival. In the more severe cases, ECMO support may be required to maintain gas exchange until the condition resolves,

Table 104b.5 Recognised risk factors for primary graft dysfunction after lung transplantation

DONOR FACTORS	RECIPIENT FACTORS	PROCEDURAL FACTORS
Age >60 years	Age >60 years	Single lung transplantation
Smoking >20 pack years	Ventilator support	Cardiopulmonary bypass
Pneumonia on CXR or purulent secretions on bronchoscopy	Pulmonary fibrosis	
Primary graft dysfunction of other organs	Pulmonary hypertension	
	Obesity	

CXR, Chest X-ray.

and a case can be made for early initiation in severe cases to avoid the burden of ventilator-induced lung injury (VILI).

Currey et al. demonstrated that implementation of an evidence-based algorithm for respiratory and haemodynamic management in the postoperative period was feasible and safe, and was associated with a reduction in severity of PGD.[28]

INFECTIONS

The infectious agents of most concern during the immediate post-transplant period are multiresistant bacterial pathogens, particularly in those undergoing transplantation for chronic suppurative lung disease. The risk of pneumonia, the most common infectious complication, is increased by the need for prolonged ventilation (in the case of PGD) and airway complications (discussed below). Angioinvasive aspergillosis infection – although rare – may result in rapidly progressive necrotising pneumonia, bronchial anastomotic dehiscence or even pulmonary arterial or venous anastomotic dehiscence, leading to exsanguinating haemoptysis. Another mould infection that can result in significant morbidity and mortality is scedosporium, particularly in the CF population in whom this organism can frequently be a pre-transplant coloniser, which is relatively difficult to treat. An aggressive diagnostic approach – including bronchial washings or computed tomography (CT)-guided fine needle aspiration of focal pneumonic lesions to look for respiratory viruses and CMV, bacteria, fungi and pneumocystis jiroveci pneumonia (PJP) – is essential to facilitate early diagnosis and the initiation of appropriate treatment.

ACUTE REJECTION

The incidence of acute rejection after lung transplantation has been declining. The ISHLT Registry reports that 28% of patients undergo treatment for acute rejection during the first 12 months after transplantation.[2] Hyperacute rejection is a form of humoral rejection that occurs in the first 24 hours following transplantation in recipients who have pre-formed anti-human leucocyte anitgen (HLA) antibodies. With improved sensitivity of testing, it is rarely seen, but it needs to be distinguished from IRI.

Symptoms and signs of acute rejection are non-specific and include dyspnoea, cough, sputum production, fever, declining FEV_1 (forced expiratory volume at 1 s) on spirometry and the appearance of alveolar infiltrates. The major differential diagnosis is lower respiratory tract infection. If unrecognised and untreated it can lead to rapid onset of severe graft dysfunction and a clinical picture of ARDS. It is important to remember that rejection and infection can occur simultaneously. Trans-bronchial biopsy and bronchial washing are required for pathological confirmation. The severity of acute lung rejection is graded histologically.[42] Treatment for biopsy-proven acute rejection in the first instance involves pulsed steroid therapy.

Respiratory failure occurring during the first 72 hours after transplantation is usually due to PGD. However, respiratory failure occurring at any time after this suggests another cause – usually either infection or rejection. Acute cellular rejection is very uncommon in the first week post-transplant but acute antibody-mediated rejection (AMR) may occur if there are preformed donor-specific antibodies. Treatment of acute AMR is intensive and involves a combination of plasmapheresis, administration of high-dose intravenous immunoglobulin (IVIG) and rituximab.

AMR can also occur later and is usually associated with acquired anti-HLA and less commonly non–anti-HLA antibodies. The relationship between the level of antibodies and loss of lung function does not have a high positive predictive value. Unlike AMR in other solid-organ transplant recipients, there are no standardised diagnostic criteria. Key diagnostic criteria include the presence of antibodies directed towards donor HLA and characteristic lung histology with or without evidence of complement 4d within the graft. Exclusion of other causes of allograft dysfunction increases confidence in the diagnosis.[43]

AIRWAY COMPLICATIONS

Peri-anastomotic bronchial ischaemia is relatively common, as re-anastomosis of the bronchial arteries is

not performed. The establishment of bronchial blood flow to the transplanted lung occurs over the first month post-transplant via ingrowth of collaterals from the recipient, but until then the transplanted lung is reliant on low-pressure retrograde collateral bronchial flow of (deoxygenated) blood from the pulmonary artery.[44,45] Major airway complications were reported in 1.4% of lung transplant recipients in a contemporary United Network for Organ Sharing (UNOS) Registry analysis.[44,46] Although rare they are associated with significant morbidity and mortality.[46] Ischaemia of the anastomosis predisposes to a number of airway complications including bronchial stenosis at or beyond the anastomosis, bronchomalacia, endobronchial infections and bronchial anastomotic dehiscence.[46] The latter is often associated with persistent large air leaks and development of fatal mediastinitis. Repeated bronchoscopic assessment of the anastomosis is undertaken during the first 4 to 6 weeks until healing is complete. A variety of bronchoscopic interventional procedures have been developed to treat airway complications, including balloon angioplasty and stenting.[45,46]

CHRONIC REJECTION OR BRONCHIOLITIS OBLITERANS SYNDROME

Chronic rejection is referred to as BOS. Patients may require admission into the ICU for complicating infection and ventilatory support. The diagnosis is based on a sustained decrease of greater than 20% in FEV_1 or the pathological presence of obliterating bronchiolitis. The incidence is highest after the first year; however, the risk increases to 60%–80% 5–10 years after transplantation, although meticulous targeting of cyclosporin levels has demonstrated reduced rates.[47] It is the major complication that adversely affects long-term survival, and may be progressive, may plateau or may progress gradually. Treatment for established BOS has not proven to be effective; consequently, in the event of deterioration, prolonged mechanical ventilation or ECMO is not recommended unless imminent re-transplantation is being considered in special circumstances. The severity of lymphocytic bronchiolitis on transbronchial biopsies is associated with increased risk of BOS and death independent of acute rejection.[48] The ISHLT recommendations are conditional, due to low-quality evidence, and include switching from cyclosporine to tacrolimus, a trial of azithromycin, consideration of antireflux surgery for patients with confirmed gastro-oesophageal reflux and re-transplantation for end-stage refractory BOS.[49]

OTHER PULMONARY COMPLICATIONS

1. Vascular anastomotic complications: kinking or thrombosis of the pulmonary venous anastomoses is occasionally seen in the immediate postoperative period. Focal opacities on the X-ray should prompt suspicion of this complication. Early diagnosis can be made with transoesophageal echocardiography or contrast CT. Surgical correction or anticoagulation, where suitable, is important to prevent pulmonary venous infarction and potentially systemic embolisation. Pulmonary arterial anastomotic complications are rare and may result in pulmonary hypertension and right ventricular dysfunction.[50]
2. Donor-recipient size mismatch: this may result in (a) overdistension in undersized lungs if the recipient's body weight is used to calculate tidal volumes; or (b) atelectasis and altered mechanics in oversized lungs.[51]
3. Phrenic nerve palsy: this is a relatively uncommon complication, occurring in 6%–9% of patients and is more frequent in heart–lung transplantation. It results in longer hospital stays and duration of ventilation.[26]

Fig. 104b.2 depicts the differential diagnosis of respiratory failure specific to the early post-transplant phase. Down the track, in addition to the potential causes in any other patient, rejection (both cellular and antibody mediated) and infection (particularly CMV, aspergillus, PJP) should be considered.

EXTRAPULMONARY COMPLICATIONS

1. Renal: renal dysfunction is common, with an incidence of 25% at 1 year and 37% at 5 years after transplant. This is usually due to CNI toxicity caused by reversible afferent and efferent arteriolar vasoconstriction in the acute phase, and interstitial fibrosis, chronic arteriolopathy and tubular atrophy in the chronic phase.[52] Management centres on lowering the levels of CNI, which must be balanced against the risk of rejection. Associated comorbidities that can worsen renal failure, such as hypertension, diabetes and hyperlipidaemia, should be aggressively treated. Other factors should be considered in the setting of acute kidney injury (AKI). Haemolytic uremic syndrome, due to thrombotic microangiopathy secondary to CNI use, has been described.[53] The diagnosis is made when there is progressive anaemia, new-onset thrombocytopenia, and inexplicable AKI in conjunction with haemolysis. It occurs most commonly within the first 3 months post-transplantation. Reduction of the dosage or switching to an alternative CNI is usually effective.
2. Gastrointestinal: patients with CF are at particular risk of distal intestinal obstruction syndrome in the postoperative period, with an incidence of 10% reported by Morton et al.[54] A history of meconium ileus and previous laparotomy were found to be risk factors. These patients require aggressive management with timely laparotomy with enterostomy when non-operative therapy is unsuccessful.
3. Neurological: neurological complications are common; the early ones include steroid-related delirium,

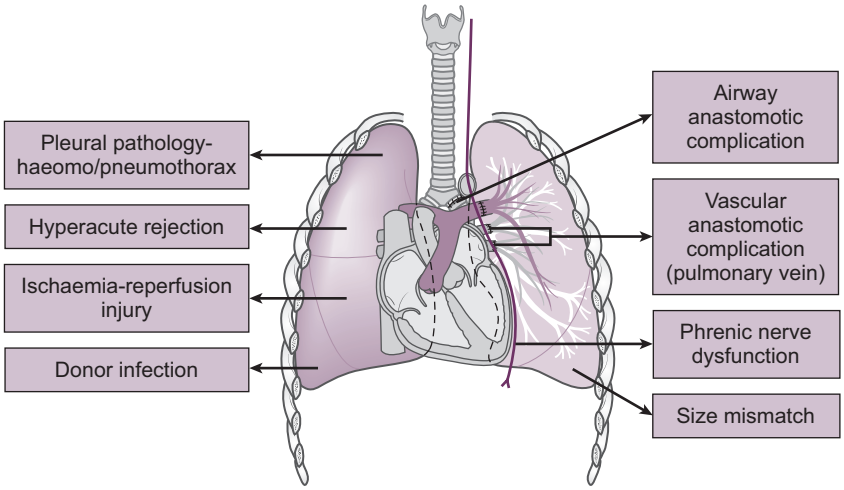

Figure 104b.2 Specific differential diagnoses for respiratory failure in the early post-transplant phase.

encephalopathy, seizures and strokes. A study of 100 patients reported a 26% incidence in the form of severe headaches, seizures, strokes and confusion. The majority were due to CNI toxicity or infections.[55] In a recent study, encephalopathy was often considered multifactorial in nature, primarily due to postoperative hypoxemia in 8 out of 29 cases, and sepsis in 3 cases.[56] The mechanism of CNI toxicity is unknown, and not necessarily related to elevated levels. CNI-associated posterior reversible encephalopathy syndrome (PRES) is characterised by headache, confusion, seizures, decreased level of consciousness, visual abnormalities and focal deficits, and usually occurs in the first month after transplantation.[57] It is always accompanied by hypertension. MRI typically shows reversible cortical and subcortical white matter changes in the posterior cerebral hemispheres.[58] The differential diagnoses include progressive multifocal leukoencephalopathy, viral encephalitis, cerebral lymphoma, cortical venous thrombosis and watershed infarcts following CPB. CNI-associated PRES generally has a favourable prognosis with early diagnosis and treatment, including alternating or discontinuing CNIs and blood pressure control. It should be considered in patients exhibiting neurological symptoms after transplantation.

4. PTLD and other malignancies.

Transplant patients are at increased risk for developing PTLDs, ranging from benign polyclonal hyperplasia to aggressive high-grade lymphoma. The disorders tend to occur within 1 year (peaking at 3–4 months). PTLDs develop in 4%–10% of lung transplant patients; as opposed to an approximate 2% in other solid organ transplant recipients.[59] Most are associated with concomitant EBV infections, which stimulate B-lymphocyte proliferation, which is unopposed because of cyclosporine-induced inhibition of T-lymphocytes. Treatment consists of decreasing or ceasing cyclosporine and administering antiviral agents (i.e. valaciclovir). Other therapies include the administration of rituximab, a CD20 monoclonal antibody and chemotherapy.[59] After immunomodulation, regression occurs in 23%–61% of patients.

There is also an increased incidence of other malignancies; particularly aggressive skin cancers in solid organ transplant recipients (three to four times increased risk), which is even higher in lung transplant recipients.

CONCLUSIONS

Lung transplantation has emerged as the most effective treatment available for end-stage lung disease. Donor numbers limit transplantation, so that only a small percentage of patients who might benefit are able to receive a transplant. This has resulted in an increased utilisation of higher risk donors with an associated risk of PGD. This poses significant challenges during the initial ICU phase. Nonetheless, the large majority make a good recovery following transplant surgery and return to a quality of life similar to that of a healthy population. Advances in donor management and organ preservation should increase the number of suitable organs, while ongoing refinements to post-transplant management will likely further improve long-term survival.

The critically ill child

Shelley D Riphagen

The chapters on paediatric intensive care are intended to help intensivists outside specialist paediatric centres manage common paediatric emergencies. They should be read in conjunction with relevant adult chapters, as there are many areas of commonality.

CARDIORESPIRATORY ADAPTATION AT BIRTH

Dramatic physiological adaptation takes place at birth. Intracardiac pressure relationships in the foetal circulation undergo significant changes associated with clamping of the umbilical cord and subsequent disconnection of the placenta. At birth, systemic vascular resistance rises rapidly as the continuous supply of vasodilating prostaglandin and the large low-resistance vascular bed of the placenta is disconnected from the newborn circulation at cord clamping. At the same time, the newborn takes the first breath of air, resulting in a sudden and progressive fall in pulmonary vascular resistance, an increase in pulmonary blood flow and left atrial venous return with an additional increase in left-sided pressures causing physiological closure of both the foramen ovale and ductus arteriosus. Blood, which previously short-circuited the right side of the foetal heart and lungs via the foramen ovale, is forced to follow the postnatal/adult pattern of circulation.

Although there is a fall in pulmonary vascular resistance at birth, changes initiated at the time of birth are incomplete and progressive, with further reduction in pulmonary vascular resistance associated with regression in arteriolar muscularisation over days to weeks.

Reversion to foetal physiology, however, may occur during the first days to weeks of life in the case of respiratory pathology, or other causes of hypoxia and acidosis. Reversion to foetal pattern circulation means that desaturated blood short-circuits the lungs through the foramen ovale, resulting in further profound desaturation and hypoxaemia, with consequent increases in pulmonary vascular resistance and worsening acidosis. Urgent measures to reverse hypoxaemia must be instituted to prevent progression to death.

Pulmonary circulation pathophysiology is probably related to abnormalities of endogenous nitric oxide production, and the manipulation of this agent has proven useful in therapy.[1]

CAUSES OF TRANSITIONAL (POSTNATAL REVERSION TO FOETAL) CIRCULATION

A 'foetal' pattern may persist due to low lung volume states (e.g. hyaline membrane disease and perinatal asphyxia), pulmonary hypoplasia (e.g. diaphragmatic hernia and Potter syndrome), meconium aspiration syndrome, chronic placental insufficiency, perinatal hypoxia and acidosis from any cause, sepsis (e.g. group B streptococcal infection) or hyperviscosity syndrome.

Return to foetal circulation may need to be medically or surgically induced in the case of 'duct dependent' congenital cardiac defects associated with either obstructive lesions on the right or left side of the heart, and as a temporising measure in the case of transposition of the great arteries to improve mixing of oxygenated and deoxygenated blood until normal circulation is restored. This may be partly achieved by infusion of prostaglandin E_2 (a placental-derived vasodilating hormone) and/or re-opening of the foramen ovale by balloon atrial septostomy or open septectomy.

Some intracardiac or vascular shunt lesions result in high pulmonary blood flow and increasing pulmonary pressure states. If left untreated, this elevated pulmonary vascular resistance may become fixed and will make subsequent surgical repair unfeasible.

GROWTH AND DEVELOPMENT

There is progressive growth and maturational development of all organ systems throughout childhood. This necessitates knowledge of normal/expected parameters and organ function at different ages in childhood. Drug and equipment calculations are age- or weight-based, and there is less room for error. Small miscalculations, depending on the size of the child, may have significant implications. Physiologically, organs in children are still undergoing maturation. Incomplete maturation of renal and liver function, especially in neonates, needs to be considered regarding fluid management and drug dosing. Similarly, the ability to recover from injury in children is better than in adults because of ongoing organ growth and development potential in early childhood. Premature infants with significant 'chronic lung disease' may still have

ABSTRACT

Neonates, infants and young children differ from older children and adults in several ways that make them more susceptible to disease and more likely for disease to progress to critical illness without being easily recognised.

Although the principles of resuscitation and stabilisation of critically ill children is similar to adults, the main challenge in their care is recognising and identifying the critically ill child in order to initiate appropriate emergency management. The initial symptoms of critical illness in young children are often non-specific and may appear relatively benign; however, they may be the only early signs of compensation in a situation of deteriorating cardiovascular status.

The non-verbal nature of communication in young children, and the need to translate symptoms usually via a third-party caregiver, means that subtle detail can be lost in translation unless parents' concerns, often of apparently vague, non-specific symptoms, are taken seriously and examined closely.

the potential to recover near-normal lung function by adulthood. The brain in children undergoes significant continued maturation and development in early childhood. Ongoing neurologic maturation is evident by progressive attainment of motor milestones as myelination of motor and sensory nerves progresses in a head toe manner. Neural plasticity may allow for seemingly remarkable recovery from certain types of brain injury. Neurological development and achievement of motor milestones occurs in a head to toe manner as myelination of major motor nerves is completed.

MATURATION

The immaturity of systems and biochemical processes at birth alters the physiological response to stress and drugs. Thermoregulation, immune function, respiratory, renal, hepatic and neurological function are all immature at birth, even in the full-term infant. This immaturity is magnified in the preterm infant with associated surfactant deficiency causing respiratory distress, liver glucuronyl transferase deficiency causing jaundice, and the necessity to be nursed in a thermocontrolled environment. Human body temperature is maintained within narrow limits. The thermoneutral zone is the range of ambient temperature within which the metabolic rate and oxygen consumption is ideal for effective organ function and cellular mechanisms. Thermoregulatory mechanisms are less effective in neonates (no shivering or sweating), who are also disadvantaged by a high surface area to body weight ratio and a lack of subcutaneous insulation. The thermoneutral zone (environmental temperature of 36.5°C) is higher in premature infants and falls with increasing postnatal age. Oxidation of brown fat, found in the interscapular and peri-renal areas (non-shivering thermogenesis), is the major source of endogenous heat production when these babies are 'cold stressed'. Cold stress, per se, increases neonatal mortality and in the presence of respiratory or cardiac disease, may lead to decompensation.

SPECTRUM OF DISEASE

Congenital structural abnormalities of major systems including the heart, lung, brain and skeleton, among others, are usually evident at birth; however, some may become exposed in early childhood, often in the setting of an apparently mild intercurrent illness which 'unmasks' the problem. A good example of this is a young child with a ventricular septal defect, who develops bronchiolitis due to a common cold virus, and becomes significantly unwell requiring ventilation.

Inborn errors of metabolism, although present from birth, may become evident only during an intercurrent period of stress: something as seemingly insignificant as weaning or a mild respiratory tract infection.

The immature immune system puts children at higher risk than adults for the development of serious bacterial and viral illnesses. The inflammatory response of the newborn is attenuated. Febrile response to infection may be lacking, and both cellular (chemotaxis and phagocytosis) and humoral (complement activity and opsonisation) responses may be impaired. Cell-mediated immunity is significantly compromised in infants born without thymic function (DiGeorge syndrome); however, in the normal newborn, T-cell function is quite well developed. The B-cell system, responsible for antibody production, is immature at birth; however, to mitigate this risk, the neonate has passive immunity against some infections because of transplacental transfer of maternal antibodies. In the breast milk fed neonate, additional natural immunity is acquired as a result of immunoglobulin A in breast milk, which protects against some acquired gastrointestinal infections. Overall, the immaturity and inexperience of the immune system result in a markedly increased susceptibility to infection in the first 6 months of life. Congenital abnormalities of the immune system usually present in childhood with recurrent or overwhelming infection in this at-risk period.

The response to any illness may be physiologically immature and the mode of presentation much less well defined than in adults. For the most part, however, children are the scaled-down version of adults and, after the neonatal period, physiological principles that apply in adults generally also apply in children.

MANAGEMENT OF THE CRITICALLY ILL CHILD

Of paramount importance in the management of critically ill children are early recognition and identification of the presenting clinical emergency, and appropriate resuscitation and adequate stabilisation prior to transfer to a tertiary institution with paediatric intensive care facilities.[2]

RECOGNITION

Recognition and identification of the clinical emergency is the most challenging component of management of the critically ill child, as this element is more difficult than in adults and older children for a number of reasons. Children of various ages have different normal physiological parameters and it is important for those dealing with children to be familiar with these norms. For those unfamiliar or infrequently involved in the care of critically ill children, it is important to have a readily available information source of normal values for age. Resources are available on the Internet and as hand-held applications to provide ready access to this information.[3]

Non-verbal and younger children lack the communication skills to express their malaise in a specific

manner. Generically, as children become more unwell they will become pale, lethargic, go off their meals and eventually may start vomiting. This may be the only historical evidence of developing shock in the young child, as blood is redirected away from non-essential vascular beds including skin, muscle and gut, and the primitive 'diving reflex'[4] is employed to maintain perfusion to essential organs. Older children respond in the same ways as adults with appropriate pyrexia to an infective trigger, whereas very young children, and especially neonates, may become hypothermic. Tachycardia is one of the most important signs in the deteriorating child, and an unexplained or incompletely explained tachycardia, or one that does not respond to antipyresis and analgesia must be regarded very seriously. As a child's condition deteriorates, the child may progress from being cool peripherally with a palpable peripheral-to-central skin temperature difference, to peripheral mottling and eventually a prolonged central capillary refill time. Pulses in the deteriorating child may be noticeably different peripherally from those taken centrally, even in those with a preserved blood pressure. Disinterest in eating and then drinking, which may progress to vomiting, suggests the development of ileus and gastric stasis as perfusion to the gut is reduced. Visceral perfusion abnormality may also be noticed by the parents, as they report abdominal distension or a reduction in wet nappies or passing urine. During all this time, the deteriorating child may still have perfectly normal saturations and remain lucid, though with increasing lethargy and drowsiness. Increasing tachypnoea may not necessarily identify a respiratory focus of decompensation, but may represent the attempt to compensate for the metabolic acidosis associated with shock.[5,6]

In summary, the skill involved in recognising the deteriorating child early relies on careful history taking with the acknowledgement that the parents know what is normal for their child. Alteration from normal must not be ignored or dismissed until the child has been thoroughly and thoughtfully examined. Physiological and biochemical parameters that are not entirely normal must be critically evaluated to ensure that the early signs of decompensation are not missed. An attempt must be made to treat what is presumed wrong, with the intention that the response to treatment results in normalisation of the physiological disturbance. If this is not the case, the child should remain under vigilant and regular review, with physiological parameters documented to detect a deteriorating trend. Senior paediatric, consultant or specialist opinion should be sought to ensure that a diagnosis has not been missed.

RESUSCITATION

Identification of the presenting clinical emergency, treatment of the most likely diagnoses, awareness of the potential differential diagnosis and repeated evaluation of response to treatment are all key elements to the successful management of a critically ill or injured child. Successful treatment should return physiological parameters to within the normal range for age, where they should remain. If this does not occur, escalation of resuscitation may require more invasive organ support in the form of ventilation, infusion of inotropes and the provision of renal, hepatic and haematological support. In extreme cases, extracorporeal life support may be required.

STABILISATION AND TRANSFER

Stabilisation of a critically ill child at a referral hospital prior to transfer infers resuscitation has begun, physiological parameters are stable or returning towards normal and the appropriate level of organ support required is in place. In some situations, the organ support required (e.g. haemofiltration) may not be available during the retrieval process, and it is important to minimise delay of the transfer to a place where equipment and staffing levels are present to optimise the eventual outcome of the child.[7]

Good stabilisation implies that the child has had resuscitation procedures completed at the referral hospital and the child has appropriate airway and vascular access contingency plans to deal with destabilisation during the transfer. Ventilated children, for example, should have the appropriate-sized endotracheal tube confirmed in an ideal position (usually in the middle of the trachea, seen at C2–C3 on the chest X-ray), a gastric tube to decompress the stomach and facilitate ventilation, and the adequacy of ventilation monitored with continuous oxygen saturations and end-tidal carbon dioxide monitoring as minimum.

Children who have required volume resuscitation are on inotropes, or those who are potentially cardiovascularly unstable should have enough vascular access established to allow commencement or escalation of inotropes during transfer. Adequate cardiovascular monitoring, in the form of continuous electrocardiographic trace and regular intermittent non-invasive or continuous invasive arterial blood pressure monitoring, should be in place. Where a central line is in place in children, central venous pressure monitoring adds to the evaluation of response to treatment.

Arterial access in children is warranted in those who are cardiovascularly unstable and/or on inotropes; those who need targeted blood pressure management (e.g. for intracranial perfusion pressure); and those who require frequent blood gas or electrolyte monitoring. Peripheral arteries including radial, dorsalis pedis and posterior tibialis are preferable. Central arterial access attempts must completely avoid the brachial artery, as it is an end artery. Thrombosis may lead to limb loss. Attempt should be made to minimise blood gas monitoring by correlation of end-tidal CO_2 with arterial blood gas measurement of $PaCO_2$. Excessive

blood gas monitoring and the performance of blood tests that do not result in changes of treatment should be minimised as eventually they result in the need for red cell transfusion. The risk–benefit of this practice must be considered.[8,9]

Vascular access can be extremely challenging in critically ill children, and familiarity with intraosseous needle insertion,[10,11] and the use of the external jugular vein, may provide rapid access for the early commencement of resuscitation fluids and the institution of inotropes. Intraosseous access is technically easy and provides 'central' access to a non-collapsible venous system, into which almost all resuscitation drugs can be rapidly infused. The limb accessed must be carefully monitored.[12] The placement of central venous lines (femoral and jugular) in children is technically more difficult than in adults because of the diminutive size of the vessels, the short neck in small children and the bleeding problems that may be present in critical illness. Central venous cannulation should be attempted only by those skilled in this procedure.[13] Femoral central venous access is preferable to jugular access in children who have a coagulopathy or any suggestion of raised intracranial pressure. Central venous catheters utilising the Seldinger technique have greatly increased successful placement. Ultrasonography is useful to determine the exact location of veins and is the standard of care in many institutions.[13] Multilumen catheters are recommended when infusing multiple drugs and for parenteral nutrition. Complications including catheter-related sepsis are the same as in adults. This risk can be reduced by adherence to a care bundle of measures.[14] The need for prolonged venous access may warrant regular catheter changes, or surgical or interventional radiological implantation of a central venous device (e.g. Infusaport, Broviac, Hickman catheter or peripherally inserted central catheter).

In children undergoing resuscitation or those with the suggestion of, or potential for, raised intracranial pressure, a urinary catheter with hourly fluid balance allows a more complete assessment of the adequacy of resuscitation. Resuscitation is a process, which is often ongoing for the first 24 hours or more of care. It is not expected that the child will immediately recover during the resuscitation and stabilisation process, so the delay in transferring the child to a definitive place of care should be minimised and be specific to the requirements of each patient.[15] In some children, stabilisation may not be achievable and the time-critical nature of the problem may require transfer under very unfavourable circumstances. Good examples are children with a time-critical neurosurgical emergency,[16] neonates with obstructed total anomalous pulmonary venous drainage or occasionally transposition of the great arteries with intact ventricular septum,[17] and some surgical abdominal emergencies among others.

PAEDIATRIC INTENSIVE CARE TRANSFER

Transfer by a team skilled in the retrieval of critically ill children is associated with reduced morbidity, critical incidents and mortality.[15] There are, however, some circumstances where the disease process is time critical, and the time delay in waiting for a paediatric retrieval team imposes an unacceptable risk.[16] In these cases it is important to use the most competent and skilled team available at the time, usually an anaesthetist, paediatrician and intensive care or senior paediatric nurse. Advice and remote telephonic assistance should be available from the paediatric retrieval team or accepting paediatric intensive care unit (PICU). For those performing time-critical retrievals, it is essential that delay is minimised and only life-saving procedures are allowed to delay the transfer. In these cases it is helpful to have a discussion with the accepting team, in terms of their expectations for transfer and of what to expect about the patient's condition. A checklist for retrieval in these circumstances is helpful to ensure that all eventualities have been considered.

PAEDIATRIC INTENSIVE CARE

The development of PICU separate from adults, recognised the unique diseases, problems and requirements of critically ill children, especially very young children. Centralisation and modernisation of paediatric intensive care, along with dedicated paediatric retrieval teams, have dramatically improved outcomes in children. Critical illness or injury in children is not common, and the reduced incidence of disease means that centres that see higher volume of a specific illness become more skilled at dealing with it, and children have better outcomes.[18] Super-specialisation of paediatric intensive care is evolving (e.g. in the care of children with highly complex congenital cardiac lesions).[17,18]

The PICU does not function in isolation and the intensive care team needs support from all other paediatric sub-specialties and specialist paediatric therapists in providing the highest level of comprehensive care for this group of children. The PICU is only one part of the delivery of tertiary paediatric hospital care to children, which starts with the provision of excellent pre-hospital care; advice and support for level 1 and 2 hospitals in the resuscitation and stabilisation of critically ill children; and the subsequent safe transfer by specialised paediatric intensive care retrieval teams to the appropriate PICU.

The adult intensive care unit, with its technically skilled nursing and medical team, may be an appropriate and safe place for a critically ill child, especially if ventilated, to await retrieval, as long as the adult intensive care unit (ICU) team is appropriately supported by local paediatric consultants, and the

paediatric retrieval team or the accepting PICU continue to provide management advice on the care of the critically ill child.

MINIMUM STANDARDS

Suggested minimum standards for a PICU should be adopted. In general, a PICU should provide:

- a specialist trained in paediatric intensive care available at short notice, and available 24/7 for ongoing management advice
- a comprehensive range of paediatric sub-specialty support, available 24/7
- immediately available junior medical staff with advanced life support skills including advanced airway and vascular access competence
- nursing staff with experience in paediatric intensive care, and a nurse:patient ratio to facilitate the appropriate level of care of each patient
- allied health professionals with specific training in paediatrics, including ready access to physiotherapists, dieticians, pharmacists, speech and language therapists, occupational therapists and child psychologists, as well as ancillary support staff including clerical and portering staff
- specialised advanced life support equipment for children ranging in age from neonates to adolescents
- 24-hour laboratory, radiological and pharmacy services
- purpose-built PICU, recognising the special physical and emotional needs of critically ill children of different ages, and their families
- a programme for teaching, continuing education, research and quality assurance for all members of the PICU multidisciplinary team
- the skills and expertise to transfer critically ill children within the hospital for investigations and treatment
- an in-house paediatric intensive care retrieval team, or at least an arrangement with an external retrieval team to provide critical care transfer of children into the PICU
- support services and facilities for parents and families, whose children are critically ill in intensive care.

Neonatal intensive care units have many similar and additional requirements.

PAEDIATRIC MONITORING

Technology has allowed most aspects of adult monitoring to be applied to neonatal and paediatric practice. The ideal paediatric haemodynamic and respiratory monitoring system should be non-invasive, painless and readily interfaced with the child; constitute minimal risk to the child; provide specific, reproducible and readily understood data relevant to the child's status; and respond rapidly to changes in status. It should provide continuous visual and/or auditory display of data and have appropriate alarms. There should be facilities for recording data, and ideally it should be inexpensive and require low maintenance.

PULSE OXIMETRY

Pulse oximetry provides continuous non-invasive measurement of arteriolar saturation (Sa_{O_2}) and provides a rapid indication of hypoxaemia. Accurate information is given:

- when the oxyhaemoglobin dissociation curve is shifted to the left (e.g. foetal haemoglobin and alkalosis) or to the right (e.g. sickle-cell disease and acidosis)
- in the presence of carboxyhaemoglobin (functional saturation is accurate)
- with moderately severe desaturation (e.g. cyanotic heart disease with saturations >50%)
- with anaemia (haemoglobin concentrations above 5 g/dL)
- when skin is pigmented.

Errors occur in the presence of extreme hypoperfusion, excessive movement and rapidly changing ambient light and extreme desaturation. A range of sensors is available to monitor children of all ages.

TRANSCUTANEOUS tc_{CO_2} AND ARTERIAL P_{CO_2} MONITORING

Oxygen and carbon dioxide diffuse through well-perfused skin from the superficial capillary network and can be measured using modified polarographic and glass electrodes, respectively. The electrodes are heated to 43°C–45°C to arterialise the capillary blood and maximise capillary blood flow. Under optimal conditions, there is good correlation between arterial and transcutaneous gas tensions. Hence continuous monitoring of blood gas tensions is possible in a non-invasive manner. The Ptc O_2 (transcutaneous) to pO_2 gradient have been used as indices of the status of the microcirculation. The accuracy of these devices is mainly confined to the neonatal period.

DRUG INFUSIONS

All drugs used in the care of critically ill children, including those used for cardiovascular support, should be administered according to body weight, or occasionally body surface area. Accurate delivery is crucial. Accurate drug infusions require accurate devices, of which syringe pumps are the most useful. Potentially lethal errors in calculating drug dilutions are minimised by the use of dose/dilution/infusion rate guidelines that should be agreed upon within an

institution by pharmacy and paediatric intensive care collaboration.[19] It is safer, with fewer drug errors and communication errors, and is time saving and potentially cost saving to have infusions made up in the same way by all referring institutions within the PICU network. These should be disseminated to referral institutions by the PICU and agreed at clinical, clinical governance and management levels. Potential errors in drug dosing in PICU occur in bigger children, when their weight equals or exceeds adult weight, but paediatric drug dosing regimens based on body weight continue to be used. Above 50 kg body weight in an older child, it may be preferable to administer drugs according to adult dosing schedules with awareness of maximum dosing in adults.

PAIN RELIEF AND SEDATION IN CHILDREN

The management of pain and agitation in children has received inadequate attention and has tended to be underestimated and under-rated. Infants and children are often unable or unwilling to complain of pain, and neonates are commonly intubated without adequate anaesthesia (use of a combination of opiate, atropine and muscle relaxant). In the past, some believed that the neonate could not perceive pain.[20] It is now clear that neonates possess all the anatomical and neurochemical systems necessary for pain perception and exhibit physiological and behavioural responses to pain. Consensus regarding the best anaesthetic for the neonate during intubation is still unavailable.[21] Stress responses associated with pain and agitation may increase morbidity and mortality in critically ill patients. Analgesia can be provided by narcotic infusions, local blocks and regional techniques in children of all ages. Painful procedures in the PICU must always be accompanied by appropriate analgesia. Sedative agents can reduce agitation and minimise harmful stress responses; however, all opiates and benzodiazepines may result in a withdrawal reaction after discontinuation, and an attempt should be made to wean agents to a minimum once noxious procedures have been completed. Agents, such as oral or intravenous cloinidine,[22] are useful as opiate-sparing and benzodiazepine-avoiding adjuncts, with minimal withdrawal effects on discontinuation. Having parents at the bedside for most of the child's waking day, distraction with play therapy, reading and videos, and appropriate surroundings including reduced noise and light levels, all help to alleviate children's anxiety, and do not come at the cost of withdrawal.

OUTCOME OF PAEDIATRIC INTENSIVE CARE

Depending on admission criteria, mortality in paediatric ICUs ranges from under 5% to 15%.[23] If patients with pre-existing severe disabilities are excluded, the majority of survivors have a normal or near-normal life expectancy. Several scoring systems have been developed or modified for paediatric application to predict ICU mortality. These scoring systems allow comparison between different ICUs, internal audits, stratification of patients for research purposes and analysis of cost–benefit. The updated Paediatric RISk of Mortality (PRISM) score[24,25] and the Paediatric Index of Mortality (PIM) score[26] are applicable to a wide range of critically ill infants and children. Although PRISM performs marginally better, PIM is easier to collect and hence less prone to errors in data collection. PIM also has the advantage that it predicts mortality based on admission parameters, whereas PRISM is based on the worst variables in the first 24 hours. In many paediatric ICUs, deaths occur within the first 24 hours. PRISM is often recording the dying process rather than predicting it. Specialised scores have been developed for specific problems; for example, the Modified Injury Severity Scale and Paediatric Trauma Score for paediatric trauma, and the modified Glasgow Coma Scale for neurological insults. Numerous scoring systems have been developed for meningococcaemia, the best validated being the Glasgow Meningococcal Septicaemia Prognostic Score.[27] Compared with adult intensive care, children with equivalent Therapeutic Intervention Scoring System scores have a lower in-hospital and 1 month mortality. Although multiple organ failure increases mortality, the prognosis is considerably better than for adults.[28] There is evidence that mortality is lower in specialist paediatric ICUs[29,30] and that paediatric ICUs with a larger workload have better outcomes than those looking after fewer children. General hospitals should therefore have facilities for urgent resuscitation of children prior to early transport to a specialised PICU. Unless unavoidable, critically ill children, particularly those requiring mechanical intervention, should not be cared for in an adult ICU for longer than 24 hours. The American Academy of Pediatrics, the Society of Critical Care Medicine, the British Paediatric Association and the Australian National Health and Medical Research Council have all stated that children should receive intensive care in specialist paediatric units.

Upper airway obstruction in children

Paul James, Sara Hanna

Upper airway obstruction is a particular clinical challenge in the paediatric population. The physics of air flow, the relative narrowness of the paediatric airway combined with the high rate of oxygen consumption in the child can produce rapid and unexpected deterioration in the clinical condition of a child. Moreover, severe airway obstruction occurs infrequently in non-specialist centres, and will require immediate intervention by the team present to secure a safe airway and maintain oxygenation. Successful management relies on an understanding of the paediatric airway, knowledge of the symptoms and signs that suggest unusual diagnoses or life-threatening obstruction, a realisation of what can and cannot be diagnosed without endoscopy and meticulous attention to basic anaesthetic principles.

ANATOMICAL AND DEVELOPMENTAL CONSIDERATIONS

The upper airway technically extends from the nares to the junction of the larynx with the trachea. It includes the nose, the paranasal sinuses, the pharynx and the larynx. It changes in size, shape and position from the neonatal period through infancy and childhood to resemble the adult airway by the age of 8 years.[1]

Children have a proportionally larger head and occiput relative to body size. The large head forces the neck into flexion when supine, which is a potential cause of airway obstruction.

NOSE

The nose is made up of nasal bones, nasal part of the frontal bones and frontal processes of the maxillae. The septum divides the cavity into two with the exterior opening at the nares and the opening into the nasopharynx at the choanae.

If the membrane that separates the palatal processes during development does not rupture the neonate will have choanal atresia and will present with airway obstruction.

Infants are obligate nasal breathers, and secretions, oedema and blood easily block the small nasal apertures. Similarly, cellulitis, oedema or abscess formation in the paranasal sinuses will lead to airway obstruction.

PHARYNX

The pharynx forms the common upper pathway of the respiratory and alimentary tracts. It is divided into three regions: the nasopharynx, oropharynx and laryngopharynx, which open into the nasal cavity, mouth and larynx, respectively.

The pharyngeal isthmus separates the nasopharynx and oropharynx. It closes off during swallowing.

The adenoids lie on the roof and posterior wall of the nasopharynx. These atrophy with age, but enlargement in early childhood may obstruct breathing. They may also be dislodged during instrumentation of the nose.

The oropharynx extends from the soft palate to the tip of the epiglottis. It is attached anteriorly to the base of the tongue via the glossoepiglottic folds, between which lies the valleculae.

At the entrance to the oropharynx is a collection of lymphoid tissue known as Waldeyer ring. This consists of the lingual tonsil at the base of the tongue and bilateral palatine tonsils as well as the adenoids and tubal tonsils. Inflammation, infection or invasion of this tissue may obstruct breathing. The shape and dimension of the oropharynx affect airway function, particularly during sleep.

The relatively large tongue decreases the size of the oral cavity and more easily obstructs the airway. Decreased muscle tone also contributes to passive obstruction of the airway by the tongue.

The laryngopharynx extends from the tip of the epiglottis to the lower border of the cricoid cartilage. The larynx bulges back into the centre of the laryngopharynx leaving a recess on either side, known as the piriform fossa. This is a common site for impaction of swallowed foreign bodies.

LARYNX

The larynx is situated between the pharynx and trachea, extending from the base of the tongue to the cricoid cartilage.

ABSTRACT

A systematic approach to upper airway obstruction in children is described. Severe life-threatening conditions are rare but prompt sensible management is key to a good outcome. The variable causes are outlined with reference to airway anatomy and pathology. Red flags in the history and examination that should alert the practitioner to the more serious or complex problems are highlighted along with a highly practical guide to managing these problems both in and outside a specialist centre.

management

The larynx consists of the thyroid cartilage, the cricoid cartilage, the paired arytenoids and the epiglottis, together with the small corniculate and cuneiform cartilages.

The laryngotracheal tube forms from the ventral wall of the foregut. The primitive glottis is formed at 10 weeks gestation when the true vocal cords split. Failure of this process results in a congenital laryngeal web or atresia of the larynx. Incomplete division of the embryonic foregut results in a tracheo-oesophageal fistula.

The cricoid cartilage is shaped like a signet ring with the widest portion lying posterior. This is the only complete cartilage ring in the respiratory tract and is the narrowest portion of the larynx. Any oedema, infection or inflammation at this level results in airway compromise. Acquired subglottic stenosis as a result of prolonged or repeated tracheal intubation also occurs at this level. The larynx lies more anteriorly and higher, being at the level of the fourth cervical vertebra at birth, the fifth cervical vertebra at 6 years and the sixth cervical vertebra in the adult.

The epiglottis is a leaf-shaped structure attached to the posterior border of the thyroid cartilage by the thyroepiglottic ligament. The infant epiglottis is narrower, softer and more horizontally positioned than in the adult.

The more superior location of the larynx in children may create difficulty in visualising the laryngeal structures because of the acute angulation between the base of the tongue and the laryngeal opening.

The vocal cords are innervated by the recurrent laryngeal nerve, which, if damaged, results in paralysis of the corresponding vocal cord, causing it to lie motionless in the midline and at a lower level than the opposite side. Bilateral paralysis results in complete loss of voice and the two vocal cords may then flap together causing a valve-like obstruction during inspiration.

The highly compliant and poorly developed cartilage leads to increased susceptibility to dynamic airway collapse in the presence of obstruction. Loss of muscle tone in the pharynx leads to airway obstruction at the level of the soft palate and epiglottis. Laryngomalacia is a congenital abnormality of the larynx and results from the laryngeal structure being more pliable and less rigid than in the adult.[2]

PATHOPHYSIOLOGY

Resistance to laminar air flow increases in inverse proportion to the fourth power of the radius (Poiseuille's law) resulting in a marked increase in resistance to air flow with airway narrowing. The perpendicular cartilaginous ribs, which reduce the effect of the 'bucket handle' movement of the rib cage, and the immature intercostal muscles result in a mechanical 'disadvantage', and children are more reliant on the diaphragm for inspiration. Signs of increased respiratory effort to overcome airway obstruction include head bobbing (use of neck muscles), subcostal and sternal recession, tracheal tug and forced expiration (abdominal muscle contraction in expiration). Chronic airway obstruction may lead to chest wall deformity.

A higher metabolic rate and oxygen consumption, together with a smaller functional residual capacity and fewer fatigue-resistant fibres in the diaphragm, means there is little respiratory reserve and children with airway compromise can deteriorate very quickly.

However, children with chronic obstruction may manage surprisingly well with 'tolerable' airway noises and increased levels of respiratory work. Acute changes in airway calibre in these children may cause precipitous deterioration with accompanying hypoxia.

CLINICAL PRESENTATION

Stridor is a harsh, vibratory sound produced by turbulent air flow and is the cardinal feature of upper airway obstruction. Symptoms and signs vary with the level of obstruction, the aetiology and the age of the child.

When faced with a child with possible airway obstruction the clinician must decide whether investigation and intervention are necessary and, if so, in what time scale. Very few diagnoses are truly clinical as it is only on direct endoscopy that the true cause of the problem can be confirmed. However, a careful history and examination are key to the decision-making process. Features that suggest obstruction needing urgent evaluation include episodes of colour change (pallor, cyanosis), apnoea, biphasic stridor, stridor when asleep and stridor from birth.

Extrathoracic obstruction is more pronounced during inspiration as the negative intraluminal pressure causes further airway narrowing. Obstruction is characterised by stridor and the prolongation of inspiration. Intrathoracic airway diameter increases on inspiration and signs and symptoms occur mainly on expiration. There is prolonged expiration, wheeze and air trapping as seen in asthma, which is a common misdiagnosis.

Biphasic stridor is characteristic of mid-tracheal lesions or impending complete obstruction at any level (Fig. 106.1).

AETIOLOGY

The aetiology may be classified in a number of ways including according to the site of obstruction (i.e. nose, pharynx or larynx), whether it is congenital or acquired, or whether it is due to infection, malignancy, trauma, etc.

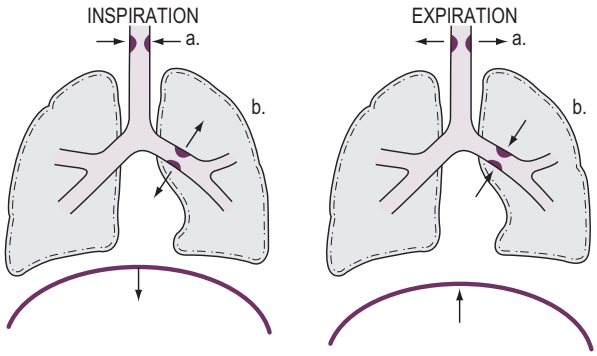

Figure 106.1 Dynamics of (a) extrathoracic, and (b) intrathoracic airways obstruction.

Box 106.1 Common causes of upper airway obstruction in neonates/infants

Nose
- Choanal atresia

Oral cavity
- Encroachment of tongue on airway
- Macroglossia: Beckwith–Wiedeman, hypothyroidism
- Micrognathia: Pierre–Robin syndrome
- Haemangioma or venous/lymphatic malformation of tongue

Laryngeal abnormalities
- Laryngeal atresia
- Laryngomalacia
- Vocal cord paralysis
- Laryngeal cleft

Subglottic abnormalities
- Subglottic stenosis – congenital or acquired
- Subglottic haemangioma

Extrinsic lesions
- Mediastinal masses
- Cystic hygroma
- Foregut malformations
- Vascular abnormalities including rings and slings

Boxes 106.1 and 106.2 list the more common causes according to the age of the child.

INFECTIONS OF THE UPPER AIRWAY

Viral and bacterial infections causing upper airway obstruction present in a very similar way and are often concurrent. A logical and useful approach to diagnosis is to identify the site of infection and consider the nature of the condition.[3]

PHARYNGEAL INFECTIONS

In the pharynx the site of infection is the peritonsillar bed in 49% of cases, the retropharyngeal space in 22% of cases and the parapharyngeal spaces resulting in abscess formation in 2%.[4]

Box 106.2 Common causes of upper airway obstruction in children

Oral cavity

Encroachment of tongue on airway
- Macroglossia: Beckwith–Wiedeman, hypothyroidism
- Micrognathia: Pierre–Robin syndrome
- Haemangioma or venous/lymphatic malformation of tongue

Other oral mass lesions
- Ectopic–lingual thyroid/thyroglossal duct cyst/dermoid cyst/ranula

Nasopharynx/oropharynx/retropharyngeal space
- Adenoid/tonsillar inflammation and abscess
- Lymphatic malformation
- Supraglottitis
- Foreign bodies
- Trauma/burns
- Neoplasms

Larynx/cervical trachea

Supraglottic
- Laryngomalacia
- Epiglottitis

Glottic abnormalities
- Vocal cord paralysis
- Laryngeal cleft
- Recurrent respiratory papillomatosis

Subglottic abnormalities
- Croup
- Subglottic stenosis
- Congenital
- Acquired (prolonged or traumatic intubation)
- Subglottic haemangioma

Bacterial tonsillitis and peritonsillar abscess (quinsy)

Tonsillitis is caused by the aerobes *Streptococcus pyogenes, Streptococcus pnemoniae* and *Staphylococcus aureus* and the anaerobes *Fusobacterium* spp., *Prevotella* spp., *Porphyromonas* spp. and *Actinomyces* spp. Aerobes predominate in the acute primary infection, whereas anaerobes are associated with abscess formation or extension across tissues. Treatment is with third-generation cephalosporins or co-amoxiclav as there is a high incidence of penicillin resistance.[5] Metronidazole or carbapenems should be added if there is extension or abscess formation. Clindamycin or linezolid should be added to reduce bacterial exotoxin release if toxic shock is suspected.

Surgical removal in the acute setting is controversial as there is potentially an increased risk of bleeding, but if there is pus then drainage is indicated to prevent spontaneous rupture.[6]

Infectious mononucleosis (glandular fever)

Infectious mononucleosis is caused by the Epstein–Barr virus, which is a virus transmitted in saliva. Airway

obstruction can occur and, despite steroids, 40%–88% of patients with airway obstruction require tonsillectomy.[7] The use of steroids does reduce the duration of fever, pharyngitis and abnormal haematological findings.[8]

Retro- and parapharyngeal abscess

Retropharyngeal abscesses are more common in boys (ratio 2:1) and occur at a median age of 3 years. The incidence appears to be rising.[9] The principal symptoms are fever, sore throat, trismus, torticollis, neck swelling and pain. Airway obstruction is rare.[10]

Staphylococci and streptococci are the usual causal agents, but growth is often polymicrobial and treatment is with broad-spectrum antibiotics. Surgical drainage is indicated if there are symptoms persisting for 2 days or more, prior administration of antibiotics, and fluid on computed tomography scan with a cross-sectional area of greater than 2 cm^2. Complications include mediastinitis and Lemierre syndrome.

Lemierre syndrome

Described in 1936, Lemierre syndrome occurs when a pharyngeal/tonsillar infection is complicated by thrombophlebitis and septic emboli. The organism is usually *Fusobacterium necrophorum*. Local effects classically include thrombosis in the ipsilateral internal jugular vein and more distant spread with suppuration most commonly affecting the lungs, but also causing septic arthritis, osteomyelitis, meningitis, and liver, renal and skin abscesses.[11]

Ludwig angina

Ludwig angina is a diffuse infection of the submandibular and sublingual spaces. Severe pain, fever, malaise and dysphagia occur with swelling that can be large enough to cause airway compromise. Antibiotic choice is as for tonsillar abscess, and surgical drainage is indicated if there is pus formation.[12]

LARYNX/TRACHEAL INFECTIONS

Croup

Croup (laryngotracheobronchitis) is common and usually caused by the virus parainfluenza, influenza type A or B, respiratory syncytial virus or rhinovirus. It is the commonest cause of acquired acute stridor in children and is a clinical diagnosis. There is a sudden onset of a seal-like barking cough usually accompanied by stridor, hoarse voice and respiratory distress. Symptoms are usually worse at night. It commonly affects children aged 6 months to 3 years with a peak incidence at 2 years. Only 2% of cases are admitted to hospital each year, of which only 0.5%–1.5% will require intubation.[13]

A Cochrane review investigated the use and effectiveness of steroids in the treatment of children with croup and recommended all children should receive either dexamethasone 0.15 mg/kg or prednisolone 1–2 mg/kg orally.[14]

Nebulised epinephrine (adrenaline) 1/1000, 0.5 mL/kg to a maximum of 5 mL may be used to reduce airway swelling acutely in severe croup. This is a short-term measure and may allow time for the steroids to work or for experienced personnel to be called to the child. It may be repeated if necessary after 30–60 minutes, but further doses should be used with caution as repeated need suggests an extremely narrow airway.

If intubation is indicated, visualisation of the larynx should not be a problem; however, a smaller tracheal tube than normal for the age is usually required because of subglottic oedema. Once the obstruction is bypassed, most children can be managed on a Swedish nose with minimal sedation and arm splinting. Extubation may be attempted after 72 hours (or earlier if a large leak develops). Around 10% will require re-intubation.

Epiglottitis

Very few clinicians have seen epiglottitis since the introduction of *Haemophilus influenzae* type B vaccination in 1992. In children, it is still almost always due to infection with *H. influenzae* type b (Hib), although it can be caused by beta-haemolytic streptococci, staphylococci or pneumococci. In a recent retrospective study, 10% of children presenting with epiglottitis were found to have Hib infection, despite having being vaccinated.[15]

It occurs usually in children aged 2–6 years, with a peak incidence at 3 years.

Epiglottitis is painful. There is an abrupt onset of high fever, sore throat, dysphagia, soft stridor and drooling. The child may prefer to sit leaning forwards with mouth open.

The key to management is to secure the airway under inhalation anaesthesia with an ear, nose and throat (ENT) surgeon standing by if a tracheostomy becomes necessary. Visualisation of the laryngeal inlet may be difficult. A bacterial swab of the epiglottis should be taken once the airway is secure. Antibiotic treatment with an extended-spectrum cephalosporin (e.g. ceftriaxone) is indicated. Recovery usually occurs about 48 hours after the institution of antibiotic therapy and confirmed by visualisation of a normal epiglottis on laryngoscopy.

Bacterial tracheitis

Bacterial tracheitis is uncommon. The condition may occur at any age. The usual pathogens are *S. aureus, H. influenzae,* streptococci, and *Neisseria* species.[16]

The signs and symptoms of bacterial tracheitis are frequently intermediate between those of viral croup and epiglottitis. Coughing produces copious tracheal secretions and retrosternal pain. The voice may be hoarse and stridor prominent. The larynx, trachea and bronchi can become acutely obstructed with purulent

debris and inflammation with adherent pseudomembranes overlying friable tracheal mucosa.

Most patients with bacterial tracheitis will require tracheal intubation.

At laryngoscopy, the epiglottis and supraglottic structures will appear normal, although slough and pus may be visible beyond the vocal cords. Significant pneumonia and systemic symptoms of bacterial septicaemia are not unusual. Ceftriaxone is a reasonable first-line antibiotic therapy. The average duration of tracheal intubation is 6–7 days and antibiotic therapy and hospitalisation may be required for up to 14 days.

Diphtheria

Diphtheria is caused by *Cornyebacterium diphtheriae* and *Cornyebacterium ulcerans*. It begins with a croup-like illness, cough and sore throat, but often progressing to death through sepsis, suffocation by the 'pseudomembranes' of serocellular exudate and direct effects of the powerful exotoxin, which has an affinity for neural endings (paralysis), cardiac muscle (heart block and myocardial failure) and the adrenal glands (hypotension with endocrine failure). Unless there is a high index of suspicion, it is a diagnosis easily missed. Treatment includes the administration of specific antitoxin and appropriate antibiotics.

Respiratory papillomatosis

Respiratory papillomatosis is characterised by recurrent proliferations of squamous papillomata within the airway, anywhere from lips to lungs. The viral pathogen is most commonly human papilloma virus types 6 and 11. The recurrent nature of this condition often necessitates multiple surgical procedures. The current management philosophy is toward a more conservative approach, aimed at ameliorating airway symptoms while limiting subsequent scarring of the larynx. Surgical debulking is the treatment of choice and several modalities have been used, including cold steel dissection, microdebridement, suction diathermy, cryotherapy, CO_2 or other laser ablation and radiofrequency cold ablation.

Any of these may be followed by systemic administration or direct injection of antiviral agents (e.g. cidofovir) into the resection sites, with the aim of reducing the frequency of reoperative surgery for recurrent papillomas.[17]

TRAUMA

INHALATIONAL BURNS

Inhalational injury should be suspected with burns occurring in a closed space, and when facial burns, singed nasal hairs and oropharyngeal carbonaceous material are present. Respiratory complications are the major cause of mortality in children who are burnt. Direct airway burns or inhalation of products of combustion may lead to rapidly progressive oedema. The situation may be compounded by small airway and lung injury and by the need to provide adequate analgesia. Early intubation is strongly recommended prior to an emergency situation developing. Tracheal tube fixation is critical and may be problematic with extensive facial burns; it may require suturing of the tube to the nasal septum or securing the tube to the teeth.

FOREIGN BODY ASPIRATION

Foreign body aspiration is one of the leading causes of death in children. It is most common in those under 3 years, but can occur at any age.[18] Most deaths occur at the time of aspiration due to complete upper airway obstruction. Of those children who reach hospital, the mortality is low.[19] The most common aspirated object is 'food', usually nuts. Peanuts account for one-third of all foreign body aspirations.

Often the inhalation event is not witnessed, and the history may be less clear than expected. Presentation varies from severe acute upper airway obstruction through to a well, pink child with a persistent cough.

More than 90% of foreign bodies lodge below the upper airway in a main bronchus, slightly more commonly on the right side in children.[20]

As the majority of inhaled material is organic in origin, a plain radiograph may fail to demonstrate an abnormality – especially in the first 24 hours, although X-rays in inspiration and expiration may show evidence of gas trapping.[18]

Management is as per the 'choking child' basic life support algorithm. Children with effective cough should be closely observed and encouraged to cough by themselves. If the cough is not effective and the child is conscious, the rescuer may intervene with five back blows followed by five chest thrusts (or abdominal thrusts in older children).

If the child is not conscious, the child should have airway, breathing and circulation assessed and managed as per the basic life support guidelines, with assisted ventilation and chest compressions.

Most children who reach hospital with an inhaled foreign body, or the possibility of such, should have a rigid bronchoscopy under general anaesthesia.[21]

Most anaesthetists will use an inhalational induction with sevoflurane in order to maintain spontaneous ventilation.

N_2O is avoided, particularly if there is radiological evidence of gas trapping. The cords and upper trachea are sprayed under direct laryngoscopy with 4 mg/kg lidocaine. Maintenance of ventilation and oxygenation during rigid bronchoscopy in children is controversial. The options are a spontaneously breathing technique (reduces the chance of distal movement or dislodgement of the foreign body) or muscle relaxation and the use of positive-pressure ventilation (reduces atelectasis and desaturation episodes). It is difficult to demonstrate the superiority of one technique over another.[19]

SUBGLOTTIC STENOSIS

Subglottic stenosis may be congenital or acquired (usually due to post-intubation laryngeal injury).

The main feature is chronic, inspiratory stridor often made worse by intercurrent viral respiratory tract infection. When a child presents acutely, the management is as for croup. However, ENT referral is necessary for diagnosis and management. The surgeon will grade the severity of the stenosis according to the size of endotracheal tube that can pass relative to that expected for age. This assessment and clinical condition will inform the decision to intervene.[22]

Treatment options available include inhaled or oral steroids to reduce inflammation and balloon dilatation of the narrowed airway with minimal mucosal trauma. Symptoms are resolved or improved in up to 70% of cases. If this fails, a laryngotracheal reconstruction (LTR) whereby a cartilage graft, from either the costal cartilages or the thyroid cartilage, is inserted into a vertical laryngotracheal fissure in order to expand the stenotic segment. Some stenoses will also require a posterior graft inserted into a posterior cricoid chondrotomy. In a double-stage LTR, a tracheostomy is inserted to safeguard the airway postoperatively and the grafted area is stented for approximately 6 weeks. A further procedure is then performed to remove the stent and assess the airway. A tracheostomy is not used in a single-stage LTR and the child is left intubated with an age-appropriate endotracheal tube for 5–7 days postoperatively, both stenting and safeguarding the airway. All patients receive antireflux medication postoperatively to negate the negative impact of gastric contents on mucosal healing.

CONGENITAL

PIERRE ROBIN SEQUENCE

The Pierre Robin sequence is a congenital anomaly presenting with micrognathia, glossoptosis and a cleft palate. Although there is a spectrum of airway obstruction most children can be managed by conservative measures or with a nasopharyngeal airway for a few months. The natural history shows that, with normal growth, airway compromise resolves without immediate surgical intervention as previously advocated. However, a few children do require tracheostomy.[23]

CYSTIC HYGROMA

Conspicuous at birth, cystic hygroma or lymphangioma is a relatively rare cause of upper airway obstruction in infancy. The tumours consist of masses of dilated lymphatic channels. They usually occur in the neck but may involve tissues of the tongue and larynx, and occasionally extend into the mediastinum. Airway obstruction may be due to infection or haemorrhage into the lesion. Surgical excision has been the mainstay of treatment, although complete removal is difficult and recurrence is common. Although some authors have reported watchful waiting of cystic hygroma, it should be considered only in patients who are asymptomatic. The medical treatment consists of the administration of sclerosing agents.

LARYNGOMALACIA

Laryngomalacia is the commonest cause of congenital stridor and usually presents within the first 2 weeks of life. Clinicians should not give this diagnosis without full airway assessment to any baby with life-threatening symptoms or stridor that is obvious at birth. Airway obstruction results from the collapse of supraglottic structures on inspiration, and expiratory symptoms are not a feature. Stridor often gets worse initially for 6–9 months before gradually improving, with most children being free of symptoms by 18–24 months.[24]

It is a dynamic condition and the supraglottic collapse is most obvious during the 'waking phase' of anaesthesia if a formal airway assessment is done.

The majority of children will not require surgical intervention, but the remaining 5%–10% require some form of surgical treatment. Surgical options include division of the aryepiglottic folds to 'open' the constricted supraglottis, resection of the redundant mucosa and suspension of the prolapsing epiglottis to uncover the laryngeal introitus. A degree of gastrooesophageal reflux disease is often associated with laryngomalacia, and all children should therefore receive antireflux medication. This possibly reflects changes in airway and intrathoracic pressures in response to the airway obstruction, as opposed to being a causal factor. A neurological form of the condition exists and may be seen in children with neurological or neuromuscular conditions, such as cerebral palsy. In such cases, surgical intervention should be approached with caution and it may be most appropriate to manage severe airway collapse with a tracheostomy.[25]

OTHER

INFANTILE HAEMANGIOMA

Infantile haemangiomas are the most common tumours of infancy, affecting approximately 1 in 10 children.[26] These are highly proliferative vascular tumours that may grow very quickly, causing obstruction when the airway is involved; if these are left untreated there is a 50% mortality rate. Most airway haemangiomas will co-exist with cutaneous lesions (but not vice versa).[27] The PHACES syndrome comprises airway haemangiomas with associated deep or diffuse cutaneous, segmental haemangiomas as well as posterior fossa malformations, arterial anomalies, cardiac/aortic defects, eye anomalies and a sternal defect.[28]

Medical and surgical interventions have included steroids, chemotherapeutic agents (vincristine, interferon-α), laser treatment, surgical excision,

tracheostomy or a combination of these, but the spectacular effect of propranolol on cutaneous haemangiomas of infancy was described for the first time in 2008[29] and confirmed by a meta-analysis as being the best treatment available for infantile haemangiomas.[30] The mean dose of propranolol was 2 mg/kg/day (range 0.5–3 mg/kg/day). The mean treatment duration was 6 months (range 1.5–10 months). Clinical improvement was seen in a range of 24 hours to 3 weeks (mean 3.8 days). Complications related to propranolol usage were found in one child (2.94%) who developed bronchoconstriction during the first week of treatment.

Because of the possible side effects of propranolol, current infantile haemangioma treatment centres recommend that a full cardiovascular and respiratory review be performed prior to initiation of therapy.

VOCAL CORD PALSY

Vocal cord palsy may be idiopathic, a result of a neurological abnormality, or traumatic (birth or iatrogenic).[31] It may be uni- or bilateral.

Unilateral palsy presents with stridor and dysphonia, which often resolves with time as the contralateral vocal cord compensates.

Bilateral vocal cord palsy is potentially life threatening, and a tracheostomy may be necessary in approximately half of the cases. Magnetic resonance imaging of the brain is mandatory in order to exclude an Arnold–Chiari malformation with hydrocephalus.[32] Spontaneous recovery rates of up to 70% are reported.[31]

ANAESTHESIA FOR RELIEF OF UPPER AIRWAY OBSTRUCTION

The principle behind safe induction of anaesthesia in the obstructed airway is the maintenance of spontaneous ventilation. Muscle relaxants should be avoided before the airway is secure in order to avoid the potentially disastrous 'can't intubate, can't ventilate' scenario.

A gaseous induction using 100% oxygen with either sevoflurane or halothane is the technique of choice. The aim is to attain a plane of anaesthesia that is deep enough to allow laryngoscopy, but this is a slow process. If the airway becomes obstructed following loss of consciousness, it can be improved by applying continuous positive airway pressure, changing the patient's position (lateral or semi-prone position), using simple airway manoeuvres or simple airway adjuncts, such as a nasal airway.

Sufficient depth of anaesthesia for laryngoscopy may not be achieved because of the obstructed airway. A laryngeal mask airway may help. If it is impossible to secure the airway then direct access to the trachea via a cricothyroidotomy or tracheostomy should be gained.

Important points are:

- A prepared induction should be undertaken with efficient suction apparatus, a range of tracheal tubes, suitable stylets, bougies, trained staff, full monitoring, etc.
- Induction in the adopted position, for example, sitting in epiglottitis, is advocated. The child is laid flat after induction and prior to intubation.
- Care must be taken not to distend the stomach as this will compound difficult ventilation.
- Orotracheal intubation is quickest and safest, and should be performed initially. After adequate tracheal suction, the tube can be changed to a nasotracheal one. Muscle relaxants may be used at this point if the operator is confident of the ability to intubate and/or ventilate.[33]

CARE OF THE SECURED AIRWAY

Successful management of upper airway obstruction in children requires optimal care of the nasotracheal tube. Such children must always be nursed in a paediatric intensive care unit with adequate nursing ratios. The nasotracheal tube must be positioned at the level of the clavicular heads (T_2) on chest X-ray. A meticulous technique of fixation must be employed to prevent accidental extubation. Adequate humidification is important to prevent obstruction of narrow tubes by secretions.

Repeated suctioning of secretions is required. Instillation of saline (0.5–1.0 mL) prior to suction may be necessary to encourage the removal of secretions. Light sedation is used to improve tolerance of the tracheal tube and to reduce the risk of self-extubation. Arm restraints may also be advisable, particularly in very young children.

In the event of clinical deterioration after intubation, a simple mnemonic may aid successful management; DOPES represents *d*isplacement of the tube, *o*bstruction of the tube, *p*neumothorax, *e*quipment failure and *s*tomach distension.

A true 'can't intubate, can't ventilate' scenario is rare in children. More often the situation has arisen due to 'operator error', for example, suboptimal positioning of the child, inadequate anaesthesia, a distended stomach, a blocked endotracheal tube or understandable panic. However, the only objective in this situation is to maintain oxygenation and if none of the basic manoeuvres resolves the situation the options are to perform a needle cricothyrotomy or a formal tracheostomy.

TRACHEOSTOMY

Tracheostomy remains a life-saving procedure and must be undertaken if tracheal intubation is impossible. It is best performed under general anaesthesia

with the neck extended. The airway can be maintained by facemask or laryngeal mask airway. Tracheostomies have been formed under local anaesthesia.

Care of a newly created tracheostomy is similar to that of an endotracheal tube, with the additional problem of some discomfort and the likelihood of fresh blood in the airway. Stay sutures in the tracheal wall lateral to the incision aid recannulation if accidental dislodgement occurs prior to formation of a well-defined tract.

The first tracheostomy tube change is undertaken once a tract has been established, usually between 5 and 7 days.

NEEDLE CRICOTHYROIDOTOMY

Cricothyroidotomy is the creation of an opening in the space between the anterior inferior border of the thyroid cartilage and the anterior superior border of the cricoid cartilage, to gain access to the airway below the glottis. It is difficult and risky in a small child. There are purpose-made paediatric kits available and these should be immediately available in every paediatric anaesthetic room.

Newer cannulae have both a 15 mm and a Luer-lock connector. It is not possible to ventilate a patient with a self-inflating bag via a needle cricothyrotomy and the cannula should be connected via the Luer-lock connection to an oxygen flowmeter via a Y-connector. The oxygen flow rate is initially set at the child's age in years. Ventilation occurs by occluding the open end of the Y-connector with a thumb for 1 second. If this does not cause the chest to rise, the flow should be increased by increments of 1 L/min.

Expiration must occur via the upper airway, even in situations of partial upper airway obstruction. If upper airway obstruction is complete, the gas flow must be reduced to 1–2 L/min. This will provide some oxygenation but little ventilation. Insufflation will buy a little time in which to secure a surgical airway. Complications include bleeding, pneumothorax, pneumomediastinum, subcutaneous emphysema, tracheo-oesophageal fistula, infection, haematoma and catheter dislodgement.

The recent national audit of major complications of airway management in the United Kingdom showed that the 'can't intubate, can't ventilate' scenario is rare in paediatric practice. Cricothyroidotomy and jet ventilation is difficult and risky, with the only reported attempt being unsuccessful. Tracheostomy by an ENT surgeon has been used successfully more often.[34]

Acute respiratory distress in children

Tavey Dorofaeff

ACUTE RESPIRATORY FAILURE IN CHILDREN[1]

Acute respiratory failure in children, as in adults, is a failure of gas exchange – inadequate oxygenation and carbon dioxide clearance. Respiratory distress refers to both the sensation of breathlessness and the signs of increasing effort to breathe as a consequence of deteriorating gas exchange. The signs and symptoms in children are listed in Box 107.1.

EPIDEMIOLOGY[2,3]

Data extracted from the Australian and New Zealand Intensive Care Society (ANZPIC) database show that bronchiolitis, pneumonia, asthma, seizures and diabetic ketoacidosis were the top five admission diagnoses of all non-elective child admissions to intensive care in 2015. Of all admissions, just under 50% (48.9%) required some form of respiratory support. Respiratory admissions with any pathology numbered 33%, with 58% of these requiring respiratory support. Of this group, 17% were invasively ventilated, 28% received non-invasive ventilation and 60% received high-flow nasal cannula (HFNC) oxygen. The mean length of stay for respiratory admissions was 3.89 days. This is slightly longer than the combined average duration of stay of 3.63 days. The mortality rate overall was 3.4%. Those patients with a primary respiratory diagnosis had a mortality rate of 1.2% (ANZPIC, unpublished data, 2014/2015). These figures mirror data held elsewhere; however, there is a significant change in the usage of high-flow nasal oxygen, which will be discussed later in the chapter.

VENTILATORY REQUIREMENTS AND MECHANICS OF CHILDREN[4,5]

Neonates and small infants have a higher resting metabolic requirement for oxygen, which is estimated to be 7 mL/kg/min compared to 4 mL/kg/min for a school-age child or an adult.

Neonates and small infants have many differences compared with adolescents and adults, which give them a distinct disadvantage, particularly when illnesses affect the lung and reduce the compliance of the lungs or increase the airways resistance.

Specific differences in neonates and infants:

- Diaphragmatic breathers
- Compliant rib cage
- Reduced ability to generate negative pleural pressures
- Primary mechanism to increase minute ventilation is by tachypnoea
- Limited ability to increase tidal volume
- Lung volume close to functional residual capacity (FRC) at end expiration
- Tendency for airways to collapse at end expiration.

As children grow, these issues that affect neonates, infants and toddlers become less of a disadvantage as the child develops an upright and bipedal body habitus.

The airways of all children are disproportionately smaller than an adult's. Any obstruction of the lumen of the airways with increased mucous production or bronchoconstriction also increases airways resistance to the fourth power of the radius (Hagen–Poiseuille equation: $\Delta P = 8\mu LQ/\pi r^4$ where ΔP is the pressure reduction, L is length, Q is volumetric flow rate and r is radius). Hence, anatomically small airways are a distinct disadvantage. This is particularly the case in neonates and infants, but applies across the age (and size) range.

SIGNS AND SYMPTOMS OF ACUTE RESPIRATORY FAILURE

Signs and symptoms of respiratory failure in children that indicate the need for an increasing level of respiratory support are not subtle and are usually apparent from a brief focused clinical exam of the respiratory system. They relate to the developmental changes that influence the ways in which children compensate for, or decompensate from, respiratory failure. Due to pulmonary mechanics, neonates and small infants tend to become tachypnoeic.

Premature babies, term babies and very young infants can manifest apnoeas that may relate to severe tachypnoea or may be unrelated to the work

ABSTRACT

Respiratory distress is common in unwell children. A primary diagnosis of a respiratory illness is a leading indication for an admission to a paediatric intensive care unit (PICU). Bronchiolitis, asthma and pneumonia are the diseases that lead to the highest rates of children's admissions to the PICU. For the newborn, respiratory distress syndrome, transient tachypnoea of the newborn and neonatal pneumonia are leading admission indications to neonatal intensive care. In this chapter, we will concentrate on those disorders that a general intensivist is most likely to encounter in children.

Box 107.1 Causes of respiratory failure in children

Common causes of respiratory failure in the neonate
Congenital
Respiratory distress syndrome of prematurity
Congenital heart disease
Laryngo/tracheo/bronchomalacia
Vascular rings and slings
Diaphragmatic hernia
Pulmonary hypoplasia
Gastroschisis and omphalocele
Neuromuscular and skeletal disorders
Acquired
Transient tachypnoea of the newborn
Meconium aspiration syndrome
Neonatal pneumonia
Pulmonary haemorrhage
Diaphragmatic palsy

Common causes of respiratory failure beyond the neonatal period
Bronchiolitis
Pneumonia
Asthma
Croup
Tumours
Trauma
Acute-on-chronic respiratory failure with chronic neuromuscular conditions
Acute respiratory failure with acute neuromuscular conditions
Acute respiratory distress syndrome
Respiratory failure related to immunocompromised host

of breathing, which is a significant symptom none the less. An intricate interplay of brainstem control and respiratory mechanics and airway control lead to this phenomenon that is not entirely understood. Bradycardia is almost routinely associated as a secondary consequence of the hypoxia that develops.

There are a number of other signs of respiratory distress that the reader will be very familiar with.

- Tachypnoea
- Distress/irritability/air hunger
- Grunting
- Hypoxia/cyanosis
- Bradypnoea – pre-arrest sign that requires urgent attention
- Bradycardia – pre-arrest sign that needs immediate attention.

(See Table 107.1.)

Basic physiological parameters are mostly recorded in well, non-hospitalised children. Children who are hospitalised will often exhibit compensated parameters, which, for their illness, are expected. These parameters need to be matched with clinical observation and experience.

Table 107.1 Normal heart and respiratory rates relative to age for hospitalised children

AGE GROUP	RESPIRATORY RATE MEAN (5TH–95TH PERCENTILE)	HEART RATE MEAN (5TH–95TH PERCENTILE)
0–3 months	41 (27–62)	140 (113–171)
3–6 months	38 (25–58)	135 (108–167)
6–9 months	35 (23–54)	131 (104–163)
9–12 months	33 (22–51)	128 (101–160)
12–18 months	31 (21–48)	124 (97–157)
18–24 months	29 (20–45)	120 (92–154)
2–3 years	27 (18–42)	115 (87–150)
3–4 years	25 (18–40)	111 (82–146)
4–6 years	24 (17–37)	106 (77–142)
6–8 years	23 (16–35)	100 (71–137)
8–12 years	21 (15–31)	94 (66–129)
12–15 years	19 (13–28)	87 (61–121)
15–18 years	18 (13–25)	82 (57–115)

Adapted from Bonafide CP, Brady PW, Keren R, et al. Development of heart and respiratory rate percentile curves for hospitalized children. *Pediatrics*. 2013;131(4):e1150–e1157.

PHYSICAL EXAMINATION

Respiratory examination findings are more challenging to elucidate in an active child who may be uncooperative or acutely distressed. In addition, the rate of breathing is much faster. A physical exam requires a skilled physician with a well-tuned knowledge. With practice, skills in observation, auscultation and percussion can be developed. As a rule, a truncated 'adult' type of exam that is limited to inspection and auscultation will give the examiner the best information while limiting distress to the child.

As children become more upright and mobile, they develop more of an adult body habitus, so the signs and symptoms are similar to adult respiratory failure. By the time a child is a teenager, the signs and symptoms parallel those in adult respiratory medicine.

PREMATURITY AND NEONATAL CHRONIC LUNG DISEASE[6–8]

The lungs develop throughout the foetal period until late childhood. Lung development is divided into five stages: embryonic, pseudoglandular, canalicular, saccular and alveolar. The embryonic and pseudoglandular phases have very little gas exchange ability. At 28 weeks of gestation, the middle of the canalicular stage, a significant amount of the ventilation can occur within

the respiratory bronchioles; 28–32 weeks corresponds to the saccular stage. At around 32 weeks, gestation intrinsic surfactant production begins. In preparation for premature birth this may be stimulated by the administration of corticosteroids to the mother. This is conventional therapy for any mother with threatened delivery prior to 32 weeks. Additional factors, such as foetal stress and infection, will also augment alveolar development.

Total alveolar surface area is increasing from 32 weeks and continues into childhood. This is the result of increasing maturity of alveoli, replication and increasing numbers.

Underdevelopment of the lungs of the premature infant is only one of the many issues that affect infants born prematurely. As a result, they require complex neonatal intensive care and care that will continue into childhood.

There is some complexity in the description of prematurity, gestation and birthweight. It is briefly described as follows:

- a term newborn is delivered from 37 weeks after the mother's last menstrual period; prematurity occurs when a newborn is less than 37 weeks of completed gestation
- extremely low birth weight is less than 1000 g
- very low birth weight less than 1500 g
- low birth weight is less than 2500 g
- small for gestational age is less than 5th percentile of weight for gestational age.

Chronic neonatal lung disease (CNLD) is defined as either:

- oxygen requirement at 28 days post-delivery (irrespective of premature gestation), or
- oxygen requirement at 36 weeks of gestational age.

All premature infants will have some degree of abnormal lung development. Bronchopulmonary dysplasia and hyaline membrane disease are pathological findings on biopsy or autopsy of premature infants who have respiratory failure. They are often used synonymously to describe CNLD and respiratory distress syndrome. The pathological features of CNLD include alveolar septal fibrosis with alternating collapse and hyperinflation of acini. Smooth muscle hypertrophy/hyperplasia may also be present. Chest X-ray (CXR) may reveal generalised hyperinflation, multiple cystic areas and opacities. A novel type of CNLD exists (Wilson Mikity syndrome) where babies may not have an initial oxygen requirement but go on to develop an oxygen requirement towards term or beyond.

Complications of prematurity are a common co-morbidity in children admitted to a paediatric intensive care unit (PICU) with severe respiratory failure; this is frequently in the context of an acute viral chest infection. CNLD, airway reactivity and pulmonary hypertension exacerbate any symptoms the infant may have otherwise suffered, increasing the need for invasive and non-invasive respiratory support.

Apnoea is a feature of prematurity and is a common symptom of illness in premature infants from birth until about 3 months of corrected age. Important differential diagnoses include sepsis (bacterial and viral), intraventricular haemorrhage and pain. Respiratory stimulants, such as caffeine, can be used to treat apnoea, though this is not always effective. Quite often the infant may need non-invasive support, such as HFNC oxygen, continuous positive airway pressure (CPAP) or bi-level positive airway pressure (BiPAP), or ultimately invasive ventilation to manage the underlying condition and the apnoea.

Central hypoventilation due to a *PHOX2B* mutation is increasingly recognised as a congenital form of depressed ventilatory drive beyond the neonatal period. It manifests as hypoventilation during sleep. These children usually need non-invasive or invasive support. If undiagnosed, these children can present as sudden infant deaths.

Maternal tobacco use during pregnancy is a significant cause of prematurity, and it impairs lung development. Environmental tobacco smoke exposure exacerbates chronic lung disease, asthma and recurrent bronchiolitis in older infants.

LARYNGOMALACIA/TRACHEOMALACIA/BRONCHOMALACIA[9,10]

This results from cartilaginous weakness of the larynx, trachea, main bronchi or any combination of these. There may be malacia at single or multiple levels. Laryngomalacia is usually primary in nature. Tracheomalacia and bronchomalacia can be primary or secondary, and are caused by intrinsic anatomical abnormalities of the airways or secondary to external factors causing distortion or compression of the airways. Abnormalities of size or path of mediastinal blood vessels (primarily the aorta, pulmonary artery and right subclavian artery) and chest masses are the most common.

The result is a 'floppy' airway that tends to collapse during inspiration and/or expiration. Depending on whether these vessels are intra- or extrathoracic, stridor (extrathoracic) and/or wheeze (intrathoracic) will be present. Respiratory embarrassment may range from mild to severe, and includes cardiorespiratory arrest from acute airways obstruction – so-called 'malacic' spells.

What might be a mild illness for a normal infant becomes one that may require ventilation for a child with malacia. Ventilator weaning is often troublesome in these infants. Severe long-segment malacia can be an indication for long-term non-invasive home ventilation or tracheostomy and invasive ventilation. Over the first 18–24 months of life there is growth of the cartilage and improvement in the airway rigidity.

Tracheopexy (suspending the trachea on the sternum) and tracheal stenting are possible alternative interventions. Where malacia is a secondary effect of another abnormality, surgery to correct this defect may be warranted (e.g. vascular slings or rings, pulmonary atresia with poststenotic dilatation of the pulmonary artery); however, malacia often persists post-surgical correction. Management can be complicated and prolonged. Supportive therapies in lieu of growth and maturity of the large airways are the most common approach.

CONGENITAL HEART DISEASE[11]

Many congenital cardiac lesions present with respiratory features. Careful examination will help to elucidate the presence or absence of congenital heart disease. Features to look for include:

- Cyanosis
- Tachypnoea
- Tachycardia
- Hepatomegaly
- Murmurs, heaves and thrills in the precordium
- Absent femoral pulses
- Plethora or oligemia on chest radiography
- No improvement in cyanosis with supplemental oxygen
- Acidosis/lactataemia.

Although antenatal ultrasound scanning detects a significant number of lesions, early discharge or home birth means that symptoms can develop or go unappreciated until acute decompensation occurs.

Congenital heart lesions producing acute respiratory failure are likely to fall into one of the groups listed below:

- *Left heart obstruction (e.g. critical aortic stenosis, interrupted aortic arch and coarctation of the aorta):* this leads to pulmonary oedema, reduced pulmonary compliance and respiratory failure.
- *Large left-to-right shunts (e.g. ventricular septal defect and patent ductus arteriosus):* excessive pulmonary blood flow can cause pulmonary oedema, airway compression and obstruction. Minor intercurrent infection results in decompensation.
- *Cyanotic lesions:*
  - there is an obstruction to pulmonary blood flow (e.g. tetralogy of Fallot and critical pulmonary stenosis)
  - the pulmonary and systemic circuits are in parallel (e.g. transposition of the great arteries)
  - there is complete mixing of systemic and pulmonary blood (e.g. single ventricle and truncus arteriosus)
  - pulmonary venous abnormalities such as total anomalous pulmonary return.

Early institution of intravenous prostaglandins in company with other supportive measures, such as intubation, ventilation, judicious fluid therapy and inotropes, will be lifesaving in these infants. There are no contraindications to the commencement of prostaglandins in a collapsed infant where a paediatric cardiologist is not available to make an immediate assessment. An exception is for total anomalous pulmonary venous drainage where prostaglandin use most likely will be ineffectual, but it can worsen the cyanosis. This diagnosis requires expert assessment that is not immediately available to many collapsed infants at their initial presentation.

COMPLICATIONS OF CARDIAC SURGERY

DIAPHRAGMATIC PALSY

Palsy of the diaphragm is almost exclusively a complication of cardiothoracic surgery. These infants are difficult to wean from ventilation. If there is paradoxical upward movement of the affected diaphragm during inspiration, surgery to plicate the diaphragm is required. This stabilises the affected hemidiaphragm so the normal hemidiaphragm can still create a negative pleural pressure for inspiration. The palsy will often improve with time.

RECURRENT LARYNGEAL NERVE PALSY

Palsy of the recurrent laryngeal nerve results from an inadvertent injury sustained from surgery within the central structures of the chest. The most clinically significant manifestation is paresis of the ipsilateral vocal cord. Normal vocal cord function is necessary to maintain airway patency. Unilateral paresis is tolerable, but bilateral paralysis is poorly tolerated, sometimes resulting in recurrent extubation failure. Occasionally, a tracheostomy is needed to maintain a patent airway; fortunately, this is an uncommon situation.

VASCULAR RINGS AND SLINGS[12,13]

Vascular rings and slings may be considered complete or incomplete and result from aberrant vessels and the ductus arteriosus (or ligamentum arteriosus, if the duct is closed) leading to a constricting lesion of the trachea or bronchi. The most common type of sling is the pulmonary artery sling: an anomalous left pulmonary artery and the ductus encircling the trachea posteriorly. Vascular rings most commonly result from a right-sided aortic arch or a double aortic arch. There are a number of combinations: double aortic arch and derivatives causing complete ring, right-sided aortic arch and anomalous right subclavian artery, right-sided aortic arch, mirror image vessel branching and left ductus arteriosus, and an anomalous innominate artery.

Airway obstruction requires surgical correction. Tracheobronchomalacia often remains once the obstruction is relieved if the lesions have led to a secondary

malformation of the airway; this can lead to significant morbidity.

CONGENITAL DIAPHRAGMATIC HERNIA[14,15]

There are two types.

BOCHDALEK HERNIA

A Bochdalek hernia involves a deficiency in the postero-lateral part of the diaphragm. Most occur on the left side. A variable amount of the abdominal viscera herniates through into the chest. The presentation is dependent upon whether a hernia is diagnosed antenatally or not and whether pulmonary hypoplasia and pulmonary hypertension are present. Antenatal diagnosis may allow for the use of foetal intrauterine therapy; however, this is still experimental. The spectrum of clinical course ranges from profound, non-survivable hypoxia and pulmonary hypertension in the newborn to mild tachypnoea in infancy or an incidental finding diagnosed when a child comes to medical attention. Therapy involves respiratory support as appropriate and surgical closure of the defect. Children with severe respiratory failure may need extensive medical stabilisation with high-frequency oscillatory ventilation (HFOV), nitric oxide therapy and extracorporeal life support (ECLS). About 10% of children with congenital diaphragmatic hernia (CDH) have a chromosomal abnormality.

MORGAGNI HERNIA

A Morgagni hernia is in the anterior diaphragm. Typically, only the bowel will herniate through the defect. It is extremely uncommon for this hernia to cause respiratory discomfort. It is often an incidental finding or is associated with mild respiratory disease. Clinically significant hernias are repaired electively.

PULMONARY HYPOPLASIA

This is usually secondary to a space-occupying lesion within the chest, which limits room for lung development and results in abnormal pulmonary vasculature and pulmonary hypertension. CDH, cystic adenomatous malformation, congenital neuroblastoma and great vessel abnormalities are common causes. Pulmonary hypoplasia can be idiopathic. Depending on the residual lung function it can have a spectrum of clinical significance from an incidental finding to the requirement for long-term respiratory support.

OMPHALOCELE AND GASTROSCHISIS[16]

An omphalocele results from failed development of the abdominal wall musculature. The abdominal organs are contained within a protruding thin-walled peritoneal sac. There is a high incidence of associated abnormalities (50%–70%) and chromosomal defects (30%). Gastroschisis is herniation of the small bowel (usually) through an ischaemic defect in the abdominal wall. Approximately 15% of these children have associated defects or chromosomal abnormalities. Neither abnormality causes respiratory failure; however, surgical reduction may lead to increased intra-abdominal pressure, which limits excursion of the diaphragm and ventilation of the lungs. This is more likely with an omphalocele as more abdominal viscera are exteriorised.

NEUROMUSCULAR AND SKELETAL DISORDERS[17]

Any disorder that affects the ability of the muscles to 'drive' the ventilatory pump, or that causes a chest wall deformity, can compromise the effectiveness of ventilation. In the neonatal period these present with hypoventilation, desaturation and apnoea. Ventilator dependence as a neonate with these disorders indicates that the child is unlikely to survive without intensive support and, most likely, mechanical ventilation. Parents should be counselled appropriately. Spinal muscular atrophy (SMA) type 1 is the most common example of this. Less severe neuromuscular disorders may survive the neonatal period but go on to develop respiratory failure later (e.g. Duchene muscular dystrophy, SMA types 2 and 3). The amount of support offered needs to take into consideration ethical treatment, rational expenditure of resources and the wishes of the family and child (if appropriate).

ACQUIRED NEONATAL DISEASES[4]

TRANSIENT TACHYPNOEA OF THE NEW BORN

Transient tachypnoea of the newborn (TTN) is transient delayed clearance of foetal lung fluid. In the transition from intrauterine life the infant has to aerate the majority of its alveoli within a few minutes; a truly amazing feat. Not surprisingly, some infants may be slow to progress through this process. It is often an issue in infants that have little exposure to catecholamines due to a rapid operative delivery. Although these infants may require oxygen or CPAP, it is seldom that they need invasive ventilation.

MECONIUM ASPIRATION SYNDROME[18]

Meconium is the term used it describe faecal material of an infant prior to and in the first days of life. Passage of meconium is normal after birth. Passage of meconium prior to or during birth is an indicator of foetal stress. If inhaled or aspirated by the infant during delivery it induces a chemical pneumonitis and obstructive lung disease. If there is meconium present

and if the neonate is apnoeic, it is recommended that he/she be suctioned below the vocal cords before bag mask ventilation. Either intubation and suction via the endotracheal tube (ETT) or the use of a specialised meconium aspirator is recommended.

Once an infant develops meconium aspiration syndrome (MAS) the infant will need some degree of respiratory support. Non-invasive respiratory support and invasive ventilation are standard treatment options. Antibiotics are commonly administered as there is concern that sepsis might be an additional cause of foetal distress. Natural lung surfactant is deactivated by meconium. Surfactant therapy has not been shown to improve overall survival, but it may reduce hypoxia, though it can be poorly tolerated. There are conflicting recommendations regarding its use.

ECLS is indicated for severe MAS. Of all disease entities treated with ECLS (including all neonatal, paediatric and adult causes) MAS has the greatest survival. The Extracorporeal Life Support Organization (ELSO) database figures show that survival from severe respiratory failure due to MAS is upward of 90% with some units boasting near-100% survival.

NEONATAL PNEUMONIA[19]

Neonates are at constant risk of pneumonia. Due to the relative immaturity of their immune system, they are especially at risk from encapsulated bacteria and Gram-negative bacteria, such as *Escherichia coli*, *Klebsiella* and *Serratia*. Group B *Streptococcus* is carried as a vaginal commensal by up to 50% of women so is a common neonatal pathogen. This organism also causes sepsis and meningitis in infants and newborns. Early infections less than 14 days are likely to have come from the mother at birth, prior to delivery (chorioamnionitis, prolonged rupture of membranes) or by transplacental infection (*Listeria monocytogenies*).

Viruses, such as cytomegalovirus, varicella and other herpes viruses, tend to cause a generalised viraemia rather than isolated pneumonia. Fungal and protozoan infections are virtually unheard of in causing neonatal pneumonia and tend to cause a systemic infection.

PULMONARY HAEMORRHAGE[11]

Prematurity, surfactant deficiency and persistent foetal circulation with pulmonary hypertension all predispose an infant to the risk of pulmonary haemorrhage. Vitamin K deficiency can also present with pulmonary haemorrhage. However, gastrointestinal bleeding and intracerebral bleeding are far more common. Children with abnormal pulmonary vascularity of the bronchial arteries can also present with catastrophic pulmonary haemorrhage; however, this tends to present later in life. Disseminated intravascular coagulation can result in pulmonary haemorrhage in the setting of severe sepsis.

COMMON ACQUIRED DISEASES BEYOND THE NEONATAL PERIOD

BRONCHIOLITIS[20–25]

Bronchiolitis is the most common cause of respiratory failure beyond the neonatal period in children. Bronchiolitis is caused by infection and inflammation in the bronchioles resulting in obstructive lung disease leading to hypoxia, tachypnoea and air trapping. Chest radiographs show hyperinflation (and collapse) of lung segments and often right upper lobe collapse and/or consolidation. Respiratory syncytial virus (RSV) and human metapneumovirus (hMPV) are the most common viral pathogens. Additionally, bronchiolitis can be caused by human bocavirus, adenovirus, parainfluenzae, influenza virus and rhinovirus; all are implicated in the hospitalisation of children. Data from the Australasian ANZPIC registry show that bronchiolitis is the primary emergent diagnosis leading to PICU admission.

Treatment is primarily supportive, with the majority of infants supported by non-invasive respiratory support (largely HFNC oxygen). Only a few infants require invasive ventilation. These tend to be the very young infants in whom apnoea is a feature of the disease, and infants with underlying medical conditions, such as chronic lung disease, cardiovascular disease and neuromuscular disease.

Up to 20% of infants who require invasive ventilation for bronchiolitis have a concurrent bacterial infection, so antibiotics are often started empirically until haematology and inflammatory markers become reassuring and cultures are negative. A number of infants with bronchiolitis who need respiratory support must be transferred from their regional hospital to the nearest PICU. Although transfer with non-invasive support can be done safely for short road transfers, aeromedical transfer often necessitates intubation to secure the airway for the limitations of the aeromedical environment. Children transferred to a tertiary centre are more likely to be ventilated than those admitted from the onset of their illness.

Steroids, epinephrine (adrenaline), bronchodilators and hypertonic saline have been investigated for the treatment of bronchiolitis. None has consistently shown significant benefit in hospitalised children. Specific antiviral therapy is not indicated in the immunocompetent. Recombinant RSV antibody provides passive prophylaxis against RSV and is indicated in infants with chronic lung disease or congenital heart disease.

PNEUMONIA[26–30]

ANZPIC data show that about 13% of respiratory admissions were for pneumonia. About half of these patients required invasive ventilation. Community-acquired pneumonia is caused predominantly by

viruses followed in frequency by staphylococcal and streptococcal bacteria. Atypical infections such as *Mycoplasma pneumoniae* and *Chlamydia* also feature. Respiratory support is escalated as required to support the work of breathing and provide acceptable gas exchange. High-flow oxygen therapy is increasing in frequency and is the next most common therapy after supplemental low-flow oxygen.

If ventilation is required, current recommendations in paediatric acute respiratory distress syndrome (pARDs) (of which pneumonia is a secondary cause) should be followed. Tidal volume should be limited to less than 8 mL/kg with sufficient positive end-expiratory pressure (PEEP) to maintain lung distention. Permissive hypoxia and hypercarbia should be employed.

Treatment with empirical antimicrobials based on local sensitivity patterns should commence as soon as possible. Antibiotics should be changed to narrow-spectrum agents once organism sensitivities are known. The exception to this rule is in the treatment of cystic fibrosis where broad-spectrum cover may be needed to mitigate against the development of antimicrobial resistance. Bronchoscopy for samples is often not possible owing to the small calibre of the ETT. Blind bronchoalveolar lavage is almost routine for intubated patients. Endotracheal suction samples are also used; however, poor sensitivity and specificity limit their value.

ASTHMA[31–36]

Asthma is frequently diagnosed in childhood but not all wheezy exacerbations are asthma. They may be manifestations of an acute viral illness that presents with a constellation of symptoms including wheezing and tachypnoea, but they do not respond to bronchodilators. As an intensive care physician it is important to make an assessment of these patients regarding the underlying aetiology. The management of a wheezy lower respiratory infection is purely supportive but may often require some mechanical respiratory support.

Acute severe asthma requires specific treatments for the inflammation and bronchoconstriction that are the pathophysiological basis of asthma. For all but the most severe asthma, metered dose inhalers and spacers have been shown to have superior drug deposition. If there is significant hypoxia, oxygen-driven nebulisers are necessary. Nebulisers of salbutamol and ipratropium bromide should be given as a matter of urgency. Salbutamol nebulisers may need to be given continuously. Once the oxygen and nebulised bronchodilators have commenced then steroids are the next most important part of the asthma management. Gastric stasis is common in acute severe asthma, so oral steroids should not be relied upon. Anti-inflammatory doses of intravenous steroid should be given urgently to all patients who do not significantly improve with the initial burst of bronchodilators. Frequently, patients are also mildly dehydrated due to poor oral intake and increased insensible losses so a small fluid bolus can be helpful along with the commencement of intravenous maintenance fluids.

Intravenous salbutamol is sometimes necessary, but it can lead to side effects of tachycardia, tremor, lactic acidosis and a resultant compensatory increase in respiratory drive. An intravenous bolus of magnesium sulphate and/or aminophylline will often improve bronchoconstriction in severe refractory asthma, but it can have adverse effects. These last three medications are contentious and have protagonists and antagonists. However, the side effects of medical therapy are less than the risks of invasive ventilation.

Non-invasive ventilation (NIV) with continuous positive airways pressure (CPAP) or bi-level airways pressure (BiPAP) is increasingly used in asthma. Asthma was thought to be a contraindication, but NIV is now considered to have a place in acute severe asthma. It should not replace invasive ventilation if this is deemed to be necessary. Invasive ventilation should be approached with caution and with preparations made for managing cardiac arrest and pneumothorax should these occur. The approach taken for the ventilation of severe paediatric asthma is the same as for an adult patient. The reader is referred to Chapter 35 for the salient issues regarding ventilation of patients with asthma. Volume ventilation is preferred as this will adapt to the changing compliance of the lungs as the bronchi relax. High pressures may be needed. The alveoli are protected from these forces by the airway obstruction. The combination of steroid therapy and muscle relaxants puts the child at risk for critical illness neuropathy/myopathy. Fortunately, most children do not require more than 48 hours of ventilation. General anaesthesia and ECLS have been used on rare occasions.

Acute asphyxial asthma can present as a community cardiorespiratory arrest in children. The profound bronchoconstriction may have resolved by the time the child presents in the emergency department. These children have usually suffered a severe hypoxic-ischaemic brain injury. It is exceptionally rare for a child who presents with severe asthma to have a respiratory arrest once therapy has begun, but aggressive up-front treatment is mandatory.

Asthma is the second most common reason for admission emergently to a PICU for respiratory disease. Significant respiratory support is seldom required; however, this is a reflection of regional admission criteria.

CROUP[37–39]

Croup or laryngotracheobronchitis is infection and inflammation of the upper and lower airways. Children are more prone to croup owing to the smaller

airway radius. Further narrowing leads to a marked increase in resistance and turbulent flow. In the past, intubation was frequently required; however, the use of steroids and epinephrine (adrenaline) nebulisers now means very few children require intubation. If required, intubation for severe croup is best undertaken in the operating theatre with a gaseous induction and preservation of spontaneous breathing. If there is no significant lower airway or lung parenchymal inflammation, these children can be often supported with a nasal ETT and be awake and sometimes ambulant. Parainfluenza virus is the commonest cause of this condition. Important differentials to consider with severe stridor are foreign body, bacterial tracheitis and epiglottitis. Epiglottitis has become very uncommon with effective *Haemophilus influenzae* B vaccination.

TUMOURS

Neuroblastoma and lymphomas are the most common tumours that develop in children and cause respiratory compromise. Lymphomas tend to arise centrally from mediastinal nodes. A rapidly growing mediastinal T-cell lymphoma is a true oncological emergency. Mediastinal compression results in life-threatening respiratory and cardiovascular compromise. Maintenance of spontaneous breathing and positioning the patient in a forward sitting position are simple measures that may improve ventilation. Children will often find their preferred position. Intravenous steroids may need to be commenced before diagnosis if the respiratory compromise is severe. Intubation of these patients is risky and best done in the operating theatre with a gas induction and ear, nose and throat surgeons on standby.

ACUTE NEUROMUSCULAR DISEASE

For the most part, the acute neuromuscular conditions that children succumb to are similar to those for adults. The reader is referred to the relevant chapters. Guillain–Barré, tetanus, botulism, acute demyelinating encephalomyelitis and acute spinal injury are supported with ventilation while expectantly awaiting the return of neurological function. In Australia, tick bite paralysis can cause severe paralysis in children. The toxin binds covalently with the acetylcholine receptor complex. The cholinergic block lasts long after the source of the toxin is removed. Quite often, children require prolonged courses of supportive ventilation and intensive care. This is in contrast to the North American tick where paralysis resolves relatively quickly.

CHRONIC NEUROMUSCULAR CONDITIONS

Chronic neuromuscular disorders that are not diagnosed at birth are often diagnosed in infancy and early childhood. These children often require intermittent respiratory support with intercurrent illnesses. Many of these diseases are life-limiting and eventually children with severe neuromuscular or progressive conditions will suffer severe respiratory infections that need ventilation for prolonged periods. Cerebral palsy, Duchenne muscular dystrophy and spinomuscular atrophy are examples. Intubation can be difficult owing to scoliosis, limited jaw opening or facial dysmorphism. Ventilation is often troublesome due to chest wall deformity and underlying chronic lung disease. Weaning from ventilation is slow and laborious and may involve a protracted stay in the PICU on invasive ventilation and NIV. Some children cannot be weaned from invasive ventilator support after a severe infection so there is a risk that these children will die a very medicalised death. End-of-life care and limitation of interventions are important issues to discuss with parents and caregivers.

TRAUMA

The reader is referred to the chapters on head, chest and paediatric trauma. Pulmonary contusions and rib fractures are less common in small children. Head injury is common. As children grow, their bones ossify and they become involved in more risky activities so pulmonary contusions and rib fractures become more common. Infants tend to cope better with rib fractures, but older children have more significant issues with pain and lung expansion, as experienced by adult patients.

The management of severe chest trauma in children is no different to that in adults: maintain distension of as much of the lung as possible, and ensuring adequate ventilation. High frequency ventilation or ECLS can be used for pulmonary contusions. ECLS was previously contraindicated, but there are case reports in the literature of its use.

Bronchoscopy can be useful for pulmonary hygiene and the removal of blood casts from the bronchial tree. Lung isolation and independent ventilation are difficult in children and are seldom necessary.

ACUTE RESPIRATORY DISTRESS SYNDROME[40–50]

pARDS may occur in children of all ages from a variety of direct and indirect lung insults, as it does in adults. In children, common causes of pARDS include shock, pneumonia, sepsis, near-drowning and cardiac disease (congenital).

pARDS was redefined after the publication in June 2015 of the Proceedings of the Pediatric Acute Lung Injury Consensus Conference. This defined the criteria for the diagnosis of pARDs primarily for the purposes of research. Its use is mainly for the comparison and analysis of modalities of therapy for acute respiratory distress. Additionally, they have defined 'at risk' criteria. Tables 107.2 and 107.3 list these criteria.

Table 107.2 Paediatric acute respiratory distress syndrome criteria: adapted from consensus statements

Age	Excludes perinatal lung disease
Timing	Within 7 days of known insult
Oedema	Not explained by cardiac disease or fluid overload
Chest imaging	New infiltrates
Oxygenation	**Non-invasive ventilation** (No stratification) CPAP >5 cmH_2O. P/F ratio <300. SF ratio <264 **Invasive ventilation** Mild: OI <4 or >8, OSI <5 or >7.5 Moderate: OI <8 or >16, OSI <7.5 or >12.3 Severe: OI >16, OSI >12.3 $OI = (Fi_{O_2} \times \text{mean airway pressure} \times 100)/Pa_{O_2}$ $OSI = ((Fi_{O_2} \times \text{mean airway pressure} \times 100)/O_2 \text{ sat})$ (Used when Pa_{O_2} not available. Wean O_2 to give sat of 97% and use values required to achieve this value) SF ratio = O_2Sat/Fi_{O_2} PF ratio = Pa_{O_2}/Fi_{O_2}
Special populations	Cyanotic heart disease – cannot be explained by congenital heart disease Chronic lung disease – cannot be explained by chronic lung disease Left ventricular dysfunction – cannot be explained by left ventricular dysfunction

CPAP, Continuous positive airway pressure.

Table 107.3 Paediatric acute respiratory distress syndrome risk criteria: adapted from consensus statements

Age	Excludes perinatal lung disease
Timing	Within 7 days of known insult
Oedema	Not explained by cardiac disease or fluid overload
Chest imaging	New infiltrates
Oxygenation	**Oxygen therapy** (oxygen/high-flow nasal cannula oxygen) Needing oxygen supplementation to maintain O_2 sats 88%–97% Minimum oxygen flows to achieve criteria <1 year 2 L/min, 1- to 5-year 4 L/min, 5- to 10-year 6 L/min, >10 years 8 L/min (oxygen flow = $Fi_{O_2} \times$ total flow rate) **CPAP/BiPAP** Fi_{O_2} >40% to maintain sats 88% – 97% **Invasive ventilation** Fi_{O_2} >40% maintain Sa_{O_2} >88. But OI <4 or OSI <5 $OI = (Fi_{O_2} \times \text{mean airway pressure} \times 100)/Pa_{O_2}$ $OSI = ((Fi_{O_2} \times \text{mean airway pressure} \times 100)/O_2 \text{ sat})$ (Used when Pa_{O_2} not available. Wean O_2 to give sat of 97% and use values required to achieve this value)

BiPAP, Bi-level positive airway pressure; *CPAP*, continuous positive airway pressure.

With permission from Khemani RG, Smith LS, Zimmerman JJ, Erickson S, Pediatric Acute Lung Injury Consensus Conference Group. Pediatric acute respiratory distress syndrome: definition, incidence, and epidemiology: proceedings from the Pediatric Acute Lung Injury Consensus Conference. *Pediatr Crit Care Med.* 2015;16(5 Suppl 1):S23–S40.

Treatment modalities for pARDS are very similar to those for adults with the open-lung/low-tidal-volume strategy, and acceptance of permissive hypoxia and hypercarbia. HFOV is commonly employed. ECLS is considered if there is a reversible or treatable cause. The reader is referred to Chapter 33 on acute respiratory distress syndrome.

FOREIGN BODIES

Laryngeal, tracheal and bronchial foreign bodies are commonplace in children. Commonly, if not swallowed, they become lodged in the retropharynx. If they traverse the cords then they are likely to lodge at the level of the cricoid membrane (the narrowest part of the paediatric airway).

The shape of the foreign body is of crucial importance as to its final resting place. Sharp and slender foreign bodies (such as needles) and particulate food material (i.e. pieces of nuts) travel further down the bronchial tree.

Nut fragments and food particles are an important cause of morbidity. In particular, peanuts release arachidonic acid, which causes local inflammation. The resultant inflammation causes stenosis of the airway and pneumonia beyond the level of the obstruction.

Button batteries from small electrical devices tend to be swallowed and lodge in the oesophagus of the stomach. These are less of an issue in the airway.

Bronchoscopy (flexible and rigid) should be performed if there is any concern of a foreign body.

IMMUNOCOMPROMISED PATIENTS[29,51]

A PICU within a hospital with an active oncology service and, importantly, a bone marrow transplant service, will see a significant number of immunocompromised children. Quite often they present with generalised sepsis, localised pulmonary sepsis or with pulmonary complications of conditioning regimens for transplant.

Solid organ transplant patients are less immunocompromised after the initial transplant but can still present with immunosuppression-related infections.

The amount of HIV seen in a paediatrics unit mirrors that seen in the heterosexual community as the majority are from maternal transmission. Developing and third-world countries where HIV rates are extremely high in the adult population will see a lot more HIV in their critically unwell patients.

Previously undiagnosed leukaemia and lymphomas can present with respiratory failure due to:

- Sepsis
- Hyper-leukocytosis and viscosity/sludging in pulmonary vessels
- Disseminated intravascular coagulation and sequelae
- Multisystem organ failure
- Mass effects.

Genetic immunodeficiency states are rare. Severe combined immunodeficiency, combined variable immunodeficiency and chronic granulomatous disease can all present with severe respiratory failure in undiagnosed patients. T-cell defects present with opportunistic infections such as *Pneumocystis*, *Nocardia* and fungal infections. B-cell deficiencies present with severe viral or encapsulated bacterial infection. Chronic granulomatous disease presents with recurrent bacterial infections that need an efficient oxidative burst to destroy them (e.g. *Staphylococcus aureus*). Infection with an unexpected organism or severe respiratory failure in an infant that cannot be explained warrants a thorough investigation and assessment of the patient's immunocompetence.

Treatment of respiratory failure in the immunocompromised is directed towards the primary problem along with the respiratory support and antimicrobial therapy as appropriate. In some cases the immunosuppression, with steroids for example, may need to be decreased. Post-transplant lymphoproliferative disease is an example of this.

In many chemotherapy and bone marrow transplant regimens, bone marrow stimulation or autologous stem cell rescue is used to minimise the period of neutropenia and minimise the risk of sepsis in the face of aggressive chemotherapy.

INVESTIGATIONS

RADIOLOGY[6,52–55]

Although CXR is often mandatory in patients with respiratory disease to delineate the extent of lung involvement, the presence of pneumothorax or effusion or to check the position of the tracheal tube and central venous lines, routine radiology investigations can expose children to unnecessary ionising radiation. Investigations that use ionising radiation should be done only if they will answer questions important to diagnosis or management of the patient. Exposure to therapeutic radiation as a percentage of total lifetime radiation has been estimated to have risen from 15% to 50% in the United States over the last 30 years: CXRs are a significant contributor to this radiation. Children are most at risk. A chest computed tomography (CT) scan has a 1:1000 chance of inducing malignancy.

Standard CT and high-resolution spiral CT with thin cuts can provide better diagnostic detail than a plain CXR; however, their use should be justified in light of the increasing lifelong radiation exposure and the risk of transporting a critically ill patient to the scanner.

Although magnetic resonance imaging is not a good modality for lung parenchyma, it does not use ionising radiation and is safe with cumulative dosing.

Ultrasound is becoming routine in emergency departments and intensive care units (ICUs). Focused chest ultrasound can assist in the diagnosis of pneumonia, pleural effusions and pneumothorax with only a small amount of training required. Ultrasound should be used routinely for the placement of central venous lines, and it can assist with the insertion of chest drains, and the placement of intra-arterial lines and peripheral intravenous lines (where veins are not visible on the skin surface).

MICROBIOLOGY[5,22,26–28]

Appropriate microbiological samples have a crucial role in diagnosis and therapy. It is important to sample blood and respiratory secretions before administering antimicrobial therapy if possible.

Nasopharyngeal aspirate, nasal brushings or blood tests can, by the use of DNA/RNA polymerase chain reaction, detect significant viral and atypical (i.e. mycoplasma or Chlamydia) infections of the respiratory system. In children admitted to the PICU, RSV and hMPV infections are by far the most common.

Bronchoscopy is used in the PICU but to a lesser extent than in the adult ICU. It is used to inspect the airways, clear secretions and obtain samples. The need to use very small bronchoscopes for infants, plus limited experience and reduced availability of equipment limit the utility of this modality in the PICU. When required, it is undertaken by respiratory physicians or intensivists with keen interest in the procedure.

THERAPY FOR CHILDREN WITH SEVERE RESPIRATORY FAILURE

SUPPORTIVE CARE/FAMILY-CENTRED CARE

Even in the most critically ill children, parents are encouraged to be involved in the care of the child as much as is practical. The calming influence of a parent or grandparent cannot be understated and is a valuable adjunct to sedation regimens in the PICU and the neonatal intensive care unit (NICU). By inviting parents to participate in the care of their critically ill child, a partnership is forged that promotes trust and compliance with necessary medical interventions. If the child does not survive, the benefit for the parents in the subsequent grieving process should not be underestimated. Siblings may also benefit. However, this has to be matched with the needs of the patient.

NORMOTHERMIA, FLUID BALANCE AND NUTRITION[48,56–58]

Maintenance and promotion of homeostasis are the hallmarks of good intensive care. This includes adequate nutrition, euvolemic fluid balance and normothermia (unless therapeutic hypothermia is undertaken). Small infants have a large body surface to weight ratio so maintenance of normothermia can be challenging, particularly during procedures and transportation around and between hospitals. Clinicians and nursing staff need to pay particular attention at these times. Adequate nutrition promotes recovery from critical illness, so nutritional goals should be set early and all attempts made to reach these, including the use of transpyloric feeding tubes and intravenous nutrition if required. Avoidance of overfeeding is also an important consideration. Impaired carbon dioxide clearance in severe respiratory failure makes this vital as excess calorie intake promotes increased CO_2 production.

Minimising fluid overload and increased lung water are crucial and can lead to prolonged ventilator weaning if not addressed. Diuretics are commonly used to treat generalised oedema but have side effects of electrolyte imbalance and metabolic alkalosis. If fluid overload can be avoided then this is recommended.

Adherence to 'bundles' of care is necessary. The standardisation and promotion of high-quality care is augmented by the use of 'bundles' and 'checklists'. Ventilator-associated pneumonia, central line sepsis bundles and pre-procedure checklists are examples of these.

ANTIMICROBIAL USE

Antimicrobial use should always be with consideration of the local pattern of pathogen sensitivities and promote good antimicrobial stewardship to minimise the impact of resistance patterns. Patients on antimicrobial therapy often benefit from specific input by infectious diseases specialists, and routine consultation is an important part of antimicrobial stewardship.

NON-INVASIVE RESPIRATORY SUPPORT

HIGH-FLOW NASAL CANNULA OXYGEN THERAPY[59–63]

HFNC oxygen therapy has made its way rapidly into the PICU armament of support. Its introduction has preceded the supportive research relating to its use. Nonetheless, it appears to be a very useful tool at the lower end of respiratory support. HFNC oxygen therapy consists of a simple circuit comprising a gas flow regulator, an oxygen mixer, a humidifier, a gas warmer, large-calibre tubing and a patient interface. The patient interface is most commonly a soft plastic or silicone nasal cannula. The cannula may be semi-occlusive of the nares or non-occlusive. The gas flow is matched to the peak inspiratory flow so the nasopharynx is continuously replenished with a fresh gas supply. A small but not insignificant amount of PEEP is the result. Flow would be prescribed at 2 L/kg and occasionally 3 L/kg. This therapy is cheap and

is currently undergoing randomised trials to assess its efficacy. This is despite the huge uptake clinically at the bedside. There is evidence in paediatrics to suggest that this therapy is reducing intubation rates and, indeed, PICU admissions.

NASAL AND FACE MASK NON-INVASIVE VENTILATION[64]

Non-invasive ventilation supports neonatal and paediatric patients alike. Helping premature neonates in this way is useful and beneficial, and it avoids many risks associated with long-term invasive ventilation. Even very premature infants can have a brief period of invasive ventilation and surfactant instillation, and then for the majority of the time they are supported on bubble CPAP for the weeks and months they are in the NICU. Neonatologists as a rule use a nasal prong patient interface. This is due to its simplicity, lack of bulk, ease of securing and effectiveness. As patients grow, the use of masks becomes easier and the NIV devices are more able to synchronise and provide BiPAP efficiently. Soft, malleable facial structure, the general uncooperativeness of patients and difficulties with an adequate seal make patient interfaces difficult to match with individual patients. Newer plastics, the manufacturing of devices and improved cushioning help to decrease these problems. Older children, like adults, are most suited to mask ventilation support; however, with persistence and a range of masks, younger children can be supported with NIV.

Triggering and delivery of support can be limited in some devices. With newer machines and triggering modes, such as NAVA (neurally adjusted ventilatory assistance), this will change. NAVA relies on a special nasogastric tube that has electrodes that detect the electrical signal passing down the vagus nerve. The strength of this impulse is proportionate to the amount of ventilator support required by the patient. NAVA can be used in non-invasively ventilated and invasively ventilated spontaneously breathing patients.

The single most valuable resource, other than equipment, is experienced personnel who are able to persevere, use alternative interfaces and understand the equipment. In the acute setting it is very common to require sedation to augment patient compliance with the NIV. This should be used only where suitable staff members are present and emergency equipment is available for intubation.

INVASIVE VENTILATION

CUFFED VERSUS UNCUFFED ENDOTRACHEAL TUBE/NASAL VERSUS ORAL[65,66]

The debate regarding cuffed versus uncuffed ETT is not likely to be resolved. Both types are reasonable to use and each type has its advantages and disadvantages. For short-term use, security and reliable ventilation, most paediatric anaesthetists would prefer a cuffed ETT. In PICU, when ventilation is expected to be difficult or when changing the ETT is likely to cause significant deterioration, cuffed ETTs are preferred. For longer-term PICU management the issue is less clear. Cuffed ETTs need to be the appropriate size and care needs to be taken to monitor the inflation pressure and the positioning of the cuff. With either cuffed or uncuffed ETT, a leak of inspired gas around the ETT (cuff deflated if present) is a desirable finding when considering extubation and the risk of post-extubation stridor. The presence of a leak does not guarantee the patient will not suffer this complication. Usually, it is local policy that directs the use of cuffed or uncuffed ETTs.

Nasal verses oral positioning for long-term ETTs is another contentious issue. Either route is used up to the age of around 8 years when maxillary and ethmoid sinuses become aerated. Oral intubation is used first when intubating a critically unwell child due to lack of reserve and the need to expedite positive-pressure ventilation. If the intubation is uncomplicated and the patient tolerates the procedure then the ETT may be changed to a nasal ETT. However, this is dependent on local PICU policy and preference rather than clear evidence. Arguably, a nasal ETT is more comfortable for the patient and easier to secure but can cause pressure areas. The risk of changing the ETT should override any decision to match the culture of the PICU with respect to the positioning of the ETT.

CONVENTIONAL VENTILATION[5,67,68]

The debate as to volume- or pressure-regulated ventilation is ongoing, although it appears that volume control may be more lung protective. Pressure control ventilation has historically been used in children owing to early ventilators not being able to guarantee delivery of the small tidal volumes that babies and infants require. With newer, more sophisticated ventilators the volume control can be adjusted up to the nearest millilitre. Accurate volume measurement also requires the use of cuffed ETT in a majority of cases.

Triggered modes are used in patients who are spontaneously breathing. The aim is to have the patient lightly sedated, exercising the respiratory muscles and synchronising well with the ventilator. Appropriate triggering, inspiratory time and cycling to expiration are all important to synchrony.

PEEP of at least 5 cmH_2O (0.66 kPa) is routinely used in all paediatric and neonatal patients, albeit empirically. Children expire to near their FRC so that any loss of muscle tone will lead to greater likelihood of pulmonary atelectasis – hence a small amount of distending pressure is desirable. As in adults, PEEP is increased and recruitment manoeuvres are used to promote open lung ventilation. PEEP is unlikely to be increased beyond 15 cmH_2O (2 kPa). Adult strategies advocate higher PEEP but neonatal and paediatric preference is usually to change to HFOV if adequate gas exchange cannot be maintained.

HIGH-FREQUENCY OSCILLATOR VENTILATION[5,69–73]

HFOV has been instrumental in the care of infants with severe respiratory failure from any number of causes. In essence it is a set pressure – the mean airway pressure (MAP), with the oscillation of 6–12 Hz around this. Oscillations are sinusoidal with negative and positive deflections. MAP, frequency and amplitude of the ventilator waveform influence oxygen and carbon dioxide clearance in discrete but not entirely independent ways. MAP and inspired oxygen are the primary determinants of oxygenation. Frequency and amplitude are the primary determinants of carbon dioxide clearance. Alveolar ventilation is said to occur by convective and diffusional mechanisms. These include bulk gas movement, laminar and turbulent flow, Pendeluft ventilation (between alveoli), collateral ventilation by alveolar channels and Taylor dispersion.

Children ventilated with HFOV are often heavily sedated and have neuromuscular-blocking agents administered. However, depending on pathology and stability, they may be allowed to breath on top of the oscillations of the ventilator. These spontaneous breaths are not supported, so the clinician must ensure that the bias flow through the circuit is sufficient to maintain the MAP and allow for this tidal ventilation by the patient. For neonates and small infants this tidal volume is negligible compared with the bias flow. For older children this can be challenging and unachievable. Secretion clearance and humidification of gases can be challenging. High bias flow results in inadequate humidification while 'rain-out' (excessive fluid) within circuits is frequently an issue. Weaning can be achieved while on HFOV, but most units convert to conventional ventilation for weaning, especially in older children who need larger tidal volumes.

VENTILATOR STRATEGIES[15,74,75]

The general strategy in the ventilation of any neonatal or paediatric patient is the maintenance of lung distension and gas exchange, whilst minimising trauma to the lung due to overdistention, underdistention, atelectasis and oxygen toxicity. Muscle relaxants are used liberally in the initial stages of severe respiratory disease, as recommended by the Consensus Conference on Acute Lung Injury. Spontaneous breathing and early extubation are encouraged as the clinical situation allows.

Ventilation is hazardous and exposes patients to numerous risks and potential healthcare-associated injury. It is important to liberate the patient from dependence on mechanical support of any type as expeditiously as possible. Physicians, nurses and allied health staff must be proactive and creative to achieve this.

EXTRACORPOREAL LIFE SUPPORT[74,76–78]

Historically, adult ICUs had abandoned ECLS in the face of poorly constructed studies, while NICUs and PICUs fostered and nurtured its development. Dramatic improvements in ECLS were promoted by improvements in cardiopulmonary bypass technology, developments in congenital heart surgery and the need to support neonates with severe respiratory failure such as meconium aspiration. Neonates across the spectrum of the ELSO registry have the greatest survival rates.

ECLS for neonates, infants and small children is typically achieved by surgical cannulation in the neck with the right common carotid and right internal jugular vein being accessed. Femoral vessels may also be used in older children, but they are unable to provide adequate flows in babies and infants. Veno-arterial ECLS is common, but veno-venous ECLS via a double-lumen catheter or two-vein cannulation is becoming more common for pure respiratory support.

Paediatric fluid and electrolyte therapy

Sophie Skellett

Fluid and electrolyte therapy is an important aspect of the care of critically ill children. In some regards, children and infants differ from adults, but many of the controversies regarding fluid therapy are similar.

Fluid therapy may be required to correct or maintain fluid and electrolyte balance for normal physiological function in acutely unwell children for a number of reasons. It is important to distinguish these reasons as the treatments differ, and one or more of these conditions may co-exist:

- **Fluid resuscitation**: to rapidly expand effective circulating volume in the intravascular space in order to restore blood flow to the vital organs.
- **Maintenance fluids**: if children and infants are unable to tolerate enteral feeds or fluids to meet their fluid needs.
- **Fluid replacement**: to compensate for ongoing losses such as gastrointestinal losses from vomiting, diarrhoea.

CHILDREN AND INFANTS ARE DIFFERENT

They require proportionally greater volumes of water for their weight than adults to maintain their fluid equilibrium and are more susceptible to fluid depletion and fluid losses. The reasons include:

- High total body water (TBW) content: TBW in preterm neonates can be as high as 80%; infants 70%; children 65%; adults 60%. As the child grows the intracellular space increases and the extracellular space reduces.
- Higher surface area to body mass index: higher transepidermal losses, particularly in neonates, and more susceptible to changes in temperature.
- Higher metabolic and respiratory rates: increased use for growth (dramatic in the first year particularly) and increased water loss from lungs.
- Immature renal function: low glomerular filtration rate (GFR) at birth (25% of adult values) gradually increasing over the first year and immature renal concentrating function in neonates and infants, which can result in water loss in urine even in the face of dehydration.
- Dependency on caregivers for fluids and food, particularly relevant for neonates and infants. To compound this, dehydration in this group is not always easy to identify.[1]

The susceptibility of children and infants to greater fluid and electrolyte disturbances means that great care and attention must be paid to intravenous (IV) fluid therapies as the morbidity and mortality following inadequate or improper management can be significant. Children and infants, unlike adults, are prescribed IV fluids based on their body weight. Additionally, children and infants are at greater risk of developing cerebral oedema and neurological complications as a result of hyponatraemia compared to adults.[2]

FLUIDS IN RESUSCITATION

The controversies regarding fluid resuscitation in paediatrics currently include the size of the fluid bolus used for resuscitation and the composition of the fluid bolus given.

BOLUS SIZE

For approximately the past 3 decades accepted practice for the management of circulatory failure and shock has been prompt, and early resuscitation with IV fluid boluses each of 20 mL/kg repeated until circulatory status was stable and vital organ perfusion restored. Although this was largely based on observational studies,[3] the practice – widely promoted by national resuscitation training courses (European Paediatric Advanced Life Support [EPALS], Pediatric Advanced Life Support [PALS], Advanced Paediatric Life Support [APLS]) – has occurred alongside a huge reduction in paediatric mortality from sepsis in the developed world. In 2010 a large randomised controlled trial (RCT) of fluid bolus therapy 20–40 mL/kg of either 0.9% saline or 5% albumin solution versus maintenance fluids only in East African children with severe febrile illness was published, which showed that bolus therapy was associated with a

ABSTRACT

There have been many recent controversies regarding the use of intravenous fluids in both children and adults. The correct bolus size for fluid resuscitation for children in the developed world remains unknown but what is recognised is that far more care has to be taken in our approach, with careful assessment of our patients after every fluid treatment. Isotonic fluids are the fluids of choice for resuscitation, and there is increasing interest in the potential benefits of balanced solutions. In critically ill children the morbidity that fluid overload confers is increasingly recognised, leading clinicians to adopt more conservative fluid strategies particularly once haemodynamic stability has been achieved. Children and infants are particularly susceptible to fluid and electrolyte disorders, hence the assessment of weight and fluid balance becomes an imperative on the intensive care unit along with the use of isotonic fluids as maintenance therapy – at least initially. An individualised approach to fluid therapy in each patient is advocated.

significantly higher mortality.[4] This study was set in a resource-poor setting with no intensive care back-up and notably fewer than 3% of patients met the World Health Organization (WHO) criteria for the diagnosis of shock, hence it is probable that some patients treated with fluids did not require them.[5] This trial therefore does not offer conclusive evidence that fluid bolus therapy is unsafe. Nevertheless it has caused those who look after critically ill children to pause and re-think about fluid resuscitation in children and infants.

It is important therefore that after giving an IV fluid bolus there is careful re-assessment of the child's clinical status so that further boluses are only given if necessary. This assessment should include the capillary refill time (CRT) (central and peripheral), blood pressure, peripheral and central pulse volume, heart rate, liver edge, presence or absence of basal lung crepitations (the latter two may indicate fluid overload [FO]), urine output and the level of consciousness of the child. If further fluid boluses are indicated they ***should not*** be withheld but careful re-assessment should follow each one. Current recommendations for IV fluid bolus size vary from 10 mL/kg (WHO recommendation) to 20 mL/kg (PALS, EPALS, APLS) dependent on clinical scenario. In the case of sepsis, early use of inotropes or vasopressors should be considered; that is, after two IV fluid boluses of 20 mL/kg have been given, as this represents more than half the circulating volume of the child.

TARGETED FLUID BOLUS THERAPY

Following the publication of the Rivers paper[6] in 2001, the adoption of early goal-directed therapy (EGDT) in the treatment of septic shock in children became common (although not universally accepted) in the developing world. Standard management of septic patients via EGDT involves achieving a number of target parameters aimed at improving oxygen delivery to the tissues during resuscitation; this includes fluid bolus therapy to a targeted central venous pressure (CVP) value. However, subsequent trials in adults have not replicated the early success of EGDT. The ProMISE,[7] ARISE[8] and ProCESS[9] trials were all large randomised studies comparing outcomes for EGDT versus usual care for septic shock in the United Kingdom, Australia and New Zealand, and the United States, respectively. These trials recruited over 4000 patients at 140 sites. Patients were randomised to an EGDT protocol and compared to usual treatment, which included prompt IV antibiotics and adequate fluid resuscitation. All three trials found that the EGDT group received increased use of IV fluid, pressors and inotropes, and that the mortality outcome between the groups was not different. One trial found EGDT patients had significantly worse organ-failure scores, more days receiving haemodynamic support and longer stays in the intensive care unit (ICU). All three trials concluded that EGDT conferred no morbidity or mortality advantage in the care of patients with septic shock. It seems likely that CVP-directed IV fluid bolus administration is not a useful practice and more conservative fluid strategies may be indicated; further studies in paediatrics may be useful. Why are the results so different? In the past 15 years mortality from septic shock has reduced markedly in adults and children and there have been changes in many aspects of ICU practice; combined, these may have made any minor benefits derived from EGDT, at the time of the first trial, less significant.

FLUID OVERLOAD

The physiological rationale for fluid therapy is worth highlighting. Its value is only in increasing stroke volume and hence the cardiac output. If an increase in cardiac output is not achieved by volume expansion, the potential harm from fluid therapy outweighs the benefits. The ability of the clinician to estimate fluid responsiveness or indeed cardiac output[10] remains poor; hence frequent reassessment is indicated.

The morbidity and mortality resulting from fluid administration during resuscitation and intensive care admission are largely related to FO, though the fluid composition may also influence this. Is it just that sicker children need more fluid resuscitation? One study in over 600 children looked at oxygenation, length of ventilation and outcome in relation to the percentage of FO at 48 hours while controlling for severity of illness.[11] It found that the percentage of FO at 48 hours correlated to length of ventilation and oxygenation index but not mortality; similar results were seen in another smaller paediatric study.[12] Other studies in both adults and paediatrics have suggested a deleterious effect on renal function and mortality associated with FO though the evidence for this is not yet conclusive.[13–16] It would appear that positive fluid balance after restoration of effective circulating volume may negatively affect organ function in children on ICU and should be avoided and treated promptly. Critically ill children are particularly susceptible to FO when given large volumes of IV fluid because of the high incidence of inappropriate antidiuretic hormone (ADH) secretion, which is discussed below.

There are certain clinical situations where a smaller fluid bolus size should be considered.

DIABETIC KETOACIDOSIS

The mortality from diabetic ketoacidosis (DKA) is usually due to cerebral oedema and hence large fluid shifts should be avoided. It is uncommon for a child with DKA to present with shock; they will be dehydrated but these fluid losses can be more slowly replaced. However if the child presents with severe DKA (defined as pH <7.1) with shock they may cautiously be given one 10 mL/kg fluid bolus to restore effective

circulating volume and very carefully re-assessed. Some studies suggest that rapid, large volume fluid administration in DKA is associated with a greater risk of cerebral oedema.[17]

CARDIAC FAILURE

Assessing volume status in infants and children presenting with heart failure is difficult. Lesions leading to volume overload and congestive heart failure (e.g. ventricular septal defect presenting at 6 weeks of age) benefit from diuresis. However, a history of poor feeding, weight loss and excess energy expenditure may result in a volume deplete state, in which case the clinician may trial fluid resuscitation. In this setting it can be difficult to determine if fluid may improve the infant's condition or cause worsening heart failure. If the clinician decides to try IV fluid therapy, this should be restricted to 5–10 mL/kg bolus of isotonic fluid with careful re-assessment to determine if the condition is improved or made worse by fluid therapy.

TRAUMA

Recent studies in mostly adult trauma patients indicate that excessive fluid and blood administration causes excessive morbidity and mortality in the least severely injured patients.[18] The WHO recommendation for cautious fluid and blood therapy with bolus sizes of 10 mL/kg with careful re-assessment after each bolus appears sensible and may prevent early clot destabilsation. When giving blood, bedside haematocrit evaluations may help guide further therapy. It is worth noting that the majority of traumatic injuries sustained by children are head injuries causing traumatic brain injury (TBI). TBI outcome can be positively influenced by maintaining good blood pressure and oxygenation. Fluid bolus therapy and inotropes can be used to help maintain good blood pressure, but FO may adversely affect cerebral oedema.

BOLUS COMPOSITION

It is widely accepted that fluid boluses should be composed of isotonic fluids and the most commonly used is 0.9% saline (Na^+ 153 mmol/L, Cl^- 153 mmol/L). Hypotonic fluid boluses are known to cause hyponatraemia resulting in dangerous fluid shifts, which potentially cause cerebral oedema and seizures as water moves intracellularly. Additionally, isotonic fluids expand the intravascular compartment more effectively than hypotonic fluids.[19]

GLUCOSE-CONTAINING FLUIDS

Glucose-containing fluids are quickly metabolised to water; hence, the glucose content should not be taken into consideration when calculating tonicity of an IV fluid to be given as they are effectively hypotonic in vivo. Glucose-containing fluids should never be used unless they are required to correct hypoglycaemia as hyperglycaemia is associated with poor outcome in critically ill children, particularly those with central nervous system (CNS) disease and trauma. Hypoglycaemia is also associated with poor outcome in the acutely unwell child so must be vigorously looked for and corrected if found. If a child or infant has a blood glucose <3 mmol/L then 2 mL/kg 10% dextrose should be given as a bolus and the blood glucose rechecked within 5 minutes; if the hypoglycaemia recurs, repeat the bolus and ensure maintenance fluids with glucose are started to maintain normoglycaemia. There is no evidence that tight control of glycaemia (maintaining blood glucose 4–7 mmol) in critically ill children is of any benefit; indeed, it may lead to increased numbers of children suffering hypoglycaemia from the higher doses of insulin administered.[20]

COLLOID AND CRYSTALLOID DEBATE

Saline at 0.9% is isotonic, cheap and infection free, hence its wide spread use. Colloids are definitively indicated for fluid therapy in some circumstances, such as blood to replace blood loss in haemorrhage, but their routine use for volume expansion is declining as studies fail to show superiority over crystalloids, and in some situations they even indicate that they may cause harm.[21] A large Australian study, the SAFE study, compared human albumin solution (HAS) 4.5% with 0.9% saline in adults for fluid resuscitation and found no difference in mortality between the two groups at 1 month.[22] Subgroup analysis indicated a trend to improved survival in the sepsis group with the use of 4.5% HAS and a trend for decreased survival with its use in resuscitation in trauma patients, but statistical significance was not reached. Once commonly used in paediatric practice, the use of 4.5% HAS is now declining; it is worth noting that it is expensive, carries an infection risk and because albumin is in suspension in 0.9% saline it carries the same risk of causing hyperchloraemic acidosis. Additionally, it is becoming clear that colloid solutions do not offer the advantages over crystalloid solutions with respect to hemodynamic effects once previously thought.[23] Synthetic colloids, though infection free, are expensive so are not commonly used in children, particularly the large synthetic molecules that interfere with coagulation and renal function.

HYPERCHLORAEMIC ACIDOSIS

Normal saline (0.9% saline) bolus therapy is associated with the development of hyperchloraemic acidosis as comparatively it contains a much higher concentration of chloride (Cl^-) ions than is present in the plasma, and it has a pH of 5.5 – hence it is not 'normal'. It also has a slightly higher concentration of sodium (Na^+) ions than in the plasma, but this is a much smaller

difference. Normal plasma concentration of sodium ions is 140 mmol/L, normal plasma concentration of chloride ions is 100 mmol/L. After several large fluid boluses have been given a metabolic acidosis ensues from chloride excess. Calculating the anion gap (AG) shows a normal result in the face of an acidosis:

$$AG = (Na + K) - (Cl + HCO_3) \text{ range } 8–12 \text{ mmol/L}$$
(where HCO_3^- = bicarbonate)

For many years this acidosis was not thought to be significant, but some studies have suggested that this may not be the case and that either the acidosis and/or the chloride load may have deleterious effects on coagulation and kidney function; hyperchloraemia has been shown to induce renal vasoconstriction and reduce GFR.[24] This suggests that perhaps a more 'physiological' solution should be considered for fluid bolus therapy. These 'physiological solutions' – also called 'balanced solutions' – contain lower concentrations of chloride and a buffer is provided so that the solutions are electroneutral. Buffers used in some of these solutions include acetate, lactate, gluconate and maleate. One large retrospective study in adults compared the use of balanced solutions and unbalanced solutions (0.9% saline) for resuscitation in over 30,000 patients and found decreased incidence of acute kidney injury and a suggestion of improved survival in the much smaller group receiving balanced fluid resuscitation.[25] Additionally a recent prospective RCT involving almost 16,000 adult ICU patients, the SMART trial (isotonic solutions and major adverse renal events trial), found the use of balanced crystalloids for intravenous fluid administration resulted in a lower rate of the composite outcome of death from any cause, new renal-replacement therapy, or persistent renal dysfunction than the use of 0.9% saline.[26] In contrast the SPLIT trial (saline versus Plasma-Lyte for ICU fluid therapy) found no significant differences in the incidence of acute kidney injury, length of ventilation or outcome between patients receiving 0.9% saline and those receiving the balanced solutions.[27] Studies looking at the outcome between balanced and unbalanced solutions in children have yet to demonstrate a convincing argument, but this is an interesting area for further development. Some examples of balanced solutions are shown in Table 108.1.

KEY POINTS

1. Patients with capillary leak may need large amounts of fluid resuscitation.
2. Each fluid bolus must be followed by careful assessment; inadequate resuscitation results in poor organ perfusion whilst excess fluid administration is associated with organ dysfunction and poor outcomes.
3. Fluid bolus size in sepsis in the clinical setting including intensive care should be 20 mL/kg of isotonic crystalloids.
4. Certain clinical settings may require smaller fluid bolus sizes (e.g. cardiac failure, trauma).
5. Glucose-containing fluids should not be used for resuscitation.
6. Hypotonic fluids should not be used for resuscitation.
7. The use of balanced isotonic crystalloids rather than 0.9% saline in resuscitation will reduce the incidence of hyperchloraemic acidosis, which may be advantageous.
8. Hypoglycaemia is very dangerous in infants and hyperglycaemia is less dangerous than in adults.

MAINTENANCE FLUIDS

Children and infants who are unable to tolerate enteral feeds and fluids may require IV fluid maintenance. The aim is to provide fluid and electrolytes in order to maintain the extracellular volume and hence tissue perfusion with a normal electrolyte balance; it is calculated based on 'expected' daily fluid and electrolyte losses. There is controversy within current paediatric practice regarding both the most effective means of calculating routine maintenance requirements for infants and children, particularly whether weight or body surface area is the more appropriate, and what the composition of maintenance fluids should be.

Commonly used formulae for calculating IV fluid requirements in hospitalised children and infants are those developed by Holliday and Segar in 1957, but there remains no consensus for their use, even 60 years later.[28] It is clear that there are problems with applying these 'standard' calculated volumes to the entire hospitalised paediatric population, particularly to critically ill children who often have conditions that impair normal water and electrolyte handling.

Table 108.1 Electrolyte composition plasma and crystalloids

	Na^+ mmol/L	Cl^- mmol/L	K^+ mmol/L	BUFFER mmol/L	OSMOLALITY mOsm/kg
Plasma	140	100	5	HCO_3^-[25]	280
0.9% saline	154	154	0	0	286
Hartmann's/Ringer's lactate	131	111	5	Lactate[29]	274
Plasmalyte	140	98	5	Acetate[27] Gluconate[24]	271

The Holliday and Segar formulae for calculating paediatric maintenance fluids were based on expected energy expenditure. The caloric expenditure for the average active child was calculated based on body weight and for every 100 calories burned there was approximately 100 mL water lost. This resulted in the maintenance fluid requirements for every 24 hours calculated as below, giving the so-called 4-2-1 rule for calculating maintenance:

4 mL/kg/h for first 10 kg body weight of the child or infant, plus
2 mL/kg/h for every kilogram between 11 and 20 kg body weight, plus
1 mL/kg/h for every kilogram above 20 kg body weight

Daily electrolyte requirements were also calculated based on dietary intake as follows:

Na^+ – 3 mmol per 100 calories
K^+ – 2 mmol per 100 calories
Cl^- – 2 mmol per 100 calories

As a result, fluids subsequently chosen for 'standard' maintenance for children and infants were often 0.45% saline with dextrose or more hypotonic fluids (0.18% saline/4% dextrose) at volumes far higher than needed for inactive hospitalised children and infants. This practice still continues in a few centres, resulting in an increased risk for the development of hyponatraemia and FO. This risk is greatly increased when there is inappropriate ADH release, which is relatively common – particularly in acutely unwell children. In the 1950s when the formulae were developed, this was not a recognised entity. A more recent meta-analysis studying hospitalised children demonstrated that the use of isotonic IV maintenance fluids with Na^+ concentrations similar to that of plasma reduce the risk of hyponatraemia when compared with hypotonic intravenous fluids.[29]

ANTIDIURETIC HORMONE

Sodium and water regulation is usually controlled by a combination of interactions of arginine vasopressin (also known as antidiuretic hormone or ADH), the renin–angiotensin–aldosterone axis and natriuretic peptides. Normally when plasma osmolality increases, ADH is released from the posterior pituitary in response to the activation of osmoreceptors in the hypothalamus and baroreceptors in the carotid sinus, aortic arch and left atrium. ADH acts on the kidney at the collecting ducts making them more permeable to water (by insertion of aquaporin channels) and by increasing medullary tonicity resulting in the conservation of water.[30] When patients are unable to drink in response to thirst then ADH will be the main determinant of plasma osmolality. If disease states or drugs affect the release or action of ADH then sodium/water homeostasis will be disturbed. In critically ill children and infants there are a number of triggers that can cause ADH to be released without the usual trigger of an increase in plasma osmolality or volume depletion; this is called the syndrome of inappropriate ADH (SIADH). The triggers include:

- **CNS disease**: meningitis, encephalitis, head injury, space occupying lesions
- **Pulmonary disease**: ventilation, pneumonia, asthma, hypoxaemia, hypercapnia
- **Drugs**: opiates, barbiturates, valproate, ciprofloxacin
- **Surgery**: postoperative states
- Pain, nausea, vomiting, hypoglycaemia, inflammation, cancer.

The result is retention of excess free water making the patient susceptible to the development of both hyponatraemia and FO. The diagnosis of SIADH can be made by the patient fulfilling the following criteria:

- Plasma osmolality less than 275 mOsm/kg with serum sodium less than 135 mmol/L and an inappropriately high urine osmolality.

This will usually occur in the clinical setting of a positive fluid balance. Consequently, adjustments need to be made to the volume and sometimes the sodium concentration of maintenance fluids.

Volume adjustments to 'standard' maintenance for children and infants in intensive care should be made not only in the setting of SIADH but for a variety of other reasons including: reduced metabolic rate when sedated and muscle relaxants are used, reduced water losses if ventilated with humidified inspired gas and maintenance of body temperature.[31–36] Table 108.2 outlines the adjustments that should be made in each setting and Tables 108.3 and 108.4 give a guide to maintenance fluid volumes in the active, sick and sick plus intubated ventilated patient.

Worked example: 15 kg child with a head injury

Standard maintenance = 4 mL/kg/h for first 10 kg weight + 2 mL/kg/h for each kg between 10 and 20 kg weight
= (4 × 10) + (5 × 2) = 50 mL/h maintenance fluid[28]
Adjust for SIADH by × 0.7[32]
Adjust for muscle relaxant decrease in metabolic rate × 0.7[28]
Adjust for ventilation with humidified gas × 0.75[31]
Adjust for maintenance of body temperature 36° – 12%
Total fluids for maintenance becomes = (50 × 0.7 × 0.7 × 0.75) – 12%
= 16 mL/h

This wide variety in IV maintenance fluid needs of different critically ill patients requires that each child and infant has a tailored approach to their IV fluid prescriptions daily, and emphasises the vital importance of close monitoring of the fluid balance of children and infants in the ICU with daily weights when possible.

Table 108.2 Modifications to the fluid intakes for active children shown in table 108.3

	ADJUSTMENT
DECREASE	
Humidified inspired air[31]	×0.75
Basal state (e.g. paralysed)[28]	×0.7
High ADH (IPPV, brain injury)[32]	×0.7
Hypothermia	12% per ˚C
High room humidity	×0.7
Renal failure	×0.3 (+urine output)
INCREASE	
Full activity + oral feeds[28]	×1.5
Fever	+ 12% per ˚C
Room temperature >31˚C	+ 30% per ˚C
Hyperventilation[33]	×1.2
Neonate – preterm (1–1.5 kg)[34]	×1.2
– Radiant heater[35]	×1.5
– Phototherapy[36]	×1.25

ADH, Antidiuretic hormone; *IPPV,* intermittent positive-pressure ventilation.

Table 108.3 Approximate intravenous fluid requirements for children (mL/kg/day)

ACTIVE CHILD IN HOSPITAL	
<10 kg	100 mL/kg/day
10–20 kg	1000 mL + (50 mL/kg/day for each kg over 10 kg)
>20 kg	1500 mL + (20 mL/kg/day for each kg over 20 kg)
SICK, BUT NOT INTUBATED	
<10 kg	50 mL/kg/day
10–20 kg	500 mL + (30 mL/kg/day for each kg over 10 kg)
>20 kg	800 mL + (20 mL/kg/day for each kg over 20 kg)
INTUBATED, WITH HUMIDIFIED INSPIRED GASES	
<10 kg	35 mL/kg/day
10–20 kg	350 mL + (20 mL/kg/day for each kg over 10 kg)
>20 kg	550 mL + (12.5 mL/kg/day for each kg over 20 kg)

Table 108.4 Approximate intravenous fluid requirements for children (mL/h)

	WEIGHT IN kg											
	3	5	7	10	15	20	25	30	40	50	60	70
Active	12	20	30	40	50	60	65	70	80	90	95	100
Sick	6	10	14	20	25	30	35	40	45	55	60	70
Intubated	4	7	10	14	17	21	25	28	32	40	45	50

COMPOSITION OF MAINTENANCE FLUIDS

To prevent the development of hyponatraemia from maintenance fluids there have been many recent studies performed in hospitalised children, in both the ward and intensive care setting, which have shown that using isotonic maintenance fluids, such as 0.9% saline, in place of hypotonic solutions, reduces the risk of developing hyponatraemia.[29,37–39] Most of these studies also concluded that using isotonic maintenance was associated with few side effects and did not predispose to hypernatraemia. Hypernatraemia does not occur as a result of the use of 0.9% saline in patients unless there is a renal concentrating defect or a large extra renal free water losses because the kidney is capable of excreting hypertonic urine.[30] As yet there is little evidence to suggest that the use of balanced solutions for maintenance therapy confers any advantage in children but this is an area of increasing interest. Dextrose can be added to maintenance fluids for children and infants to give sufficient glucose to prevent hypoglycaemia and limit tissue catabolism (in the short term).

In general, it is recommended that children and infants have isotonic IV fluid maintenance at least as initial therapy, but note specific conditions may require more targeted therapy (see below). Children and infants should then have at least daily plasma electrolyte measurements, fluid balance measurements and weight measurements (where possible) in order to tailor their ongoing IV fluid needs for both maintenance therapy and correction of any fluid deficits.

Most importantly, it should be recognised that children and infants should be fed enterally whenever possible and as soon as possible, obviating the need for IV maintenance fluid therapy as this provides both gut protection and nutrition.

KEY POINTS

1. Use isotonic crystalloid fluids for maintenance initially, then tailor fluid according to electrolyte and fluid needs.
2. Use restricted fluid volumes of ‘standard’ maintenance for critically ill children and infants.
3. Fluid balance, weight and urine output measurements should be carefully monitored and action taken when ongoing fluid accumulation is present

outside the setting of haemodynamic instability requiring fluid resuscitation.

4. Measure daily plasma electrolyte levels and watch out for hyponatraemia and the development of SIADH.
5. Enteral feeds are far superior to IV fluid maintenance and should be used whenever possible.

REPLACEMENT FLUIDS

Children may also need IV fluids to account for losses of red blood cells, plasma, water or electrolytes beyond the usual losses in urine, stool and sweat. In these situations the aim is to replace any depleted fluids and restore electrolyte imbalances.

Children who present with dehydration and shock should be treated with fluid bolus therapy to restore effective circulating volume and then any further fluid deficits should be corrected. The speed of fluid deficit replacement is determined by the child's clinical condition; in most cases of gastroenteritis this may be achieved in 24 hours (and preferably by the enteral route) but for children with DKA, hypernatraemia and or CNS pathology deficit fluids should be replaced more slowly over 48 hours. Do not forget to check the blood glucose of any child presenting with dehydration, particularly in the setting of altered mentation. Weight loss is the best method of assessing the degree of dehydration[1]; however, recent weights are often not available for comparison.[39] Clinical assessment of dehydration is less reliable[1]; however, some of the more useful clinical signs are:

- decreased peripheral perfusion, as demonstrated by prolonged CRT
- deep breathing
- decreased skin turgor.

Because of the difficulty in determining the degree of dehydration, a number of other methods of assessing this have been developed. These include a number of clinical scores, such as the clinical dehydration scale and Gorelick scores[41,42]; bedside ultrasound measurement of the ratio of aortic diameter to inferior vena cava diameter (IVC)[43] or degree of inspiratory IVC collapse[44]; urinary ketone measurement[45]; and capillary digital videography.[46] A recent meta-analysis[47] looked at the usefulness of the various techniques and concluded that clinical dehydration scores were more accurate than unstructured clinical examination, though still not optimally accurate. However, current evidence does not support the use of ultrasound or urinalysis to determine the severity of dehydration in children; there was insufficient evidence to assess the usefulness of capillary digital videography.

IV fluid therapy is usually given to treat cases of severe dehydration, whilst for mild to moderate dehydration oral/enteral rehydration is preferred where possible. Dehydration can be classified as either mild to moderate (5%–10%) or severe (>10%).

MILD TO MODERATE

Thirst, normal to mildly prolonged CRT, normal to slight increase in respiratory rate, mild decreased tissue turgor.

SEVERE

Prolonged CRT, signs of shock, decreased skin turgor, altered mental status, tachypnoea and hyperpnoea, tachycardia and/or bradycardia.

The child's water deficit can be calculated following an estimation of the degree of dehydration expressed as percentage of body weight. The deficit is usually replaced over 48 hours, but this should be adjusted according to the child's clinical condition and plasma electrolyte measurements as rehydration proceeds.

Worked example: 10 kg child with 10% dehydration from diarrhoea

$$\text{Deficit} = 10\ \text{kg} \times 0.1 \times 1000\ \text{mL} = 1000\ \text{mL}$$

The child received one 20 mL/kg bolus of 0.9% saline (200 mL) to restore effective circulating volume leaving 800 mL deficit to be replaced over 48 hours = 16.5 mL/h

Maintenance requirement = 4 mL/kg/h for first 10 kg weight = 40 mL/h

Then the child should be given: 40 + 16.5 mL/h = 56.5 mL/h for 48 hours.

The more common causes of increased loss of fluid from the intravascular space in children and infants are outlined in Table 108.5.

The replacement of ongoing fluid losses in the ICU depends on accurate measurements of all the losses (e.g. stoma, gastric, wound and chest drain losses, urine output) and fluid balance measurements together with serum electrolyte, blood gas and lactate analysis. Ongoing losses are best measured and replaced either hourly, or over each subsequent 4-hour period depending on the clinical setting.

The type of fluid chosen will be dependent on the type of fluid loss. Table 108.6 indicates typical electrolyte losses in different bodily fluids.

A few conditions requiring special consideration with regard to fluid management in children and infants are outlined below:

1. In a child with oliguria following a severe ischaemic or hypoxic insult (such as birth asphyxia, drowning or cardiac arrest), it may be helpful to measure the urine sodium concentration to determine fluid therapy.[48] In oliguria due to acute tubular necrosis, where the restriction of fluid intake may be necessary, the urine sodium is usually more than 40 mmol/L. In oliguria due to hypovolaemia, the urine sodium is usually less than 20 mmol/L. Urinary sodium

Table 108.5 Causes of fluid loss from the intravascular space in children and infants (dehydration and or volume depletion)

Excess loss of fluids and electrolytes	Vomiting and diarrhoea	**GI**: gastroenteritis, malabsorption, intussusception, inflammatory bowel disease, short gut syndromes, volvulus, obstruction, pyloric stenosis, hepatitis, hepatic failure, appendicitis, peritonitis, drug toxicity **CNS**: infections and raised intracranial pressure **Renal**: infections, renal failure **Endocrine**: DKA, congenital adrenal hypoplasia, Addisonian crisis, thyrotoxicosis
	Renal losses	Renal tubular acidosis, polyuric renal failure, DI, diuretics, concentrating defects
	Endocrine losses	DKA, central DI, cerebral salt wasting
	Other	Haemorrhage, surgical and chest drain losses
Accumulation of fluid in the interstitial space (3rd spacing)	Heart failure, sepsis, peritonitis, pancreatitis, protein losing enteropathy, nephrotic syndrome, ascites	
Increased insensible losses or poor intake	Burns, prematurity, fever, increased sweating, hyperventilation, stomatitis, coma, dysphagia	

CNS, Central nervous system; *DI*, diabetes insipidus; *DKA*, diabetic ketoacidosis; *GI*, gastrointestinal.

Table 108.6 Typical electrolyte losses in different bodily fluids

FLUID	Na^+ mmol/L	K^+ mmol/L	Cl^- mmol/L	BICARBONATE mmol/L
Gastric	70	5–15	120	0
Ileostomy	130	15–20	120	25–30
Diarrhoea	50	25	40	50

measurement is an unreliable guide to volume status if diuretics have been administered.

2. Conditions requiring increased free water to compensate for losses[30] are prematurity, burns, fever, diarrhoea.
3. Conditions requiring increased free water to compensate for renal concentrating defects[30] are nephrogenic diabetes insipidus (DI), sickle cell disease, renal dysplasia. In such circumstances, the administration of hypotonic fluids may be indicated.
4. Conditions requiring increased salt and water to compensate for solute diuresis[30] are polyuric phase of renal acute tubular necrosis, DKA, cerebral salt wasting.
5. Condition requiring salt and water restriction in the setting of polyuria[30] is renal failure.
6. Conditions requiring fluid restriction for oedematous states[30] are heart failure, nephrotic syndrome (isotonic fluids but small volumes).

SODIUM

Sodium is the principal determinant of effective plasma osmolality as it is the main extracellular ion and cannot move freely into cells. Changes in serum sodium should be interpreted in conjunction with the child's hydration status as they are usually due to changes in body water rather than total body sodium.

In the first 1 or 2 days of life, small preterm babies often have poor urine output and high transcutaneous fluid losses. They are therefore prone to hypernatraemia and hyperkalaemia, and such infants should usually be given 10% dextrose without sodium or potassium. From 2 days of age, 2–4 mmol/kg/day of sodium and potassium will usually be sufficient, but much higher intakes of sodium are needed in some preterm neonates owing to their impaired renal conservation of sodium.

CAUSES OF HYPONATRAEMIA

- Associated with euvolaemia/hypervolaemia: increased body water due to excessive water intake or retention, especially in the presence of high levels of ADH; glucocorticoid deficiency; heart failure; renal failure; nephrotic syndrome; SIADH
- Associated with hypovolaemia: low body sodium due to diuretic therapy, cerebral salt wasting, excessive loss in sweat, diarrhoea or vomiting; poor renal conservation of sodium, or a low sodium intake (e.g. breast milk).

Hyponatraemia (defined as serum sodium (Na+) < 135 mmol/L) can cause hyponatraemic encephalopathy with serious neurological morbidity and even mortality. Children and infants, and those with hypoxaemia or CNS disease, are particularly at risk of hyponatraemic encephalopathy as there is reduced tolerance to brain oedema. Symptoms are usually apparent at serum sodium levels of 125 mmol/L or less and may result in seizures.

Hyponatraemia due to sodium deficit should usually be corrected slowly, raising the serum sodium by a maximum of 0.5 mmol/L/h[49] to prevent large fluid shifts and the development of central pontine myelinolysis (CPM). The risk of CPM is thought to be related to the chronicity of the hyponatraemia. However, if the child is seizing, urgent treatment to elevate the serum sodium may be required using 3% saline 4 mL/kg to raise the serum sodium by 3 mmol/L.[50] This can be repeated if the child is still seizing, targeting a level of 125 mmol/L. Hyponatraemia due to water excess rather than sodium deficiency should be treated with a restriction of water intake and diuretics in the non-urgent setting.

CAUSES OF HYPERNATRAEMIA

- Associated with hypovolaemia: diuretics (loop); post obstructive diuresis; acute and chronic renal disease; sweating, fistula, burns, diarrhoea, vomiting; DI (central, nephrogenic); osmotic diuresis (caused by glycosuria); inadequate fluid intake; high insensible losses
- Associated with euvolaemia/hypervolaemia: increased body sodium from the administration of large amounts of sodium (e.g. sodium bicarbonate, hypertonic saline, total parenteral nutrition [PN]) or salt poisoning.

Hypernatraemia (defined as serum sodium >145 mmol/L) also affects the CNS and can cause seizures, haemorrhage, coma and death. Fluid moves out of the brain causing structural changes with neuronal cell shrinkage; severe hypernatraemia is defined as serum Na+ greater than 170 mmol/L.

Shock should be treated with IV fluid bolus therapy and the water deficit should then be corrected very slowly using 0.9% saline so that the serum sodium falls no faster than 0.5 mmol/L/h, to prevent cerebral oedema.[51] If salt ingestion causes severe acute hypernatraemia without dehydration, peritoneal dialysis or haemofiltration may be indicated.

POTASSIUM

Potassium[52] is predominantly an intracellular ion, so total body potassium is poorly represented by the serum concentration. The concentration of potassium in the serum depends on pH as well as the total body potassium (which is usually about 50 mmol/kg). A child may have hypokalaemia without a deficit of total body potassium in the presence of alkalosis and, conversely, there may be a large total body deficit of potassium without hypokalaemia in the presence of acidosis.

All patients with volume depletion will have a potassium deficit, though it is not usually clinically significant; however, if it is not corrected along with the volume replacement then significant hypokalaemia may develop.[30] Commonly, potassium is not added to replacement fluid until an adequate urine output is obtained. Potassium can be infused into a peripheral vein usually at concentrations up to 20 mmol/L. Higher concentrations must only be given centrally at a rate of no more than 0.3 mmol/kg/h, and this should be accompanied by cardiac monitoring. Hypokalaemia on the paediatric intensive care unit (PICU) is common due to the use of loop diuretics; to minimise this, a potassium-sparing diuretic should be given alongside.

CALCIUM, MAGNESIUM AND PHOSPHATE

Hypocalcaemia in children occurs in:

- Sick neonates in the first 2 days of life and in infants of diabetic mothers
- Exchange transfusion with citrated blood (a temporary effect) and alkalosis
- Magnesium deficiency, loop diuretics, renal insufficiency
- Infants fed cow's milk (which has a high phosphate content), vitamin D deficiency, and hypoparathyroidism.

Hypocalcaemia and hypomagnesaemia cause jitters, tetany, cardiac arrhythmias, laryngospasm and convulsions. The doses of calcium and magnesium are given in Table 108.4. The normal IV maintenance requirements in infants are 1 mmol/kg/day of calcium and 0.3 mmol/kg/day of magnesium.

OEDEMA

Oedema is common in children in ICUs. It may be due to:

- FO (often in combination with SIADH)
- Capillary leak (due to the effects of hypoxia, ischaemia, acidosis or sepsis)
- Hypoalbuminaemia
- Heart failure
- Renal failure.

Multiple causes can co-exist, and it can be difficult to decide which is the most important. Children with oedema and high levels of ADH will have a serum osmolality less than 270 mosm/kg (with hyponatraemia) and a urine osmolality greater than 100 mosm/kg; the appropriate treatment is fluid restriction. On the other hand, in children with oedema due to capillary leak, fluid restriction and attempts to remove water (diuretics, dialysis) are unlikely to reduce the oedema, and often cause hypovolaemia; in fact, large amounts of fluid (e.g. blood and normal saline) may be needed to preserve the intravascular volume in these children – the oedema will resolve only when the capillary damage resolves.

PARENTERAL NUTRITION

Although IV maintenance fluids may contain glucose, they offer a very poor source of long-term nutrition, particularly when small children are concerned. A solution of 5% dextrose with sodium and potassium chloride provides maintenance amounts of water, sodium, potassium and chloride, but few calories and no protein, trace elements or vitamins.

For example, 100 mL/kg/day of 5% dextrose provides 17 kcal/kg/day (70 kJ/kg/day), which is less than 20% of the requirement of a normal infant (let alone a child with increased calorie requirements).

It has been estimated that, although an adult has the energy reserve to survive for about a year on 3 L of 10% dextrose a day, a small preterm infant will survive only 11 days on 75 mL/kg/day of 10% dextrose.[53] Therefore if IV maintenance fluids are used for more than a few days, a pronounced macronutrient deficit may develop, which predisposes the child to an increased infection rate, muscle weakness (which may prolong mechanical ventilation) and subsequently delay recovery. Therefore attempts to establish enteral feeding as early as possible should be attempted. Depending on the case mix in the intensive care (intensive care with a high general surgical population may be different) most children are able to absorb adequate amounts of food from the gut. Studies have indicated that enteral delivery of 66% of the nutrient target has been associated with improved outcomes in children receiving mechanical ventilation.[54] If this cannot be achieved and in the setting of poor gut function, PN should be considered. Specialist advice should be sought as delivery PN in children and infants is not without a number of risks including infection and PN-associated liver disease (Table 108.7).

Table 108.7 Potential complications associated with parenteral nutrition

Hyperglycaemia
Hypoglycaemia
Sepsis
Extravasation of solutions with necrosis of tissue
Thrombocytopenia
Hypoproteinaemia
Electrolyte imbalance
Acidosis
Anaemia
Hyperlipaemia
Uraemia
Cholestatic jaundice

The timing of administration of PN in critically ill children has recently been the subject of investigation in the PEPaNIC trial.[55] This large paediatric RCT randomised critically ill children in the PICU to early or late (7 days) PN. Mortality was similar in the two groups, but the use of late PN resulted in clinically superior outcomes: fewer infections, shorter length of ventilation, shorter hospital stay, lower plasma levels of γ-glutamyltransferase and alkaline phosphatase (suggestive of less cholestasis in children in the late-parenteral-nutrition group). This mirrors results in adult studies.[56] The explanation of these results is most likely multifactorial, but it should be noted that the actual caloric needs of the critically ill child are difficult to accurately estimate,[57] and the early PN group may have been overfed and/or this may reflect the risks associated with parenteral feeding and the central catheter needed to deliver it.

The usual requirements for amino acids, dextrose and fat in PN in children are shown in Table 108.8. The amino acid solution can be mixed with dextrose in the pharmacy department to make a 'nutrient solution'. For short-term nutrition, the solution need not provide fluoride, iron or vitamins A, D and E, but a paediatric multivitamin preparation should be given to children on long-term PN. Fat can be given as a 20%

Table 108.8 Parenteral nutrition

STANDARD NUTRIENT SOLUTION	
Amino acids	1–2 g/kg/day
Dextrose	10–20 g/kg/day
Lipid	1–3 g/kg/day
Sodium	4 mmol/kg/day
Potassium	3 mmol/kg/day
Calcium	7.5 mmol/L
Phosphate	7.5 mmol/L
Magnesium	4 mmol/L
Manganese	0.2 µmol/kg/day
Zinc	3 µmol/kg/day
Copper	0.5 µmol/kg/day
Iodide	0.04 µmol/kg/day
Chromium	0.005 µmol/kg/day
Hydroxycobalamin	20 µg/L
Vitamin K	2 mg/L
Folic acid	1 mg/L
Multivitamin preparation	

Notes: 1 mL/kg/day of fluid is needed for each kcal/kg/day; 1 kcal = 4.2 kJ; total kcal/kg/day = g/kg/day of (amino acids × 4) + (dextrose × 4) + (fat × 10).

emulsion, either through a separate IV line or alternating with the nutrient solution. Nutrient solutions for paediatric use contain high concentrations of calcium, magnesium and phosphorus, and they should not be mixed with the fat emulsion, even in a Y-connection placed just before the cannula. The types of lipid used for PN formulations may impact on the development of PN-associated liver disease, which accounts for substantial morbidity and mortality, particularly in infants with intestinal failure. Newer lipid preparations (e.g. SMOF, this is a mixture of 4 different lipid sources; soybean oil, olive oil, medium chain triglycerides and fish oil – hence the name) and medium chain triglycerides rather than the standard soya-based lipid (e.g. intralipid) have been shown to reduce liver disease associated with PN in some infants on long-term PN, and it has become standard use in many centres.[58]

For a child on PN, it is important that abnormal fluid losses (see Table 108.5) be replaced with an appropriate solution (in addition to the nutrient solution), and that PN always be introduced and withdrawn slowly. A dislodged IV cannula should be replaced immediately in a child on PN, to prevent rebound hypoglycaemia. If nutrient solution is not available at any time, it should be replaced with an infusion of a similar amount of dextrose. Frequent, careful monitoring is essential initially, and particularly in preterm babies, but can be less frequent once a child is stabilised on PN.

Acknowledgements

I would like to acknowledge Professor Frank Shann, Professor of Children's Critical Care Medicine, Royal Children' Hospital, Melbourne, Australia, as the previous author and I have used much of his invaluable material; and Dr Tom Brick, Consultant Paediatric and Neonatal Intensive Care, Great Ormond Street Hospital, London, United Kingdom, for reviewing my work and keeping me on track.

Sedation and analgesia in children

Andy Petros

ASSESSMENT OF DEPTH OF SEDATION AND PAIN

There is no one perfect scoring system to assess the adequacy of sedation or pain relief in children. The wide age spectrum from preterm neonates to 16-year-old teenagers requires age-appropriate tools. Consequently, there are a number of validated tools to match the various age groups. These tools fall into two main categories: (1) those that assess and score a number of behaviours considered typical of distress and (2) those that simply judge the level of consciousness. One example of the latter is the University of Michigan Sedation Scale (UMSS) which assess level of consciousness on a scale of 0–4 with 4 being unconscious.[1] Another frequently used scale is the State Behavioral Scale (SBS) specifically designed for and tested in young intubated and mechanically ventilated patients.[2] Perhaps the most commonly used tool for assessing distress in children is the COMFORT scale subsequently modified to the COMFORT behavior scale (COMFORT-B).[3] Both have been validated for pain and sedation in ventilated and spontaneously breathing 1–3-year-olds. Neither score can be used in patients receiving muscle relaxants. It is important to achieve optimal levels of sedation, as over-sedation can lead to tolerance, dependency and withdrawal symptoms.

The Richmond Agitation-Sedation Scale (RASS) is a single tool that is easy to use and includes both agitation and sedation. It correlated highly against the visual analogue scale and the UMSS, and allowed the accurate assessment of awareness in both ventilated and spontaneously breathing patients, and it may improve our ability to titrate sedatives and assess for delirium in paediatrics.[4]

Assessing postoperative pain in pre-verbal children can be difficult, and the Face, Legs, Activity, Cry and Consolability (FLACC) scale[5] and the Multidimensional Assessment of Pain Scale (MAPS)[6] are both useful tools. In preterm and term neonates the Neonatal Pain, Agitation and Sedation Scale (N-PASS),[7] the Premature Infant Pain Profile (PIPP)[8] and CRIES (Cry, Requires oxygen, Increased vital signs, Expression, Sleeplessness) scales have all been used and are objective measures of pain in this group.[9]

The bispectral index (BIS) is a numerical scale derived from the encephalogram, which purports to correlate with the level of consciousness. It is most commonly used in adult anaesthesia but is also used in children, and a range of 40–60 is considered an adequate level of sedation. The use of BIS in children has its limitations. It can be useful in children receiving muscle relaxants in whom it is not possible to assess behavioural indicators.

Vet et al. identified 25 randomised controlled trials reporting optimal sedation levels, scoring systems and agents used on the paediatric intensive care unit (PICU).[10] The most frequently used paediatric sedation scores were COMFORT, COMFORT–B, Ramsay (an adult score) and SBS. Six studies (23%) reported the use of BIS.

ACHIEVING ADEQUATE SEDATION

Pain, discomfort, anxiety, loss of the sleep–wake cycle, withdrawal symptoms and delirium are the challenges in paediatric intensive care. A European systematic review concluded that optimal sedation was achieved only 58% of the time, and there was a tendency to over-sedate in 32% of their observations.[10]

Numerous attempts have been made at producing protocols and sedation guidelines for children. However, because of the relative paucity of evidence for the various agents available, there are no universally adopted guidelines. The Pediatric Cardiac Intensive Care Society 2014 consensus statement on the use of sedation, analgesia and muscle relaxant attempted to establish some guidelines. It concluded that the management of the cardiac patient requires an individualised sedative and analgesic strategy that maintains hemodynamic stability.[11] In a mixed PICU environment protocolised sedation did not produce any significant advantages over physician-led management.[12] In practice, the common default position on the PICU are nurse-led adjustments according to their subjective assessment of the child.

Rather than using continuous infusions of sedatives and leaving adjustments to any one individual, there is evidence that interruption of infusions

ABSTRACT

One of the main objectives for any intensivist, adult or paediatric, must be to ensure their patient is pain free with minimum distress while in intensive care. Children are arguably more in need of good sedation than adults as they are often too young to reason with and can become distressed by being separated from their parents. There is an art in providing good sedation and analgesia whether the child is receiving muscle relaxants or when they are improving and weaning from ventilation. The use of continuous infusions can lead to excess amounts of either sedative or analgesic being given, resulting in problems with withdrawal and delirium, thereby complicating the patient's stay and subsequent recovery. The appropriate choice of agents together with the use of validated scoring systems to assess pain and discomfort and reliance upon a good evidence base should inform our management of children on the ICU.

evidence base

significantly reduces the length of mechanical ventilation, the duration of ICU stay and the total dose of midazolam administered,[13] and may be a technique worth pursuing.

Strategies to promote a normal sleep–wake cycle include maintaining a quiet environment and natural light during the day and no artificial light during the night, to help promote the normal day/night pattern. Eye masks, earplugs and other noise reduction strategies can potentially decrease the need for chemical sedation.

AGENTS FOR SEDATION

Sedative agents do not provide analgesia. Hence a combination of analgesics and sedatives is the standard approach to ensure the child is comfortable and accepts mechanical ventilation. The most commonly used sedatives on PICU are benzodiazepines, followed by ketamine, and barbiturates; enteral agents are also used and include chloral hydrate and alamemazine.

BENZODIAZEPINES

Benzodiazepines are the agents of first choice to reduce anxiety in children. Their main sites of actions are in the limbic and reticular activating system on gamma-aminobutyric acid ($GABA_A$) receptors. These transmembrane proteins have five subunits surrounding a selective chloride ion pore with binding sites for both GABA and benzodiazepines. GABA opens these chloride channels, resulting in neuronal hyperpolarisation and decreased excitability. Benzodiazepines increase the affinity of GABA for the receptors and enhance GABA-mediated inhibitory transmission.

Benzodiazepines have a large volume of distribution due to their lipid solubility and are metabolised in the liver, being oxidised to active metabolites or converted to glucuronides, and are excreted in urine. The production of active metabolites and enterohepatic recirculation prolongs their duration of action.

MIDAZOLAM

Midazolam is probably the most commonly used benzodiazepine on the PICU and is the drug of choice in combination with morphine to provide sedation and analgesia on the PICU.[14] A single dose has an onset of action within 1–5 minutes and can last 30–120 minutes. It is metabolised in the liver to the equally potent 1-hydroxymidazolam. The standard intravenous (IV) sedative dose is 0.1–0.2 mg/kg; the oral dose is 0.5 mg/kg and is used for premedication. As an infusion (1–4 µg/kg/min) it is commonly used in combination with an opioid such as morphine (10–40 µg/kg/h). In higher doses it can cause respiratory depression and particular care has to be taken in children with compromised cardiac function where it can induce significant hypotension. Midazolam is not commonly used in neonatal intensive care because of concerns over neurodevelopment and neurological damage.[15] It is increasingly being recognised that midazolam is a major cause of withdrawal and delirium post-ICU. The use of midazolam as a continuous infusion may soon become obsolete on the PICU.

CLONIDINE

Clonidine is a α_2-adrenoreceptor agonist with a half-life of 9–12 hours. It can be administered either orally or intravenously. If given orally it is metabolised by the liver and excreted by the kidney with approximately 50% unchanged in urine. Clonidine has an important role in managing opioid withdrawal by ameliorating the symptoms of withdrawal.

DEXMEDETOMIDINE

Dexmedetomidine is a selective α_2-agonist with a similar pharmacology to clonidine, although it is about eight times more potent. The use of dexmedetomidine is increasing on the PICU and has become a viable alternative to midazolam, and may well replace it as the sedative agent of first choice. A number of studies in children have investigated the safety and efficacy of dexmedetomidine. A continuous infusion of 0.7 µg/kg/h without a loading dose was well tolerated with minimal effects on heart rate and blood pressure.[16] In a single centre retrospective report of 144 children with a median age of 34 months, dexmedetomidine 0.05–2.0 µg/kg/h was well tolerated, although withdrawal symptoms were reported as a problem.[17] It is used increasingly on the PICU because of its short half-life of 2 hours and relative lack of respiratory depression; it allows fewer opioids to be used and shortens the duration of mechanical ventilation. Bradycardia and hypotension are seen with both clonidine and dexmedetomidine during continuous infusion. Dexmedetomidine has been used in term and preterm neonates for up to 24 hours without serious side effects.[18]

KETAMINE

Ketamine is a non-competitive antagonist of the excitatory neurotransmitter *N*-methyl-D-aspartate (NMDA) receptor sites in the central nervous system (CNS). Its onset of action is about 2 minutes to achieve maximal effect when given intravenously and can be longer when given intramuscularly. It has a duration of action of 10–20 minutes after an IV dose of 1–2 mg/kg. Ketamine produces a dissociative anaesthetic state where the patient appears to be awake with eyes open but is anaesthetised and pain free.

Systemic effects include increased cerebral blood flow and intracranial pressure. Cardiovascular effects include an increase in cardiac output, pulmonary vascular resistance and systolic and diastolic pressures. It is metabolised in the liver and its metabolites are less potent.

Ketamine is very useful in paediatric practice for venous access or repeated minor surgical procedures. It also has a role in severe asthma as the agent of choice for intubation and continued sedation as opposed to morphine, which can release histamine. A continuous infusion of 10–40 μg/kg/min can be used. Ketamine increases secretions of saliva and can cause unpleasant hallucinations.

PROPOFOL

Because of its short half-life and rapid wake-up time, propofol is the mainstay of sedation in adult intensive care. However, in paediatric intensive care it has a limited role. There are well-documented reports of serious adverse events and deaths while using continuous infusions of propofol in children. Propofol infusion syndrome (PRIS) was reported by Bray[19] and includes hyperkalaemia, metabolic acidosis, hyperlipidaemia, myocardial dysfunction, brady-arrythmias, rhabdomyolysis and death. Doses of greater than 4 mg/kg/h for greater than 48 hours are significant risk factors. Immature hepatic metabolism of the lipid carrier, and consequent accumulation and infiltration into the cardiac conduction system is speculated as the cause of the arrhythmias.[20] In 2001 the Committee on Safety of Medicines and the Medicines Control Agency in the United Kingdom both advised against the use of propofol in children younger than 16 years of age as a continuous infusion on the PICU.

Propofol bolus given at 1.5–2.5 mg/kg for intubation produces a rapid loss of consciousness. On rapid induction it can cause respiratory depression and apnoea, and a reduction in systemic blood pressure by reducing systemic vascular resistance.

CHLORAL HYDRATE

Chloral hydrate is an orally active agent with sedative–hypnotic properties and is able to produce sedation without significant respiratory depression. It is a prodrug being metabolised to tri-chloroethanol, which is then excreted in urine. It is a useful enteral agent to supplement IV sedation or it can be effective on its own at 30–50 mg/kg. Its absorption can be variable depending on the activity of the gut. Chloral can be used in neonates but with caution as its metabolites have a longer half-life in this group and it accumulates in renal impairment. It can also cause withdrawal symptoms when used for greater than 7 days if stopped abruptly.

PHENOTHIAZINES

Phenothiazines have potent central anticholinergic sedative effects. Antagonism of central acetylcholine synapses and central histamine H_1-receptors may be responsible for their sedative activity. The use of promethazine has declined, whilst alimemazine increases and is usually given orally. Alimemazine is an H_1-histamine antagonist, which is more powerful than promethazine. Given at 1–2 mg/kg it provides good sedation within 30–40 minutes lasting for 4–6 hours. It should be used with caution in neonates, if at all.

THIOPENTAL

Thiopental has a number of uses on the PICU, including the induction of anaesthesia for elective intubation at 2–4 mg/kg, as an infusion (1–5 mg/kg/h) to reduce raised intracranial pressure and in refractory status epilepticus. When used for the latter two conditions, continuous electroencephalogram (EEG) monitoring to ensure burst suppression should accompany it. A retrospective review of eight UK PICUs revealed that thiopentone was the most commonly used anticonvulsant to treat refractory convulsive status epilepticus on admission to the PICU.[21]

ISOFLURANE

Isoflurane is not a suitable or practical agent to use on the PICU. Occasional case reports continue to surface using tailored devices, such as the Anesthetic Conserving Device (AnaConDav), a modified heat and moisture exchanger, suggesting it may provide an alternative in difficult cases needing prolonged sedation.[22] However, the use of isoflurane is rare.

EVIDENCE BASE FOR SEDATION

Applying the principles of Level of Evidence (Level) and Grade of Recommendation (Grade) there is very little high-quality evidence to guide the use of sedation in children on the PICU.[23] Reviewing the current literature reveals only one systematic review[24] that advocates the use of continuous sedation in children (Level 1a, Grade B). As to which sedative agents to use, there have been no validated randomised controlled trials (RCTs) to help; only anecdotal evidence is available (Level 5).

There is reasonably good recent evidence (Level 1b, Grade B) supporting the use of clonidine,[25] or dexmedetomidine[26] as continuous IV agents to achieve sedation. The use of dexmedetomidine in neonates has been shown to be safe and effective for up to 24 hours.[18]

Daily interruption of sedation until the child becomes fully awake[13] or reaches a specific COMFORT score[27] has been shown to significantly reduce the length of mechanical ventilation, the duration of ICU stay and the total dose of midazolam in two recent studies in children (Level 1b Grade B).

Sedation in neonates can be difficult as the developing brain is very vulnerable. A systematic review of three papers in the Cochrane database reports that there is insufficient evidence to support the use of midazolam in neonates and that there may be an increased associated risk of adverse neurological effects (Level 1A, Grade A). When IV sedation is needed in neonates, morphine is the single agent of choice and is safer than midazolam (Level 1A, Grade B).[28]

AGENTS FOR ANALGESIA

MORPHINE

Morphine is the mainstay of analgesia on the PICU and as part of a sedative regimen for children. Its main action is via μ-receptors in the CNS. In neonates it is the only agent used and provides sufficient analgesia and sedation. Morphine has a number of unwanted actions, including respiratory depression even with therapeutic analgesic doses, and the release of histamine from mast cells resulting in bronchospasm. The active metabolite, morphine-6-glucuronide further prolongs its activity. The bolus dose is 0.1–0.2 mg/kg and the infusion rate is 10–40 μg/kg/h.

Nurse or patient-controlled analgesia devices are very useful following surgery. They deliver a continuous background infusion of a fixed dose of opioid and allow the patient or nurse to administer an extra dose at fixed time intervals if more analgesia is required.

FENTANYL AND ALFENTANIL

Fentanyl is 100 times more potent than morphine; it is cardiovascularly stable over a wide range of doses and is a frequent substitute for morphine. An induction dose of 1–2 μg/kg IV is sufficient for intubation, and infusions of 1–6 μg/kg/h produce effective sedation in children and neonates on mechanical ventilation. Fentanyl causes dose-dependent respiratory depression and at very high doses it can produce chest wall rigidity. A bolus is often helpful prior to painful procedures in neonates with pulmonary hypertension.

Alfentanil is a synthetic opioid structurally related to fentanyl. It has a more rapid onset and a shorter duration of action, but approximately 10%–20% of its potency. It is rarely used on the PICU.

REMIFENTANIL

Remifentanil is an ultrashort-acting potent synthetic opioid 10 times more potent than fentanyl and 1000 time more potent than morphine; it is ideal for stimulating procedures such as physiotherapy or chest drain removal. It is ideal for neurosedation because of its short half-life. It can be stopped briefly to enable a window of consciousness allowing neurological assessment.

Following initial redistribution, remifentanil is metabolised rapidly via non-specific esterases. Having a context-sensitive half-time of 3–5 minutes, its duration of action is not influenced by the total time of infusion. Rates of infusion of 3–80 μg/kg/h produces satisfactory analgesia and sedation in ventilated children aged 1 month to 12 years and for those over 12 years of age 3–120 μg/kg/h.

The use of remifentanil in children and neonates in intensive care is increasing.[29] In an RCT of neonates and infants, the authors concluded that remifentanil could be the ideal opioid for analgesia and sedation of mechanically ventilated infants.[30]

PARACETAMOL AND NON-STEROIDAL ANTI-INFLAMMATORY DRUGS

The IV dose for infants weighing less than 10 kg is 7.5 mg/kg every 6 hours; in children it is 15 mg/kg and the total daily IV dose should be limited to 60 mg/kg. The oral dose is 20–30 mg/kg for one dose, then 15–20 mg/kg/day up to 60 mg/kg/day. Higher doses are required when used rectally, 30–40 mg/kg initially then 15–20 mg/kg 6 hourly to a maximum of 60 mg/kg/day. It is metabolised in the liver and renally excreted.

Non-steroidal anti-inflammatory drugs (NSAIDs) are less commonly used on the PICU. Most NSAIDs work by inhibiting cyclo-oxygenases, which increase prostaglandin levels, which in turn sensitises peripheral nerve endings to agents such as histamine and bradykinins. Concerns around compromising renal function and increasing bleeding tendency have reduced the use of NSAIDs on the PICU.

EVIDENCE BASE FOR ANALGESIA

There is evidence for using continuous IV opioid infusions (Level 2b, Grade B). Continuous morphine therapy appeared to be effective in controlling neonatal postoperative pain, as judged by nursing observations.[31]

The combination of opioid and non-opioid analgesia is supported by work from Wong[32] who undertook a systematic review of 31 RCTs and concluded that multiple doses of NSAIDs on a background of continuous opioid infusion gave significant benefit (Level 2b, Grade A).

Patient-controlled analgesia (PCA) has not been rigorously evaluated in terms of advantage over any other form of intermittent analgesia. However, a meta-analysis of 49 studies revealed children using PCA had lower visual analogue scale pain intensity scores than children who did not receive PCA (Level 1b, Grade B).[33]

A recent Cochrane review of eight trials and 614 infants concluded that paracetamol may reduce the total need for morphine following major surgery, and when combined with morphine it is useful in severe pain.[34]

SUCROSE IN NEONATES

There is good evidence for the beneficial effect of 0.5 mL sucrose (24%) in reducing heel-prick pain and 2 mL is useful reducing venipuncture and intramuscular injections. The effectiveness of sucrose for reducing pain/stress from other interventions, such as arterial puncture, subcutaneous injection, insertion of nasogastric or orogastric tubes, bladder catheterisation, eye examinations and echocardiography examinations, were inconclusive.[35]

WITHDRAWAL SYNDROMES

Iatrogenic withdrawal syndrome is a well-recognised problem in children receiving benzodiazepines and opioids for periods greater than 5 days. Recent work

suggests that monitoring for withdrawal should start as early as 3 days and that rates of infusion of midazolam greater than 0.35 mg/kg/h or 6 μg/kg/min will put children at high risk of withdrawal.[36] Infusion of fentanyl for greater than 5 days or a total dose greater than 1.5 mg/kg is associated with greater than 50% incidence of withdrawal.[37] The Sophia Observation withdrawal Symptoms scale is a useful tool when weaning from sedation/analgesia,[38] as is the Withdrawal Assessment Tool-1 (WAT-1).[39]

MANAGEMENT OF DELIRIUM

Delirium is an increasingly recognised problem following PICU admission and can result in significant cognitive impairment on leaving intensive care. Delusional memories were reported in almost one-third of children following their PICU admission and were associated both with the duration of opiates/benzodiazepines and with the increased risk of developing post-traumatic stress.[40] A significant minority of school-aged children admitted to the PICU are at risk of reduced mental and physical well-being in the short term.[41]

Two validated bedside tools help to incorporate delirium monitoring into the critical care setting. The Preschool Confusion Assessment Method for the ICU (psCAM-ICU) identifies delirium in critically ill infants and children less than 5 years of age. The Pediatric Confusion Assessment Method for the Intensive Care Unit (pCAM-ICU) assesses delirium in children 5 years of age and older.[42] The ps/pCAM-ICU were adapted from the adult Confusion Assessment Method for the ICU (CAM-ICU).[43] In practice the RASS is a used to measure the sedation level prior to using tools such as the Cornell Assessment of Pediatric Delirium (CAP-D) or pCAM-ICU to assess delirium.[44]

REGIONAL TECHNIQUES

Although a number of regional blocks are described, the most commonly encountered regional block used for postoperative pain is the lumbar epidural. The procedure is usually performed in theatres and is not commonly instituted on the PICU. However, it is important that the advantages and complications of this technique are known, as it may remain in situ for days while on the PICU. A complication rate of 1.5/1000 has been reported, with dural puncture and intravascular injection seen most commonly at the time of insertion. Other complications include epidural infection and excessive motor blockade and high-level blockade, which is particularly important in smaller children.

HOLISTIC APPROACH

The use of physical restrains with arms tied to cot sides and elbows splinted to prevent self-extubation have been superseded by chemical restraints. Rapid developments in the adult ICU world are leading the way and guiding us to attempt to make the child's stay on the PICU as normal as possible. Measures such as eye masks, earplugs and other noise reduction strategies[45] and single rooms improve quality of sleep and reduce the prevalence of delirium in the adult ICU setting[46] and should be considered on the PICU. These initiatives will be more challenging in the paediatric population but should not be impossible.

SUMMARY

The purpose of sedation and analgesia in children while on the PICU is to reduce pain, anxiety and distress. We are moving away from an era when chemical restraint is the standard of care. We need to adapt to novel measures that allow our children to be comfortable and pain free, yet interactive while being ventilated and, most importantly of all, not suffer from iatrogenic complications caused during and following their stay on the PICU. Symptoms of withdrawal and delirium are our major challenges following discharge. The child's need for the PICU should not be further complicated by problems caused by the sedation and analgesia we administer.

Guidelines for the route of administration, bolus and infusion doses of commonly used sedative and analgesic agents in children. (Modified from the British National Formulary for Children)

DRUG	ROUTE	DOSAGE
Diazepam	IV	Bolus: 0.2–0.4 mg/kg Infusion: NOT recommended
Midazolam	IV	Bolus: 0.1–0.2 mg/kg Infusion: 1–4 μg/kg/min
Lorazepam	IV	Bolus: 0.1 mg/kg
Chloral hydrate	Oral	30–50 mg/kg 6–8 hourly
Alimemazine	Oral	1–2 mg/kg 6 hourly
Ketamine	IV	Bolus: 1–2 mg/kg Infusion: 10–40 μg/kg/min
Clonidine	Oral IV	4 μg/kg Infusion: 0.1–2 μg/kg/h
Dexmedetomidine	IV	Infusion: 0.7–1.4 μg/kg/h
Thiopentone		Bolus: 2–4 mg/kg Infusion: 1–5 mg/kg/h
Paracetamol	Oral	20–30 mg/kg stat then 15–20 mg/kg to a max of 60 mg/kg/day
	IV	Bolus: 7.5 mg/kg <10 kg 15 mg/kg >10 kg
	Rectal	30–40 mg/kg stat then 15–20 mg/kg to a max of 60 mg/kg/day

DRUG	ROUTE	DOSAGE
Morphine	IV	Bolus: 0.1–0.2 mg/kg Infusion: 10–40 µg/kg/h
Fentanyl	IV	Bolus: 1–2 µg/kg Infusion: 1–6 µg/kg/h for children 0–1.5 µg/kg/h for neonate
Remifentanil	IV	Infusion: 3–80 µg/kg/h 1 month–12 years 3–120 µg/kg/h 12–18 years

IV, Intravenous.

Shock and cardiac disease in children

Johnny Millar

SHOCK

Shock is the clinical state resulting from insufficient oxygen delivery to meet oxygen demand, and is described in detail in Chapter 15. Shock in children is most commonly due to hypovolaemia or sepsis and remains an important cause of global infant and child mortality. The cellular effects of tissue hypoxia in shock are the same in children and adults, but there are important developmental changes in anatomy, physiology and immunity during childhood, which influence the incidence, presentation and natural history of shock.

DEVELOPMENTAL DIFFERENCES

BODY FLUID COMPARTMENTS[1]

Although the extracellular fluid volume in children is greater than in adults when indexed to body weight, the small absolute volumes involved are critical when blood or fluid loss causes shock; 100 mL blood loss is inconsequential for an adult, but represents one-third of the blood volume for a neonate (Table 110.1).[1]

CARDIAC[2–4]

There are many differences between the newborn and the mature heart that have important effects on function, particularly under stress. The newborn heart has a relatively small left ventricular muscle mass that must cope with the newly imposed demands of the systemic circulation. In response to increased afterload, the neonatal myocardium increases in mass by both hypertrophy and hyperplasia, with the capacity for the latter of these mechanisms being lost after the first 6 months of life. Neonatal cardiac myocytes appear small and blunted with a higher proportion of non-contractile elements than mature myocytes. The fewer myofibrils are poorly aligned and there are sparser, disorganised-looking mitochondria. Less efficient handling of calcium by the myocyte membrane and sarcoplasmic reticulum make the neonatal myocyte more dependent on extracellular fluid calcium concentration, which may contribute to limited cardiac reserve.

The physiological consequence is a stiffer, less compliant ventricle that is less able to generate contractile force. Physiological changes at birth (see later) increase both volume and pressure load to the left ventricle. The ability of the ventricle to increase output in response to further volume or pressure loading is limited. The neonatal heart functions at a high state of beta-adrenergic stimulation and therefore has a restricted capacity to increase contractility and rate. Following birth there is a steady increase in stroke volume index and cardiac index over the first 3 years of life.

VASCULAR[5]

Antenatal pulmonary blood flow is low (<10% of combined ventricular output) through a relatively muscularised high-resistance circulation. Blood ejected by the right ventricle is mostly diverted through the ductus arteriosus to the systemic circulation. Pulmonary vascular resistance (PVR) falls abruptly at birth with a concomitant increase in pulmonary blood flow. The PVR then falls more slowly, reaching adult levels over the next 6 weeks as a result of pulmonary vascular remodelling. The increase in pulmonary blood flow immediately following birth results in increased preload to the left ventricle. With clamping of the umbilical cord, the low resistance placental circulation is removed and the systemic vascular resistance rises acutely, causing an increase in systemic arterial pressure. Following the transition from foetal to neonatal circulation, the systemic vascular resistance index remains relatively constant throughout early childhood.[6]

MICROCIRCULATION

There are animal and human data to support the notion of maturation of the microcirculation.[7,8] The infant and young child's microcirculation is leakier at baseline and functions at a higher turnover of fluid and protein than the adult. This state of higher turnover may predispose the child to greater capillary leak in response to inflammatory and traumatic stimuli resulting in hypovolaemic shock.

IMMUNITY AND THE INFLAMMATORY RESPONSE[9,10]

The newborn has had little prior exposure to pathogens and has limited capacity to respond to infection,

ABSTRACT

Distinctive maturational changes in body composition, cardiovascular function, immunity and the inflammatory response throughout childhood influence the susceptibility to and consequences of shock in children. Children with unrecognised and untreated shock will decompensate rapidly. Septic shock remains an important cause of paediatric mortality, even in the developed world. Children with septic shock are more likely to present with cold shock and myocardial dysfunction than vasodilated, warm shock, necessitating a different treatment approach.

Heart failure in children can be due to primary or secondary myocardial dysfunction or the consequences of congenital heart disease. Congenital heart disease is increasingly prevalent and it is important for all critical care practitioners to develop an approach to diagnosis and initial treatment of common presentations and complications.

Table 110.1 Body fluid compartments during childhood (mL/kg)

AGE	TOTAL BODY WATER	EXTRACELLULAR FLUID	INTRACELLULAR FLUID	BLOOD
Pre-term newborn	800	550	300	95
Birth	750	450	300	85
1 year	700	350	350	80
5 years	650	250	400	75
Adult	600	200	400	70

Friis-Hansen B. Body water compartments in children: changes during growth and related changes in body composition. *Pediatrics*. 1961;28(2): 169–181.

so is at increased risk of invasive infection. This risk persists beyond the newborn period as the immune system remains immature through infancy and early childhood, with deficits in both innate and adaptive immunity. In addition to immature barriers to infection, infants have lower levels of circulating complement components and defective natural killer cell function. A mature pattern of cytokine and chemokine production is not attained until later in childhood. B cells are geared towards producing immunoglobulin (Ig)M rather than IgG or IgA, and there are multiple distinct deficiencies in T-cell function. The inflammatory response to sepsis also appears to undergo complex developmental changes, the implications of which are hard to define. Aspects of the pro- and anti-inflammatory response are qualitatively and quantitatively different in children compared to adults, including a relative exaggeration of the anti-inflammatory response.

Like adults, children are placed at risk of infection by therapeutic immunosuppression, but there are also a large number of congenital diseases that are characterised by generalised or specific defects in immune function.

RECOGNITION OF SHOCK

Recognition of early shock is very important as children compensate well initially, but their capacity to do so is rapidly exhausted and decompensation can then be sudden; during the early stages of compensated shock in infants, signs may be limited to tachycardia and tachypnoea (Table 110.2). Hypotension is a late finding and demands urgent attention.

INITIAL ASSESSMENT AND INVESTIGATION

HISTORY

- Fever, feeding, urine output, diarrhoea, vomiting
- Rapid breathing, sweating, tiring while feeding
- Irritability, lethargy
- Trauma

Table 110.2 Ninety-five percent ranges for heart rate, blood pressure and respiratory rate in childhood[11–13]

AGE	HEART RATE (BEATS PER MINUTE)	MEAN BLOOD PRESSURE (mm Hg)	RESPIRATORY RATE (BREATHS PER MINUTE)
Birth	95–145	40–60	29–65
6 months	110–175	50–90	22–58
1 year	105–170	50–100	22–50
4 years	80–140	50–100	20–26
7 years	70–120	60–90	17–24
14 years	60–100	65–95	12–20

- Potential for trauma in infants
- Potential for ingestion
- Vaccination history.

EXAMINATION

- Temperature
- Conscious level
- Peripheral perfusion, capillary refill
- Rash
- Skin turgor
- Mucous membranes
- Pulses
- Heart rate, rhythm
- Blood pressure
- Respiratory rate.

INITIAL INVESTIGATIONS

- Chest X-ray
- Arterial blood gas, lactate
- Full blood count and film examination
- Blood glucose
- Plasma electrolytes, urea, creatinine, liver function tests.

If there is evidence of sepsis or if there is no obvious cause for shock, take cultures and start antibiotic therapy (Table 110.3).

Table 110.3 Suggested initial antibiotic treatment of septic shock in children

FIRST FEW DAYS OF LIFE	
Benzylpenicillin	60 mg/kg 12-hourly
Gentamicin	5 mg/kg 36-hourly
BEYOND FIRST FEW DAYS OF LIFE	
Flucloxacillin	50 mg/kg 6-hourly
Cefotaxime	50 mg/kg 6-hourly
Gentamicin	6 mg/kg 24-hourly
IF HOSPITAL ACQUIRED, REPLACE FLUCLOXACILLIN WITH	
Vancomycin	25 mg/kg load then 15–20 mg/kg 8-hourly

- Blood cultures – peripheral blood and from any lines already in place
- Urine cultures (suprapubic aspirate or in–out urinary catheter in young infants)
- Throat swab
- Urine, stool and nasopharyngeal aspirate for virology
- Do not do a lumbar puncture in a shocked child. Commence antibiotics following other cultures. Cerebrospinal fluid for bacterial and viral culture and polymerase chain reaction can be obtained later.

TYPES OF SHOCK

The traditional classification of shock (Chapter 15) is valid in children, but a combination of these is likely to be present in any given clinical situation. In particular, it is best to think of septic shock as a clinical entity that incorporates features of several shock types.

HYPOVOLAEMIC SHOCK

This is a common presentation in childhood, which is particularly secondary to water and electrolyte losses with diarrhoea and vomiting.

The initial compensatory response to hypovolaemia is an increase in catecholamine secretion, leading to poor peripheral perfusion, tachycardia and a normal blood pressure with diminished pulse pressure. Lethargy and tachypnoea secondary to increasing metabolic acidosis are variably present. Up to 15%–20% of the circulating blood volume may be lost before hypotension occurs. With further volume loss, end-organ perfusion and oxygen delivery are compromised leading to worsening acidosis, coma, oligo/anuria and ultimately myocardial dysfunction.

The cause of hypovolaemia is usually evident from the history and examination, but hidden blood loss must be considered, particularly in infants where unreported head or abdominal trauma may have occurred with few external signs.

TREATMENT

Ensure adequate airway protection and breathing and administer oxygen. After establishment of intravenous (or intraosseous) access, early and aggressive intravenous fluid resuscitation is vital to restore the circulating blood volume. Give fluid (10–20 mL/kg 0.9% NaCl) rapidly with frequent clinical reassessment to verify signs of reversal of shock. Give blood if shock is due to ongoing blood loss.

CARDIOGENIC SHOCK

See section on Cardiac Disease.

DISTRIBUTIVE SHOCK

CAUSES

These include anaphylaxis, spinal cord injury or administration of vasodilators. Septic shock in children may have a distributive component, but this is not as common a finding as in adults (see below).

PRESENTATION

In distributive shock, tissue perfusion is inadequate despite an initially normal circulating blood volume and normal (or high) cardiac output. Abnormal vasomotor tone with profound vasodilatation leads to a reflex tachycardia (in spinal cord injury absence of sympathetic activity may result in bradycardia). Examination reveals warm peripheries, tachycardia and hypotension with a wide pulse pressure. The cause of distributive shock is likely to be clear from clinical examination.

TREATMENT

Attend to airway and breathing, obtain intravenous access and give rapid fluid boluses (20 mL/kg 0.9% NaCl). If there is inadequate reversal of shock then vasopressors may be necessary to restore blood pressure (or counteract the effects of vasodilator drugs).

Anaphylaxis must be treated specifically and urgently. Table 110.4 shows paediatric epinephrine (adrenaline) doses.

OBSTRUCTIVE SHOCK

CAUSES

These include pericardial tamponade, tension pneumothorax, pulmonary embolus and mediastinal mass.

PRESENTATION

In obstructive shock, extracardiac restriction of cardiac output prevents adequate oxygen delivery. There may be obstruction to the pulmonary or systemic outflow

Table 110.4 Paediatric cardiac drug doses

DRUG	DOSE
Adenosine	0.1 mg/kg (max 3 mg); increase by 0.1 mg/kg/dose to 0.3 mg/kg (max 12 mg)
Alprostadil (PGE_1)	10–50 ng/kg/min
Amiodarone	25 µg/kg/min for 4 h, then 5–15 µg/kg/min
Atropine	0.02 mg/kg (max 0.6 mg)
Bicarbonate (10% $NaHCO_3$)	1–2 mL/kg
Digoxin	15 µg/kg, then 5 µg/kg after 4 h, then 3–5 µg/kg 12-hourly
Dobutamine	2–10 µg/kg/min
Epinephrine	
Bolus	10 µg/kg (0.1 mL/kg 1:10,000)
Infusion	0.05–0.5 µg/kg/min
Anaphylaxis	10 µg/kg (0.01 mL/kg 1:1000) by deep intramuscular injection
Esmolol	500 µg/kg over 1 min, then 25–250 µg/kg/min
Isoproterenol	0.05–0.5 µg/kg/min
Levosimendan	12.5 µg/kg over 10 min, then 0.2 µg/kg/min for 24 h
Metaraminol	
Bolus	0.01 mg/kg
Infusion	0.05–0.5 µg/kg/min
Metoprolol	0.1 mg/kg over 5 min (max 5 mg)
Midazolam	
Bolus	0.1 mg/kg
Infusion	1–4 µg/kg/min
Milrinone	0.25–0.75 µg/kg/min
Morphine	
Bolus	0.1 mg/kg
Infusion	10–60 µg/kg/h
Nitric oxide (inhaled)	10–20 parts per million
Norepinephrine	0.05–0.5 µg/kg/min
Sodium nitroprusside	0.5–3 µg/kg/min
Vasopressin	0.0005–0.002 U/kg/min

PGE_1, Prostaglandin E_1.

Walsh EP. Clinical approach to diagnosis and acute management of tachycardias in children. In: Walsh EP, Saul PJ, Triedman JK, eds. *Cardiac Arrhythmias in Children and Young Adults with Congenital Heart Disease*. Philadelphia, PA: Lippincott, Williams & Wilkins; 2001:95–113.

tract or circulation, or compression by pericardial tamponade or tension pneumothorax.

TREATMENT

Treatment is aimed at ensuring adequate circulating volume and identifying and remedying the cause of the obstruction. Tamponade and tension pneumothorax require urgent drainage.

SEPTIC SHOCK[14–17]

In Australia and New Zealand, septic shock accounts for 2.1% of paediatric admissions to the intensive care unit (ICU) and has a mortality of 17%. The clinical presentation of septic shock in young children is different to adults, who reliably present with peripheral vasodilation, hypotension and a relatively high cardiac output ('warm shock'). The picture in children is usually dominated by myocardial suppression and peripheral vasoconstriction ('cold shock'). Hypovolaemia occurs rapidly due to capillary leak secondary to the sepsis-induced inflammatory response. Septic shock in children may be difficult to distinguish from cardiogenic shock or hypovolaemic shock. Neonatal sepsis often presents with features of persistent pulmonary hypertension, with right heart failure and a degree of cyanosis depending on patency of the ductus arteriosus and foramen ovale.

TREATMENT[16,17]

Despite the concerns raised by the findings of the Mortality after Fluid Bolus in African Children with Severe Infection (FEAST) trial,[18] current guidelines for the treatment of septic shock in the developed world continue to emphasise the importance of prompt and aggressive fluid resuscitation, along with the early institution of inotropic therapy. Both of the consensus guidelines cited here are currently undergoing revision.

Airway

Administer supplemental oxygen to all children with shock. Intubate patients who are unable to protect their airway or have impending respiratory failure.

Circulation and access

If peripheral access is difficult and the child is obtunded or severely shocked, consider intraosseous access early. Give fluid boluses (10 mL/kg) to restore circulating blood volume. Children with septic shock often require large amounts of fluid resuscitation – occasionally more than 100 mL/kg. In patients who do not have reversal of signs following 60 mL/kg of fluid, gain central venous access. This allows measurement of central venous pressure, administration of inotropes or vasoconstrictors and measurement of central venous saturation (see below). Insert an arterial line for frequent sampling and invasive monitoring of blood pressure.

Echocardiography is an important means of guiding inotrope and vasopressor management, allowing

assessment of cardiac filling, contractility and PVR. Invasive measurement of cardiac output is rarely performed in children; pulmonary artery catheter insertion is technically difficult and although several non-invasive methods are available to estimate cardiac output in children none are widely used.

Inotrope/vasodilator/vasoconstrictor therapy (see Table 110.4 for drug doses)

Do not delay starting vasoactive drugs if there is difficulty gaining central venous access. Dilute infusions of inotropes and vasoconstrictors may be administered through a peripheral line, with care taken to avoid and check for extravasation.

Decreased contractility on echo or clinical suspicion

Dobutamine is a useful first-line inotrope in children and is relatively safe to administer through a peripheral intravenous line. Although dopamine is still widely used, it inhibits anterior pituitary release of thyrotropin, growth hormone and prolactin[19] and may be relatively ineffective in young infants. Epinephrine should be started as a second-line drug if cardiac function remains inadequate despite dobutamine.

Hypotension and warm peripheries

A vasoconstrictor may be used alone if myocardial function is adequate or is added to an inotrope if contractility is poor. Norepinephrine is the drug of choice, but an inadequate response to it may be due to the down-regulation of catecholamine receptor numbers or function. Apparent norepinephrine resistance warrants a trial of vasopressin; however, a randomised controlled trial in paediatric shock failed to demonstrate any outcome benefit with vasopressin treatment (and showed a trend towards increased mortality).[20]

Hypotension and cool peripheries

Treat decreased contractility as above. As discussed earlier, peripheral vasoconstriction is a compensatory mechanism to maintain adequate perfusion pressure. Do not add a vasodilator to an already hypotensive patient. A vasoconstrictor may be needed in addition to an inotrope if hypotension persists.

Normotension and cool peripheries

If blood pressure is normal or high, addition of a vasodilator may reduce afterload and improve cardiac output. Sodium nitroprusside (SNP) has a short half-life and can be discontinued rapidly if the blood pressure falls. In addition to being a powerful vasodilator, milrinone has inotropic effects, but should be used with care because of its relatively long half-life.

Pulmonary hypertension

If there is evidence of pulmonary hypertension during shock start an inotrope (dobutamine or epinephrine) to support the right ventricle. Intubate (if not already done), ventilate using a high Fi_{O_2} to a normal $PaCO_2$ and correct acidosis. Inhaled nitric oxide should be added to reduce PVR.

Antibiotics

Early and appropriate antibiotic therapy is associated with improved survival and morbidity.[21] Administer antibiotics to patients in whom the cause of shock is not immediately apparent. After appropriate cultures, selection of antimicrobials is guided by the clinical picture, including any available results from prior cultures. In the absence of specific information, a suggested first-line treatment schedule is shown in Table 110.3, but consideration must be given to local antibiotic stewardship and prescription practices, and resistant organism prevalence. A search for the source or site of infection should be undertaken and it may be necessary to drain collections or remove infected tissue.

Blood transfusion

Transfusion of packed red cells to replace blood loss is essential. In a patient with ongoing evidence of inadequate oxygen delivery current guidelines recommend transfusion to maintain a haemoglobin of >10 g/L, particularly in septic shock.[16,17]

Corticosteroids

Give hydrocortisone to shocked patients who are at risk of absolute adrenal insufficiency (recent or ongoing treatment with corticosteroids, known hypothalamic/pituitary/adrenal disease or purpura fulminans). There is no good evidence to support the routine administration of corticosteroids in paediatric septic shock. Current adult guidelines suggest the use of hydrocortisone in fluid and inotrope resistant septic shock.[17] However, there are limited and conflicting data in children, and corticosteroid use remains controversial.[22,23]

Intravenous immunoglobulin

Intravenous pooled immunoglobulin (IVIG) has been used in both children and adults with septic shock, but there is no high quality evidence for an effect on mortality.[24] IVIG has the potential to neutralise superantigens in toxic shock syndrome and its use is often suggested or recommended in this setting, but again clear evidence regarding clinical efficacy is lacking.[25] Anticytokine and antiendotoxin monoclonal immunoglobulin therapies remain experimental.

Extracorporeal membrane oxygenation

Current guidelines recommend extracorporeal membrane oxygenation (ECMO) for refractory septic shock or for respiratory failure in acute respiratory distress syndrome associated with sepsis.[16,17] There is emerging

evidence that central veno-arterial ECMO cannulation via sternotomy is superior to peripheral or neck cannulation in refractory paediatric septic shock, allowing insertion of larger cannulae and consequently higher ECMO flows.[26]

Insulin

Hyperglycaemia is common in shock and may be exacerbated by epinephrine and corticosteroid treatment. Treat sustained hyperglycaemia with insulin infusion, but critically ill children are relatively sensitive to insulin[27] and have limited metabolic reserve, increasing the risk of hypoglycaemia. Tight glycaemic control in critically ill children does not confer any mortality or morbidity benefit and increases the incidence of severe hypoglycaemia.[28]

GOALS OF TREATMENT

The goals of treatment are to reverse the shock state and ensure ongoing adequate tissue oxygen delivery. Frequent clinical reassessment is aided by laboratory investigations including:

- *heart rate:* normal for age (see Table 110.2)
- *blood pressure:* normal for age (see Table 110.2)
- *central venous pressure:* 10–12 mm Hg (1.33–1.96 kPa)
- *central capillary refill:* <3 seconds
- *mental state:* normal
- *urine output:* >0.5 mL/kg/h
- *serum lactate:* <2.0 mmol/L
- *central venous saturation:* >70%.

Plasma lactate concentrations are indicative of inadequate tissue oxygenation and therefore a useful marker of shock. Hyperlactaemia can also be due to dead gut, liver dysfunction or epinephrine infusion.[29]

Measurement of central venous saturation (Scv_{O_2}) can be used to assess adequacy of oxygen delivery in the absence of a pulmonary artery catheter.[30] A sample taken from the superior vena cava (SVC) or SVC/RA (right atrium) junction is best; sampling from within the RA may be polluted by poorly saturated blood from the coronary sinus or by interatrial shunting. Although goal-directed treatment of septic shock in children with a target Scv_{O_2} >70% was associated with improved survival in one single-centre study,[31] the clear lack of demonstrable benefit from early goal-directed therapy in adult septic shock[32,33] demands a more cautious approach to rigorous pursuit of such targets. In children with structural heart disease and intracardiac mixing, an $Sa_{O_2} - Scv_{O_2}$ difference of ≤30% is roughly equivalent to an Scv_{O_2} >70% in a conventional circulation.

CARDIAC DISEASE

Appropriate drug doses for this section are given in Table 110.4.

Box 110.1 Causes of cardiogenic shock

- Primary cardiac disease
  - Congenital heart disease
  - Post cardiac surgery
  - Cardiac trauma
  - Myocarditis
  - Cardiomyopathy
  - Arrhythmias and conduction defects
  - Endocarditis
- Local disease with cardiac effects
  - Constrictive pericarditis
  - Pericardial tamponade
  - Compression of heart by tumour, tension pneumothorax
- Systemic disease with cardiac effects
  - Sepsis
  - Hypoxic ischaemic injury
  - Autoimmune disease
  - Kawasaki disease
  - Drug ingestion

CARDIOGENIC SHOCK

Cardiogenic shock can be difficult to distinguish from septic shock. Causes of cardiogenic shock are listed in Box 110.1.

Patients present with tachycardia, low pulse volume and poor peripheral perfusion as vasoconstriction maintains blood pressure in the initial stages. Tachypnoea, obtundation and decreased urine output are present early. Examination may reveal a gallop rhythm, hepatomegaly, sweating and peripheral oedema. The presence or absence of a cardiac murmur is unlikely to be helpful in acute diagnosis. Ongoing shock leads to progressive hypoperfusion of end organs.

INVESTIGATION

Initial investigations include chest X-ray, electrocardiogram (ECG) and echocardiogram, with further tests prompted by individual findings. Take blood cultures and start antibiotics if there is no known cause for cardiogenic shock.

TREATMENT

Treat as described for septic shock in the preceding section (see Table 110.4).

Consider ECMO early if the patient is deteriorating or unresponsive to therapy.

CARDIAC FAILURE[34,35]

Children with heart failure are a diverse group of patients with a heterogeneous group of diseases leading to worsening heart function. Cardiac failure can be due to primary or secondary myocardial

Table 110.5 Causes of heart failure in children

CAUSE	EXAMPLES
BIRTH–2 WEEKS	
Sepsis	Neonatal sepsis, group B *Streptococcus*
Hypoxic ischaemic injury	Birth asphyxia
SVT	Congenital/neonatal
Congenital heart block	Isolated or with structural heart disease
Arteriovenous malformations	Vein of Galen malformation
Duct-dependent systemic circulation	Aortic coarctation or stenosis, HLHS
Persistent pulmonary hypertension of newborn	Secondary to sepsis, hypoxic ischaemic injury, etc.
Anaemia	Twin-to-twin transfusion, Rhesus incompatibility
Cardiomyopathy	Infant of diabetic mother, congenital
Neonatal myocarditis	Enterovirus
Cardiac tumour	Rhabdomyoma
2 WEEKS–6 MONTHS	
Large volume left to right shunt lesions	VSD, AVSD, truncus arteriosus, AP window
Cardiomyopathy, myocarditis	
Coronary lesion	ALCAPA
Metabolic	Hypothyroidism
LATER CHILDHOOD	
Unrepaired congenital heart disease	
Left ventricular failure	Left to right shunt lesions Aortic or mitral valve disease
Right ventricular failure	Pulmonary or tricuspid valve disease Pulmonary hypertension
Systemic right ventricular failure	Congenitally corrected transposition
Operated congenital heart disease	
Left ventricular failure	Residual aortic or mitral valve disease Subaortic stenosis
Right ventricular failure	Pulmonary valve disease (repaired TOF) Pulmonary hypertension
Systemic right ventricular failure	Post Senning or Mustard
Single ventricular failure	Post aortopulmonary shunt, Glenn or Fontan
Arrhythmia	Post Fontan, Senning, Mustard
Cardiomyopathy, myocarditis	
Acquired cardiac disease	Rheumatic heart disease, endocarditis, Marfan syndrome, cor pulmonale
Transplant rejection	

ALCAPA, Anomalous origin of left coronary artery from pulmonary artery; *AP*, aorto-pulmonary; *AVSD*, atrioventricular septal defect; *HLHS*, hypoplastic left heart syndrome; *SVT*, supraventricular tachycardia; *TOF*, tetralogy of Fallot; *VSD*, ventricular septal defect.

disease, or the effects of congenital heart disease or its treatment (Table 110.5).

INVESTIGATIONS

- Chest X-ray
- ECG
- Echocardiogram
- Further imaging with computed tomography, magnetic resonance imaging and cardiac catheter may be warranted
- Blood gas
- Electrolytes, renal and liver function
- Coagulation
- B-type natriuretic peptide, troponin I

- Viral cultures – urine, stool and nasopharyngeal aspirate
- Serum amino acids
- Urine amino and organic acids
- Serum carnitine.

TREATMENT

Treat any identified underlying cause for heart failure (sepsis, correctable congenital heart disease, arrhythmias, anaemia). Further treatment is in the following sections on cardiomyopathy, congenital heart disease and disorders of cardiac rhythm.

CARDIOMYOPATHY[36]

Primary cardiomyopathy is rare in childhood (1.13–1.24 per 100,000 children per year) with the highest incidence in the first year of life. With increasingly sophisticated diagnostic approaches, the cause of cardiomyopathy can be identified in most cases.[37] Dilated and hypertrophic cardiomyopathies account for the majority (~80%) of cases, and there is considerable phenotypic overlap between the different types of cardiomyopathy. The 5-year mortality or transplant rate for children with dilated cardiomyopathy is 46%, with younger children and those who are sickest at presentation being at highest risk.

The clinical presentation is usually one of congestive cardiac failure. Infants present with poor feeding and failure to thrive, along with tachycardia, tachypnoea and sweating. There may be a hyperdynamic precordium and a gallop rhythm. In older children a careful history will often elicit decreased physical activity in comparison to their peers for many months. The clinical presentation becomes more like that seen in adults, with hepatomegaly, ascites, oedema and poor peripheral perfusion.

TREATMENT (SEE Table 110.4 FOR DRUG DOSES)[38]

Compared to adult heart failure, there are relatively few data on which to base treatment of heart failure in children. However, recent consensus guidelines have been published, providing guidance on management whilst acknowledging the weak evidence base. Mainstays of chronic treatment are diuretic therapy and angiotensin converting enzyme (ACE) inhibitors, or beta blockers. The sicker child in the ICU with acute or acute on chronic heart failure will require further measures.

Oxygen

Treat decompensated heart failure with facemask oxygen.

Ventilation

Intubation and positive-pressure ventilation improve gas exchange and reduce the work of breathing. Although positive pressure probably has no direct effect on left ventricular contractility, it improves output by reducing left ventricular afterload.[39] High pressures may impair cardiac output by reducing preload and increasing afterload to the right ventricle.

Afterload reduction

Vasodilator therapy is useful as long as an adequate blood pressure can be maintained. SNP is a potent pure vasodilator. Milrinone has the additional advantage of some inotropic and lusitropic effects.

Inotropes

Dobutamine or milrinone (if vasodilatation is tolerated) can be used as first-line agents. Despite limited data in children, levosimendan is being used increasingly in paediatric heart failure. It appears capable of increasing cardiac output at minimal metabolic cost and is a potent vasodilator.

Blood transfusion

Correct anaemia. Transfuse packed red blood cells to maintain Hb >10 g/dL.

Cardiac resynchronisation therapy[40]

Cardiac resynchronisation therapy (CRT) has been shown to be very effective in the treatment of subpopulations of adults with heart failure. Patient selection and systematic assessment is made difficult in children by the heterogeneous nature of heart failure in this age group and the relatively low prevalence of the underlying diseases. In addition, there are important technical considerations related to size. Nonetheless, CRT has been successfully applied in paediatric heart failure, with a relatively low rate of non-responders, and work continues to identify appropriate selection criteria.

Mechanical support[41–43]

Veno-arterial ECMO (see Chapter 41) or centrifugal ventricular assist device (VAD) can provide excellent short-term mechanical support, but are unsuitable for the longer periods necessary for bridging to transplantation. There are very few durable VADs available for such support of the smaller child. The Excor Paediatric VAD ('Berlin Heart') is the most widely used of these, with a range of ventricular chambers down to 10 mL. Successful support to transplantation or recovery can be achieved in 70%–90% of cases, but there is a high risk of infective, bleeding and thrombotic complications. Larger (>30 kg) children can be supported with smaller continuous flow implantable devices designed for adults, which may carry less risk of complications. Development of miniaturised versions of these devices for children is ongoing, but as yet none is ready for clinical use.

AN APPROACH TO CONGENITAL HEART DISEASE

An in-depth discussion of congenital heart disease and its management is beyond the scope of this chapter.

What follows is an overview of situations in which the intensivist or emergency physician may encounter congenital heart disease, based loosely on age and mode of presentation.

NEWBORN WITH CYANOSIS[43,44]

Most cyanosed newborns have respiratory disease and this needs to be treated appropriately. Cyanosis in the absence of respiratory distress is likely to be due to congenital heart disease. Cyanotic heart disease is likely if the Pa_{O_2} does not rise to 150 mm Hg (≈20 kPa) after the baby has been breathing 100% oxygen for 10 minutes. The presence or absence of a murmur is not particularly helpful; many children with cyanotic heart disease do not have a murmur and murmurs can be heard in many newborn infants. There may be diagnostic clues on examination and chest X-ray, but all such infants need an urgent echocardiogram for definitive diagnosis.

SEVERE CYANOSIS (Sa_{O_2} <70%) (SEE Table 110.4 FOR DRUG DOSES)

Table 110.6 shows the features of congenital heart lesions presenting with severe cyanosis at birth. These infants must be treated urgently.

1. Intubate and ventilate to reduce oxygen consumption and treat any respiratory disease. Use a high Fi_{O_2} and avoid high pressures that might increase PVR.
2. Start alprostadil (prostaglandin E_1, Prostin) to keep the ductus arteriosus open. There is a risk of exacerbating pulmonary oedema in obstructed total anomalous pulmonary venous drainage, but unless this diagnosis has been made with certainty the ductus should be kept open.
3. Correct metabolic acidosis.
4. Use an inotrope if there is evidence of heart failure (see above).
5. Inhaled nitric oxide may be helpful in persistent pulmonary hypertension of the newborn and severe Ebstein anomaly.
6. Refer for advice and urgent transport to a specialist paediatric cardiac centre. Persistent severe cyanosis may require ECMO support prior to definitive treatment.

LESS SEVERE CYANOSIS (<90%)

Less profound cyanosis is seen in neonates with transposition of the great arteries (TGA) and adequate mixing, milder forms of pulmonary stenosis (including tetralogy of Fallot) and Ebstein anomaly. There is a degree of cyanosis associated with all defects where there is mixing of pulmonary and systemic venous blood (e.g. unobstructed anomalous pulmonary venous drainage, single ventricle lesions). These infants are less sick and desaturation may be relatively difficult to detect without pulse oximetry. All such children require careful assessment and prompt referral to a paediatric cardiac centre.

Table 110.6 Differential diagnosis of severe cyanosis in the newborn

LESION	PATHOPHYSIOLOGY	CHEST X-RAY	MANAGEMENT
Transposition of great arteries	Pulmonary and systemic circulations in parallel, without mixing	Normal cardiac size Narrow pedicle ('egg on side' appearance) Normal/increased pulmonary vascularity	Alprostadil Balloon atrial septostomy
Pulmonary atresia/critical pulmonary stenosis	No forward flow from right ventricle Intracardiac right to left shunting Pulmonary blood flow via ductus arteriosus	Normal cardiac size Absent pulmonary artery silhouette Reduced pulmonary vascularity	Alprostadil Will need surgery or catheter procedure
Neonatal Ebstein anomaly	Severe tricuspid regurgitation Intracardiac right to left shunting +/– pulmonary valve disease	Massive atrial enlargement Lung fields difficult to see	Alprostadil Inhaled nitric oxide May need surgical procedure
Obstructed TAPVD	Severe pulmonary venous obstruction Pulmonary oedema	Normal cardiac size Diffuse pulmonary interstitial oedema	Cardiac surgical emergency
Persistent pulmonary hypertension of the newborn	High PVR Right heart failure Right to left shunting through ductus arteriosus	Normal cardiac size and silhouette Reduced pulmonary vascularity	Alprostadil Inhaled nitric oxide Inotropes Look for and treat underlying cause

PVR, Pulmonary vascular resistance; *TAPVD*, total anomalous pulmonary venous drainage.

NEWBORN WITH CARDIAC FAILURE

In lesions that cause obstruction to the left side of the heart (aortic stenosis, coarctation, hypoplastic left heart syndrome) systemic blood flow is provided by the right ventricle through the ductus arteriosus. Patients may not present until the ductus arteriosus begins to close when systemic blood flow diminishes and the left ventricle fails in the face of greatly increased afterload. There is a rapidly deteriorating clinical picture of pallor, cold peripheries and barely palpable pulses. Tachycardia and tachypnoea are universal and there is progressive hepatomegaly, cardiomegaly and pulmonary oedema. This is accompanied by profound metabolic acidosis and oliguria.

Other conditions presenting with cardiovascular collapse in the first 2 weeks of life are sepsis, inborn errors of metabolism, myocarditis/cardiomyopathy and sustained tachyarrhythmia. These can be difficult to differentiate initially and all neonates presenting in this fashion should be treated with appropriate antibiotics (see Table 110.3) until a definitive diagnosis is made.

TREATMENT (SEE Table 110.4 FOR DRUG DOSES)

1. Intubate and ventilate with resuscitation drugs to hand.
2. Sedate and ventilate to reduce oxygen consumption.
3. Start inotropes – dobutamine or epinephrine depending on severity of cardiac dysfunction.
4. Start alprostadil – a high dose (50–100 ng/kg/min) may be needed to reopen the ductus arteriosus.
5. Refer for advice and urgent transport to a paediatric cardiac centre.

INVESTIGATIONS

- Chest X-ray
- Echocardiogram
- ECG
- Arterial blood gas, electrolytes, renal and hepatic function
- Full blood count and film examination
- Coagulation
- Blood cultures
- Serum amino acids
- Urinary amino and organic acids.

CYANOSIS BEYOND THE NEWBORN PERIOD

Infants and young children with unoperated tetralogy of Fallot may present with episodic profound cyanosis associated with crying and agitation. These 'tet spells' are mostly due to dynamic obstruction of the right ventricular outflow tract with consequent right to left shunting through the ventricular septal defect (VSD). Administration of oxygen and bringing the child's knees up tight to the chest will often terminate the spell (presumably by increasing systemic vascular resistance). Volume expansion may be helpful. If there is persisting cyanosis try sedation with morphine. In very resistant spells either a beta blocker (esmolol) or a peripheral vasoconstrictor (metaraminol) can be used. Inotropes and vasodilators will worsen the cyanosis.

Children with unrepaired or undiagnosed atrial or VSDs (or residual defects following repair) may become cyanosed under conditions of increased PVR, for example during acute respiratory illness. Cyanosis due to progressive pulmonary vascular disease with unrepaired long-standing left to right shunt (Eisenmenger's complex) is increasingly rare.

Certain operations for congenital heart disease leave patients with obligatory intracardiac mixing, producing cyanosis. Pulse oximetry readings in these patients will usually be in the range of 70%–85% (parents will know their child's usual saturations). These children often have pulmonary blood flow supplied via an aorto-pulmonary shunt (e.g. modified Blalock Taussig ['BT'] shunt or central shunt).

Two operations redirect systemic venous return directly to the pulmonary artery, bypassing the heart: the Glenn, or bidirectional cavopulmonary connection (SVC to pulmonary artery) and the Fontan (inferior vena cava and SVC to pulmonary artery). Patients with a Glenn remain cyanosed, whereas patients with a Fontan have variable desaturation. In both cases pulmonary blood flow is extremely sensitive to PVR. If these patients require mechanical ventilation it is important to use low pressures and low rates if possible as positive intrathoracic pressure will impair pulmonary blood flow.

EMERGENCIES AND IMPORTANT PRESENTATIONS

Dehydration

Dehydration is particularly dangerous in cyanosed patients. These patients often have a high haematocrit and further haemoconcentration places them at risk of thrombosis. Intravenous rehydration should be aggressively pursued in dehydrated children with cyanotic heart disease.

Profound desaturation

Acute profound desaturation in a patient with shunt-dependent pulmonary blood flow suggests the possibility of shunt blockage and is a life-threatening emergency. Give volume (10 mL/kg 0.9% NaCl) and repeat if necessary. Discuss urgently with a paediatric cardiac centre and consider giving heparin (100 U/kg).

Intercurrent respiratory illness

Respiratory tract infections are common in childhood and these have important effects on children with limited or shunt-dependent pulmonary blood flow (see above). Increased work of breathing and increased PVR will worsen cyanosis. Respiratory failure must be treated on its merits, but the nature of pulmonary

blood flow and the potential for increasing PVR must be borne in mind if mechanical ventilation is necessary.

HEART FAILURE BEYOND THE NEWBORN PERIOD[45]

Congenital-heart-disease-related heart failure beyond the newborn period may be due to the consequences of an unrepaired left to right shunt lesion. High pulmonary blood flow places a volume load on the left ventricle. Left ventricular enlargement and increased end-diastolic pressures ensue and the patient presents with tachycardia, tachypnoea, sweating, poor feeding and poor growth. There is often a gallop rhythm and a systolic murmur, and peripheral vasoconstriction leads to cool peripheries. These children respond well to diuretics and ACE inhibitors, but may need inotropes and positive-pressure ventilation at presentation. Worsening cardiac failure in the first few months of life is often due to the normal fall in haematocrit at this age and will respond to blood transfusion.[46] These children will need repair of the underlying lesion, but this is rarely urgent.

An important lesion to consider in the infant with previously undiagnosed disease is anomalous origin of the left coronary artery from the pulmonary artery (ALCAPA). These children present with poor growth and episodic inconsolable crying in the first few months of life. There is cardiomegaly and evidence of antero-lateral infarction on ECG. Echo confirms markedly diminished ventricular function, ventricular dilation and mitral regurgitation. This lesion warrants rapid surgical repair.

Heart failure is an important problem in both children and adults with treated congenital heart disease. There are multiple potential causes for systolic or diastolic dysfunction in this population, such as residual shunts, valvular dysfunction, abnormal loading conditions, dysrhythmias and the consequences of previous surgeries. Ischaemic cardiomyopathy occurs rarely, but it can be seen following repair of coronary artery abnormalities or operations involving manipulation or reimplantation of the coronaries, most notably the arterial switch operation.[47]

EMERGENCIES AND IMPORTANT PRESENTATIONS

Intercurrent respiratory illness

Respiratory tract infections will cause an exacerbation of heart failure in children with congenital heart disease. Increased work of breathing and fever are poorly tolerated and often necessitate hospitalisation. This is most commonly seen in infants with unrepaired left to right shunt lesions and viral respiratory tract infections during the winter. It may be difficult to differentiate the effects of the respiratory disease from the heart failure, but initial attention to treatment of respiratory failure must be accompanied by careful assessment of the underlying disease.

DISORDERS OF CARDIAC RHYTHM[48,49] (SEE Table 110.4 FOR DRUG DOSES)

SINUS BRADYCARDIA

Sinus bradycardia (see Table 110.2) may appear more dramatic due to the frequent occurrence of sinus arrhythmia in children. Pathological causes of bradycardia include sinus node dysfunction, hypothermia, high intracranial pressure, cervical spinal cord injury, hypothyroidism, drug effects (beta blockers, digoxin, amiodarone, clonidine) and organophosphate poisoning. Sinus bradycardia very rarely needs treatment apart from addressing any underlying cause. Atropine or isoproterenol (isoprenaline) will increase the heart rate if necessary (Table 110.4).

SINUS NODE DYSFUNCTION

Sinus node dysfunction causes bradycardia, sinus pauses and alternating bradycardia/tachycardia. It is most common following operations for congenital heart disease, particularly those involving extensive atrial surgery, and can occur many years later. Sinus node dysfunction is rare in children with structurally normal hearts and is well tolerated in this group. Emergency treatment involves treatment of bradycardia, if symptomatic, and consideration for pacemaker insertion.

COMPLETE HEART BLOCK

Complete heart block is usually congenital in children, with more than 90% being due to the transplacental passage of maternal autoantibodies in autoimmune disease. In later childhood, complete heart block is most likely to be associated with recent cardiac surgery or complex forms of congenital heart disease (congenitally corrected TGA, left atrial isomerism), but may also occur with myocarditis, cardiomyopathy, cardiac transplant rejection and some muscular dystrophies.

MANAGEMENT

Atropine will increase the ventricular rate and an infusion of isoproterenol will maintain it pending establishment of temporary or permanent cardiac pacing.

Inotropes should be used in patients with poor ventricular function due to long-standing bradycardia or underlying myocardial disease.

Transvenous temporary pacing is difficult in small children and external cardiac pacing may be necessary as a resuscitative measure.

Asymptomatic patients may still require insertion of a pacemaker, depending on cause, ventricular escape rate and myocardial function.

Table 110.7 Age-related approximate electrocardiogram intervals (and upper limits of normal)[50]

	NEWBORN	6–12 MONTHS	5–8 YEARS	12–16 YEARS
PR interval (ms)	100 (120)	110 (140)	130 (160)	135 (180)
QRS duration (ms)	65 (85)	65 (85)	80 (100)	90 (110)
QTc interval (ms)	420 (450)	410 (450)	410 (445)	410 (450)

All intervals in milliseconds. QTc = corrected QT interval = QT$\sqrt{}$(heart rate/60).

FIRST-DEGREE HEART BLOCK

A prolonged PR interval (Table 110.7 for normal intervals in different age groups) can be seen in normal children during periods of increased vagal tone. Pathological causes of first-degree block include hypothermia, electrolyte abnormalities, acute rheumatic fever and any of the causes of complete heart block described above.

SECOND-DEGREE HEART BLOCK

Isolated Mobitz type I block (Wenckebach) is usually well tolerated. Mobitz type II is more likely to be symptomatic and require a pacemaker. Either form of second-degree atrioventricular (AV) block should be investigated for an underlying cause.

TACHYARRHYTHMIAS

Sinus tachycardia (see Table 110.2) is more common than tachyarrhythmia. Underlying causes (fever, pain or agitation, drugs) should be considered and treated.

SUPRAVENTRICULAR TACHYCARDIA (See Chapter 22)

Re-entrant supraventricular tachycardia (*SVT*) is common in childhood. Most cases occur in the first few months of life in the absence of congenital heart disease. However, structural heart disease should be ruled out in all cases.

The re-entry circuit usually involves the AV node and an accessory conduction pathway. These tachycardias are abrupt in onset and have a relatively fixed rate. In neonates and infants, the accessory pathway is discrete from the AV node and may conduct in either direction (accessory-pathway-mediated SVT). In older children and adults, the alternative conduction route is often within the AV node itself, with two limbs of the node conducting at different frequencies and with different refractory periods (AV node re-entrant tachycardia).

Diagnosis

The ECG shows a narrow complex (see Table 110.7) tachycardia at greater than 200 beats per minute. P-waves are often difficult to discern, but occur with a 1:1 ratio to the QRS complexes. P-waves are usually inverted, but morphology and position will depend on the nature of the re-entry circuit.

Treatment

If shocked give:

- oxygen by mask, and sedation (midazolam)
- synchronised cardioversion (1 J/kg).

If stable:

1. *Vagal stimulation:* apply ice water to entire face for less than 30 seconds, gag, tracheal suction or held inspiration if ventilated. Give carotid sinus massage in older children. Do not apply eyeball pressure.
2. *Adenosine rapid intravenous bolus and flush:* give as centrally as possible. If unresponsive increase the dose (see Table 110.4). Adenosine is painful and causes vasodilatation.
3. *Atrial or transoesophageal overdrive pacing:* may terminate the arrhythmia.
4. *If unsuccessful or the tachycardia reverts after successful termination:* consider amiodarone or digoxin.
5. Do *not* use digoxin or verapamil if there is pre-excitation on the ECG (they both may enhance anterograde conduction in the accessory pathway).
6. Do *not* use verapamil in infants (it can cause shock and cardiac arrest).
7. *Following conversion to sinus rhythm:* check ECG for evidence of pre-excitation and look for structural disease.

Automatic SVTs are caused by an ectopic rapidly firing focus within the atrium or AV conducting tissue. These are unusual in the absence of structural heart disease and are commonly seen following cardiac surgery. Typically there is variability of the ventricular rate.

Ectopic atrial tachycardia (EAT) has an abnormal P-wave axis on the ECG with normal conduction to ventricles. Junctional ectopic tachycardia (JET) arises at the AV node or high in the bundle of His. There is complete AV dissociation on the ECG, the ventricular rate being greater than the atrial rate.

Treatment is aimed at reducing automaticity with adequate sedation and analgesia, and avoiding catecholamines and other chronotropes. Keep serum potassium, calcium and magnesium in the high normal range. Whole-body cooling is useful. Amiodarone can be used in resistant postoperative JET.

Atrial fibrillation

Atrial fibrillation is rare in children and is usually associated with cardiomyopathy or previous atrial surgery.

Box 110.2 Causes of ventricular arrhythmias in children

- Congenital heart disease (repaired tetralogy of Fallot, aortic stenosis)
- Cardiomyopathy
- Myocarditis
- Ischaemia (coronary abnormalities, Kawasaki disease)
- Transplant rejection
- Electrolyte abnormalities (hypo/hyperkalaemia, hypocalcaemia)
- Drugs (tricyclic antidepressants)
- Cardiac channelopathies (long QT syndrome, Brugada syndrome)
- Cardiac tumours
- Commotio cordis

Atrial flutter

Atrial flutter is an atrial re-entrant tachycardia. It can occur in newborns in the absence of structural heart disease but is more common in older patients with congenital heart disease, particularly those who have had surgery involving extensive atrial manipulation. Atrial flutter rates in children are faster than adults (>400 per minute in newborns). Diagnosis may be evident from the sawtooth baseline pattern of the ECG, but this may not be revealed until adenosine is given, blocking AV conduction.

Treat shocked patients as described above for SVT.

In the stable patient, atrial or transoesophageal overdrive pacing may terminate the arrhythmia.

VENTRICULAR ARRHYTHMIAS

Isolated premature ventricular contractions are common in infants and children with normal hearts. Ventricular arrhythmias are very rare in children (most cases of paediatric cardiac arrest present with severe bradycardia or asystole). Documented ventricular fibrillation or ventricular tachycardia must prompt an exhaustive search for an underlying cause (Box 110.2).

Emergency treatment of ventricular arrhythmias is described in Chapter 115.

Neurological emergencies in children

Anthony J Slater

Neurological emergencies are the most common life-threatening emergencies in children. In developed societies, after the first year of life, the leading cause of death in childhood is injury, particularly traumatic brain injury. There is a range of conditions affecting the brain, spinal cord and peripheral nervous system that require prompt recognition, resuscitation and definitive management. The pathophysiology, clinical features, treatment and outcome of these acute neurological emergencies are influenced by several important differences between adults and children. These differences include response to injury, developmental maturity and capacity for growth and recovery.

PATHOPHYSIOLOGY OF BRAIN INJURIES IN CHILDREN

Brain injuries are usually caused by a primary event (e.g. trauma, ischaemia, infection or metabolic disturbance), and are frequently accompanied by secondary injuries including oedema, altered cerebrovascular autoregulation, tissue hypoxia or other cytotoxic events. Therapy administered after the event will not influence the outcome of the primary injury; however, appropriate resuscitation, treatment and the avoidance of iatrogenic complications may prevent or reduce the impact of secondary injuries.

Features of brain injury particular to the paediatric patient are described below.

DIFFUSE CEREBRAL SWELLING

Diffuse brain swelling in the absence of oedema is a frequent early finding in paediatric brain injury, and is due to generalised cerebral vasodilation. It often resolves in 1–2 days if there is no other significant brain injury. With more severe primary traumatic injury, diffuse cerebral swelling may be accompanied by areas of contusion, multifocal petechial haemorrhage and vasogenic oedema that progress over several days.

CEREBRAL BLOOD FLOW AND METABOLISM

The cerebral perfusion pressure (CPP) represents the difference between mean arterial pressure (MAP) and intracranial pressure (ICP):

$$CPP = MAP - ICP$$

If autoregulation is disturbed as part of the illness, CPP becomes the major determinant of cerebral blood flow, particularly in areas with more severe damage. The ideal CPP in childhood is not known. The normal range of MAP varies with age from 40 mm Hg (5.32 kPa) in a term neonate to 80 mm Hg (10.64 kPa) in an adolescent. The target CPP is usually adjusted with age, taking into consideration the normal blood pressure for age. For example, for an adolescent patient the therapy may be directed at maintaining a CPP of 60 mm Hg (7.98 kPa), whereas for a child aged 5 years the aim may be to maintain a CPP of 50 mm Hg (6.65 kPa). In conditions where vasogenic oedema occurs, arterial hypertension may increase vascular shift of fluid and worsen brain swelling; however, treatment aimed at lowering arterial pressure (e.g. with vasodilators) may interfere with homeostatic mechanisms and should be used cautiously.

The brain comprises 12% of body weight in infancy compared with 2%–3% in adulthood. Cerebral oxygen and glucose consumption are therefore proportionately greater in childhood and glycogen stores are readily depleted. Hypoglycaemia occurs commonly in severe illnesses such as sepsis; therefore blood glucose should be monitored regularly.

HYPOVOLAEMIA

Children have small blood volumes and commonly develop hypovolaemia from scalp bleeding or intracranial haemorrhage. For example, hypovolaemia will develop in a 5-kg infant (blood volume 400 mL) following blood loss of less than 100 mL. Hypovolaemia should be treated aggressively with fluid boluses of 20 mL/kg to ensure adequate cerebral perfusion.

ABSTRACT

The principles of providing physiological support to children with brain injuries are similar to those applied in adults; however, it is important to appreciate the physiologic differences in children.

The approach to an unconsciousness child should focus on early consideration of treatable causes of coma such as bacterial meningitis or viral encephalitis; empiric treatment should commence if lumbar puncture is contra-indicated or delayed.

Children with seizure disorders require intensive care either to gain control of status epilepticus, or to manage the depressant side effects of therapy. A structured approach to monitoring and escalating therapy is needed to minimise the risk of further neurologic injury.

Autoimmune disorders of the brain (acute demyelinating encephalomyelitis, anti-*N*-methyl-D-aspartate receptor encephalitis), spinal cord (transverse myelitis) or peripheral nerves (Guillain–Barré syndrome) may present as an emergency due to respiratory failure, depressed conscious state, or seizures. These conditions usually, but not universally, respond well to immunosuppression.

KEYWORDS

Coma
status epilepticus
meningitis
encephalitis
autoimmune
metabolic encephalopathy
spinal cord

RELATIVE GROWTH

The child's short stature and proportionately large head confer a number of risks. The toddler's head is at the level of the front of a motor vehicle and isolated head injury is therefore common following pedestrian injury in this age group. The neck muscles are relatively weak in infancy and they support a large head. This renders the brain prone to deceleration injury in motor vehicle crashes and in cases of domestic violence. Injury inflicted by shaking an infant by the shoulders snaps the head to and fro leading to compression of brain tissue and rupture of delicate bridging veins.

BONE DEVELOPMENT

The bones of the skull in the first year of life are thin with open sutures and open fontanelles. Beyond 2 years, the skull sutures close and the cranial vault thickens. In young children there tends to be less bony protection from high-impact trauma, although the nonrigid skull may expand to partially decompress expanding lesions.

UNDIAGNOSED COMA

An ordered approach to diagnosis and treatment is required for a child with a depressed conscious state of unknown origin. This approach must consider common life-threatening and rare treatable diseases (Box 111.1).

Box 111.1 Causes of coma in children

STRUCTURAL	METABOLIC
Trauma	Post-ictal state
Accidental	Infection
Inflicted	Meningitis
Hydrocephalus	Encephalitis
Haemorrhage	Autoimmune
AVM	Encephalitis
Aneurysm	Acute disseminated encephalomyelitis
Tumour	Drugs and toxins
Tumour	Hypoxia–ischaemia
Cerebral	Circulatory shock
abscess	Biochemical
	Hypoglycaemia
	Sodium and/or water disorder
	Calcium disorder
	Acid base disorder
	Hyperthermia
	Hepatic failure
	Haemolytic–uraemic syndrome
	Inborn errors of metabolism

AVM, Arteriovenous malformations.

INITIAL MANAGEMENT

Management should always begin with rapid assessment of the adequacy of airway, ventilation and circulation. If inadequacies are detected, interventions aimed at correcting them should occur immediately. Once venous access is obtained, blood should be collected for routine tests including immediate measurement of blood glucose. If hypoglycaemia is demonstrated 1 mL/kg of 25% glucose or 2.5 mL/kg of 10% glucose should be given intravenously as the neurological sequelae of unrecognised hypoglycaemia can be profound.

Concurrent with the initial assessment and resuscitation, relevant details of the present and past history should be obtained. A detailed neurological and general physical examination should be performed. It is important to accurately document the conscious state so that changes over time, particularly deterioration, can be easily recognised. The Glasgow Coma Scale (GCS) is appropriate for this purpose; the responses of children change with development and therefore the GCS requires modification for paediatric use (Table 111.1). After completing the clinical assessment, the likely diagnosis is often apparent, and appropriate investigation and treatment can commence. Multiple factors may compound to produce coma. For example, a child with severe gastroenteritis may have hyperthermia, hyponatraemic dehydration, metabolic acidosis and hypovolaemic shock.

CONTROLLED VENTILATION

Indications for ventilating a comatose child are:

- upper airway obstruction or loss of airway reflexes
- apnoea or respiratory failure
- rapidly worsening coma
- signs of progressive elevation of ICP (i.e. bradycardia, hypertension, abnormal pupillary light reflexes and localising signs).

Raised ICP should be considered in any case of rapidly progressive coma. If critical intracranial hypertension is suspected clinically, management should include moderate hyperventilation and intravenous mannitol (0.25–0.5 g/kg) or hypertonic saline given as 3 mL/kg of 3% solution (0.5 mmol/mL).[1] Once ventilation is initiated and stability achieved, adequate sedation and analgesia are required. Muscle relaxants may be necessary to facilitate ventilation and prevent straining; however, their use precludes further neurological assessment, and therefore if long-acting muscle relaxants are continued, ICP monitoring is advisable. Hyperventilation is a short-term manoeuvre and, if used during the early resuscitation phase, a gradual return to a low–normal $PaCO_2$ should be the aim. This is best achieved with end-tidal CO_2 and ICP monitoring. Particular attention should be paid

Table 111.1 Glasgow coma scale for children

GLASGOW COMA SCALE (4–15 YEARS)		CHILD'S GLASGOW COMA SCALE (<4 YEARS)	
RESPONSE	SCORE	RESPONSE	SCORE
EYE OPENING		EYE OPENING	
• Spontaneously	4	Spontaneously	4
• To verbal stimuli	3	To verbal stimuli	3
• To pain	2	To pain	2
• No response to pain	1	No response to pain	1
BEST MOTOR RESPONSE		BEST MOTOR RESPONSE	
• Obeys verbal command	6	Spontaneous or obeys verbal command	6
• Localises to pain	5	Localises to pain or withdraws to touch	5
• Withdraws from pain	4	Withdraws from pain	4

• Inappropriate words	3	Cries only to pain	3
• Incomprehensible sounds	2	Moans to pain	2
• No response to pain	1	No response to pain	1

to restoring intravascular volume and maintaining an adequate CPP.

CRANIAL COMPUTERISED TOMOGRAPHY

A computed tomography (CT) scan is required in comatose children with localising signs, and in those in whom the diagnosis is not clear. A CT should also be performed if the conscious state is abnormal and there is a history of trauma. Even if the general condition does not warrant controlled ventilation, a CT is often best performed under general anaesthesia. Unwanted movement will cause poor-quality images, and sedation alone may place the child at risk of hypoventilation or aspiration.

LUMBAR PUNCTURE

Lumbar puncture (LP) should be performed when there is reasonable suspicion of meningitis or encephalitis. The risks and contraindications to LP are discussed under bacterial meningitis.

ADDITIONAL INVESTIGATIONS

Additional investigations include arterial blood gas analysis, serum electrolytes, glucose, urea, creatinine, liver function tests, serum ammonia, serum and cerebrospinal fluid (CSF) lactate and pyruvate, and urine analysis. Appropriate screening of blood and urine will exclude common poisons and drug intoxications.

SPECIFIC TREATMENT

The clinical signs and results of investigations generally guide treatment. If hypoglycaemia occurs, it should be corrected rapidly and care should be taken to ensure that it does not recur. Appropriate glucose-containing intravenous fluid should be commenced with regular blood glucose monitoring. Herpes simplex encephalitis can present in many ways and is not excluded by the absence of CSF pleocytosis. Acyclovir therapy should therefore be considered in any patient in whom herpes cannot be confidently excluded.

STATUS EPILEPTICUS

Convulsive status epilepticus (CSE) is usually defined as a continuous convulsion lasting 30 minutes or longer or repeated convulsions lasting 30 minutes or longer without recovery of consciousness between convulsions.[2] As 30 minutes is generally considered too long to wait before starting treatment, an alternative 'operational definition' of a seizure lasting more than 5 minutes has been proposed for adults and older children (>5 years old). Terminology has been adapted to fit clinical scenarios with practical implication. ***Impending SE*** refers to continuous seizures lasting more than 5 minutes, or intermittent clinical or electroencephalograph (EEG) seizures lasting more than 15 minutes without full recovery between seizure; ***refractory SE*** refers to clinical or EEG seizures lasting longer than 60 minutes despite treatment with at least one first-line and one second-line antiepileptic drug (AED);

super-refractory SE refers to refractory CSE that continues or recurs 24 hours or more after the onset of general anaesthesia administered to control the CSE.[3]

It is acknowledged that the biology and clinical features of CSE in young children differ from that in adults.[4] The common causes of CSE in children are:

- prolonged febrile convulsion
- epilepsy associated with the first presentation, AED withdrawal or intercurrent illness
- central nervous system (CNS) infection (e.g., meningitis or encephalitis)
- metabolic disturbance (e.g., hypoglycaemia, hyponatraemia, hypocalcaemia)
- trauma, including inflicted injury.

PATHOPHYSIOLOGY

Many physiological changes occur during prolonged seizures. There is an initial phase of compensation lasting less than 30 minutes. Following a period of transition there is a phase of decompensation commencing between 30 and 60 minutes and evolving over hours. Physiological changes during the compensated phase include tachycardia, hypertension, increased catecholamine release and increased cardiac output. Changes within the brain include increased cerebral blood flow and increased cerebral utilisation of glucose and oxygen. After 30–60 minutes the mechanisms for homeostatic compensation fail. During the decompensated phase there may be falling blood pressure and cardiac output, hypoglycaemia, hypoxia, acidosis, electrolyte disturbance and rhabdomyolysis. The cerebral physiology is characterised by failing autoregulation and reduced cerebral blood flow, and oxygen and glucose utilisation. Over hours a deficit in brain energy develops and this is associated with the development of brain damage.[5]

EXCITATORY AMINO ACIDS AND BRAIN INJURY

Mesial temporal sclerosis is the most common acquired brain lesion following CSE. There is evidence that the accumulation of a number of excitatory and inhibitory amino acids has a role in the pathophysiology of neuronal injury. In particular, glutamate accumulation and stimulation of *N*-methyl-D-aspartate receptors (NMDAR) lead to an influx of intracellular calcium, which triggers a number of cytotoxic events and ultimately cell death.[6]

MANAGEMENT

The initial management is as for other neurological emergencies, with attention to the airway and oxygenation. Most seizures in childhood cease spontaneously in a short time, but if they persist after presentation to an emergency department they should be stopped to avoid metabolic and ischaemic neuronal damage. Hypoglycaemia should be excluded or detected early.

FIRST-LINE THERAPY

Benzodiazepines remain the first-line AED for stopping seizures and should be administered for seizures that do not stop spontaneously within 5 minutes. The efficacy of benzodiazepines is reduced if administration is delayed.[7] Therefore, there is strong argument for first-line therapy to be administered pre-hospital either by the parents, care providers or paramedics.[8] Intravenous access is unlikely in the community; however, midazolam can be administered via the buccal, intranasal or intramuscular route. Buccal midazolam is more effective, easier and more socially acceptable to administer than rectal diazepam.[9–11] Once intravenous access is available lorazepam is usually considered the drug of choice because, compared with diazepam, it is at least as effective, is safer and has a longer duration of action.[12–14] If a seizure has not responded to two doses of benzodiazepine, a second-line AED should be administered. If a benzodiazepine has been administered prehospital then only one further dose should be administered in the emergency department.

SECOND-LINE THERAPY

Traditionally phenytoin has been the second-line AED of choice in most situations. It is given as 20 mg/kg IV over 20 minutes, which is followed by maintenance dosing (4–8 mg/kg/day in 2–3 doses). It causes minimal sedation or respiratory depression, but is not suitable in neonates and in patients who are already on maintenance doses. Fosphenytoin, a prodrug of phenytoin, can be administered intramuscularly and has less irritant effect when given IV.[15] Fosphenytoin is used preferentially in the United States. When phenytoin is contraindicated, phenobarbitone (20 mg/kg IV over 20 minutes) should be given. Respiratory depression and hypotension can occur with phenobarbitone, particularly when administered after benzodiazepines. Further doses can be safely administered to ventilated children who have ongoing seizures. Intravenous levetiracetam is now used in some centres as the second-line AED of choice due to the superior safety profile and the capacity to administer the drug more rapidly than phenytoin or phenobarbitone.

THIRD-LINE THERAPY

Levetiracetam, more commonly considered a third-line AED, is effective against a broad range of seizure types and can be administered enterally or IV. Case series have described the use of intravenous levetiracetam at doses of 20–60 mg/kg in children with CSE and reported the drug to be safe and effective either as a single agent or in combination with other AEDs.[16] Rapid infusion of leviteracetam of up to 60 mg/kg (maximum 3 g) infused over 6 minutes has been reported without adverse cardiorespiratory effects.[17] Valproate is commonly used for maintenance therapy in epilepsy. There are several reports of successfully using intravenous valproate to abort CSE in children.

The doses reported range from 20 to 40 mg/kg. The rate of infusion reported also varies from 5 to 30 minutes.[18] Valproate can rarely cause encephalopathy or hepatotoxicity. Therefore levetiracetam may have a safety advantage over valproate as a third-line agent for CSE. In some centres rectal paraldehyde (0.3 mL/kg, max 5 mL, mixed with an equal quantity of olive oil) is used in the management of CSE. One advantage of paraldehyde is that it can be administered rectally if intravenous access is difficult to obtain.

FOURTH-LINE THERAPY

If CSE continues for longer than 30–60 minutes despite the administration of two or at most three different AEDs, induction of intravenous anaesthesia should occur followed by intubation and ventilation and admission to intensive care. Thiopentone 2–5 mg/kg slowly IV then 1–5 mg/kg per hour by continuous infusion into a central vein can be given. Thiopentone necessitates endotracheal intubation and mechanical ventilation, and possibly inotropic drugs to counter its hypotensive effects. Continuous EEG monitoring is recommended with a target end-point of burst suppression. If breakthrough seizures occur repeating bolus doses of 1–2 mg/kg should be administered. If dosing is titrated by adjusting the infusion rate without repeat bolus dosing, unnecessary delay in achieving the therapeutic goal will occur. Blood concentrations need to be monitored during prolonged use. Thiopentone infusions are associated with significant risks of hypotension, infection (particularly ventilator associated pneumonia), and ileus. Midazolam infusion has been used as an alternative to thiopentone. After a bolus of 0.2 mg/kg (maximum 10 mg) an infusion is commenced at 0.1 mg/kg per hour. If seizures continue or recur the bolus dose is repeated and the infusion is increased up to 1 mg/kg per hour if tolerated, although even higher doses have been reported.[19–21] High doses necessitate mechanical ventilation for respiratory depression; however, lower doses are effective at controlling CSE in some cases without the need for ventilation. There are also small case series describing the use of ketamine to control refractory CSE in children with requirement for ventilation.[22]

Finally, continuous administration of inhalational anaesthetic agents can be used in ventilated intensive care unit (ICU) patients resistant to other therapeutic strategies. General anaesthesia is not without risk, but is highly effective at controlling CSE, and can provide time to adjust the dose and stabilise the levels of other AEDs.

OUTCOME

The outcome of CSE is dependent on the aetiology. Neurologically normal children in whom CSE is precipitated by fever are considered to have a good prognosis with mortality reported between 0% and 2%.[23] The incidence of neurological deficits or cognitive impairment in this group is also very low. In acute symptomatic CSE (where CSE is a symptom of an acute neurological process such as infection or trauma) mortality is 12–16% and the incidence of new neurological dysfunction is more than 20%.[23] However, in this setting it is very difficult to tease out the extent to which prolonged seizures contribute to neurological sequelae.

ELECTROGRAPHIC STATUS EPILEPTICUS

Electrographic status epilepticus (ESE) is relatively common in critically ill children. Retrospective studies of continuous EEG monitoring in symptomatic or encephalopathic children in paediatric intensive care unit have reported that 30% of monitored children were found to have electrographic seizures. Approximately one-third of cases were ESE and another third had electrical seizures with no clinical manifestations.[24] ESE but not electrical seizures (without status) is associated with worse neurodevelopmental outcomes and increased mortality.[24,25] However, it is not known if the ESE itself contributes to permanent neurologic injury, or if the presence of ESE is a maker of more severe brain disease. Risk factors for ESE have been identified, including young age, convulsive seizures or CSE prior to EEG monitoring, acute structural brain injury, and interictal eleptiform discharges. However, it is not possible to accurately predict which critically ill children will have ESE.[26] Acknowledging that resources for continuous EEG monitoring vary between centres, ICUs should develop local guidelines for selecting suitable cases for continuous EEG monitoring.

BACTERIAL MENINGITIS

PATHOPHYSIOLOGY

Bacterial meningitis (BM) usually occurs following haematogenous spread of organisms carried in the nasopharynx. In childhood the common bacteria causing BM are *Streptococcus pneumoniae*, *Neisseria meningitidis* and *Haemophilus influenzae* type b (Hib). Group B *Streptococcus*, *Escherichia coli* and *Listeria monocytogenes* are the most common causative organisms of neonatal BM. Occasionally, meningitis occurs as a complication of other pathology such as base of skull fracture, chronic middle ear infection or infection of a congenital dermoid sinus.

In the early stages of the disease cerebral hyperaemia occurs. This can be followed by cerebral ischaemia, which may occur by several different mechanisms. Local vasculitis of vessels traversing the subarachnoid space can progress to arterial thrombosis and focal infarction. Other vascular abnormalities, including vasospasm and sagittal sinus thrombosis, can also occur. Cerebral oedema is relatively common in

meningitis and is caused by a combination of vasogenic, cytotoxic and hydrostatic factors. If cerebral oedema is severe, raised ICP and impaired cerebral perfusion can occur, leading to global cerebral ischaemia.

CLINICAL FEATURES

In children the typical features of BM are fever, headache, photophobia, neck stiffness and vomiting. The history may extend over several days; however, in fulminant cases the time from first symptom to coma and death may only be a few hours.[27] Neonates and young infants do not present with the typical localised symptoms and signs. Instead, they present with generalised signs of illness including lethargy, poor feeding and pallor. Generalised or focal convulsions, or apnoea may be the presenting clinical symptoms. Tuberculous meningitis usually presents with a more insidious onset of symptoms and may be associated with focal neurological signs.

Complications occur commonly in BM. During the early phase, meningitis may be associated with septic shock and disseminated intravascular coagulation. Fluid and electrolyte abnormalities are relatively common, particularly hyponatraemia and hypoglycaemia. Focal and generalised convulsions are also relatively common and may progress to status epilepticus. During the recovery phase subdural effusions or hydrocephalus may occur.

INVESTIGATIONS

LP for CSF microscopy, culture, and polymerase chain reaction (PCR) testing is required for definitive diagnosis of BM, and to guide antibiotic therapy. Although an LP can be performed safely in the majority of children with BM, it may precipitate brainstem herniation if raised ICP is present.[28] Identifying children at risk of this complication is difficult; however, it is generally recommended that empirical antibiotic therapy be commenced and LP deferred if any of the following clinical features are present: depressed conscious state, decorticate or decerebrate posturing, focal neurological signs or other signs of raised ICP. A normal CT scan does not exclude the possibility of elevated ICP.[28] Therefore, the decision to defer an LP should be based on clinical rather than radiological signs. In addition to signs of increased ICP, other indications for deferring the LP include cardiorespiratory instability, and severe coagulopathy. If LP is deferred, alternative methods of establishing a bacterial diagnosis include blood culture and PCR testing of blood.[29,30]

MANAGEMENT

RESUSCITATION

Severely ill patients require rapid resuscitation. Comatose patients require intubation and ventilation to prevent airway obstruction and hypoventilation. Hypovolaemia should be treated rapidly with boluses of fluid. Patients with septic shock will also require inotropic support.

CEREBRAL RESUSCITATION

General principles of supporting brain injury apply to BM. These include optimising cerebral oxygen delivery, controlling ICP and preventing cerebral metabolic stress. The role of ICP monitoring is controversial. There is some anecdotal evidence to support the use of ICP monitoring in a small number of selected cases. Unfortunately, there are no large studies that assess the benefit or harm of ICP monitoring and ICP-targeted therapy in BM.

ANTIBIOTIC THERAPY

Empirical broad-spectrum antibiotics should be selected based on likely pathogens and local resistance patterns. A common protocol for BM is to use ampicillin plus cefotaxime for the first 3 months of life and to use a third-generation cephalosporin (cefotaxime or ceftriaxone) after 3 months of age.[31] In regions where penicillin- and cephalosporin-resistant *Pneumococcus* occurs, vancomycin should be added to the initial empirical antibiotics until the causative organism is identified and the antibiotic sensitivities are known. When cephalosporin-resistant *Pneumococcus* are found to be the causative organism in meningitis, both a third-generation cephalosporin and vancomycin should be continued as vancomycin penetrates into CSF poorly and therefore should not be used as a single agent. The addition of rifampicin should be considered.[32]

ADJUVANT THERAPY

If dexamethasone is used as adjuvant therapy it should be used only for children over 3 months of age and ideally be given before the first dose of antibiotics and continued for 4 days (0.15 mg/kg 6 hourly).[33] There is evidence that dexamethasone reduces the incidence of neurological sequelae and sensorineural deafness; however, the beneficial effects are greatest in Hib meningitis *(Haemophilus influenzae)*.[34,35] A meta-analysis of steroid trials in BM suggest that the improved outcome with steroids is seen in high-income but not low-income countries.[36] With immunisation, changing epidemiology and the emergence of antibiotic-resistant pneumococcal strains, it is possible that the relationship between risk and benefit of dexamethasone therapy has changed. However, current recommendations support the use of dexamethasone prior to or at the time of the first doses of antibiotics for children older than 3 months of age with BM.[31,32] Oral glycerol has also been investigated as an adjuvant agent. One large randomised controlled trial and a meta-analysis demonstrated reduced neurological sequelae and reduced hearing loss with oral glycerol compared with placebo.[37,38]

FLUID THERAPY

There is consensus that hypovolaemia should be treated rapidly and aggressively; however, fluid therapy after the initial resuscitation is controversial. Hypotonic fluids should not be administered in BM owing to the risk of hyponatraemia and cerebral oedema.[39,40] Hyponatraemia is often attributed to the syndrome of inappropriate antidiuretic hormone (ADH) secretion and therefore fluid restriction is logical. However, there is evidence that ADH is *appropriately* elevated in response to hypovolaemia[41] and that hyponatraemic patients with BM tend to be more dehydrated than normonatraemic patients.[42] Compared with fluid restriction, fluid therapy aimed at providing maintenance plus correcting the fluid deficit has been reported to result in a more rapid correction of sodium and ADH[41,43] and has also been associated with reduced short-term morbidity and neurological sequelae at follow-up.[44] The trials of fluid therapy in BM have all been undertaken in low-income countries where delayed presentation is common. The effect of fluid therapy on the outcome of BM in populations where children present early and mortality is low is unknown.

OUTCOME

Bacterial meningitis is associated with significant mortality and morbidity. Overall mortality for BM in childhood is 5%–10%; however, in children requiring mechanical ventilation, a mortality rate of 30% has been reported with major neurological sequelae occurring in 33% of survivors.[45]

ENCEPHALITIS

Common causes of encephalitis include herpesviridae enteroviruses (herpes simples, varicella zoster, cytomegalovirus, Epstein–Barr), and respiratory viruses (adenovirus and influenzae). The most significant causes worldwide are the insect-transmitted arbovirus encephalitides including Australian (Ross River and Murray Valley), Japanese B and St Louis. These can cause profound coma and are associated with a significant incidence of residual neurological deficit.

Presenting symptoms of encephalitis include seizures, focal neurological deficits in the setting of an acute febrile illness, confusion and coma. Meningeal irritation may not be obvious. CSF analysis may show a pleocytosis, and in the early phase this can consist predominantly of neutrophils. Herpes simplex encephalitis is the most important diagnosis to make because it is treatable. EEG, CT and magnetic resonance imaging (MRI) are helpful in making the diagnosis. MRI is more sensitive than CT for detecting signs of encephalitis, particularly during the early stages of the illness. PCR on CSF may also aid rapid diagnosis.[46,47] Acyclovir, if used early, improves outcome and should be commenced when the diagnosis is suspected.

The enteroviruses are important causes of encephalitis in children. In addition they cause other acute neurological illnesses, including acute flaccid paralysis due to transverse myelitis and Guillain–Barré syndrome.[48] Pleconaril is a promising new antiviral agent that appears to have clinical benefit in enteroviral infections, including CNS disease.[49] Acyclovir is recommended for varicella zoster encephalitis, foscarnet and ganciclovir for cytomegalovirus and oseltamivir for encephalitis due to influenza.[50] The outcome of viral encephalitis is worse in infancy than in older age groups.

ANTI-*N*-METHYL-D-ASPARTATE RECEPTOR ENCEPHALITIS

Knowledge and understanding of immune mediated neurologic disorders is expanding rapidly. Several disorders have been described with clinical and laboratory features of encephalitis associated with the presence of auto-antibodies to either intracellular or neuronal surface antigens.[51] Of this group of disorders, anti-NMDAR encephalitis is the condition that most frequently presents in childhood and adolescence. A Californian study of encephalitis epidemiology found anti-NMDAR encephalitis to be more common than the most frequent type of viral encepahalitis (enterovirus).[52]

Approximately 60% of children present with psychiatric symptoms such as psychosis or hallucinations. Younger children may present with behavioural change, temper tantrums or hyperactivity. Altered behaviour can progress to unresponsiveness fluctuating with periods of agitation. Other presenting symptoms can be movement disorders (including dystonia, dyskinesia, chorea, choreoathetosis, ataxia, catatonic posturing or myoclonus), seizures or status epilepticus. Autonomic instability (hypertension, tachycardia or hyperthermia) or central hypoventilation necessitating mechanical ventilation may occur during the acute phase of the illness.[51,53]

INVESTIGATION

Once suspected, the diagnosis is confirmed by detection of serum and CSF NMDAR antibodies. CSF analysis may reveal mild pleocytosis, elevated protein and oligoclonal bands; however, CSF may be normal initially. MRI may be normal or demonstrate nonspecific T2 or fluid-attenuated inversion recovery (FLAIR) signal hyperintensity in the frontal or parietal cortex, hippocampus, basal ganglia cerebellum or brainstem.[54] Anti-NMDAR encephalitis can be a para-neoplastic condition associated with ovarian, testicular or mediastinal teratomas, Hodgkin lymphoma and neuroblastoma. Therefore screening for tumours

should be undertaken with abdominal, pelvic and testicular ultrasound followed by abdominal and thoracic MRI.

MANAGEMENT

There is evidence that early treatment improves outcome. If present, tumour removal speeds recovery. First-line immunotherapy consists of high-dose methylprednisolone, intravenous immunoglobulin (IVIG) or plasmapheresis and should be administered regardless of whether or not a tumour is identified and removed. Patients who do not respond or who relapse should be considered for second-line therapy with more aggressive and sustained immunosuppression using rituximab or cyclophosphamide.[51,54]

Therapeutic decisions are challenging as clinical recovery is slow and there is little evidence to support different treatment strategies. Supportive medical therapy is often required; sedation may be needed for agitation, and psychiatry consultation should be sought for the management of behavioural disturbance or psychosis.

OUTCOME

Recovery from anti-NMDAR encephalitis is slow over weeks to months. Prolonged hospitalisation and rehabilitation is usually required.[54] Complete recovery is reported in about 50% of children and adolescents with the condition, with another 30% considered to have a good outcome at 2 years.[55] Cognitive sequelae include impaired memory and executive functions. Relapse occurs in 10–15% of patients.

NONTRAUMATIC INTRACRANIAL HAEMORRHAGE

Nontraumatic intracranial haemorrhage (ICH) is uncommon in children. Arteriovenous malformations (AVM) are a more common cause of haemorrhage in children than aneurysms (Box 111.2).[56] The presenting features are similar to those seen in adults, and include sudden severe headache, altered conscious state and seizures. Diagnosis can usually be made by CT scan. Raised ICP, if present, is managed in the usual manner. A mass lesion or acute obstructive hydrocephalus requires neurosurgical assessment. Following a diagnosis of ICH, further investigations may be required to clarify the underlying cause. These include coagulation profile and platelet count. Angiographic images can be obtained with CT, MRI, or digital subtraction. In some cases, definitive cerebral angiography may be required to define the underlying vascular malformation or tumour. Definitive surgery or endovascular treatment of an AVM can be planned once the underlying lesion has been defined. A period of close observation is required as children may be at greater risk of rebleeding from an AVM than adults. The efficacy of therapies (e.g. calcium channel blockers) used to prevent vasospasm in adults has not been studied in children with aneurysmal haemorrhage. Sequelae of ICH include hemiparesis, aphasia, seizures and hydrocephalus.

HYPOXIC–ISCHAEMIC ENCEPHALOPATHY

The most common causes of hypoxic–ischaemic encephalopathy outside the neonatal period are:

- near-miss sudden infant death syndrome
- immersion
- accidents, including drug ingestion and strangulation
- inflicted injury.

PATHOLOGY

The brain depends on an uninterrupted supply of oxygen and glucose to produce, via aerobic glycolysis, sufficient high-energy adenosine triphosphate (ATP) to maintain neuronal membrane and synthetic function. Under anoxic conditions anaerobic glycolysis occurs, which produces lactic acid but less ATP (by 18 times). As there are virtually no stores of ATP, rapid neuronal failure ensues. If ischaemia accompanies hypoxia, there is associated failure of both substrate delivery and metabolic waste removal, which amplifies the cellular insult. Ischaemia produces coma in less than 10 seconds and cerebral damage in as little as 2 minutes.

Following restoration of cerebral blood flow there is a period of relative hyperaemia followed by relative hypoperfusion. Cytotoxic cerebral oedema may subsequently develop, but significant elevation of ICP is unusual unless ischaemia and damage are profound.

MANAGEMENT

The principles of therapy are similar to those for other brain injuries. It is mandatory to provide rapid cardiopulmonary resuscitation and prevent secondary insults. In cases of out-of-hospital cardiac arrest, full resuscitation must be attempted while the history is sought. Post-resuscitation care is important for optimising outcome. Comatose patients with hyper- or hypotonia and a GCS score <8 are probably best managed by mechanical ventilation and sedation for at least 1–2 days, although benefits are not proven. Ventilation should be targeted at normocapnoea, and hyperventilation avoided owing to the risk of further cerebral ischaemia.[57] Haemodynamic disturbance may develop because of primary cardiac dysfunction or hypovolaemia secondary to fluid loss from capillary leak syndrome. Circulating volume should be restored, and inotropic agents considered, to improve the state of the circulation. The dose and choice of vasoactive agent should be individualised based on haemodynamic monitoring.

Following cardiac arrest children are usually hypothermic. Fever commonly develops during the subsequent hours and is associated with worse outcome.[58] There are trials in adults following cardiac arrest[59,60] and trials in newborns following birth asphyxia[61,62] demonstrating improved neurological outcome if hypothermia is used for between 12 and 72 hours. A more recent adult trial demonstrated that fever prevention with 'therapeutic normothermia' was as effective as 'therapeutic hypothermia'.[63] Two recent trials of therapeutic hypothermia following out-of-hospital and in-hospital cardiac arrest in children did not show any difference in survival with good functional outcome between the intervention and the control groups.[64,65] Therefore therapeutic hypothermia cannot be recommended following cardiac arrest in children; however, temperature should be actively managed to prevent fever. Hyperglycaemia has been associated with a worse prognosis and, although it may simply be a marker of injury severity, active treatment has been advocated. The role of ICP measurement is limited as intracranial hypertension usually occurs only in the setting of severe injury and poor outcome.[66]

PROGNOSIS

The major determinants of recovery are ischaemic time, cerebral metabolic rate and quality of resuscitation. There are no simple clinical rules to reliably predict outcome when a child presents following cardiac arrest. Factors that should be considered include the duration of cardiopulmonary resuscitation (CPR), the cause of arrest, pre-existing medical conditions, the location of the arrest, whether the arrest was witnessed and, the duration of arrest before resuscitation commenced.[67] In general, survival from out-of-hospital cardiac arrest is unlikely if asystole is present on arrival at hospital.[68] In immersion injuries in young children, full recovery may be possible despite prolonged ischaemia if sufficient rapid cerebral cooling has occurred. In these cases the onset of ischaemia may be delayed by bradycardia with preferential cerebral flow (the 'diving reflex'). Prolonged CPR may be justified in selected cases when profound hypothermia was induced rapidly. Coma persisting for more than 24 hours is a predictor of poor prognosis and minimal long-term improvement is likely in this group.[69] Residual neurological deficits present at the end of the first week are less likely to improve following ischaemic injury than following traumatic brain injury.

A number of ancillary tests have been investigated as predictors of neurological outcome. Somatosensory evoked potentials (SEPs) performed at the bedside are the most useful aid to prediction. One report of 109 children with severe brain injury concluded that, with appropriate patient selection, the positive predictive value for poor outcome of bilaterally absent SEPs is 100% (95% confidence interval 92%–100%).[70]

GUILLAIN–BARRÉ SYNDROME

CLINICAL FEATURES

Guillain–Barré syndrome (GBS) is characterised by acute areflexic paralysis with raised CSF protein and normal CSF cell counts. It is the most common cause of acute motor paralysis in children. There is strong evidence to support an autoimmune cause with many patients having raised anti-ganglioside antibodies. Many cases are preceded by symptoms of upper respiratory tract infection or diarrhoea. Infectious agents associated with subsequent development of GBS include *Campylobacter jejuni*, cytomegalovirus, Epstein–Barr virus, varicella zoster virus and *Mycoplasma pneumoniae*. An emerging association between GBS and acute arbovirus infection, including Zika virus, is being closely monitored globally.[71,72] The syndrome includes a number of peripheral nerve disorders that have been classified based on the distribution of weakness, antibody profiles and nerve conduction studies.[73]

Although most patients develop typical ascending, symmetrical areflexic weakness, GBS may present insidiously with apparent lethargy or loss of motor milestones in the young child. There also may be rapid progression and admission criteria to the ICU, which include respiratory failure, bulbar palsy, severe autonomic disturbance or rapidly progressive weakness. Sensory loss is usually minimal and transient. Pain in the back and legs, possibly neurogenic in origin, is common and may be the presenting feature.[74] This pain may be severe and is often difficult to control. Papilloedema and encephalopathy occasionally occur.[75] The complications of deep-venous thrombosis and thromboembolism are not common problems in young children but they may occur in adolescents.

INVESTIGATIONS

An LP should be done ideally before treatment with IVIG is commenced. CSF typically shows a WCC <10 $\times 10^6$, while CSF protein is usually raised but may be normal during the first week of illness. Nerve conduction studies may be normal if performed early. Neurophysiological criteria have been used to classify GBS subtypes according to either demyelinating or axonal neuropathies, and whether or not both sensory and motor nerves are involved.[76] Antiganglioside antibodies are raised in some but not all patients.[77]

If there is uncertainty about the clinical diagnosis then brain and spinal cord imaging, as well as screening for infection, should be considered. Contrast-enhanced spinal MRI demonstrates contrast enhancement of spinal nerve roots and the cauda equina in most patients with GBS.[78,79]

MANAGEMENT

Adequate respiratory care is the basis of minimising morbidity and mortality in GBS. Up to one-third of patients require ventilatory support and, ideally, mechanical ventilation should be undertaken electively. Early indications are increased work of breathing, fatigue, poor cough and progressive bulbar palsy. Hypercarbia is a late sign and should be avoided. In children who are old enough to cooperate, forced vital capacity (FVC) should be monitored during the progressive phase of the illness. Mechanical ventilation should be considered if FVC falls below 15–20 mL/kg. Careful frequent clinical assessment is necessary. Once mechanically ventilated, many patients require some degree of hyperventilation to prevent 'air hunger'. Although nasotracheal intubation is satisfactory initially, a tracheostomy should be performed if recovery is delayed. This will improve comfort and allow speech via the ventilator generating an air leak around the tracheostomy tube. Successful weaning is unlikely unless vital capacity exceeds 12 mL/kg and maximum negative inspiratory force is at least 20 cm H_2O (2 kPa).

Autonomic dysfunction is an important cause of morbidity and mortality in children with GBS. Airway manipulation or induction of anaesthesia, particularly in the presence of hypoxia, may provoke serious cardiac arrhythmias. Fluctuating blood pressure, urinary retention and gut dysfunction also occur.

Plasma exchange (PE) and IVIG are effective therapies. The indications for either are rapid progression, respiratory insufficiency or weakness to the point of being unable to walk unassisted. The strongest evidence for these therapies is from adult trials.[80–82] Large trials adequately powered to separately test the efficacy of PE and IVIG in children have not been performed; however, a number of small retrospective studies have described local experiences with these immune therapies in children with mixed results.[83–87] As IVIG has significant potential technical advantages over PE, IVIG is generally the first-line therapy in children. Indications for IVIG are based on the degree of functional impairment and time from onset of symptoms. The indications are not influenced by the clinical or neurophysiological subtype, or the results of antibody screening. There is no evidence to support sequential treatment using both PE and IVIG.[88,89]

Pain is a common feature of GBS and may have a neuropathic basis. Paracetamol or nonsteroidal anti-inflammatory drugs are useful, while drugs to treat neuropathic pain, including gabapentin, carbamazepine and amitriptyline, may also be beneficial.

The problems of long-term ventilation in a conscious patient, compounded by emotional immaturity, speech failure, fear of procedures and family disruption, make the management of a child with GBS and their family particularly challenging. A sensitive team approach is essential.

PROGNOSIS

The prognosis in acute GBS may be better for children than for adults. Full recovery is likely if the time from maximal deficit to onset of recovery is less than 18 days. However, complete recovery, despite a longer plateau phase, has been reported. Good recovery can occur in patients who have required ventilation and the need for ventilation may not be a poor prognostic factor in children.[83] Those presenting with a subacute course are at risk of relapse and permanent motor deficits.

ACUTE DISSEMINATED ENCEPHALOMYELITIS

Acute disseminated encephalomyelitis (ADEM) is defined as an episode of inflammatory CNS demyelination with polyfocal neurological deficits accompanied by encephalopathy (behavioural change or altered consciousness). The condition is one of several demyelinating conditions that occur in childhood including transverse myelitis, optic neuritis and multiple sclerosis. The clinical features of ADEM include encephalopathy (which is required to make the diagnosis), ataxia, hemiparesis, cranial nerve palsies, hypotonic, seizures and polyfocal neurological deficits.[90] The encephalopathy varies in severity from subtle signs of irritability and headache to life-threatening coma and decerebrate rigidity. Respiratory failure can occur from brainstem involvement or a severely impaired conscious state. Case series have reported a requirement for mechanical ventilation in 11–16% of patients.[91,92]

ADEM is preceded by a triggering event in 70% of cases, most commonly a nonspecific upper respiratory tract infection or occasionally a recent vaccination. Common agents associated with the prodromal phase include Epstein–Barr virus, cytomegalovirus, herpes simplex virus and *Mycoplasma*; however, in the

majority of cases a specific agent cannot be identified. Although the precise immunopathogenesis of ADEM is unknown, there is a consensus that ADEM is mediated by an autoimmune reaction with antibody formation to myelin.

INVESTIGATION

LP should be performed to exclude infectious encephalomyelitis. There may be a modest elevation of the CSF white cell and red cell counts. CSF oligoclonal bands and raised CSF immunoglobulin levels occur more commonly in multiple sclerosis than in ADEM.[90] MRI with T2 and FLAIR show bilateral asymmetrical hyperintense demyelinating lesions. The lesions predominantly involve the deep white matter, juxtacortical white matter and deep grey nuclei. Lesions can also occur in the brainstem, cerebellum and spinal cord. The size of lesions varies from punctate to large tumefactive (puffy/swollen) mass-like lesions.[93] Some patients with ADEM have normal MRI findings on initial presentation, but develop features typical of ADEM if the study is repeated several weeks later. In some patients the MRI changes first appear at a time when clinical improvement is occurring.[94]

A large number of infective, inflammatory metabolic and rheumatologic conditions can mimic the MRI appearances of ADEM. Therefore it is important to have a systematic approach to investigations for potential differential diagnoses. Red flags that suggest an alternative diagnosis include age of onset less than 1 year; developmental delay; gradual progression; multisystem involvement; or a family history of consanguinity or severe neurologic symptoms. MRI features that suggest an alternative diagnosis include a single supratentorial white matter lesion, symmetrical white matter involvement or lesions restricted to the brainstem or basal ganglia.[95]

MANAGEMENT

Although there are no randomised therapeutic trials in ADEM, high-dose corticosteroids are considered the treatment of choice. Intravenous methylprednisolone 30 mg/kg/day (maximum 1 g/day) for 3–5 days followed by oral prednisolone tapered over 4–6 weeks often results in rapid clinical improvement. Other treatment options include IVIG (2 g/kg intravenously for 2–3 days) and plasmapheresis.[96]

OUTCOME

Most children with ADEM recover completely, although a small percentage of children have significant neurological and neuropsychological sequelae. The most common neurocognitive abnormality identified at long-term follow-up is impaired attention.[97] Rarely is ADEM fatal. Approximately 20% of children initially diagnosed with ADEM experience a recurrence of neurological symptoms and subsequently receive the diagnosis of multiple sclerosis.[98]

METABOLIC ENCEPHALOPATHY

Approximately 0.1% of babies have an inborn error of metabolism. Acute encephalopathy is one of the many ways neurometabolic diseases present in childhood.[99] In general, acute presentations occur in the neonatal period and early infancy. Symptoms are often vague and include lethargy, poor feeding and vomiting. Some in-born errors do not present until later in childhood or even in adulthood. Although older children may present with a chronic encephalopathy, they may also present with an acute metabolic emergency, which is usually precipitated by an inter-current illness or catabolic stress.

APPROACH TO DIAGNOSIS

A careful history and examination may elicit clues to a possible metabolic problem. Family history and history of drug exposure are extremely important. Valproate, in particular, has been associated with liver dysfunction and encephalopathy. The following readily available investigations are useful to allow broad categorisation and to direct further detailed investigations: blood gas analysis; blood glucose; serum ammonia; serum lactate; plasma amino acids; blood and urine ketones; and urine metabolic screen for amino, orotic and organic acids. While lactic acidosis and hypoglycaemia can occur in a number of disease states including sepsis, persisting abnormalities require further investigation. Lactic acidosis can be further assessed with measurement of lactate/pyruvate ratio. Fig. 111.1 provides an algorithm proposed by Ellaway and colleagues to direct the investigation of metabolic disease presenting in the newborn period based on the metabolic abnormalities detected from baseline investigations.[100] This is best done in collaboration with a metabolic disease specialist or a clinical biochemist.

MANAGEMENT

Initial management includes elimination of toxic metabolites and administration of calories to switch off catabolism. Metabolic derangements, such as acidosis and hypoglycaemia, should be corrected. The role of ICP monitoring for acute intracranial hypertension is controversial; however, patients with suspected raised ICP, and unconscious patients, should receive standard modalities of support including intubation and mechanical ventilation. Hyperammonaemia should be managed by stopping enteral feeds to limit protein intake. Agents, such as arginine and sodium benzoate, can be administered to increase ammonia metabolism. Providing calories intravenously in the form of glucose

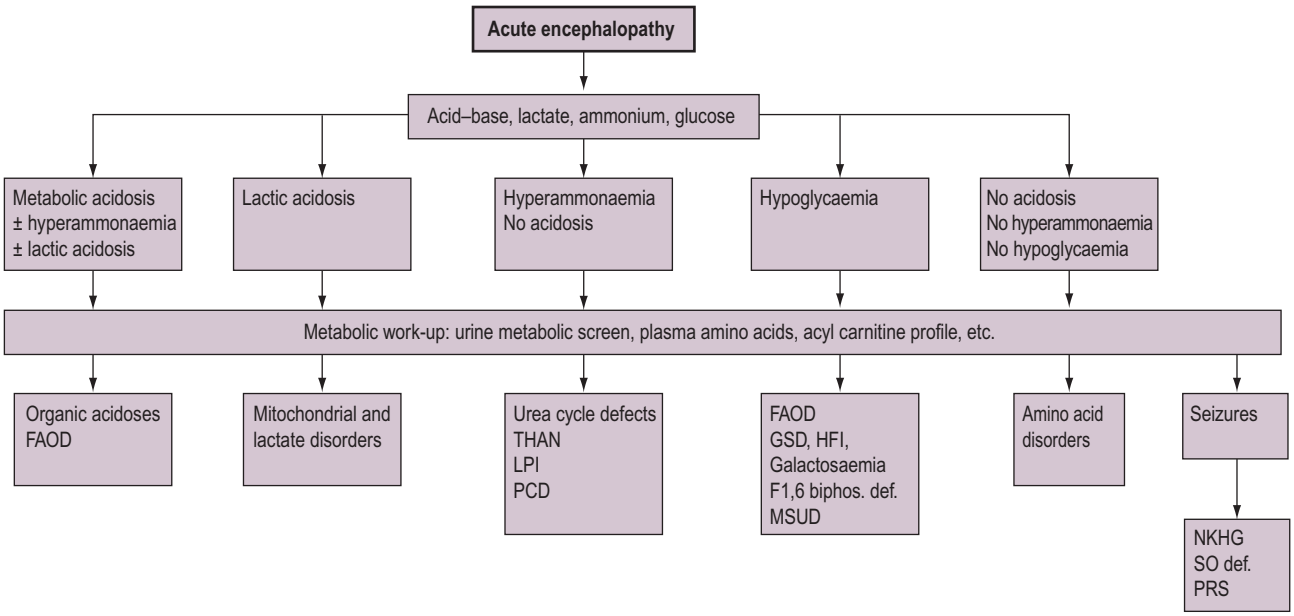

Figure 111.1 Flow diagram to guide investigation of inborn errors of metabolism presenting in the newborn period. *FAOD*, Fatty acid oxidation disorder; *F1,6 biphos. def.*, fructose 1,6 biphosphatase deficiency; *GSD*, glycogen storage disorder; *HFI*, hereditary fructose intolerance; *LPI*, lysinuric protein intolerance; *MSUD*, maple syrup urine disease; *NKHG*, nonketotic hyperglycinaemia; *PCD*, pyruvate carboxylase deficiency; *PRS*, pyridoxine-responsive seizures; *SO def.*, sulphite oxidase deficiency; *THAN*, transient hyperammonaemia of the newborn.

and fat limits the extent of catabolism and thereby helps to curtail the metabolic crisis. Haemodiafiltration is effective at controlling hyperammonaemia (urea cycle defects), leucine toxicity (maple syrup urine disease) and propionic acid (propionic acidaemia).[101,102]

SPINAL INJURY

INCIDENCE

Paediatric spinal trauma is relatively rare, comprising <5% of all spinal injuries. Approximately 5% of children with severe head trauma will have a cervical spine injury. However, a high proportion of children who die following motor vehicle trauma, particularly those who suffer immediate cardiorespiratory arrest, or who die before arrival at hospital, have disruption of the spinal cord above C3, particularly at the cervicomedullary junction.[103] The most common causes of paediatric spinal trauma are motor vehicle crashes, as either a pedestrian or passenger, falls, and diving injuries. Sports-related injuries are uncommon.

PATHOPHYSIOLOGY

The patterns of spinal injury in children differ from those seen in adults in many ways. Spinal cord injury without radiographic abnormality (SCIWORA) occurs almost exclusively in children (20%–60% of spinal cord injuries). It is associated with a high incidence of complete neurological deficit. Spinal injury in the first decade of life occurs most commonly in the first two cervical segments, with atlanto-axial rotatory subluxation, bony or ligamentous injuries, or SCIWORA and severe cord injury. Although not as common as upper cervical injuries, lower cervical injuries (below C4) do occur in young children,[104] while injury may occur at more than one level. Atlanto-axial rotatory subluxation may occur after minor trauma or without an identifiable precipitating event, and is rarely associated with neurological deficit. However, ligamentous injury is more likely to be associated with permanent neurological deficit than high cervical fractures. As the bony spine matures, the pattern of injury becomes more adult-like, with lower cervical and thoracic injuries seen in the second decade.[105]

CLINICAL FEATURES

The immediate effects of spinal cord damage are similar at any age. Frequently, an associated head injury can render clinical assessment extremely difficult; confirmation of cord injury is sometimes delayed. Clues to the diagnosis in the unconscious patient include:

- flaccidity, immobility and areflexia below the level of the lesion
- hypoventilation with paradoxical chest movement; this occurs in the absence of airway obstruction

where the intercostal muscles are paralysed and the phrenic nerves are intact
- apnoea with rhythmic flaring of the alae nasi (Duncan's sign), which is seen when the lesion is above C3
- hypotension with inappropriate bradycardia and cutaneous vasodilatation below the level of injury, due to absent spinal sympathetic outflow
- priapism.

There may be visible or palpable evidence of trauma to the spine and surrounding soft tissues, including retropharyngeal or retrolaryngeal haematomas. Spinal shock is common with temporary complete loss of function. As this resolves after 3–5 days, reflexes progressively return, usually starting with bulbocavernosus and anal reflexes. Incomplete lesions, including the Brown–Sequard cord hemisection, and anterior and central cord syndromes may become apparent at this stage.

INVESTIGATIONS

Resuscitation, including emergency intubation, should not be delayed to perform X-rays. However, the entire spinal column should be X-rayed subsequently, to demonstrate the presence of subluxation, fractures or dislocations. MRI is useful both in the acute setting and in assessment at later stages and is now accepted as the standard for identifying haemorrhage, contusion or compression of the cord. CT produces better definition of bony injuries, and may also show cord involvement by haematomas, bone fragments and foreign bodies. SCIWORA was defined in an era before MRI was routinely available. In the majority of children with SCIWORA, MRI also will be normal; however, if intramedullary lesions are demonstrated with MRI, permanent neurological deficits are more likely.[106,107] Somatosensory-evoked potentials may be useful to evaluate the integrity of the spinal cord, particularly in the comatose patient.

MANAGEMENT

Achieving control of airway, ventilation and circulation is always the first priority. If tracheal intubation is indicated, and if stability of the neck is unknown, skilled assistance is necessary to immobilise the head and neck and to prevent flexion or extension. Because of the sympathectomised state in high cord injuries, a relatively low blood pressure can be expected even after hypovolaemia is corrected. Significant hypotension becomes more likely the higher the lesion and the younger the patient. Haemodynamic support with a vasoconstrictor, such as norepinephrine (noradrenaline), is useful if hypotension is problematic following restoration of intravascular volume. As up to 20% of patients will have multiple trauma, many will require major surgical procedures, during which the spinal cord must remain protected. If muscle relaxants are required 2–3 days following the injury, suxamethonium is contraindicated owing to the risk of fatal hyperkalaemia.

Adult trials of high dose steroids in acute spinal injury have been controversial[108,109]; however, there are no studies specific to children. Steroid administration is not recommended in acute spinal injury.[110]

As with brain injuries, preventing secondary injury is vital. Adequate perfusion of the cord should be ensured, as autoregulation of blood flow is lost after trauma. The vast majority of paediatric cervical spine injuries can be effectively treated nonoperatively. The most effective means of immobilisation appears to be achieved with halo devices or thermoplastic Minerva jackets. Consideration of primary operative therapy is recommended for isolated ligamentous injuries of the cervical spine and unstable or irreducible fractures or dislocations with associated deformity, including atlanto-occipital dislocation.[110,111]

The incidence of venous thromboembolism after spinal injury in adolescents approaches that in adults; therefore patients in this age group should receive standard prophylaxis. Venous thromboembolism is rare in prepubertal children (approximately 1%), and the risk–benefit ratio of routine prophylaxis in this age group is unknown.[112] There should be early consultation with a specialised spinal injuries unit. Optimal rehabilitation requires a team of orthopaedic and neurosurgeons, rehabilitation specialists, nurses, physiotherapists, occupational therapists, psychiatrists, social workers and schoolteachers.

PROGNOSIS

The prognosis of all spinal injuries in children may be better than in adults. In one series of 113 children with spinal column injuries, 55 (48%) had no neurological deficit and 38 (34%) had an incomplete deficit; of these, 23 (20%) made a complete recovery and 11 (10%) improved. The remaining 20 (18%) children had a complete cord injury; of these, 4 improved and 3 died.[103]

Paediatric trauma

Kevin McCaffery

In developed countries, trauma continues to be the leading cause of death in children over 1 year of age.[1] When the additional vast burden of morbidity is added, it is clear that this spectrum of pathologies deserve urgent, ongoing and proactive attention.

Paediatric trauma is *complex* – an easily overlooked concept, particularly for those who mostly care for traumatised adults, yet this understanding is crucial to the provision of an effective paediatric trauma service.

This chapter is written principally from the viewpoint of the intensive care specialist faced with a seriously injured child. As intensive care involvement frequently begins with a request to assist with pre-hospital care or retrieval, key management priorities for this phase are included in the wider intensive care discussion.

OPPORTUNITIES FOR INTERVENTION

Death following trauma has long been considered to have a trimodal distribution (immediate, early <4 hours and delayed). Later publications challenge this pattern of distribution, though the concept remains philosophically useful. A number of phases can be defined in the journey of a severely traumatised patient, requiring different types of intervention (Fig. 112.1). A mature 'trauma system' or 'trauma team' would be expected to be aware of and active in all phases of trauma management from pre-injury prevention to rehabilitation following definitive care.

TRAUMA

This phase is commonly unexpected and sudden, with little opportunity to mitigate harm. All useful interventions at the point of injury are derived from those emplaced during the pre-trauma phase. *The most important interventions in the management of trauma are those that prevent injury occurring in the first place.*

PRE-TRAUMA

In a number of areas, legislation and public safety campaigns have led to decreased morbidity and mortality. Notable successes lie in the areas of motor vehicle legislation (e.g. seatbelt laws, drink–driving legislation), bicycle legislation (cycle helmets and education), water safety (pool fencing, water safety and swimming lessons) and burn reduction (smoke detectors, limitation of hot water temperature).

By any measure, politicians and legislators rank amongst the most effective members of the expanded 'trauma team', though it should be noted that they can be susceptible to influence by pressure groups, as exemplified by the turbulent (and ongoing) evolution of swimming-pool fencing regulations in Australia.[2]

PRE-HOSPITAL CARE

Two models for pre-hospital care predominate in the Western world.[3] In the United States, the prevailing concept is that of 'scoop and run' by paramedical staff to designated 'trauma centres'. The principal driver of this process was the decreased battlefield mortality seen between World War II (4.5%) and the Vietnam War (1.9%). A number of innovations contributed to this decrease, but increasing rapidity of casualty evacuation to well-equipped surgical hospitals was a key feature.

Conversely, the model adopted by several European and Scandinavian countries involves the use of paramedic-crewed ambulances supported by a well-developed network of physician-manned ambulances – essentially mobile intensive care units.

On current evidence, neither system is demonstrably superior to the other, for it is likely that differences in such variables as geography and distance, prevalence of penetrating versus blunt trauma, and cost and resource implications will favour different models in different areas.

Furthermore, in comparison with adults, seriously traumatised children are more likely to require secondary transfer to a paediatric trauma centre after initial stabilisation is undertaken, owing to concentration of paediatric expertise in a smaller number of centres.

THE DEVELOPMENT OF 'TRAUMA TEAMS, CENTRES AND SERVICES'

The concept of multidisciplinary teams and institutions with specific interest and expertise in trauma

ABSTRACT

Trauma is the leading cause of childhood death above 1 year of age in developed countries, and differs in a number of important respects from adult trauma. Anatomical, physiological and developmental differences between ages result in differing injury patterns and often management. Assessment is increasingly challenging with decreasing age. Furthermore, concentration of paediatric trauma services into fewer institutions may lead to both increased likelihood of secondary transfers and increased time to definitive care. As with adult trauma, development of trauma teams and systems active in all phases of trauma from pre-injury through to rehabilitation may assist in the development of integrated trauma response systems for paediatric trauma and advocacy for public health measures aimed at trauma prevention.

management began to develop in the 1950s and 1960s. Currently, most developed countries have accreditation processes for trauma services and designate different centres by 'level' based on their capabilities.

In addition to doctors and nurses from acute specialties, such as the emergency department, surgical subspecialties, anaesthesiology and critical care, the wider multidisciplinary team frequently includes trauma coordinators, research staff and rehabilitation specialists such as physiotherapists, psychologists and social workers. Similarly, the remit of trauma teams, centres and services has expanded beyond simple care of the traumatised patient to include data collection and analysis, development of injury-prevention strategies, education and coordination of regional trauma services.

There is growing evidence that the development of trauma teams, centres and services improves outcomes for injured adults[4] and children.[5] However, opinion is more divided on whether or not outcomes for seriously traumatised children are improved when managed in designated paediatric trauma centres compared with adult trauma centres.[6,7]

SPECIFIC PAEDIATRIC TRAUMA PRESENTATIONS

Differing mechanisms of injury may be associated with specific patterns of injury in both children and adults, though anatomical and physiological differences between age groups will alter the pattern seen. Children requiring intensive care admission will have serious injury to one or more of the following systems.

TRAUMATIC BRAIN INJURY

Brain injury, resulting either directly from trauma or indirectly from hypoxic–ischaemic insult, accounts for the majority of deaths and long-term severe morbidity in paediatric trauma. Once the insult has occurred, management is entirely focused on the prevention of secondary insults and further damage. Conventionally this involves control of intracranial hypertension, defence of cerebral perfusion pressure (CPP) and minimisation of injurious factors such as seizures, hypo- or hyperglycaemia and fever. An overview of this topic is provided below, but those wishing a comprehensive review of the current evidence base behind current management of paediatric traumatic brain injury (TBI) are directed to guideline documents published by the Brain Trauma Foundation.[8]

PAEDIATRIC TRAUMATIC BRAIN INJURY: ANATOMICAL AND PHYSIOLOGICAL CONSIDERATIONS

Adult brain volume is reached around 6 years of age, whereas skull growth continues until around 16 years of age. Children thus have less room for brain swelling within the rigid skull. This is compounded by differences between children and adults in adaptive mechanisms to defend against raised intracranial pressure (ICP), including smaller relative cerebrospinal fluid (CSF) volumes, higher intracellular concentrations of sodium and impaired ability of neurons to extrude sodium. In addition to the propensity of smaller children to raised ICP, CPP may be further compromised by the similarities in autoregulation of cerebral blood flow between small and larger children, affording smaller patients less safety margin.[9]

NEUROLOGICAL ASSESSMENT AND MONITORING OF CHILDREN

Priorities of the assessment process are as follows:

- to benchmark neurological function over time
- to identify lesions and problems requiring treatment
- to identify prognostic markers.

Neurological assessment in childhood presents challenges in compliance with examination. An appreciation of child development and the use of age-appropriate tools (e.g. a modified Glasgow Coma Score) greatly facilitate this assessment. Assessment is best done as a process involving frequent clinical assessments over time, supplemented where indicated by targeted investigations such as computed tomography (CT) or magnetic resonance imaging (MRI).

Invasive monitoring of ICP and arterial blood pressure allows identification of deleterious ICP and permits calculation of CPP.

ICP monitoring should be zero calibrated at the tragus of the ear with the patient inclined 30 degrees. The target ICP threshold requiring management has not been defined in paediatrics, but current evidence would support an upper value of 20 mm Hg (2.66 kPa). Lower values of 15–20 mm Hg (2–2.66 kPa) may be more appropriate for small infants.

CPP is defined as *mean arterial pressure (MAP) – mean ICP*. Mean arterial pressure should be zero calibrated at the level of the right atrium with the patient inclined 30 degrees. It should be noted that the difference in zero level between ICP and MAP will not give a true CPP as stated, and that the error will increase with increasing patient length. It does, however, allow for standardisation of measurement within routine clinical practice. As with ICP, target CPP thresholds requiring management have not been defined for children, but current evidence *in TBI* supports a CPP target of ≥40 mm Hg (5.32 kPa) for 0–5-year-olds, and ≥50 mm Hg (6.65 kPa) for 6–17-year-olds.[10]

MANAGEMENT PRIORITIES IN THE CHILD WITH HEAD INJURY

Management of paediatric neurotrauma is entirely focused on minimising secondary injury to neurons. Principles include the following:

Management of intracranial pressure

This involves manipulation of intracranial contents as described in the Monroe–Kellie hypothesis. Thus, the intracranial volume lying within the incompressible skull is composed of brain tissue, blood and CSF, and any increase in the volume of one of the components must be compensated for by a reduction in volume of the others. Interventions may therefore manipulate the following volumes:

- **Blood compartment:** decreasing intracranial blood volume may be tackled in three ways:
  - *Extravasated blood:* significant collections require surgical evacuation.
  - *Venous compartment:* venous drainage may be optimised by avoidance of venous obstruction (spinal collar, internal jugular lines, excessive positive end-expiratory pressure [PEEP]) and patient positioning (30 degrees head up, head midline). One small paediatric study demonstrated that increased head-up bed angle decreased ICP but not CPP.[11] Judicious sedation and muscle relaxation decrease the incidence of coughing, shivering and asynchrony with mechanical ventilation.
  - *Arterial compartment:* manipulation of this compartment requires brain tissue with preserved autoregulation to P_{CO_2}, pH, viscosity and metabolic demand. Thus, mild hyperventilation will vasoconstrict these areas, thereby decreasing the volume of the arterial bed. Prolonged or extreme hypocarbia should be avoided due to the potential for ischaemia, particularly to vulnerable penumbral areas of the injured brain. Hypercarbia must also be avoided as it will increase ICP. Volume-controlled ventilation may permit more stable blood gases.

    Osmotic agents such as 3% (hypertonic) saline or mannitol exert a rheological effect by dehydrating red blood cells. The resultant decrease in blood viscosity permits a degree of cerebral vasoconstriction while still meeting metabolic demands. The use of hypertonic saline in preference to mannitol appears better supported in the literature to date.

    Decreasing neuronal metabolic demand can lower ICP. Seizures should be controlled and hyperthermia avoided. Second-tier therapies, such as barbiturates and therapeutic hypothermia (32°C–33°C), have been demonstrated to decrease refractory raised ICP. However, both have potential serious side effects and limited evidence to support routine use. Recent randomised controlled trials (RCTs) of therapeutic hypothermia versus normothermia in children have failed to demonstrate differences in functional outcome, and either no difference in mortality[12,13] or a trend towards increased morbidity and mortality in the cooled group.[14]
- **CSF volume:** external ventricular drainage of the lateral ventricles allows decrease in CSF volumes in addition to ICP monitoring. However, this may not be practical if the ventricles have already been effaced.
- **Brain volume:** osmotherapy with hypertonic saline or mannitol may decrease intracranial volume by dehydrating neurons in areas with an intact blood–brain barrier.

A fourth mechanism for decreasing ICP is to undertake a decompressive craniectomy. Although recent RCT data in adults demonstrated decreased ICPs in patients receiving this intervention, the operated group also experienced worse outcomes.[15] In paediatrics, although a number of small studies have demonstrated the utility of decompressive craniectomy in reducing raised ICP, evidence of effect on outcomes is lacking.[4,16]

Centres with limited experience in managing paediatric neurotrauma may benefit from structured guidelines, an example of which is the Scottish Intercollegiate Guideline Network (SIGN) guideline 110: Early management of patients with a head injury.[17]

A number of prognostic markers in head injury have been identified. These include the Glasgow Coma Scale, Injury Severity Score and initial hypotension.[18] Of note, the motor score component of the Glasgow Coma Scale may be as predictive as using the entire score.[19]

THORACIC TRAUMA

ANATOMICAL AND PHYSIOLOGICAL CONSIDERATIONS

The immature rib cage is largely cartilage, and ossifies through childhood. Compliant ribs allow transmission of greater impact energy to underlying viscera, allowing severe contusion without necessarily fracturing. Furthermore, the compliant infant chest and relatively transverse ribs impair the tolerance of upper airway obstruction.

Increased basal metabolic rate and reduced functional residual capacity result in a more rapid onset of hypoxaemia in younger children, and this may be compounded in infancy by physiologically low haemoglobin.

ASSESSMENT AND MANAGEMENT OF THORACIC TRAUMA

Immediate assessment of a child with thoracic trauma is focused on identifying life-threatening injuries, which include:

- large airway disruption
- tension pneumothorax
- open pneumothorax
- massive haemothorax
- flail segment
- cardiac tamponade.

Management is guided by the specific findings from the primary survey, but severe thoracic trauma is likely to require intubation and ventilation, with pleural or pericardial drainage as indicated. Rare, but severe, injuries that may be difficult to detect during resuscitation and therefore require a high index of suspicion include major vascular injuries, thoracic spinal injuries and traumatic diaphragmatic hernia.

A chest X-ray is a component of routine trauma assessment and may be supplemented as indicated by ultrasound assessment and CT. Angiography of the great vessels may be undertaken formally or as part of the CT scan. Serial arterial gases guide requirements for ventilatory support.

ABDOMINAL TRAUMA

ANATOMICAL AND PHYSIOLOGICAL CONSIDERATIONS

The orientation of the compliant ribs in small children affords less protection to the disproportionately large liver and spleen when compared with older children or adults, while the shallow pelvis leaves the bladder at similar risk.

Small children are difficult to examine. They are also prone to aerophagia with distension of the stomach increasing emesis risk, and in some cases leading to diaphragmatic splinting.

Paediatric abdominal trauma is largely blunt in nature, and solid organ injury occurs far more commonly than hollow visceral injury. Certain mechanisms of injury should lead to the suspicion of characteristic injuries. These include 'handlebar into epigastrium' associated with pancreatic or duodenal injury, lap-belt injuries in motor vehicle accidents leading to small bowel rupture, diaphragmatic injury or Chance fracture (flexion) of the lumbar spine. Given the difficulties in diagnosis, a high index of suspicion for abdominal injuries in trauma in children is essential.

When suspicion of abdominal injury exists, repeated clinical examination over time is supplemented by plain abdominal x-rays, ultrasonography or CT scanning as indicated. In haemodynamically stable blunt paediatric trauma, focused abdominal sonography for trauma (FAST) currently lacks the sensitivity and positive predictive power for use as a definitive screening tool, but may be a useful adjunct to better target CT assessment.[20] CT scanning of the abdomen is considered the gold standard.

In most paediatric trauma involving the abdomen, management is expectant. Laparotomy is generally reserved for the following situations:

- penetrating injury
- hollow viscus perforation (bladder rupture/pneumoperitoneum)
- haemodynamic instability despite adequate fluid resuscitation (≥40 mL/kg)
- peritonism (later sign)
- diaphragmatic rupture.

Even high grades of splenic or hepatic laceration may be managed conservatively, provided assessment is frequent and the patient is managed in a facility with the ability to intervene surgically at short notice.

SPINAL INJURY

Spinal injury in children is rare, often difficult to diagnose and potentially devastating if missed. Challenges include the anatomical and physiological differences between adults and children, which both change the types of injury commonly seen and make radiological interpretation difficult and clinical examination challenging. Furthermore, as spinal injuries are rare, the benefits of managing injured children in a paediatric facility must be balanced against the expertise available in adult spinal injury centres.

ANATOMICAL AND PHYSIOLOGICAL CONSIDERATIONS

There are differences in the immature spine and the proportionally more massive head change patterns of paediatric injury compared with adults. High lesions from the occipitoaxial junction to C3 are more common than the more typical C4–C5 lesions seen in older patients. In addition, the elasticity of paediatric

ligaments may lead to the phenomenon of spinal cord injury without radiological abnormality (SCIWORA), present in 17%–43% of paediatric cord injuries.[21,22]

Mechanisms of injury change at different stages of development, with an increasing incidence of sports injuries in older children.[21]

Pre-verbal children present challenges in assessment and even older children may regress and become uncompliant with clinical examination. Additionally, progressive ossification of the spine during childhood renders radiological interpretation problematic.

Spinal cord injury in children, particularly when very young, leads to an increased incidence of scoliosis, tracheostomy (due to the increased incidence of high lesions) and progressive pulmonary insufficiency.

ASSESSMENT AND MANAGEMENT

The possibility of spinal cord injury should be considered in all significant trauma, and particularly following motor vehicle accidents, rapid deceleration injuries or in the presence of multisystem trauma, head injuries, other injuries above the clavicle or abnormal neurological signs.

The first priority is spinal immobilisation, which should occur in the pre-hospital phase.

Clinical assessment is supplemented by plain radiography in the initial assessment. In severely traumatised patients, early neck clearance by clinical examination is not possible, and even plain radiography in three views – which has 94% sensitivity – may fail to detect SCIWORA. CT and MRI contribute additional information, but still will not detect all lesions even when motor signs are present.[23]

Spinal precautions must be maintained until either the neck is deemed to be uninjured, stable on clinical and radiological grounds or until fixation has occurred.

Use of steroids or hypothermia in paediatric spinal injury is not supported by evidence at this time and is not regarded as mainstream therapy.

Early feeding, gastric protection with proton pump inhibitors, bowel care, care of skin and pressure points and prevention of contractures are important interventions if not precluded by other injuries. Similarly, early access to rehabilitation services may improve functional outcomes.

BURNS

Burns are a common cause of accidental death in childhood.[24] Younger children predominantly suffers scalds, whereas older children are more likely to present with flame burns. Burns are often included within the extended scope of trauma as many mechanisms leading to burns are also associated with traumatic injury (motor vehicle accidents, explosions, etc.). Additionally, when confronted by the prospect of burning, patients will frequently risk or incur traumatic injuries during attempted escape.

ANATOMICAL AND PHYSIOLOGICAL CONSIDERATIONS

The increased surface area/weight ratio of children compared with adults leads to a number of problems. Fluid loss from the burn may rapidly lead to dehydration, and any surface cooling undertaken increases the risk of iatrogenic hypothermia. Furthermore, alteration in body proportions from birth to adulthood mandates the use of specific methods for estimating paediatric burn surface area such as the modified Lund and Browder chart. Estimated burn surface area may be made using the area of the child's palm with outstretched fingers with each such area corresponding to 1% of body surface area (areas of erythema should *not* be included in estimation of burn surface area).

Mechanisms of injury and patterns of burn are different to adults. Small, curious children below the level of kitchen work surfaces are commonly scalded on the face, head and upper body when pulling pans and kettles down, an injury exacerbated by a disproportionately large head. Similarly, severe hand injuries may follow attempts to grasp hot objects or, in older children, fireworks.

The small paediatric airway is particularly vulnerable to upper airway obstruction following smoke inhalation.

Finally, paediatric burn injury may result in profound and progressive disability. Thick burn scarring may distort normal somatic growth, and psychological scarring may severely compromise social development.

INITIAL MANAGEMENT

First aid for burns involves cooling for no longer than 20 minutes, using tepid (not cold) water. As burns and trauma frequently co-exist, a trauma primary survey (**a**irway + cervical spine control, **b**reathing, **c**irculation, **d**isability) should be rapidly carried out. The findings of particular relevance are listed in Box 112.1.

Once cooled, burns should be covered with sterile, non-occlusive dressings. Creams or ointments should not be applied unless advised by the local burns surgeon. Adequate hydration is required to optimise perfusion of injured areas. Fluid regimens such as the Parkland, Brooke or Galveston formulae (or modifications thereof – see Box 112.2: modified Parkland formula) are routinely initiated.

Pain relief with opioids and consideration of need for escharotomy where burns are circumferential should occur early, and be repeated frequently as required.

DEFINITIVE CARE

Major burns are best managed by burns centres. Burned patients in the intensive care unit are commonly ventilated for inhalational injury or to facilitate pain management. These patients require meticulous attention to fluid and electrolyte balance, nutrition, analgesia and wound care. Frequent trips to the operating room

Box 112.1 Primary survey findings in burns

Airway: is there actual or impending airway compromise?
- History of burn in enclosed space
- Facial burns/swelling
- Stridor or respiratory distress
- Carbonaceous sputum

Breathing: is there respiratory compromise?
- Respiratory distress
- Cyanosis
- Thoracic or upper abdominal burns
- Circumferential thoracic burns

Circulation: is there evidence of hypotension or hypovolaemia?
- Calculate burn surface area, ascertain time of injury to facilitate fluid management
- Shock from associated injuries?

Disability (neurology): is there impairment of conscious level?
- Carboxyhaemoglobin level?
- Other toxins from smoke (e.g. cyanide)?
- Associated head injury?

Box 112.2 Modified parkland formula

Patients require resuscitation fluids + maintenance fluids.

Resuscitation fluids: 3–4 mL Hartmann's solution × weight (kg) × %total body surface area burned.

Half of this volume is given in the first 8 h from time of injury, with the remainder given over the subsequent 16 h.

Maintenance fluids (commonly Hartmann's + 5% dextrose): 100 mL/kg/day for the first 10 kg, 50 mL/kg/day for the next 10 kg then 20 mL/kg/day for every kg thereafter.
- This formula is used in burns exceeding 15% of total body surface area.
- Fluid boluses given during resuscitation may be subtracted *unless* pre-existing dehydration or associated injuries exist.
- The aim is for *adequate* urine output: 1–2 mL/kg/h < 30 kg; 0.5–1 mL/kg/h > 30 kg

for dressing changes, wound debridement or skin grafting are expected. Routine antibiotics are not indicated, but patients require close monitoring for signs of evolving sepsis. Wound swabs and debrided tissue for culture assist in surveillance for sepsis.

NON-ACCIDENTAL INJURY

A significant proportion of children presenting with trauma will have been injured deliberately or through neglect, often by a parent or care giver. Although confrontational, this is an important diagnosis to consider as it has profound implications for the future safety of both the affected child and the family at large. In many countries there is an obligation on health care practitioners to report concerns to child protective services.

Although presentations are highly variable and may be covert, there are a number of risk factors that may increase the likelihood of an injury being factitious, as follows.

INJURY CHARACTERISTICS
- Delayed presentation of injury
- Injury inconsistent with history provided
- Injury inconsistent with child's developmental stage
- Injury with suspicious pattern as follows:

Bruising
- Specific patterns (e.g. belt buckle, handprints, loop marks from flex)
- Multiple bruises of differing ages

Fractures
- Fractures of different ages
- Specific patterns (e.g. spiral humeral fracture)

Burns
- Specific patterns (e.g. immersion [glove/stocking/thighs, sometimes sparing buttocks and backs of knees], cigarette or cooker-top)
- Burns of different ages

Others
- Retinal haemorrhages
- Bite marks
- Bleeding from, or trauma to, anus, genitalia or oral frenula.

In addition to features of the injury, there are numerous patient and social factors increasing the risk of factitious injury, which include amongst others:

- *patient factors:* young age, congenital anomalies, physical or intellectual disability, adoption, etc.
- *social factors:* young or single parents, unstable family situations, substance abuse and parents who were themselves abused. Environmental stresses include divorce or financial/legal/professional difficulties.

SUMMARY

Paediatric trauma differs in important respects from trauma in adults, and is associated with a vast burden of morbidity and mortality. The development of dedicated paediatric trauma teams or services appears to be associated with improved outcomes, and represents a powerful mechanism for developing and disseminating regionally appropriate protocols, undertaking research and engaging legislators.

Treatment limitation and organ procurement

James Tibballs

INTRODUCTION

Limitation of treatment either by withholding or by withdrawing life-sustaining medical treatment is common in intensive care units (ICUs). Such practice results in the majority of deaths; approximately 70% of deaths occur after either withdrawing or limiting life-sustaining treatment while failed cardiopulmonary resuscitation (CPR) accounts for 14%–19% and brain death for 13%–16%.[1–4]

Usually, decisions regarding the limitation of therapy are based on ethical considerations and are derived by discussion and mutual agreement between parents and clinicians. However, disputes sometimes arise. When such disputes are settled in court, the judgements constitute common law.

All common law cases have been decided in the child's 'best interests'– a nebulous term. Although each case has its own circumstances, a composite view reveals three legal and hence ethical criteria for 'best interests'. These are based on the present and future '*quality of life*', the '*futility*' of present treatment and a comparison of '*burdens versus benefits*' of present and future treatment and its discontinuance. These principles should guide discussions when any form of limitation of treatment is being considered. This chapter briefly discusses the derivation of these principles in legal cases (which serve as the ethical basis for withholding and withdrawing life-sustaining medical treatment), selected clinical ethical guidelines for the limitation of treatment, and of organ procurement.

BACKGROUND LEGALITIES

Although no Australian legislation exists, judgements in common-law cases on withholding or withdrawing life-sustaining treatment establish the legal basis for the limitation of medical treatment. Common-law cases often involve disputes between parents and doctors, usually because parents want treatment that doctors do not consider to be in the best interests of the child, but sometimes because parents want treatment that doctors do not support.

Palliative care cannot lawfully be withheld or withdrawn. Such care includes the provision of reasonable medical procedures for the relief of pain, suffering and discomfort, and the reasonable provision of food and water. However, artificial provision of food and hydration, such as by nasogastric tube, gastrostomy or intravenous administration, is medical not palliative care and may be legally withdrawn.

When parents and doctors agree to withhold or withdraw treatment, their decisions are usually made on ethical grounds. However, disagreements between parents and hospital staff, between hospital staff or between parents, sometimes arise because of differences in ethical opinions. This is unsurprising since one's ethical position is derived from diverse social, cultural, religious, moral and familial influences.

The common ethical and legal mantra for withholding and withdrawing treatment is the so-called 'best interests' of the child. This term, somewhat nebulous, is enshrined in, but not clarified by, section 68F of the Family Law Act 1975 (Cth), in which courts are directed to determine a child's 'best interests'.

Although the 'best interests' considered by courts in each case are specific to the circumstances of the child, when all cases are considered together three recognisable circumstances permit lawful withholding or withdrawing treatment. Several 'withholding' cases have come before Australian courts but, as only one case of withdrawing treatment from children (Baby D, see later) has been considered, it is necessary to consider a few cases from other jurisdictions with similar systems of law.

Other legal requirements in this setting are presumed. These include:

- sanctity of life but which is not absolute
- limitations of treatment are omissions not acts
- withholding and withdrawing treatment are legally equivalent
- any deliberate attempt to shorten life or cause death is a criminal act
- euthanasia either active or passive is unlawful
- competent persons, who may include teenagers, have the right of self-determination

ABSTRACT

Limitation and withdrawal of treatment is the most common mode of death in paediatric intensive care units. The basis for the withdrawal or withholding of life-sustaining treatment is when treatment is futile (prolonging death rather than saving life) or disproportionately burdensome compared with benefits or resulting in extremely poor quality of life. These ethical principles, the so-called 'best interests' of the child, are derived from case law. With the agreement of parents, organ procurement may be undertaken from a suitable organ donor when death is diagnosed as irreversible cessation of *all* function of the brain or *irreversible cessation* of the circulation. Brain death should be diagnosed by a test that shows the absence of all brain blood circulation, not by performance of an apnoeic-oxygenation test. Organ procurement after circulatory death is increasing the total availability of organs for transplantation; however, it is exacerbating a shortfall in the availability of donated hearts.

KEYWORDS

Children
withdrawal life-support
brain death
circulatory death
organ procurement

- parents, as legal guardians, make decisions on behalf of their child, but they cannot demand a particular treatment, nor demand that a particular treatment be withdrawn or withheld, nor withhold consent for treatment if not in the child's 'best interests'
- a doctor cannot be ordered to provide treatment not in the child's 'best interests'
- sedation or analgesia may be administered with the purpose of relieving pain, suffering and distress, but which may also unintentionally shorten life
- death following lawful limitation of treatment is due to the underlying disease
- parents and doctors may together decide to withhold or withdraw treatment in a child's 'best interests', but neither should do so alone and both parents should participate in discussions and agree
- a court is the final arbiter of disputes.

Although ethical standards and clinical guidelines are not legally enforceable, adherence to these may be scrutinised by courts in the context of meeting an appropriate standard of care. It is evident that ethical and legal principles are interdependent. It would be difficult, but not impossible, to imagine that legal judgements would not be ethical and vice versa. Each espouses almost identical positions. Nevertheless, an occasional judgement may astound physicians, as for example the case of 'In the matter of Baby K',[5] in which a judge ruled that mechanical ventilation could not be discontinued for an anencephalic infant.

QUALITY OF LIFE

That the future quality of life could be considered a factor in a decision to withhold treatment was foreshadowed in Australia by the Victorian case of Baby M (see below). Although the concept had already been accepted in Britain, it had been originally rejected in the Australian case of Re F; F v F.

RE F; F V F

This case,[6] concerning an infant with spina bifida, was brought hurriedly before the court in a father's affidavit, which (disputed by the mother) claimed that his infant was being denied sustenance and sedated for the apparent purpose of permitting or causing death. The judge stated that his concern was to deal only with the immediate and specific problem – that is, the administration of sustenance, which was ordered. However, he also said:

> *'… whatever may be the justification through some form of ethical assessment, for the adoption of a deliberate course of conduct designed to terminate the life of a child, the law in this community is clear and simple. It gives no warrant whatever for any such decision to be made. … Difficult problems … may be … involved in the preservation or continuation of life, but no parent, no doctor, no court, has any power to determine that the life of any child, however disabled that child may be, will be deliberately taken from it. … It does not permit decisions to be made concerning the quality of life, nor does it enable any assessment to be made as to the value of any human being'.*

BABY M

Although the Baby M case[7] was heard in the Victorian State Coroner's Court, whose findings did not, at that time, constitute law, nevertheless it suggested that a line of reasoning would be important in future cases before Australian courts. It concerned an infant born with a severe spina bifida with a large lumbar myelomeningocele, hydrocephalus, Arnold–Chiari malformation of the brainstem, vocal cord paresis and severe deformities of the lower limbs. She was relatively unresponsive, had little spontaneous movement and had difficulty swallowing, sucking and breathing. If she survived, she would be unable to walk, be doubly incontinent, have no sexual function, probably require an artificial airway and would certainly require multiple operations on her spine and lower limbs. Her quality of future life was estimated extremely poor. Accordingly, the medical staff of the hospital and parents decided that no active treatment, including surgery to close the myelomeningocele, be undertaken. Feeding was restricted to that on demand and she was given paracetamol and phenobarbital. Subsequently, she developed respiratory difficulty, was treated with an infusion of morphine and died 12 days after birth. However, a member of the 'Right-to-Life' association complained to police about the infant's treatment. An autopsy was performed. The deputy coroner ruled that the infant had died of natural causes secondary to bronchopneumonia and hypoxia secondary to vocal cord paralysis obstructing the upper airway obstruction in the presence of toxic amounts of phenobarbital and morphine.

The case focused on the validity of withholding medical treatment in circumstances based on a *quality of life*. The deputy coroner, while noting that generally quality of life factors are not valid reasons to withhold treatment, the very serious disabilities of Baby M placed her in a group who would not be selected for surgery. Medical staff involved in the case was exonerated by the deputy coroner who stated that their decisions were legally, ethically and morally sound.

BABY D

This Victorian State case concerned Baby D,[8] who had been born at 27 weeks' gestation and required intubation and mechanical ventilation for apnoea of prematurity while a twin developed normally. Several extubation attempts were unsuccessful over several months due to the development of tracheal stenosis. At one re-intubation, hypoxaemia caused cardiac arrest requiring external cardiac compression. A subsequent magnetic resonance imaging scan revealed major

hypoxic brain damage that was expected to result in severe cerebral palsy and blindness. However, she was conscious, had intact brainstem function and intact cardiorespiratory function except for life dependence on intubation. Her parents applied to the court to allow extubation (withdrawal of therapy) without re-intubation if airway obstruction re-occurred. The court sanctioned this withdrawal of therapy on the basis that continuation of life-maintaining treatment would result in a very poor quality of life, which was not in her best interests. The principle of 'double effect' of appropriate use of sedative agents to allay suffering but inevitably shortening life was also affirmed.

RE J

In this British case,[9] a 4-month-old infant was the subject of a medical recommendation to withhold mechanical ventilation. It was this case that introduced assessment of 'quality of life' as a touchstone.

The infant, asphyxiated and born prematurely at 27 weeks' gestation and weighing 1.1 kg, had required mechanical ventilation for 1 month initially and then recurrently over the course of the next 3 months. On one occasion he was resuscitated from pulselessness. At 3 months of age ultrasound studies revealed gross irreparable hypoxic brain damage. He was blind and neonatologists predicted that he would have spastic quadriplegia, deafness and be unlikely to develop even limited intellectual abilities. The judge ordered the hospital, in the infant's 'best interests', not to re-ventilate him.

On appeal it was argued that, as in Re C [1989] 2 All ER 782, court-sanctioned withholding of treatment applied to an infant who was dying or in whom death could only be postponed, whereas Baby J was in no immediate danger. It was argued that a court is justified in withholding consent to such treatment only if it is certain that the quality of the child's subsequent life would be 'intolerable' to the child, 'bound to be full of pain and suffering' and 'demonstrably … so awful that in effect the child must be condemned to die' as per Judges Dunn and Templeman in Re B [1990] 3 All ER 927.

The court baulked at the terms 'condemned to die' and 'the child must live'. Although 'Thou shalt not kill' is an absolute commandment in this context, it is permissible to add 'but need'st not strive officiously to keep alive'. A court can never sanction steps to terminate life and as Judge Taylor stated, 'The court was concerned only with the circumstances in which steps should not be taken to prolong life'. Thus, 'What doctors and the court have to decide is whether, in the best interests of the child patient, a particular decision as to medical treatment should be taken which as a side effect will render death more or less likely'. There is a 'balancing exercise' to be performed in assessing the course to be adopted in the best interests of the child. Accordingly:

> *'account has to be taken of the pain and suffering and quality of life which the child will experience if life is prolonged. … also … of pain and suffering involved in the proposed treatment itself. … I do not think that we are bound to, or should, treat (Judge) Templeman's use of the words 'demonstrably so awful' or Judge Dunn's use of the word 'intolerable' as providing a quasi-statutory yardstick. … there will be cases in which it is not in the interests of the child to subject it to treatment which will cause increased suffering and produce no commensurate benefit'.*

The issue before Lord Donaldson was whether it would be in the 'best interests' of the child to restart mechanical ventilation and subject him to all the associated processes of intensive care if at some future time he could not continue breathing unaided. In dismissing the appeal, his judgement strongly speaks to the issue of quality of life, and introduces an unacknowledged concept of futility as a basis for withholding treatment in appropriate circumstances.

Judge Taylor, concurring, also introduced a concept observed in American judgements: that of 'a substituted judgement':

> *'the correct approach is … to judge the quality of life the child would have to endure if given that treatment and decide whether in all circumstances such a life would be so afflicted as to be intolerable to that child. I say 'that child' because the test should not be whether the life would be tolerable to the decider. The test must be whether the child in question, if capable of exercising sound judgement, would consider the life intolerable'.*

The interpretation of quality of life may be variable, depending on the patient's circumstances, as illustrated by examples given by Judge Taylor in Re J. In a case of disability following an accident, as opposed to one of disability from birth, a perception by the child of what has been lost, rather than never known, may be relevant to judging the quality of life.

RE WYATT

This is another English case[10] in which the parents of a severely disabled infant and doctors could not agree on treatment should the infant's condition deteriorate. It defined the role of a court order in subsequent medical management and re-examined the meaning of 'best interests'.

At the age of 1 year after birth at 26 weeks' gestation, this infant with microcephaly and profound brain damage was blind, deaf, incapable of voluntary movement or response, and had severe spastic quadriplegia. In addition she had irreparable chronic lung damage necessitating permanent oxygen administration and had kidney dysfunction that would require dialysis. Following a dispute between the infant's parents and doctors, a court order was made that doctors could

withhold mechanical ventilation otherwise necessary to prolong life, on the grounds that to do otherwise was not in the infant's best interests. Unexpectedly, mechanical ventilation was not needed. When the infant attained the age of 18 months, the parents applied to court to have the previous declaration discharged on the grounds that she was now not terminally ill. However, Judge Hedley declined to discharge the declaration after considering that her condition was unchanged. In doing so, he remarked on the utility of 'intolerability' as the test of best interests:

> *'it is in my view essential that the concept of "intolerable to that child" should not be seen as a gloss on, much less a supplementary test to, best interests. It is a valuable guide in the search for best interests in this kind of case'.*

The declaration was reviewed when the child was 2 years of age when again the concept of 'best interests' of the child was scrutinised. The court again de-emphasised 'intolerability' as the touchstone of 'best interests' and reaffirmed its meaning as enunciated in *Re A*, that ' "best interests" encompasses medical, emotional and all other welfare issues' and that 'The court must conduct a balancing exercise in which all the relevant factors are weighed'. Notwithstanding, since any case will be highly specific: 'any criteria which seek to circumscribe the best interests tests are … to be avoided'. On this occasion, as on the previous ones, the court declined to discharge the initial declaration but added that the declaration was permissive, not mandatory, and was subject to discussion between parents and doctors before implementation. It was not the court's role to oversee the treatment plan for a gravely ill child, which was for the doctors in consultation with the child's parents.

FUTILITY

Futility is difficult to define and may be quite different according to the perspectives of parent and physician – as illustrated in the matter of Baby K[5] when doctors, opposed by the mother, sought to discontinue mechanical ventilation for an anencephalic infant solely on the basis of futility. Nevertheless, the concept has been drawn upon in an Australian case involving an adult but no children, and it has appeared in American and British cases involving adults and children.

AIREDALE NHS TRUST V BLAND

Withdrawal of treatment from persons in persistent vegetative status (PVS) came to legal notice in Britain in 1993 with Airedale NHS Trust v Bland.[11] The physicians of Anthony Bland, a young man in PVS after being asphyxiated in a crowd stampede, proposed cessation of artificial feeding and withholding of antibiotic therapy in case of infection. These actions would culminate in his death by starvation and, although unpleasant for hospital staff, would not cause discomfort or stress to the patient. His 'best interests' lay in being able to lawfully discontinue all life-sustaining treatment and medical support.

Lord Hoffmann considered that it is not just the interests of the patient that are being considered and reminded us of the American substituted judgement when he opined:

> *'in the extraordinary case of Anthony Bland, we think it more likely that he would choose to put an end to the humiliation of his being and the distress of his family. Finally, Anthony Bland is a person to whom respect is owed and we think that it would show greater respect to allow him to die and be mourned by his family than to keep him grotesquely alive'.*

Moreover, 'the decision does not involve … a decision that he may die because the court thinks that "his life is not worth living". There is no question being worth living or not worth living because the stark reality is that Anthony Bland is not living a life at all'.

Lord Mustill delivered comprehensive and clear statements related to the benefits to be gained by different parties. It was in the best interests of the community that Anthony Bland be allowed die:

> *'it is the best interests of the community at large that Anthony Bland's life should now end. …. Nothing will be gained by going on and much will be lost. The stress of the family will get steadily worse. The strain on the devotion of a medical staff charged with the care of a patient whose condition will never improve, who may live for years and who does not even recognise that he is being cared for, will continue to mount. The large resources of skill, labour and money now being devoted to Anthony Bland might in the opinion of many be more fruitfully employed in improving the condition of other patients, who if treated may have useful, healthy and enjoyable lives for many years to come.'*

In addition, according to Lord Mustill, it would be in best interests of his family that he die, and therefore in his own best interest to die:

> *'He suffers no pain and feels no mental anguish … and (he experiences) the progressive erosion of the family's happy recollections by month after month of distressing and hopeless care'. 'By ending his life the doctors will not relieve him of a burden become intolerable, for others carry the burden and he has none … he has no interests of any kind'.*

The invasiveness of treatment, the indignity and its futility should be in the best interests of the family not to experience:

> *'… account should be taken of the invasiveness of the treatment and the indignity to which, as the present case shows, a person has to be subjected if his life is prolonged by artificial means, which must cause*

considerable distress to the family – a distress which reflects not only their own feelings but their perception of the situation of their relative who is being kept alive. But in the end it is the futility of the treatment which justifies its termination'.

MESSIHA V SOUTH EAST HEALTH

This Australian case involved a 75-year-old man in a deep coma with absent cortical activity several days after sustaining an hypoxic–ischaemic injury during asystolic cardiac arrest secondary to heart and lung disease.[12] Physicians proposed withdrawing mechanical ventilation, which would culminate in his death earlier than if treatment was continued. This was opposed by family members. A judge ruled that withdrawal of treatment was permitted on the grounds of futility:

'Apart from extending the patient's life for some relatively brief period, the current treatment is futile … burdensome and … intrusive. The withdrawal of treatment may put his life in jeopardy but only to the extent of bringing forward what I believe to be the inevitable in the short term. I am not satisfied that the withdrawal of his present treatment is not in the patient's best interests and welfare'.

RE L

Dame Elizabeth Butler-Sloss stressed that 'best interests' was the appropriate test and also clarified the role of futility and 'intolerability' in paediatric cases. The issue concerned a 9-month-old infant with trisomy 18 who had multiple heart defects, chronic respiratory failure, gastroesophageal reflux, severe developmental delay, epilepsy and hypotonia, and who had already suffered cardiac and respiratory arrests.[13] In supporting the judgement of Judge Hedley in Wyatt, she remarked:

'There is a strong presumption in favour of preserving life, but not where treatment would be futile, and there is no obligation on the medical profession to give treatment which would be futile. I agree with (Judge) Hedley that the court should be focusing on best interests rather than the concept of intolerability, although the latter may be encompassed within the former'.

RE L.H.R.

Futility as noted above is sometimes difficult to define but it was done clearly in this American case in which the parents of a 4-month-old infant wanted unwilling doctors and a hospital to withdraw treatment.[14] The infant had suffered a 'medical catastrophe' 15 days after birth and had since been in a persistent vegetative state. A State Supreme Court, acknowledging that the infant never had an opportunity to develop and express ideas and was terminally and hopelessly ill with no reasonable possibility of ever attaining cognitive function, pronounced 'Under these circumstances, we find that the *life-support system was prolonging her death rather than her life*' (emphasis added). The author of this chapter continues to find this concept of 'futility' very acceptable to relatives of a child for whom it is proposed to limit treatment.

BURDENS VERSUS BENEFITS

Sometimes determination of the 'best interests' is a matter of weighing burdens versus benefits.

This was described clearly by the judgement in *In the matter of AB*[15] in which an American court ruled that, upon a request from a mother, that treatment could be withdrawn from her 3½-year-old child who had sustained hypoxic brain damage secondary to a cardiac arrhythmia. The decision hinged on the 'best interest' standard, which 'requires a weighing of the benefits and burdens of treatment options including non-treatment as objectively as possible. Factors that should be considered when making decisions about life-sustaining or life-saving treatments for a seriously ill newborn include: (1) the chance the therapy will succeed, (2) the risks involved with treatment and non-treatment, (3) the degree to which the therapy if successful will extend life, (4) the pain and discomfort associated with the therapy, and (5) the anticipated quality of life with and without treatment'.

Benefit versus burden was also the issue in the British case of *An NHS Trust v B*[16] – a case in which doctors wanted to withdraw mechanical ventilation, against the wishes of parents, from an 18-month-old child who had spinal muscular atrophy (SMA) type I. The child's illness had progressed to the point where the only spontaneous movement possible was that of eyebrows. The case is notable for three reasons. First, the court drew up an extensive list of burdens and benefits specific to the child that serve as a good illustration of factors needing consideration in an individual case. Second, although the burdens appeared to heavily outweigh the benefits and hence favour discontinuation of treatment, Judge Holman ruled in favour of continuing mechanical ventilation via endotracheal intubation. Third, as the judge also ruled against the need for a tracheostomy, this created a difference between withdrawing treatment (cessation of mechanical ventilation) and withholding treatment (tracheostomy).

This astounding decision attracted considerable media attention in Britain. The decision is not in agreement with a previous case of a 16-month-old ventilated child with SMA type I, *Re C*,[17] in which the judicial decision was to allow the withholding of mechanical ventilation against parental wishes in the event of a future respiratory arrest once the present mechanical ventilation had been successively weaned. The decision was also not in agreement with a subsequent case – *Re K*,[18] in which the court ruled that it was appropriate to cease parenteral nutrition and allow to die a

5½-month-old infant with congenital myotonic dystrophy who had required mechanical ventilation for intermittent episodes of septicaemia associated with central venous access. The judge distinguished the circumstances from those in *An NHS Trust v B* on the basis of age and development.

MOHAMMED'S CASE

The Australian case of *TS & DS v Sydney Children's Hospital Network* ('Mohammed's case')[19] was adjudicated on the basis of a preponderance of burden over benefit in determining a child's best interests. Parents demanded invasive mechanical ventilation for their 9-month-old infant with a severe neurodevelopmental disorder due to pyruvate dehydrogenase deficiency. After a prolonged period of hypoxaemia, their infant was unresponsive, had seizures, blindness, deafness and cardiac failure requiring continuous positive airway pressure. Doctors advised against invasive ventilation on the basis that the infant's condition was incurable. The court ruled that such ventilation would cause pain and discomfort, would provide only temporary benefit and would not alleviate his underlying condition. Rather, his best interests were to receive pain relief and palliative care. Notably, the judge rejected evidence related to the medical assessment of Mohammed's quality of life. Subsequently, Mohammed was given non-invasive ventilation, and was discharged from hospital but succumbed to his condition after some months.

CLINICAL GUIDELINES ON WITHHOLDING AND WITHDRAWING TREATMENT

The withholding and withdrawal of life-sustaining treatment are the subjects of numerous guidelines. Most relevant and useful are those of the Royal College of Paediatrics and Child Health (RCPCH) and those of the American Academy of Pediatrics.

ROYAL COLLEGE OF PAEDIATRICS AND CHILD HEALTH GUIDELINES

The RCPCH guidelines,[20] revised in 2014, are an excellent overview of the issues and a considerable improvement on the previous edition of 2004.

The new guidelines, based on relevant case and statute law (for Britain), take into account the developments in palliative care and acknowledge the wishes and preferences of young people who are able to make decisions for themselves. Limitation of treatment is based on the 'quantity or quality of life' and sets out circumstances under which withholding or withdrawing life-sustaining treatment *might* be ethically permissible and describes situations in which individual children should be spared inappropriate invasive procedures. It purposefully avoids stating the circumstances under which treatment *must* be limited and the conditions of children for whom appropriate procedures *should* be denied.

Treatment limitation is defined as withholding treatment that has not been commenced or withdrawing treatment that has already started, or to impose limits on that treatment (e.g. by agreeing on a maximum level of respiratory or cardiovascular support that will be provided).

The guideline defines life-sustaining treatments as those that have the potential to prolong life. They may include experimental therapies that are not validated by research, as well as more conventional treatments such as CPR, mechanical ventilation, intravenous inotropes, antibiotics, renal dialysis and clinically assisted nutrition and hydration.

The basis for limitation of life-sustaining treatment in these guidelines is the concept of 'best interests' as defined in statute law, case law and in published professional guidance. Determination of clinical best interests involves balancing benefits and burdens of treatments and outcomes, whilst considering the ascertainable wishes, beliefs, values and preferences of the child and their family, the cultural and religious views of the latter, the views of those providing care for the child and what choice is least restrictive of future options.

The guidelines consider limitation of treatment under the following situations:

I. **When life is limited in quantity**. If treatment is unable or unlikely to prolong life significantly it may not be in the child's best interests to provide it. These situations comprise:
   - **A. Brainstem death**, as determined by agreed professional criteria appropriately applied. In this circumstance intensive technological support is no longer necessary and should be withdrawn unless organ donation is being considered.

Curiously, this condition is not only inconsistent with the overall stated aim of these guidelines, as indeed it was in the 2004 version, which is to describe conditions under which life-sustaining treatment *may* be withdrawn, but is also not applicable in Australia. This situation is superfluous – its inclusion is hardly necessary since life has already ceased. In Britain, 'brain stem death' is legal death (permitting organ procurement), whereas in Australia it is a legal requirement to show that death of all brain function has ceased. (Any short-term reasonable requirements of parents should be respected, e.g. continuation of treatment until the imminent arrival on scene of close family members.)

   - **B. Imminent death**, where physiological deterioration is occurring irrespective of treatment and its continuation can no longer restore life or health. It is no longer appropriate to continue treatment because it is futile and

burdensome to do so, and little or no benefit is likely to be derived from CPR. The aim should be to provide emotional and psychological support to the child and family, and to provide them with privacy and dignity for that last period of the child's life (palliative care).

C. **Inevitable death**, where death is not immediately imminent within minutes or hours but will occur within days or weeks and where the possible prolongation of life by life-sustaining treatment confers no overall benefit. In this situation a shift in focus from life prolongation to palliation is appropriate.

II. **When life is limited in quality**. This includes situations where treatment may be able to prolong life significantly but will not alleviate the burdens associated with illness or treatment itself. These situations are more difficult to define than quantity of life because of potential or actual differences in views of the health care team, children and families as to what constitutes quality of life and the values that should be applied to define it. Poignant illustrative cases are Mohammed's case (*vide supra*) in Australia and the recent case of Charlie Gard in Britain. In the latter, the child was afflicted with the rare fatal disease mitochondrial DNA depletion syndrome that causes progressive brain damage and muscle failure.

In some children, continuing treatment may prolong life significantly, yet it may be in their best interests to consider limiting it if there is no overall benefit in prolonging life because of the adverse impact entailed. In entering discussions about treatment limitation it is important to acknowledge the importance of the value that the child and his/her parents place upon their life and their view of its quality for that child, regardless of disability. These discussions may arise in the context of any or a combination of the following three conditions:

A. **Burdens of treatments**, where the treatments themselves produce sufficient pain and suffering which may be physical, psychological and emotional so as to outweigh any potential or actual benefits. Examples are invasive ventilation in severe irreversible neuromuscular disease, extracorporeal membrane oxygenation, renal dialysis and sometimes intensive chemotherapy – treatments which may be only deliverable at the expense of compromising the child's consciousness by deep sedation such that potential benefit is significantly reduced.

Where the reason for withholding or withdrawing life-sustaining treatment is on the basis of the burdens of treatment or the inevitability of demise, it may be appropriate to limit some treatments but not others. For example, it may be appropriate to withhold invasive ventilation in a child with a severe neuromuscular disorder, but to provide other less burdensome treatments, including non-invasive respiratory support, nutritional support, antibiotics or blood transfusions. In other situations, where the probability of recovery is very low, it may be appropriate to withhold CPR, but to provide other forms of life-sustaining treatment.

B. **Burdens of the child's underlying condition**; here the severity and impact of the child's underlying condition is in itself sufficient to produce such pain and distress as to overcome any potential or actual benefits in sustaining life. Some children have such severe degrees of illness associated with pain, discomfort and distress that life is judged by them (or on their behalf if they are unable to express their wishes and views) to be intolerable. All appropriate measures to treat and relieve the child's pain and distress should be taken. If, despite these measures, it is genuinely believed that there is no overall benefit in continued life, further life-sustaining treatment should not be provided, for example, in advanced treatment-resistant malignancy, or severe epidermolysis bullosa.

C. **Lack of ability to benefit**; the severity of the child's condition is such that it is difficult or impossible for them to derive benefit from continued life. Examples include children in PVS, a minimally conscious state, or those with such severe cognitive impairment that they lack demonstrable or recorded awareness of themselves or their surroundings and have no meaningful interaction with them, as determined by rigorous and prolonged observations. Even in the absence of demonstrable pain or suffering, continuation of life-sustaining treatment may not be in their best interests because it cannot provide overall benefit. Individuals and families may differ in their perception of benefit to the child and some may view even severely limited awareness in a child as sufficient grounds to continue life-sustaining treatment. It is important, here as elsewhere, that due account of parental views, wishes and preferences is taken, and that due regard is given to the acute clinical situation in the context of the child's overall situation.

Although it is possible to distinguish these different groups of decisions to limit life-sustaining treatments that are based on quality-of-life considerations, in practice combinations may be present. For example, a child or infant in the ICU may have sustained such significant brain injury that future life may provide little benefit, while both intensive treatment and future life are likely to cause the child substantial pain and distress.

III. Informed, competent, supported refusal of treatment

Adults who have the capacity to make their own decisions have the right to refuse treatments (including those intended to sustain life), even if health care professionals regard such treatments as being in the adults' best interests.

Similarly, in some circumstances the child or young person, who often has extensive experience of illness, clearly and repeatedly refuses treatment that professionals may regard as being in their best interests. In practice these refusals are likely to occur in situations where the young person's life is limited in quantity or quality or both, and where limitation of treatment may have already been considered as a possible option. Examples might include a child who requires cardiac transplantation for cardiomyopathy induced by therapy for leukaemia, or lung transplantation for complications of cystic fibrosis.

These circumstances should trigger a careful and detailed assessment of the child/young person's understanding of their illness, their capacity to make such far-reaching decisions and their understanding of the impact of their decision on their family. Also there should be a thorough exploration of parental/family views on treatment options, including the provision of supportive care and the determination of whether a consensus exists or can be reached.

If the child/young person does understand the nature and consequences of their decision, is assessed as having capacity to make the decision and is supported by their parents, the provision of further life-sustaining treatment may no longer be ethically justifiable even if it has the potential to provide some limited clinical benefit.

Other Issues. These guidelines discuss other important aspects of treatment limitation, which include but are not limited to:

i. **Initiation of CPR** is inappropriate if (a) unlikely to be successful in restarting the heart or breathing because of the child's underlying condition, or there is a limitation of treatment agreement or other end-of-life care plan that excludes its use; (b) even if successful it is likely to produce more burdens than benefits.

ii. **Clinically assisted nutrition and hydration** is legally a medical treatment in Britain (and in Australia) and in some circumstances is life-sustaining, and like other such treatments may or may not promote the best interests of the child. For example, in a child with a swallowing disorder due to a slowly progressive neurodegenerative disease, it would be appropriate, but rarely so for a child with rapidly progressive, disseminated malignant disease. It may be ethically appropriate to limit this treatment for a child in a persistent vegetative state or in a minimally conscious state. However, in Britain at present, an application to a court is required to limit such treatment for these conditions.

iii. **Muscle relaxants**, drugs that cause only neuromuscular blockade, should not be used to treat or prevent terminal gasping. This sensible advice is in contrast to the advice in the 2004 edition of the guidelines. Not only do such drugs mask distress without treating it, their use can be interpreted as an intention to hasten death, which is tantamount to euthanasia. Although terminal gasping is distressing to parents (and to staff) its significance – a response to hypoxaemia – should be explained, and appropriate palliative care given to prevent distress and suffering. (Although this may seem like 'splitting hairs' the perceived perception of the intention of treatment is important.)

iv. **Provision of palliative care.** This should begin whenever it is apparent that a child's illness may result in premature death, whether it is provided by a specialist service or the clinical team already caring for the child. It should address the child's physical needs, for example, pain and symptom relief, and address the emotional, social and spiritual needs of both the child and their family. All these aspects of palliative care can be provided wherever a child and family are cared for – whether in hospital, at home or in a children's hospice. The introduction of palliative care should not be left until a decision is made to limit life-sustaining treatment. Such care may include transferring a child out of hospital for ventilation withdrawal in a preferred place of care/place of death.

v. **Organ donation** should be considered in any child dying in the intensive care environment. Discussions about organ donation must be separated from discussions about withholding or withdrawing life-sustaining treatment. Only after a decision has been made to withhold or withdraw life-sustaining treatment is it appropriate to raise with the family the possibility of organ donation after death.

vi. **Legal input**. The health care team and parents usually come to agreement over a course of action. If agreement cannot be reached, legal advice should be sought from specialist health care lawyers. Institutions should also facilitate access to independent legal representation for the parents.

vii. **Responsibilities of the health care team**. Health care teams have individual and collective obligations to act in the child's best interests and have a responsibility to fully inform parents allowing them to reach their own independent un-coerced opinion. Doctor–parent partnered decisions should be made on the basis of confirmed clinical evidence. It is important to be clear to all involved (including the child when competent and where appropriate) as to which

treatments are appropriate and which are not; and which will be provided, and which will not. The range of chosen interventions should be recorded and updated according to circumstance and discussion with parents. All members of the treating health care team should have opportunity to be part of the decision-making process and their views accorded due weight according to knowledge, understanding and experience. Openness between disciplines and grades will enhance mutual understanding of individual roles and responsibilities, and will heighten the sense of shared moral responsibility. However, unanimity is not required. Final responsibility for decisions rests with the senior doctor in charge.

viii. **Transition to adult services**. Some children with life-limiting illnesses live beyond their 16th or 18th birthdays. Arrangements for transition should accord with best practice.

ix. **Bereavement**. Professional duties and responsibilities do not cease when a child dies. The quality of care at the end of life and after the child's death can have a major impact on the family's grieving. Each institution should have readily available specific policies that provide guidance for staff in addressing the needs of bereaved families and which describe the procedures that need to be followed when a child dies. It should include details about asking for postmortems, the needs of different religions, beliefs and cultures, and the provision of mementos for the family. There should be practical guidance on the steps that families will need to take for registering the death and making funeral arrangements. An offer of follow-up should be made to all parents of a child who has died. Follow-up contact between 1 and 2 months after the death gives the opportunity to discuss the results of a postmortem or other investigations that may shed more light on the precise cause of death. Such contact also allows professionals to answer families' medical questions and to explore their feelings.

AMERICAN ACADEMY OF PEDIATRICS GUIDELINES[21]

Issued initially in 1994, and reaffirmed in 2008, they utilise the term 'forgo' to refer to both stopping (withdrawing) treatment already begun and not starting (withholding) a treatment. Decisions turn on the 'best interests' standard. This involves balancing the benefits and burdens of treatment. Benefits may include prolongation of life (unless prolonged unconsciousness is not considered a benefit), improved quality of life after treatment (including reduction of pain or disability), and increased physical pleasure, emotional enjoyment and intellectual satisfaction. The burdens of treatment include intractable pain, irremediable disability or helplessness, emotional suffering, invasive or inhumane interventions designed to sustain life or other activities that detract from the patient's quality of life.

'Quality of life' refers to that perceived by the patient, not how others perceive it. Accordingly, a 'substituted judgement standard' should apply in which parents or surrogates must make inferences about the preferences of previously competent children. However, in states of prolonged unconsciousness, this standard cannot be easily applied.

Curiously, despite exhortation to regard quality of life only from the patient's perspective, 'Physicians and families should also consider whether continued treatment conforms with respect for the meaning of human life and accords with the interests of others, such as family members and other loved ones'.

CONCLUSIONS

In considering whether to withhold or withdraw life-sustaining treatment from a child, the appropriate test is that of 'best interests', which – although a nebulous term – essentially means a determination of the quality of life, futility and a comparison of benefits and burdens.

These three concepts are not independent as 'quality of life' with continuation of treatment may be derived by a 'comparison of benefits and burdens' flowing from treatment. 'Best interests' should also incorporate, but not exclusively, a notion of tolerability of continued treatment. The concept of futility was prominent in early cases and remains important but it is less easily defined unless it is related to prolongation of the dying process. These legal concepts may be helpful in the clinical situation when litigation is unlikely, but when parties nevertheless dispute courses of action each of which is considered correct under different ethical positions. It may be surprising to physicians that these principles are well described in law. Indeed, rather than consider withdrawal or withholding treatment under ethical principles, it is perhaps more helpful to first ask 'Is it lawful?' and then ask 'Is it ethical?' Whatever ethical position is adopted when contemplating withholding or withdrawing treatment from children, notwithstanding disputes, these principles should be observed because, in the end, the legal position is decisive.

ORGAN PROCUREMENT

This section concerns paediatric cadaveric organ procurement in Australian jurisdictions. It is an addendum to the Chapter 102, which also encompasses adult organ procurement. It focuses on legal requirements and notable differences in paediatric practices of organ procurement.

Contrary to organ procurement from adults, which may proceed with either the pre-morbid consent of the patient ('opt-in' consent) or the consent of 'next-of-kin' if the patient had not 'opted-in' to organ donation, organ procurement from a deceased child may only proceed with the consent of a parent.

As with adults, the gap between the need for organ donation for transplantation and organ procurement continues to widen. Every opportunity should be taken to maximise organ procurement in the paediatric ICU. Whenever a child is anticipated to die and would be a potential suitable donor of organs, discussions should be undertaken with their parents who should be given an opportunity to consent to organ donation from their child. Practice along these lines is equivalent to a 'soft opt-out' system of organ donation, recently adopted in Wales under their *Human Transplantation Act* (Wales) s4(2)(3), in which every (adult) person is presumed to have given pre-morbid consent, wrong that it is,[22] unless they had pre-morbidly registered a refusal. Unlike 'hard opt-out' systems, however, relatives have the right to declare unregistered refusal but they cannot stop organ procurement if refusal had not been expressed at all.

In Australian jurisdictions, according to various 'Human Tissue Acts',[23] cadaveric organ procurement may proceed when there is 'irreversible cessation of all function of the brain' (brain death) or there is 'irreversible cessation of circulation' (circulatory death). The demonstration of brain death allows procurement of any tissues and organs, including the heart.

BRAIN DEATH

The law does not define what constitutes brain death, except that it should be the lack of each and every brain function; nor does the law specify how brain death should be proven. Medical practices are quite varied and sometimes unreliable in making this diagnosis.[24,25] Provided that no confounding and remediable factors are present (see Chapter 102), the key clinical test is that of apnoeic-oxygenation. Simply put, if an oxygenated patient fails to begin spontaneous respiration in the presence of hypercapnia ($PaCO_2$ >60 mm Hg), brain death is present. However, this is an unreliable test for brain death and may contribute to or cause brain damage; it is a self-fulfilling test and recommended against by this and another author.[25,26] As is well known, hypercarbia causes an increase in intracranial pressure and will damage any live brain tissue.

It is far more preferable to diagnose brain death by showing that blood flow to the whole brain has ceased by the performance of a scan using a radionuclide, such as with technetium 99m-hexamethylpropyleneamineoxime or technetium 99m-ethylcysteinate dimer, which are brain-lipid soluble. The complete absence of radionuclide uptake, consistent with no brain blood flow, not only satisfies the legal requirement that *all* function of the brain has ceased irreversibly, but is also a convincing test for clinical staff and parents that death has indeed occurred. There are no confounding factors for this test and it may be used in any age group, including neonates. Organ procurement may then proceed in a non-time-critical manner. If some brain blood flow is demonstrated by this test, the diagnosis of brain death cannot be made but it does not stipulate that organ procurement cannot proceed under the basis of circulatory death when life-sustaining treatment is withdrawn. The timing of a scan is important – it should only be undertaken when brain death is suspected from clinical circumstances and observations, such as absent brainstem reflexes, excluding any performance of an apnoeic-oxygenation test. If some blood flow is initially evidenced by a scan, later re-performance of an isotopic scan may be confounded by residual radioactivity unless a suitable interval is allowed between scans.

CIRCULATORY DEATH

Organ procurement may proceed when the circulation of the potential donor has ceased, invariably after withdrawal of life-supporting treatment. Organ procurement is undertaken provided the circulation ceases within 90 minutes after withdrawal of treatment. Beyond this period, organs are not suitable for transplantation and planned procurement is abandoned. Surgery may be commenced between 2 and 5 minutes after the circulation ceases. The latter time is preferred and fits well with the observations that circulation may spontaneously recommence up to approximately 90 seconds after death is diagnosed, and may persist for up to approximately 3 minutes.[27]

Logistically, organ procurement after circulatory death is more difficult than after brain death because withdrawal of life-sustaining treatment can only be undertaken when the surgical transplant team is ready to operate in the unguaranteed expectation that death will occur. If it does occur, surgery then must be performed urgently in a time-critical manner to ensure the viability of organs.

This mode of organ procurement is increasing because 'brain death' arises infrequently and because parents and doctors often agree on treatment withdrawal before the condition of the child progresses to brain death. Although the availability of other organs is increasing with this practice, it does not yield a heart suitable for transplantation for the obvious reason that the heart of the donor has already failed. Nonetheless, it is possible to resuscitate a procured heart using ex-vivo techniques and later transplant it. However, this practice carries a risk of exposing the transplant team to criminal prosecution because it is difficult to argue that the circulation of the donor had ceased irreversibly, as required by law, before surgical

procurement of the heart.[28] A protocol for procurement after paediatric circulatory death is available online from a paediatric hospital: <http://www.rch.org.au/picu/Donation_after_cardiac_death_protocol/>

Paediatric poisoning and envenomation

James Tibballs

EPIDEMIOLOGY

Poisoning in childhood is common. In the year 2012–2013, almost 6500 children (0–17 years) in Australia were hospitalised after poisoning.[1] The majority were adolescents (15–17 years) at a rate of almost 600/100,000 population but significant numbers were also recorded among infants (<12 months), early childhood (1–4 years) and late childhood (10–14 years). A minority were life-threatening but no deaths occurred, and hospitalisation was required on average for 2 days. Poisoning often occurs in the home when a single prescribed or over-the-counter medication or a household product is ingested. Whatever treatment is applied to remove a poison, care should be taken to ensure that it does not cause additional illness.

Poisoning among young children is called 'accidental' – erroneously because it is usually the result of inadequate supervision or unsafe storage of poisons. Occasionally, poisoning in childhood is either truly accidental as in ingestion of a decanted chemical, or is part of a syndrome of child abuse, or is iatrogenic as when a parent mistakes medications at home or when medical or nursing staff make errors in drug administration in hospital.[2] Self-poisoning in late childhood (10–14 years) or adolescence is usually with the intention to manipulate their psychosocial environment or to commit suicide, or is the result of substance abuse. All such circumstances of poisoning require remedial action. Occasionally toxic gases are inhaled during fires.

PRINCIPLES OF MANAGEMENT

The four basic principles in management of any poisoning are:

- support vital functions
- confirm the diagnosis
- remove the poison from the body
- administer an antidote (Table 114.1).[3,4]

Individual poisons may require specific measures. Consult current toxicology texts[5–7] for details and consult Chapter 90. A working knowledge of important poisons is indispensable for paediatric practice. A number of poisons or classes of poison are potentially fatal to a small child if taken as a single tablet or a teaspoonful.[8] These include opiates (methadone, buprenorphine, lomotil), camphor, quinine derivatives, cyclic antidepressants, clonidine, sulfonylureas, salicylates, calcium channel blockers and colchicine. If a poison is unfamiliar, a poison information centre provides valuable information, but clinical judgement rests with the treating physician.

The support of paediatric vital functions (life-support) is detailed in Chapters 105–115 of this volume. When conventional resuscitation is failing, extracorporeal life-support may be required.

CONFIRMATION OF DIAGNOSIS

Commonly the diagnosis of poisoning in paediatric practice is self-evident from a history detailed by parents or guardians. Although a single poison is usually involved, the possibility of several or multiple poisons should be considered. Occasionally the diagnosis is unknown on presentation. Any child who presents with unexplained obtundation, fitting, hypoventilation, hypotension or has a metabolic derangement must have poisoning excluded.

Recognition of a 'toxidrome', a constellation of symptoms and signs, may make the diagnosis.[5–7] Although numerous toxidromes exist, the four prominent types and their causative drugs or agents are shown in Table 114.2.

Laboratory analysis of body fluid specimens can assist in the diagnosis and management of poisoning. For example, rapid routine analyses are widely available for glucose, potassium, calcium, pH, osmolarity, alcohols, paracetamol, phenytoin, digoxin, salicylate, theophylline, iron, lead and methaemoglobin. If particular toxins are suspected, discussion with laboratory staff will optimise the information to be gained.

REMOVAL OF THE POISON

Treatment should be determined by the poison, the severity of poisoning as judged by the observed and the expected effects of the poison, by the amount ingested,

ABSTRACT

Childhood poisoning is often minor but serious poisoning by true accident or self-harm may require intensive care management. The diagnosis is usually evident but must be suspected if convulsions, central nervous system obtundation or cardiorespiratory compromise are unexplained. Often, recovery occurs with only support of vital functions. Removal of poisons by extracorporeal or gastrointestinal decontamination or by forced diuresis must match the severity of poisoning to avoid complications. Potentially lethal poisons are a wide range of therapeutic drugs (paracetamol, opiates, benzodiazepines, antipsychotic drugs), lead, petroleum distillates, essential oils and caustics. Some poisons have antidotes, notably for paracetamol, naloxone for opiates, flumazenil for benzodiazepines, benztropine for phenothiazines, desferrioxime for iron, beta-blockade for amphetamines, calcium for calcium-channel blockade. An oesophageal impacted button battery must be removed urgently to avoid fatal erosion. Management of envenomation is similar to adults with the additions that the diagnosis may not be apparent and the toxicity more severe.

Table 114.1 Antidotes to some poisons

POISON	ANTIDOTES	COMMENTS
Amphetamines	Esmolol IV 500 µg/kg over 1 min, then 25–200 µg/kg/min Labetalol IV 0.15–0.3 mg/kg or phentolamine IV 0.05–0.1 mg/kg every 10 min	Treatment for tachyarrhythmia Treatment for hypertension
Anticholinergic toxidrome (antimuscarinic)	Physostigmine 0.01–0.02 mg/kg IV slowly, repeatable but titrated to improve consciousness	Beware cholinergic effects including bradycardia, bronchospasm and weakness (treat with atropine)
Benzodiazepines	Flumazenil IV 3–10 µg/kg, repeat 1 min, then 3–10 µg/kg/h	Specific receptor antagonist. Beware convulsions
Beta blockers	Glucagon 50–150 µg/kg IV then 0.20–2.0 µg/kg/min infusion Isoprenaline 0.05–2 µg/kg/min IV infusion Noradrenaline 0.05–0.5 µg/kg/min infusion	Stimulates non-catecholamine cAMP (preferred antidote) Beware β_2 hypotension Antagonises toxin at receptors
Calcium channel blocker	Calcium chloride IV 10%, 0.2 mL/kg	Antagonises at receptors
Carbon monoxide	Oxygen 100%	Decreases carboxyhaemoglobin May need hyperbaric oxygen
Cyanide	Hydroxycobalamin (Vit B_{12}) 70 mg/kg IV plus sodium thiosulphate 25% IV 1.65 mL/kg (max 50 mL) at 3–5 mL/min. Sodium nitrite 3% IV (0.33 mL/kg over 4 minutes) then sodium thiosulphate as above.	Give 50 mL 50% glucose after dose 'Cyanide antidote kit'; beware anaphylaxis Nitrites form methaemoglobin-cyanide complex: beware of excess methaemoglobin – restrict to <20%. Thiosulphate forms non-toxic thiocyanate from methaemoglobin-cyanide.
Digoxin	Magnesium sulphate IV 25–50 mg/kg (0.1–0.2 mmol/kg) Digoxin Fab IV: acute – 10 vials per 25 tablets (0.25 mg each), 10 vials per 5 mg elixir; steady state: vials, serum digoxin (ng/mL) × BW(kg)/100; empirical therapy: 10–20 vials acute poisoning, 1–2 vials chronic	Antagonises digoxin at sarcolemma Binds digoxin
Ergotamine	Sodium nitroprusside infusion 0.5–5.0 µg/kg/min Heparin IV 100 units/kg, then 10–30 units/kg/h	Treats vasoconstriction; monitor BP continuously Monitor partial thromboplastin time
Lead	If symptomatic or blood level >2.9 µmol/L dimercaprol (BAL) 75 mg/m^2 IM 4-hourly 6 doses, then calcium disodium edetate (EDTA) 1500 mg/m^2 IV over 5 days. If asymptomatic and blood level 2.18–2.9 µmol/L infuse EDTA 1000 mg/m^2 per day for 5 days	Chelating agents
Heparin	Protamine 1 mg/100 units heparin	Direct neutralisation
Hydrofluoric acid	Calcium chloride 10% IV 0.2 mL/kg Calcium gluconate gel, topically	For systemic toxicity For burns
Iron	Deferrioxamine 15 mg/kg/h 12–24 h if serum iron >90 µmol/L (500 µg/dL) or >63 µmol/L (350 µg/dL) and symptomatic, give slowly	Beware anaphylaxis

Table 114.1 Antidotes to some poisons—cont'd

POISON	ANTIDOTES	COMMENTS
Isoniazid (or hydrazine exposure)	Pyridoxine (vitamin B6) 70 mg/kg (max 5 g) IV 3–5 min if seizing, 30–60 min if not, *and* Diazepam	Metabolic acidosis may be mildly exacerbated
Local anaesthetic drug cardiovascular toxicity	Intralipid 20% IV 1.5 mL/kg over 1 min, repeat ×2 intervals 5 min then infusion 0.25–0.50 mL/kg/min as needed to maintain BP	Mechanism uncertain – may bind toxin; suitable for other lipophilic drugs including sertraline, bupropion, quetiapine and possibly clomipramine, propranolol, thiopentone, verapamil
Methanol, ethylene glycol, glycol ethers	Ethanol IV loading dose 10 mL/kg 10% diluted in glucose 5%, then 0.15 mL/kg/h to maintain blood level 0.1% (100 mg/dL), *or* Fomepizole (4-methylpyrazole) 15 mg/kg over 30 min, then 10 mg/kg 12-hourly, four doses	Competes with poison for alcohol dehydrogenase Inhibits alcohol dehydrogenase (not available in Australia)
Methaemoglobinaemia	Methylene blue IV 1–2 mg/kg over several minutes	Reduces methaemoglobin to haemoglobin
Methotrexate	Leucovorin (folinic acid) IV 100–1000 mg/m^2 6-hourly until methotrexate 0.05–0.1 µmol/L, *and* Glucarpidase 50 units/kg IV	Sustains folate cycle blocked by methotrexate Cleaves methotrexate to non-cytotoxic metabolites
Opiates	Naloxone IV 0.01–0.1 mg/kg, then 0.01 mg/kg/h as needed	Direct receptor antagonist
Organophosphates and carbamates	Atropine IV 20–50 µg/kg every 15 min until secretions dry Pralidoxime IV 25 mg/kg over 15–30 min then 10–20 mg/kg/h for 18 h or more	Blocks muscarinic effects Reactivates cholinesterase; not for carbamates
Paracetamol	N-acetylcysteine if serum paracetamol (µmol/L) exceeds: 1500 at 2 h, or 1000 at 4 h, or 500 at 8 h, or 200 at 12 h, or 80 at 16 h, or 40 at 20 h: ***Intravenous*** 300 mg/kg total in age/weight volume appropriate 5% dextrose or normal saline: In 3 phases; (i) 150 mg/kg over 1 h; (ii) plus 50 mg/kg over 4 h; and (iii) plus 100 mg/kg over 16 h. OR In 2 phases; (i) 200 mg/kg over 4 h; (ii) plus 100 mg/kg over 16 h. OR ***Oral*** 1330 mg/kg total as 140 mg/kg, then 17 doses each of 70 mg/kg 4 hourly over 72 h.	Restores glutathione-inhibiting metabolites; beware anaphylaxis, minor reactions common
Phenothiazine (and other drug) dystonia	Benztropine IV or IM 0.01–0.03 mg/kg	Blocks dopamine reuptake

Table 114.1 Antidotes to some poisons—cont'd

POISON	ANTIDOTES	COMMENTS
Potassium	Calcium chloride 10% IV 0.2 mL/kg Glucose IV 0.5 g/kg plus insulin IV 0.05 units/kg	Antagonises cardiac effects (immediate) Decreases serum potassium (rapid marked effect); monitor serum glucose
	Salbutamol aerosol 0.25 mg/kg	Decreases serum potassium (rapid marked effect)
	Sodium bicarbonate IV 1 mmol/kg	Decreases serum potassium (slight effect); beware hypocalcaemia
	Resonium oral or rectal 0.5–1 g/kg	Adsorbs potassium (slow effect)
Sulfonylureas and other drugs causing hypoglycaemia	Glucose 0.5–1.0 g/kg IV then infusion Octreotide 1–2 µg/kg IV or SC 8-hourly 2–3 doses	Monitor serum glucose frequently Refractory hypoglycaemia from sulfonylureas and quinine; inhibits insulin release
Tricyclic antidepressants	Sodium bicarbonate IV 1–2 mmol/kg to maintain blood pH >7.45, aim for 7.55	Reduces cardiotoxicity
Valproic acid	L-carnitine IV if serum valproate ≥450 mg/L, no coma and ammonia and liver enzymes normal: 25 mg/kg 6-hourly (max 6 g/day); if coma with raised ammonia and hepatic enzymes 100 mg/kg load (max 6 g) over 30 min then 15 mg/kg 4-hourly over 10–30 min until improvement	Replaces depleted carnitine levels; measure valproate – if ≥1000 mg/L start haemodialysis or haemofiltration

BAL, British anti-Lewisite; *BP*, blood pressure; *BW*, body weight; *cAMP*, cyclic adenosine monophosphate; *DMSA*, dimercaptosuccinic acid; *EDTA*, ethylenediaminetetraacetic acid; *IM*, intramuscular; *IV*, intravenous; *SC*, subcutaneous.

by the interval between ingestion and presentation, and by the existence or otherwise of an antidote.

The range of treatment options is to: (1) do nothing apart from advice and discharge home; (2) observe for a short duration in the emergency department or ward; (3) provide intensive nursing care; or (4) treat medically. The modes of medical therapy include extracorporeal decontamination, diuresis or gastrointestinal decontamination, with the last named being the most important. The task with all poisonings is to match the treatment and its intensity to the severity of the poisoning, thereby avoiding under- and overtreatment.

EXTRACORPOREAL DECONTAMINATION

Occasionally, removal from the circulation by an extracorporeal technique is needed by charcoal haemoperfusion, haemodialysis, plasma filtration or haemofiltration. Examples of toxins removable by these techniques are barbiturates, lithium, metformin, salicylates, theophylline, toxic alcohols, carbamazepine and valproic acid.[3,9] Such techniques, combined with extracorporeal circulatory support, should be applied when conventional therapy is failing or is anticipated to fail.

ALKALINE DIURESIS

Induce diuresis of 2–5 mL/kg/h with alkalinisation of the urine by 1–2 mmol/kg sodium bicarbonate intravenously then infuse 50–75 mmol/L in intravenous fluid titrated to maintain alkaline urinary pH without exceeding serum pH of 7.55. Monitor serum pH, sodium, potassium, calcium and avoid clinical problems of fluid overload. This reduces reabsorption in distal renal tubules of drugs including phenobarbitone, salicylate, methotrexate and chlorpropamide.[3]

GASTROINTESTINAL DECONTAMINATION

Since the vast majority of poisoning in childhood is by ingestion, potential exists for removal from the gastrointestinal tract before absorption. However, the correct choice and timing of a gastrointestinal decontamination technique are crucial to uncomplicated recovery. The usual choices are activated charcoal, induced emesis, gastric lavage, whole bowel irrigation or a combination of these techniques. Occasionally endoscopic removal may be needed. The efficacy, indications, contraindications, disadvantages and complications of these techniques are discussed below. A general plan of management is presented in Fig. 114.1.

A crucial point in management is the initial recognition that the patient is in a state of either 'full-consciousness' or 'less-than-full consciousness'. Traditionally, management has been dependent on a judgement of whether the gag reflex is present or absent, but in practice this is rarely tested. Since aspiration pneumonitis is a common feature of poisoning management, particularly among (but not confined to) obtunded patients, it is prudent to regard all obtunded patients as having incompetent pharyngeal reflexes.

The decision to attempt removal of a poison should always be made with due reference to two facts:

- The vast majority of childhood poisonings recover with merely supportive care or no treatment at all.
- Aspiration pneumonitis is more serious than most poisonings.

ACTIVATED CHARCOAL

Charcoal adsorbs many drugs and is regarded as a 'universal antidote'.[3,10] Although advocated as sole treatment in most poisonings, it is overused for minor

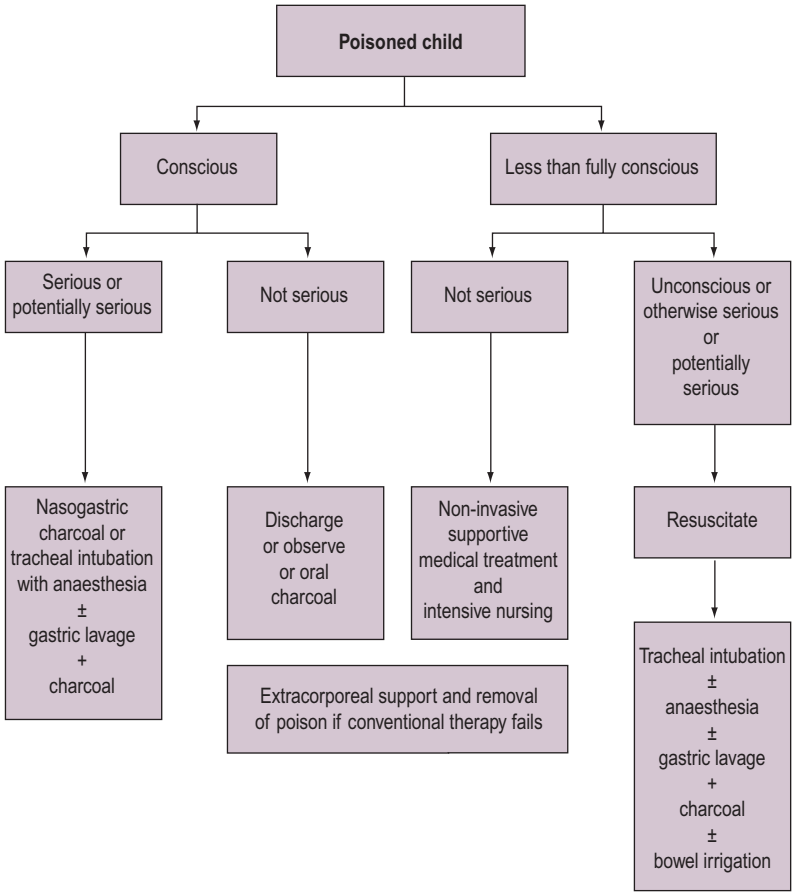

Figure 114.1 General management of the poisoned child.

poisonings, and for many poisons no data exist regarding efficacy.

Treatment of charcoal with chemicals and heat increases its surface area to approximately 950 m^2/g in so-called low-surface-area activated charcoal and to 2000 m^2/g in superactivated charcoal. The latter adsorbs paracetamol better and is more palatable.[11,12] Activated charcoal is not pleasant to drink and is associated with vomiting in 20% of poisoned children.[13] It is superior to induced emesis and gastric lavage in the treatment of symptomatic poisoned patients,[14–16] but its efficacy diminishes with time after ingestion. Activated charcoal reduces the absorption of ingested experimental drugs in volunteers by 85%–100% when administered 5 minutes after ingestion,[17–19] by 40%–75% at 30 minutes[20] and by 30%–50% at 60 minutes.[19,21] At mean times of 98 minutes[22] or more than 2 hours[23] after poisoning, it was not effective at all.

Activated charcoal alone is as effective as when combined with either emesis or with lavage,[24] but in combination with these methods has an 8.5% incidence of aspiration, compared with zero when used alone.[18]

Repeated doses of activated charcoal (multidose) enhance the elimination of some drugs by increased adsorption and by post-absorption elimination by interruption of an enterohepatic circulation and by removing the drug from the gastrointestinal mucosa ('gastrointestinal dialysis'). Although multiple reports exist in experimental and clinical practice (Box 114.1),[25] there is no convincing evidence to show that this therapy reduces mortality or morbidity. Only in life-threatening poisoning by carbamazepine, dapsone, phenobarbital, quinine or theophylline should multiple-dose activated charcoal be considered.[25]

A suitable single dose is 1–2 g/kg. A multiple-dose regimen for children is 1–2 g/kg stat followed by 0.25–0.5 g/kg 4–6-hourly. An alternative is 0.25–0.5 g/kg hourly for 12–24 hours.[26]

Contraindications

- Ileus
- A less-than-fully-conscious patient unless already intubated
- Substances not adsorbed, for example strong corrosive acids and alkalis, cyanide, metals (iron, lithium,

mercury, lead), alcohols, glycols, petroleum distillates (not all) and essential oils[5–7]

Complications

Aspiration of charcoal causes severe and often fatal pneumonitis, bronchiolitis obliterans and adult respiratory distress syndrome. Inadvertent intratracheal instillation of activated charcoal causes a significant increase in lung microvascular permeability and arterial blood gas derangements.[27]

Constipation is common after charcoal, but bowel obstruction is fortunately rare. The addition of a laxative (e.g. sorbitol or magnesium sulphate) is not recommended because, although transit time through the gut is decreased, efficacy of the charcoal is reduced and life-threatening fluid and electrolyte imbalance may occur.[28]

INDUCED EMESIS

For many reasons, induced emesis with ipecacuanha (ipecac) has disappeared from hospital practice and should not be performed routinely in this setting.[29] Ipecac contains alkaloids, mainly emetine and cephaeline, which induce emesis by stimulation of the chemoreceptor trigger zone of the medulla and by irritation of the gastric mucosa.

The efficacy of ipecac is limited and decreases with time from ingestion. Although it causes vomiting in a high percentage (93%–100%) of children within 25 minutes, the percentage of stomach contents ejected is small (28%) even when administered immediately after ingestion.[30] Moreover, solids are retained in the stomach or may even be propelled into the duodenum.[20] In adults, ipecac is even less useful and has to be given immediately to have quantifiable effects.[31]

It does not improve outcome and may reduce effectiveness of the alternative treatments of activated charcoal, oral antidotes and whole bowel irrigation. However, its use in the home is safe and is associated with fewer paediatric emergency department attendances,[32] and it is still recommended by authoritative paediatric health organisations in the United States.[33] Although ipecac was recommended inappropriately in 20% of cases reported to poisons information centres, it caused little morbidity.[34]

Experimentally, approximately 50%–83% of ingested experimental drug is removed if ipecac is given after 5 minutes,[17] falling to 2%–44% if given at 30 or 60 minutes.[21,35–38] In paediatric paracetamol poisoning, the 4-hour post-ingestion serum level was approximately 50% of controls if ipecac-induced vomiting occurred within 60 minutes of ingestion, but no benefit was derived if emesis occurred beyond 90 minutes after ingestion.[39] Similarly, serum levels of paracetamol were reduced approximately 50% if ipecac was administered at home, inducing emesis at a mean of 26 minutes after ingestion, compared with ipecac administered at a medical facility at a mean of 83 minutes.[40]

Critics claim that induced emesis merely creates work, delays discharge from the emergency department[41] increases complications and does not benefit the patient who presents more than 1 hour after ingestion.[42] Importantly, ipecac did not alter the clinical outcome of patients who presented awake and alert to the emergency department.[15]

Induced emesis appears superior to gastric lavage but inferior to activated charcoal. In salicylate poisoning, emesis retrieved twice as much as gastric lavage.[43] In adult volunteers ipecac-induced vomiting, occurring at an average of 19 minutes after ingestion, removed 54% of a tracer compared with 30% with gastric lavage performed at the equivalent times after ingestion.[14,44,45]

Contraindications

Specific contraindications include actual or impending loss of full consciousness or ingestion of corrosives or hydrocarbons.[29]

Complications

Potential complications include time-related lack of efficacy, protracted vomiting (17%), diarrhoea (13%) and lethargy (12%).[46] More serious, but rare, complications include gastric, oesophageal or brain haemorrhage, pneumomediastinum, aspiration pneumonitis, which may occur even in the fully conscious patient, delayed onset of vomiting, which is a threat if loss of consciousness subsequently occurs, and abuse in

bulimia, which may cause cardiotoxicity as well as the sequelae associated with repetitive vomiting.

In hospital, induced emesis has no practical role. Even when a child presents very early after significant poisoning, oral or nasogastric charcoal is preferred. Importantly, whenever induced emesis is used the child must be fully conscious on administration and is expected to be fully conscious when vomiting occurs.

GASTRIC LAVAGE

The place of this in the management of the poisoned victim is very limited.[47] It is invasive, ineffective and potentially harmful. It should be reserved for the child who presents very soon after a life-threatening ingestion such as iron or colchicine.

It involves the passage of a large-bore oro- or nasogastric tube into the stomach and the repeated instillation of fluid, usually water; however, some authorities advocate normal or half-normal saline. The oral route is preferred because there is less potential for traumatic injury, but an oropharyngeal airway may be needed to prevent tube occlusion by chomping. A smaller tube may be used if the poison is a liquid. Traditionally, the child should be placed in the left lateral position to limit stomach emptying, but the volume of intragastric contents rather than body position determines gastric emptying.[48]

Experimental studies on liquids indicate that gastric lavage retrieves 90% at 5 minutes,[49] 45% at 10 minutes[45] and 30% at 19 minutes,[44] and reduces the absorption or bioavailability by 20%–32% at 1 hour after ingestion.[35,50] When performed 5 minutes after ingestion of tablet drugs, it failed to prevent absorption, presumably because the tablets had not disintegrated.[18] In true overdose situations, gastric lavage within 4 hours of admission reduced serum paracetamol levels by 39%.[51]

Efficacy of gastric lavage, even with large-bore tubes, is poor because tablets are not removed and lavage encourages propulsion into the duodenum.[30] In symptomatic patients, gastric lavage alone compared with gastric lavage and activated charcoal increased pneumonic aspiration and did not alter the duration of intubation or the stay in the emergency department or the intensive care unit,[16] and was not beneficial unless performed within 1 hour of ingestion.[15] A randomised controlled trial of gastric lavage in acute overdose[24] suggested that it made no difference to the outcome of obtunded patients when preceding activated charcoal.

Contraindications

- Less-than-fully conscious patient (unless already intubated) because of the risk of aspiration pneumonitis – which is not negligible even during full consciousness.[16]
- After ingestion of corrosives because of the risk of perforation.
- After ingestion of hydrocarbons or petrochemicals because of the risk of pneumonitis.

Complications

- Aspiration pneumonitis
- Water intoxication
- Minor trauma to oropharynx (gastro-oesophageal perforation occurs rarely)
- Intrabronchial instillation of lavage fluid.

As expected, infants and children never cooperate fully for gastric lavage, thus increasing the risk of complications and the degree of psychological trauma.

If lavage is indicated (i.e. for life-threatening poisoning), rapid sequence induction of anaesthesia with intubation is mandatory. The largest possible lubricated tube of diameter similar to an appropriate-sized endotracheal tube should be used, and correct placement in the stomach confirmed. Small volumes (1–2 mL/kg) of warm tap water or 0.9% saline may be used to lavage until clear. However, most fluids should be retrieved to avoid complications with fluid and electrolytes, particularly hyponatraemia if water is used.

WHOLE BOWEL IRRIGATION

Irrigation of the bowel with an iso-osmolar solution of polyethylene glycol and electrolytes is effective in reducing the absorption of an experimental drug by 24%–67% at 1 hour after ingestion[53,54] and up to 73% at 4 hours after ingestion.[55] The technique has limited applications to sustained-release or enteric-coated drugs and remains a theoretical option for ingestions of iron, lead, zinc (substances not adsorbed by activated charcoal), packets of illicit drugs[56] and lithium.[57] The technique has been used most commonly for ingestion of calcium channel blockers, iron and antidepressants.[58] Whole bowel irrigation may be useful in delayed presentations when poisons have progressed beyond the stomach.

Since irrigation solutions are adsorbed by activated charcoal and cause desorption of drug, this necessitates prior administration of charcoal if a combined technique is used.[59] However, whole bowel irrigation did not add to the benefits of activated charcoal in an experimental model of sustained-release theophylline poisoning.[60]

A suitable regimen is approximately 30 mL/kg/h for 4–8 hours until rectal effluent is clear. A regimen of 25 mL/kg/h has been used safely for 5 days (total 44.3 L),[61] but a total of 3 L was as effective as 8 L in a simulated poisoning.[62]

Contraindications

Risk of aspiration during:

- less-than-full consciousness
- bowel obstruction or ileus.

PLAN OF MANAGEMENT

A general plan of management is suggested in Fig. 114.1, but each case of poisoning mandates a specific

management according to circumstances: consciousness and risk of aspiration, timing of presentation in relation to the severity of poisoning and the existence or otherwise of an effective antidote dictate if removal should be attempted, and by what means.

POISONING BY SPECIFIC SUBSTANCES

Like adults, children are poisoned regularly by therapeutic prescription or over-the-counter therapeutic drugs and substances (see Chapter 90). The poisons probably reflect their availability in the home. In surveys, the most common agents responsible for hospital admission of children are benzodiazepines, anticonvulsants, antiparkinsonism drugs, paracetamol, major tranquillisers, antidepressants and cardiovascular drugs.[62] Fatal poisonings are often by opiates, especially methadone[63] and pesticides, particularly paraquat and its derivatives,[64] which cause pulmonary fibrosis and hepatorenal failure.

The inquisitive nature of young children results in poisoning by substances not normally regarded as dangerous and not encountered in adults. A few of these are considered here briefly.

BUTTON AND DISC BATTERIES

Ingestion may cause electrolytic injury and potentially corrosive, toxic or pressure injury. There are many types of batteries that contain a variety of substances; the most important are lithium, mercury and potassium hydroxide.

Impaction in the oesophagus is the most significant situation; this can result in oesophageal perforation and tracheo-oesophageal fistula or aorto-oesophageal fistula. An impacted battery must be removed endoscopically as soon as possible. Lithium batteries are large and impact readily and they have higher voltages than other types. Electrolysis commences as soon as the battery surfaces are immersed in oesophageal fluid. The consequence is local and surrounding tissue destruction, including the trachea.[65,66] Strong alkali is produced at the cathode and strong acid is produced at the anode. Mercury batteries are more likely to fragment[66] but mercury poisoning is very uncommon.

Sufficient follow-up is necessary to detect early any oesophageal and tracheal damage and to ensure that a battery in the stomach or distal bowel is eliminated.

PETROLEUM DISTILLATES

Numerous by-products of petroleum distillation are utilised for industrial and domestic purposes. Ingestion of these hydrocarbons may cause central nervous system (CNS) toxicity (comprising obtundation and convulsion), pneumonitis, arrhythmias,[67] gastrointestinal irritation and occasional hepatorenal toxicity.

Pneumonitis is the most significant and it may occur during ingestion or subsequent vomiting. Although variable, these substances generally have low surface tension, which enables their rapid dispersement throughout contiguous mucosal surfaces including the respiratory tree. Prime examples are petrol, kerosene, lighter fluid, lamp oil and mineral spirits. Any child who ingests a distillate must be assessed for pneumonitis, and this should include clinical examination, a chest X-ray and at least a non-invasive measurement of oxygenation such as pulse oximetry. Although most children who ingest petroleum distillates do not develop pneumonitis, the onset of this complication may be within 30 minutes[68] and progress rapidly to severe lung disease. An adequate period of observation (6 hours) is necessary to exclude this complication. There is a poor correlation between the amount ingested and the severity of pulmonary toxicity.

Deliberate inhalation of volatile hydrocarbons, such as petrol or aerosolised paint, has the additional toxicity on myocardial tissue, including fatal tachydysrhythmia, which is possibly due to sensitisation to endogenous catecholamines. The deliberate inhalation of fumes, usually via a plastic bag, is known as 'chroming'.

ESSENTIAL OILS

The oils from certain plants contain mixtures of terpenes, alcohols, aldehydes, ketones and esters, which are used domestically for various purposes. The well-known oils are eucalyptus, turpentine, citronella, cloves, tea tree, peppermint, wintergreen and lavender. In general, small amounts cause depression of the conscious state, irritation of the gastrointestinal tract, liver dysfunction and pneumonitis if inhaled. Each has different toxicity. For example, as little as 5 mL of eucalyptus oil[69] or 15 mL of turpentine may cause depression of the conscious state.

Emesis should not be induced and gastric lavage performed only if airway protection is required.

LEAD

Children are more susceptible to lead poisoning after ingestion than are adults, possibly because of better absorption. Any amount of lead is neurotoxic.

Acute poisoning usually occurs after ingestion of a lead salt or metallic foreign body, or a lead-containing product, such as paint, a traditional remedy or a cosmetic. Acute poisoning by a salt may cause life-threatening cardiovascular collapse and encephalopathy.

Chronic poisoning can occur insidiously by multiple mechanisms, such as with ingestion of lead-contaminated water or by inhalation of leaded petrol

fumes, contaminated house dust or by parental work-related 'take-home' exposure. Chronic poisoning causes multiorgan dysfunction including neuromuscular dysfunction and encephalopathy. Unfortunately, interventions to reduce domestic lead exposure to date have been largely ineffective.[70]

Treatment consists of gastric decontamination in the case of recent ingestion of lead salts. The use of intravenous or oral chelating agents may be indicated.[71] In the case of ingestion of a lead foreign body, serial X-rays should be taken to ensure elimination, otherwise surgical/interventional removal is indicated. In the case of multiple embedded gunshot pellets and in all cases of chronic poisoning, serum lead levels should be measured to guide chelation therapy (see Table 114.1).

PARACETAMOL

This is the most common drug ingested by children in an accidental, iatrogenic or deliberate overdose situation. Overdose has the potential for hepatic failure and, less commonly, renal failure. Massive overdose may cause cardiovascular collapse and CNS depression. The onset of toxicity is delayed – up to several days. Consequently, the need for acute gastric decontamination is uncommon, but would be justifiable for acute large-dose presentations. The hepatic toxicity in part is caused by the metabolite of the drug (*N*-acetyl-*p*-benzoquinoneimine), which accumulates when endogenous glutathione, which facilitates conversion of *N*-acetyl-*p*-benzoquinoneimine to non-toxic substances, becomes exhausted. Adequate supply of glutathione is ensured by administration of N-acetylcysteine (NAC), a glutathione precursor that can be administered intravenously or orally (see Table 114.1).

The time of presentation after ingestion, as well as the dose, determines the management. If presentation is within 2 hours of ingestion, effective gastric removal or administration of activated charcoal may be all that is required pending a serum paracetamol level. In contrast, if presentation is several hours after ingestion, administration of the antidote according to serum paracetamol level takes precedence and, although it may be administered orally or intravenously, the intravenous route is generally preferred.[72] In one study, hepatic toxicity was slightly less in patients treated with the intravenous regimen compared with the oral regimen in patients whose treatment was initiated within 12 hours of ingestion. However, later than 18 hours hepatic toxicity was slightly less in patients treated with the oral regimen compared with the intravenous regimen, with no difference in toxicity in those treated with either regimen at presentations between 12 and 18 hours after ingestion.[73]

Near-simultaneous administration of activated charcoal and acetylcysteine may be of some benefit but it may also cause vomiting or desorption, thus decreasing the effectiveness of the oral antidote. If presentation is many hours after the poisoning, activated charcoal is not indicated, so the antidote could be administered orally if necessary according to serum paracetamol levels. Serial levels of paracetamol should be obtained, especially for slow-release preparations, but such cases are adequately managed if the protocol for NAC administration is followed.[74] Although numerous protocols exist for intravenous NAC administration, the recommended protocols are either that based on the Rumack-Matthew nomogram of a total of 300 mg/kg administered in three phases over a total of 21 hours[75] or on a protocol of the same dose in two phases over 20 hours (Table 114.1). In cases of massive overdose, for example 40 g or serum paracetamol level of 3300 µmol/L at 4 hours after ingestion, a protocol of 980 mg/kg of NAC over 48 hours has been successfully used.[76]

When the following doses are ingested, the antidote, *NAC*, should be commenced immediately[77] but then guided by time-related serum levels (see Table 114.1):

200 mg/kg or 10 g as a single dose (whichever is lower)
150 mg/kg/24 hours or 6 g (whichever is lower) for less than 48 hours
100 mg/kg/24 hours or 4 g (whichever is lower) for more than 48 hours

Unfortunately, toxic overdosing by chronic administration is not uncommon even in Australian and New Zealand institutions.[78] If serum levels of paracetamol cannot be obtained and >200 mg/kg has been ingested as a single dose, or liver dysfunction is present after chronic poisoning or any acute poisoning irrespective of the dose, the antidote should be given. Adverse reactions to NAC are common (approximately 7%–8%), but not serious, and they respond to an antihistamine[79] and its temporary cessation. High-dose NAC causes adverse reactions in almost 30% of patients.[76]

If hepatic function worsens despite antidote treatment, liver transplantation may be required.

IRON

Small quantities of elemental iron (>20 mg/kg) are toxic to children. A lethal dose may be reached by ingestion of a few iron tablets. The initial effects are gastrointestinal, which may include gastric erosion, followed sometimes by an interval before cardiovascular failure occurs at 6–24 hours and then followed by multiorgan failure (including encephalopathy), and hepatic and renal failure up to some 48 hours after ingestion. In addition to general supportive measures, specific management should include an abdominal X-ray to determine if unabsorbed tablets are present, in which case gastric lavage or whole bowel irrigation may be useful. Activated charcoal is useless. Chelation therapy with deferrioxamine (see Table 114.1) should be guided by the serum iron level and the clinical status.

CAUSTIC SUBSTANCES (DISHWASHER AND LAUNDRY DETERGENTS)

In a study of 743 children,[80] the incidence of oesophageal burns caused by ingestion of automatic machine dishwashing detergents was 59%, caustic soda 55% and drain cleaners 55%. All are strongly alkaline and are corrosive. Dishwasher detergents are presented as liquids, powders or tablet blocks and are commonly accessed in an open dishwasher.[81] Pharyngeal and oesophageal irritation, burns or corrosion may occur. There may be simultaneous ocular and dermal toxicity. Any child presenting with a history of ingestion of a caustic substance, irrespective of clinical signs, should be considered for oesophagoscopy and follow-up since the correlation between symptoms and signs and oesophageal burns is poor, and significant oesophageal damage may occur in the absence of more proximal injury.[82]

The recently available liquid laundry detergent pods and capsules are also alkaline and more toxic than traditional laundry products. Oral contact causes CNS obtundation, seizures, pulmonary oedema and aspirational lung disease while eye contact causes conjunctivitis and keratitis.[83–85]

ENVENOMATION

Children are subject to envenomation by a wide variety of terrestrial creatures including snakes, scorpions, spiders, bees, ants and wasps. Marine envenomation is mainly caused by jellyfish and stinging fish and only occasionally by venomous octopuses. The clinical manifestations and management of envenomation are expectedly similar to those observed in adults (see Chapter 90) but with several additional considerations:

1. A history of envenomation may not be forthcoming when a young child, unsupervised, is bitten by a snake, particularly of the elapid genus, whose fang marks may not be evident. The diagnosis should be suspected in a child who presents with sudden onset of neurological signs *and* coagulopathy. Similarly, a diagnosis of spider envenomation in a child should be among the causes considered for a painful skin lesion.
2. The clinical effects of envenomation may be more pronounced in a child compared with an adult for the simple reason of their smaller body mass in relation to injected venom.
3. The dose of an antivenom is not reduced.

Paediatric cardiopulmonary resuscitation

James Tibballs

INTRODUCTION

Basic and advanced cardiopulmonary resuscitation (CPR) for newborns, infants and children are described. The essentials of resuscitation are presented in figures for the infant and child (Fig. 115.1) and for newborns (Fig. 115.2). Recommendations are based on guidelines published by resuscitation organisations,[1–3] which are derived from evaluation of the science of resuscitation by the International Liaison Committee on Resuscitation in 2015[4] and from selected studies since that date.

This chapter is intended for medical and nursing personnel in hospital and complements Chapters 21 and 105. To add ability to knowledge, it is advisable to undertake a specialised paediatric CPR course, such as the Advanced Paediatric Life Support, Paediatric Advanced Life Support or Resus4kids courses.

DEFINITIONS

Distinctions within the term 'paediatric' are based on combinations of physiology, physical size and age. Some aspects of CPR are different for the 'newborn', infant, small (younger) child and large (older) child:

- *'newborn':* the infant at birth or within several hours of birth
- *'infant':* an infant outside the 'newborn' period and up to the age of 12 months
- *'small/young child':* a child of preschool and early primary school from the age of 1–8 years
- *'large/older child':* a child of late primary school from the age of 9 up to 14 years
- children older than 14 years may be treated as adults, but they do not have the same propensity for ventricular fibrillation (VF) as do adults.

EPIDEMIOLOGY

The causes of cardiopulmonary arrest (CPA) in infants and children are many and include any cause of hypoxaemia or hypotension or both. Common causes are trauma (motor vehicle accidents, near-drowning, falls, burns, gunshot, non-accidental injury), drug overdose and poisoning, respiratory illness (asthma, upper-airway obstruction, parenchymal diseases), postoperative (especially cardiac), septicaemia and sudden infant death syndrome. As many as 10% of infants at birth require some form of resuscitation for varied conditions of which birth asphyxia is the most common.

PREVENTION

CPA occurring in hospital may be preventable. Every institution which admits children should have a system to recognise deterioration, call for assistance and to provide rapid enhancement of the level of care, hence the use of medical emergency teams, rapid response teams and paediatric early warning scores.[5]

PROGNOSIS

Survival to discharge from cardiac arrest in hospital is reported from large series as 37%–41%.[6–8] With slightly higher survival for arrest in the paediatric intensive care unit (40%–45%).[9,10] Survival is less if arrest occurs after hours.[11] Extracorporeal CPR has a survival to discharge of 40%–55% with good neurological outcomes.[12,13]

Not unexpectedly, survival from out-of-hospital cardiac arrest is less than in-hospital arrest but is not hopeless. Overall survival from all causes is 6%–11% and survival with favourable neurological outcome up to 9%.[6,14–16] Outcomes are better when bystanders have given conventional CPR (chest compressions with ventilation) compared with compression-only CPR or no CPR, and better when the required duration of CPR is short.[14,17] In non-asphyxial arrest, compression-only CPR may be better.[18] A favourable neurological outcome can be predicted by pre-hospital return of spontaneous circulation (ROSC), the presence of a shockable rhythm and a witnessed arrest.[19] Only 1% of children arriving at hospital without ROSC have a favourable neurological outcome.[16]

ABSTRACT

This chapter describes practical aspects of techniques, equipment and drugs used in basic and advanced cardiopulmonary resuscitation (CPR). A chest compression rate of 100–120 per minute to a depth of 5 cm for children and 4 cm for infants is recommended combined with ventilation via bag-mask or tracheal intubation in advanced CPR. A compression–ventilation ratio of 15:2 is recommended for advanced resuscitation by health care personnel, and a ratio of 30:2 is recommended for basic life support by a single rescuer. Interruptions to chest compressions must be minimised. A single direct current shock of 4 J/kg followed by immediate resumption of CPR is recommended for ventricular fibrillation or ventricular tachycardia. Adrenaline 10 μg/kg is recommended for asystole and non-shockable rhythm. Automated external defibrillation for out-of-hospital arrest is encouraged. Extracorporeal CPR is sanctioned in-hospital where practical. Invasive maintenance of vital functions post arrest is crucial with either therapeutic hypothermia or normothermia. Prognostication should include clinical examination and neurological investigations.

guidelines

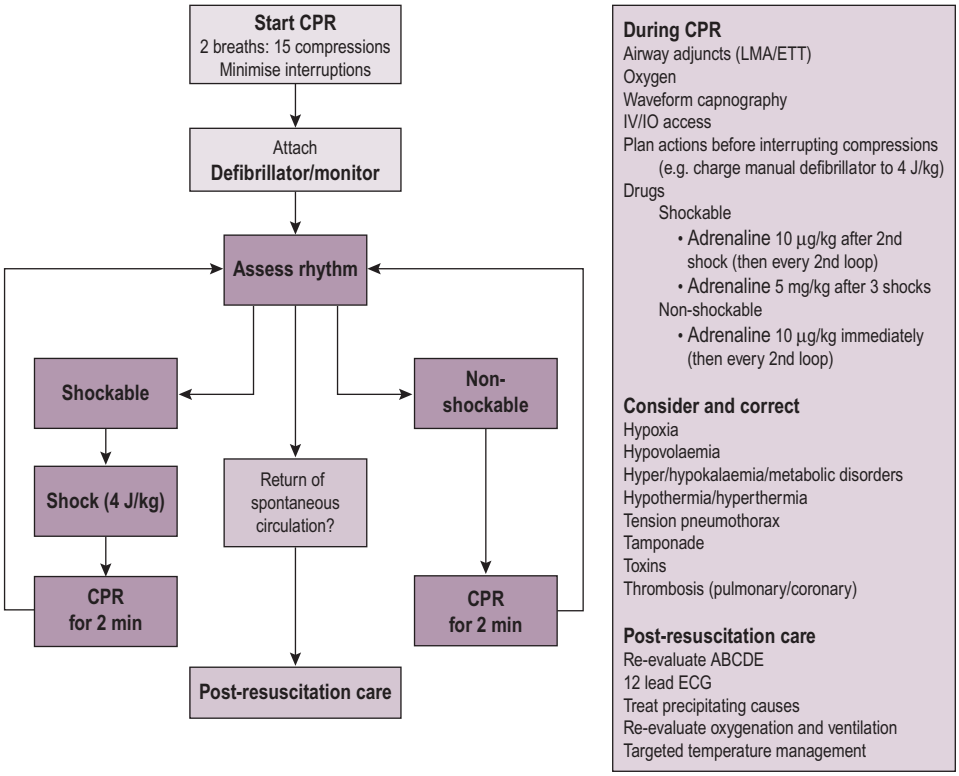

Figure 115.1 Advanced life support for infants and children. *CPR*, Cardiopulmonary resuscitation; *ECG*, electrocardiograph; *ETT*, Endotracheal tube; *IV*, intravenous; *IO*, intraosseous; *LMA*, laryngeal mask airway.

BASIC LIFE SUPPORT

ASSESSMENT OF AIRWAY AND BREATHING

If the child is not responsive to tactile and auditory stimulation, not breathing normally and not moving, the rescuer should assess the airway and breathing, which can be achieved in either the supine or lateral position. Obvious causes of airway obstruction in the pharynx should be removed. Fluids such as vomitus or blood should be aspirated with a Yankauer sucker. Solid or semi-solid objects such as food particles or foreign objects should be removed with an instrument (e.g. Magill's forceps). Since the most common cause of airway obstruction in an obtunded state is the tongue, first-aid manoeuvres to elevate it should be performed. These manoeuvres are backward head tilt, chin lift and jaw thrust. Head tilt and chin lift are often combined. If neck injury is present or suspected, neither the head tilt nor the chin lift manoeuvre should be used. Following establishment of an airway, the presence or absence of adequate breathing is assessed by inspection of movement of the chest and abdomen, and by listening and feeling for escape of exhaled air from the mouth and nose (look, listen and feel). If adequate breathing is occurring the patient should be placed on the side in a coma position.

RESCUE BREATHING (EXPIRED AIR RESUSCITATION)

If breathing is inadequate then expired air resuscitation or bag-(valve)-mask ventilation should be commenced immediately. Initially at least two breaths are recommended, but some guidelines suggest up to five. (There is no definitive evidence.) While maintaining the airway, administer slow breaths over 1–1.5 seconds to achieve adequate chest inflation. In children of all sizes, a mouth-to-mouth technique is possible by pinching the nostrils closed. In the newborn and infants, a mouth-to-mouth-and-nose technique is recommended, but if the rescuer has a small mouth then a mouth-to-nose technique is an alternative. Lack of chest rise may signify obstruction of the airway requiring repositioning of the head and neck.

ASSESSMENT OF CIRCULATION

If the child is unresponsive and not breathing, external cardiac compression (ECC) should be commenced immediately. Pulse by palpation may be performed, but the 'pulse check' has been removed from CPR guidelines for lay persons because of their inability to reliably check the pulse, which may also be an issue for health care personnel. Palpation of any major

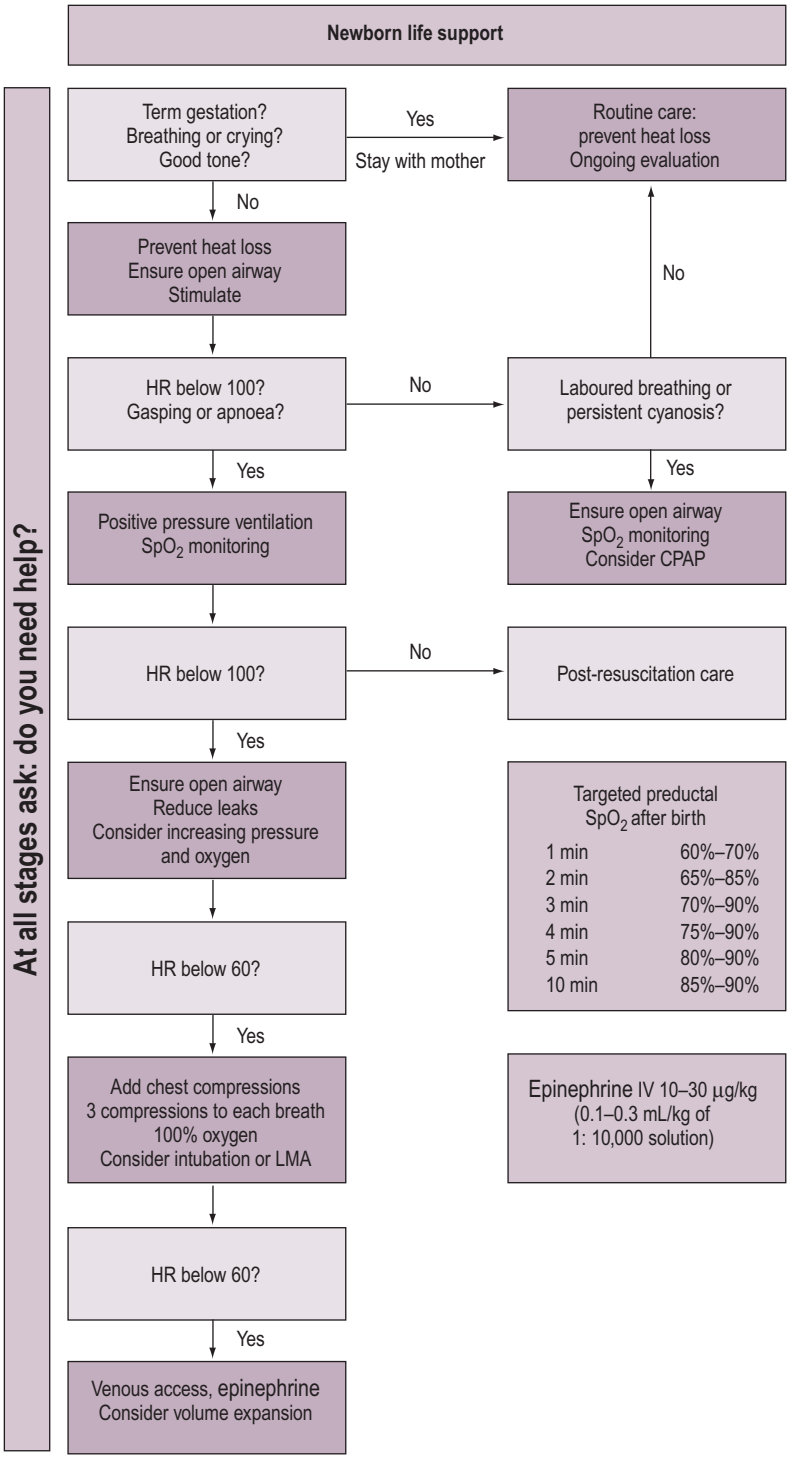

Figure 115.2 Newborn life support. *LMA*, Laryngeal mask airways. *(Reproduced with permission from the Australian Resuscitation Council, Melbourne.)*

pulse (carotid, brachial, femoral) is appropriate. If a pulse cannot be detected within 10 seconds or the rate is inadequate (<60 beats/min) then ECC should be commenced.

EXTERNAL CARDIAC COMPRESSION

Different techniques are used for infants and children of different sizes but in all patients the depth of compression is one-third the depth of their chest. This is about 5 cm for children and 4 cm for infants. For newborns and infants, two techniques are in common use. In the 'two-finger technique', the middle finger and forefinger are used. This technique is taught to laypersons and is also the preferred technique for a single health care rescuer. With the better 'two-thumb technique', the hands encircle the thorax, approaching the chest from either above or below, and the thumbs are placed either opposite, alongside or atop one another. With this technique, the rescuer must take care to avoid restriction of the patient's chest during inflation. With premature newborn and small infants, the rescuer's encircling fingers may reach and stabilise the vertebral column without limiting chest inflation. With both techniques, the sternum is compressed above the xiphoid or about one fingerbreadth below the internipple line.

Either a single hand or both hands may be used for infants and children as determined by the relationship between the size of the patient's chest and the hands of the rescuer. For young children, ECC can be performed with the heel of one hand. For older children, a bimanual technique as per adults may be used. In all ages, the 'centre of the chest' – which corresponds to the lower sternum – is compressed. Approximately 50% of each cycle should be compression. Every effort should be made to minimise 'hands-off' time (interruptions to compressions). This requires coordinated teamwork when, for example, ECC is paused to allow rhythm analysis or the application of direct current (DC) shock.

RATES OF COMPRESSION AND RATIO OF COMPRESSION TO VENTILATION

In hospitals (two or more rescuers), the ratio of compression to ventilation for infants and children should be 15:2. Resuscitation may be commenced with either ventilations or compressions. After every 15 compressions, a pause should allow delivery of two ventilations whenever expired air resuscitation or any type of mask ventilation is given. ECC can be given during the second exhalation. The aim should be to achieve about 5 cycles/min (i.e. about 75 compressions and 10 breaths/min). If circulation returns, but respiration remains inadequate, the number of ventilations should be higher, but care should be taken to avoid hypocarbia, which results in cerebral ischaemia. A sole health care rescuer may use the layperson ratio of 30:2, aiming to achieve about five cycles in 2 minutes (i.e. about 75 compressions and 5 breaths/min).

For infants and children, compressions should be delivered at a rate of 100–120 per minute (i.e. one compression every 0.6 seconds or approximately two per second). As ventilation is interposed between compressions, the actual compressions delivered will be less than 100 each minute. If the airway has been secured (e.g. by endotracheal intubation), strict coordination of compression and ventilation is not crucial; ventilation can be given against resistance imposed by chest compression. In this case about 100–120 compressions/min will be achieved, but ventilation should be limited to about 10–12 per minute and wherever possible guided by arterial blood gas analysis. This low rate is all that is needed to match low cardiac output achieved during ECC. Excessive ventilation detracts from effectiveness of ECC and causes hypocarbia.

For infants at birth the total number of recommended 'events' per minute is 120, with the aim of achieving 90 compressions and 30 inflations each minute (i.e. in a ratio of 3:1). Beyond the newborn period (i.e. when the lungs have been inflated), the compression–ventilation ratio of 15:2 should be used.

ADVANCED LIFE SUPPORT

As soon as practicable, mechanical ventilation with added oxygen should be commenced with either a bag-mask or via endotracheal intubation. Although intubation is preferred (see below), valuable time should not be wasted in numerous unsuccessful attempts. Initial effective bag-mask ventilation is sufficient and necessary prerequisite for successful paediatric CPR. Bags of appropriate sizes should be available for infants, small children and large children. A bag of ~500 mL volume should be available for infants at birth. Insertion of an oropharyngeal (Guedel) airway may be necessary to facilitate bag-mask ventilation. Access to the circulation and display of the electrocardiograph (ECG) and oximetry should also be achieved as soon as possible. Thereafter treatment should be guided by the cardiac rhythm. Underlying causes of CPA should be sought and treated.

AIRWAY MANAGEMENT

If attending personnel are skilled, the trachea should be intubated as soon as practicable. Although the role of intubation on survival is being increasingly questioned,[20] it is still regarded as advantageous and the standard intervention.[21] Tracheal intubation establishes and maintains an airway, facilitates mechanical ventilation with 100% oxygen, minimises the risk of pulmonary aspiration, enables suctioning of the trachea and provides a route for the administration of selected drugs. If difficulty is experienced at initial

intubation, oxygenation should be established with bag-mask ventilation before a re-attempt at intubation. If intubation is attempted, it should initially be via the oral route (not nasal) because oral intubation is invariably quicker than nasal, is less likely to cause trauma and haemorrhage, and enables the endotracheal tube (ETT) to be more easily exchanged if the first choice is inappropriate. On the other hand, a tube placed nasally can be better affixed to the face and so is less likely to enter a bronchus or be subject to inadvertent extubation, and is preferred for transport and long-term management. A nasogastric tube should be inserted after intubation to relieve possible gaseous distension of the stomach sustained during bag-mask ventilation.

Correct placement of the ETT in the trachea must be confirmed. In the hurried conditions of emergency intubation at CPA, it is not difficult to mistakenly intubate the oesophagus or to intubate a bronchus. There is no substitute for:

- visualising the passage of the tip of the ETT through the vocal cords at intubation
- confirmation of bilateral pulmonary air entry by auscultation in the axillae
- continuous observation of bilateral rise and fall of the chest on ventilation
- observation of the patient becoming and remaining pink.

Immediately after intubation, tracheal placement of the tube should be confirmed by capnography or colorimetric CO_2 detection. Capnography is preferred because it also affords ongoing assessment of adequacy of ECC and ventilation as well as a continuous warning of accidental extubation. Excretion of CO_2 needs effective pulmonary blood flow and ventilation of the lungs. Failure to detect CO_2 while there is either spontaneous or ECC-generated cardiac output necessitates immediate exclusion of oesophageal intubation by direct laryngoscopic inspection. If the tube is correctly located in the trachea, and CO_2 is not detected or is low, ECC should be improved and hyperventilation, if occurring, limited. Oxygenation should be confirmed with use of a pulse oximeter or measurement of arterial gas tension.

Uncuffed tube sizes (internal diameter)

- 2.5 mm tube for a premature newborn <1 kg; 3.0 mm for infants 2.0–3.0 kg; 3.0 or 3.5 mm for infants >3.0 kg and up to age 6 months; 4 mm for infants 7 months to 1 year
- for children over 1 year, the size is approximately determined by the formula: size (mm) = age (years)/4 + 4

Cuffed tube sizes (internal diameter)

- 3.0 mm for newborns ≥3 kg and ≤1 year; 3.5 mm for children 1–2 years
- for children over 2 years, the size is approximately determined by the formula: size (mm) = age (years)/4 + 3.5

Larger and smaller tubes should be available. The correct size should allow a small leak on application of moderate pressure but also ensure adequate pulmonary inflation. Cuffed tubes have the advantage of avoiding a change when deemed too small in a hazardous situation but occupy more volume in a small airway.

The tube is inserted a specific depth to avoid accidental extubation and endobronchial intubation, both of which may threaten oxygenation. Assessment of the depth of insertion at laryngoscopy is not reliable because this is performed with the neck extended, and when the laryngoscope is removed the head assumes a position of neutrality or flexion with the depth of insertion increasing automatically. Whether oral or nasal intubation, on a chest X-ray taken with the head in neutral position, the tip of the tube should be at the interclavicular line. If not, its depth should be adjusted.

Appropriate initial depths of insertion measured from the centre of the lips for an oral tube are:

- 9.5 cm for a term newborn; 11.5 cm for a 6-month-old; 12 cm for a 1 year old
- after 1 year of age the depth is given by the formula: depth (cm) = age (years)/2 + 12.

Appropriate initial depths of insertion measured at the nares for a nasal tube are:

- 11–11.5 cm for a term newborn; 13 cm for a 6-month-old; 14 cm for a 1 year old
- after 1 year of age the depth is given by the formula: depth (cm) = age (years)/2 + 15.

Laryngeal mask airways (LMA) may be used to establish and maintain an airway in the spontaneously breathing patient and for emergency relief of upper airway obstruction, but they have a limited role during CPR. Their role in provision of mechanical ventilation remains uncertain. Like bag-mask ventilation, they do not protect the airway from aspiration. Although insertion of an LMA is easier to learn than endotracheal intubation, training should not replace mastery of bag-mask ventilation. An LMA is not suitable for long-term use or during transport when endotracheal intubation is preferred. Sizes are available to suit body weight (kg) of newborns, infants and children: <5 kg size 1, 5–10 kg size 1½, 10–20 kg size 2, 20–30 kg size 2½, 30–50 kg size 3, 50–70 kg size 4, 70–100 kg size 5, and >100 kg size 6.

ELECTROCARDIOGRAPH

The ECG should be displayed with either leads or paddles. Drug therapy or immediate DC shock is determined by the existing rhythm.

ACCESS TO THE CIRCULATION

Access to the circulation via a peripheral or central vein should be attempted immediately (depending on operator skill). Any site is acceptable. Visible or palpable peripheral veins are to be found on the dorsum of the hand, wrist, forearm, cubital fossa, chest wall, foot and ankle. In infants, scalp veins are accessible and the umbilical vein can be used up to about 1 week after birth. Although the external jugulars are usually distended and easily cannulated at CPR, this may be impeded by performance of intubation or bag-mask ventilation. Cannulation of femoral, subclavian or internal jugular veins is an option, but it is difficult and hazardous in this situation. Surgical cutdown onto a long saphenous, saphenofemoral junction or basilic vein is a valuable skill sometimes required in traumatic exsanguination. Any pre-existing functioning line can be used provided it does not contain any drug or electrolyte precipitating the CPA.

INTRAOSSEOUS INJECTION

If intravenous (IV) access cannot be achieved rapidly (within 60 seconds), intraosseous (IO) access should be obtained. This route has been used for patients of all ages and provides rapid, safe and reliable access to the circulation. It serves as an adequate route for any parenteral drug and fluid administration.

A metal needle with a trocar (e.g. disposable IO needle; Cook, IL) is preferable. Although many sites have been used for bone marrow injection, the easiest to identify is the anteromedial surface of the upper or lower tibia, especially in children younger than 6 years. The site of the former is a few centimetres below the anterior tuberosity and the latter a few centimetres above the medial malleolus. The handle of the device needle is held in the palm of the hand while the fingers grip the shaft about a centimetre from the tip. It is inserted perpendicular to the bone surface and a rotary action is used to traverse the cortex. Sudden loss of resistance signifies entry to bone marrow. Correct positioning of the needle is confirmed by aspiration of bone marrow (which may be used for biochemical and haematological purposes) but that is not always possible. Bone injection guns (e.g. PerSys Medical, Houston, Texas), which propel a needle to a preset depth or drills (e.g. Arrow EZ-IO, Emergo Australia, Sydney, Australia), enable easy IO injection for infants, children and adults. The latter devices are preferred.

Volume expanders need to be given by syringe to achieve rapid restoration of circulating volume and rapid access of drugs to the central circulation. This is best achieved using a 10 mL syringe with a three-way tap in the IV tubing so that the IO needle does not become dislodged inadvertently.

Care should be exercised to avoid complications, particularly cutaneous extravasation, compartment syndrome of the leg and osteomyelitis. Contraindications include local trauma and infection.

ENDOTRACHEAL ADMINISTRATION OF DRUGS

Lipid-soluble drugs – epinephrine (adrenaline), atropine, lidocaine and naloxone – may be administered via the ETT if neither IV nor IO access is possible. Although the optimal doses of these drugs by this route are not known, work in animal models suggests doses should be 10 times the IV doses. The drugs should be diluted in normal saline up to 2 mL for infants, 5 mL for small children and 10 mL for large children. It is acceptable and simplest to squirt the drugs from the syringe (after removing the needle) directly into the ETT and disperse them throughout the respiratory tree with bagging. Neither sodium bicarbonate nor calcium salts should be administered via the tracheal route because they injure the airways.

DIRECT CURRENT SHOCK

Defibrillators should have paediatric paddles of cross-sectional area 12–20 cm^2 for use in children <10 kg body weight. For others, adult-sized paddles (50–80 cm^2) are satisfactory provided the paddles do not contact each other. Selectable energy levels should enable delivery of doses 0.5–4 J/kg. The closest level to the dose should be selected. One paddle is placed over the midaxilla opposite the xiphoid or nipple, and the other to the right of the upper sternum below the clavicle. Conductive gel (confined to the area beneath the paddles) or gel pads and firm pressure are needed to deliver optimum energy to the heart without causing skin burns. The doses for monophasic and biphasic shock are the same.

In the treatment of refractory arrhythmias, equipment failure should be excluded. An anteroposterior position of the paddles (one over the cardiac apex, one over the left scapula) may be efficacious in refractory arrhythmia. Dextrocardia may be present with congenital heart disease and the position of the paddles should be altered accordingly.

Monophasic and biphasic automated external defibrillators (AEDs) with attenuated energy doses (approximately 50 J or less) may be used for children 1–8 years of age (approximately 10–25 kg). Adult energy doses of 150–200 J may be used in children older than 8 years of age or 25 kg body weight. Although AEDs are not recommended for use in infants as they may not reliably distinguish VF from tachycardia and hence pose a risk of harmful DC shock, in the situation of a 'shockable' rhythm with poor or no cardiac output, an AED with dose attenuation may be used. If that is not available, an adult AED may be used.

Rescuers should be cognisant of the risk of inadvertent shock to themselves and colleagues during operation of defibrillators. They should ensure that they have no physical contact with the patient directly

or indirectly at the time of electrical discharge. Surgical gloves provide minimal protection against shock. Paddles should be charged only when already placed on the chest of the patient. If the need to give DC shock abates while the paddles are charged, they should be disarmed before replacing them in their cradles.

TREATMENT OF SPECIFIC ARRHYTHMIAS

The following discussion of specific arrhythmias assumes that mechanical ventilation with oxygen and ECC has been commenced. The treatment of pulseless arrhythmias is summarised in Fig. 115.3. Reversible causes of arrhythmias should be sought and treated during resuscitation. For example:

- hypoxaemia or hypotension causing bradycardia: may respond to ventilation
- hypocalcaemia and toxicity caused by calcium channel blockade: may be treated with calcium IV or IO (chloride 10% 0.2 mL/kg, gluconate 10% 0.7 mL/kg)
- hyperkalaemia: may be antagonised with a calcium salt then the serum level lowered with insulin

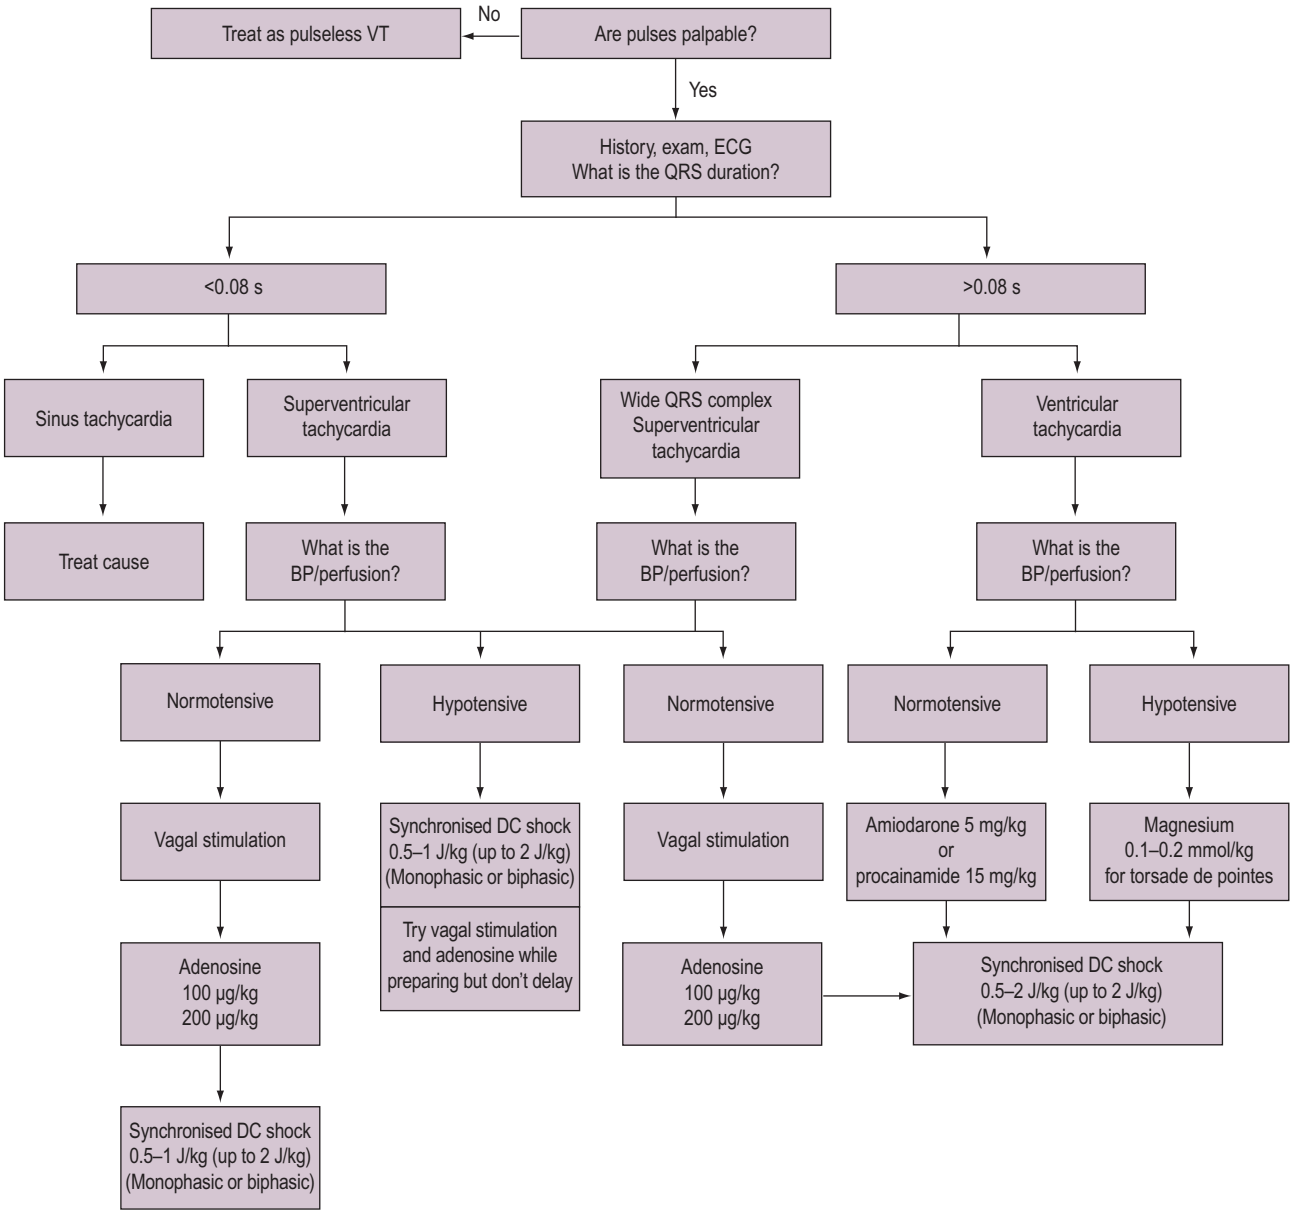

Figure 115.3 Treatment of tachyarrhythmias. *DC*, Direct current; *ECG*, electrocardiograph. *(Reproduced with permission from the Australian Resuscitation Council, Melbourne.)*

(0.05 U/kg) + dextrose (0.5 g/kg), but beware of hypoglycaemia. Additional treatments of hyperkalaemia are salbutamol, sodium bicarbonate, hyperventilation or combinations.

All drugs should be flushed into the circulation with a small bolus of isotonic fluid. To prevent their inactivation, drugs should not be mixed together in the syringe or in infusion lines.

ASYSTOLE AND BRADYCARDIA

Asystole and hypotensive bradycardia (<60 beats/min) should be treated with epinephrine 10 µg/kg IV or IO If these routes are not available, epinephrine 100 µg/kg should be administered via ETT.

Unresponsive asystole should be treated with additional similar doses of epinephrine (10 µg/kg IV, IO; 100 µg/kg ETT) every 3–5 minutes. Higher doses, up to 200 µg/kg IV or IO, may be indicated in special circumstances (e.g. beta-blocker toxicity) but should not be used routinely as they have not altered outcome and predispose to complications (post-arrest myocardial dysfunction, hypertension, tachycardia). In newborns, the initial bolus dose is 100–300 µg/kg.

Recurrent bradycardia or asystole may require an infusion of epinephrine at 0.05–3 µg/kg/min: doses <0.3 µg/kg/min are predominantly beta adrenergic; doses >0.3 µg/kg/min are predominantly alpha adrenergic. Infuse into a secure large vein. If sinus rhythm cannot be restored, sodium bicarbonate 1 mmol/kg IV or IO may be helpful, but do not allow mixing with epinephrine since catecholamines are inactivated in alkaline solution.

Sinus bradycardia, sinus arrest with slow junctional or idioventricular rhythm, and atrioventricular block are the most common preterminal arrhythmias in paediatric practice. Untreated, bradycardia progresses to asystole. Bradycardia caused by vagal stimulation should be managed with cessation of the stimulus and/or atropine 20 µg/kg IV or IO (minimum dose 100 µg) but persistent vagal-mediated bradycardia should be treated with epinephrine 10 µg/kg IV or IO

If facilities are available, bradycardia may be treated with pacing (oesophageal, transcutaneous, transvenous, epicardial) if sinus node dysfunction or heart block exists, but it is not helpful in asystole.

VENTRICULAR FIBRILLATION AND PULSELESS VENTRICULAR TACHYCARDIA

The initial dose for VF or pulseless ventricular tachycardia (VT) is a single unsynchronised DC shock of 4 J/kg followed by immediate resumption of ECC without pausing to analyse the rhythm. If VF or pulseless VT persists, subsequent single shocks of 4 J/kg are given, each followed by 2 minutes of ECC. Higher doses may be given in refractory VF.

Failure of VF to revert to sinus rhythm after the first shock should also be treated with epinephrine 10 µg/kg IV or IO or 100 µg/kg ETT every 3–5 minutes. Persistent (refractory) or recurrent VF or VT may also be treated with the antiarrhythmic drug amiodarone interspersed with single DC shocks. The dose of amiodarone is 5 mg/kg IV or IO as a bolus, which may be repeated to a maximum of 15 mg/kg. If amiodarone is not available, lidocaine in a dose of 1 mg/kg IV or IO or 2–3 mg/kg via ETT may be used, but the evidence for its efficacy is poor. An infusion of lidocaine at 20–50 µg/kg/min may be used to suppress excitability. Alternatives to epinephrine as a vasopressor, such as other catecholamines or vasopressin, have not been adequately investigated for use during CPR for children.

The witnessed (monitored) onset of VF or pulseless VT, such as in the cardiac catheter laboratory or intensive care unit setting, should be treated with successive (if needed) unsynchronised DC shocks up to a stack (salvo) of three shocks all of 4 J/kg. Rescuers should maintain the paddles on the chest and be prepared to deliver the series of the three shocks in quick succession, pausing only to verify the rhythm. Automatic external defibrillators are not suitable for this purpose because of time delays in their recognition of rhythms and charging. A precordial thump may be given before DC shock but its efficacy has not been proven.

Magnesium, 25–50 mg/kg (0.1–0.2 mmol/kg) IV or IO, is indicated for polymorphic VT (torsade de pointes).

ELECTROMECHANICAL DISSOCIATION AND PULSELESS ELECTRICAL ACTIVITY

A normal ECG complex without pulse or circulation is called electromechanical dissociation (EMD). If untreated, the ECG initially deteriorates to an abnormal but still recognisable state when it is called pulseless electrical activity (PEA). Both conditions should be treated as for asystole and their causes ascertained and treated.

PULSATILE VENTRICULAR TACHYCARDIA

Haemodynamically stable VT may be treated with an antiarrhythmic agent such as amiodarone (5 mg/kg IV over 20–60 minutes) or procainamide (15 mg/kg IV over 30–60 minutes). Since both drugs prolong the QT interval, they should not be given together. If torsade de pointes is present, magnesium (25–50 mg/kg, 0.1–0.2 mmol/kg IV or IO) may be used. If cardioversion is needed, it should be synchronised at 0.5–2 J/kg under sedation/anaesthesia. Pulsatile VT may be difficult to distinguish from wide-complex supraventricular tachycardia (SVT) when its QRS duration is >0.08 seconds.

SUPRAVENTRICULAR TACHYCARDIA

SVT is the most common spontaneous arrhythmia in childhood and infancy. It may cause life-threatening

hypotension. It is usually re-entrant with a rate of 220–300 per minutes in infants, but less in children. The QRS complex is usually narrow (<0.08 seconds) making it difficult sometimes to discern from sinus tachycardia (ST). However, whereas ST is a part of other features of illness, SVT is a singular entity, and whereas the rate in ST is variable with activity or stimulation, it is uniform in SVT. In both rhythms, a P-wave may be discernible. SVT with aberrant conduction (QRS >0.08 seconds) may resemble VT. Relative treatment of these tachycardias is summarised in Fig. 115.3.

If SVT is haemodynamically stable (adequate perfusion and blood pressure), initial treatment should be vagal stimulation. For infants and young children, application to the face of a plastic bag filled with iced water is often effective. Older children may be treated with carotid sinus massage or guided to perform a Valsalva manoeuvre (e.g. blowing through a narrow straw). If the patient is ventilated, apply vagal stimulation by tracheal or pharyngeal suction. If vagal stimulation is unsuccessful, give adenosine 100 µg/kg IV (maximum 6 mg) as a rapid bolus aided by an injection of 0.9% saline. If unsuccessful, double the dose to 200 µg/kg (maximum 12 mg) and again inject rapidly. An adenosine-induced pro-tachyarrhythmia (e.g. torsade de pointes) is rare.

An alternative drug treatment of haemodynamically stable SVT is amiodarone whose schedules are either infusions of 5 mg/kg over 1 hour followed by 5 µg/kg/min, or initially 25 µg/kg/min for 4 hours followed by 5–15 µg/kg/min. Amiodarone may cause hypotension, hypothyroidism and pulmonary toxicity. Other alternative drugs include procainamide in a dose of 15 mg/kg IV over 30–60 minutes, digoxin, a beta blocker or a calcium channel blocker. However, calcium channel blockers should not be used at all to treat SVT in infants and should be avoided or used with extreme caution in children because they may induce hypotension and cardiac depression. Haemodynamically stable SVT unresponsive to vagal stimulation and drug therapy may be treated with synchronised DC shock (cardioversion) in a dose of 0.5–1.0 J/kg.

SVT may cause severe hypotension or pulselessness, in which case synchronised DC shock (cardioversion) at 0.5–1.0 J/kg should be given immediately, progressing to 2 J/kg if necessary. While preparations are made to give DC shock, vagal stimulation and adenosine (IV or IO) may be tried provided they do not delay cardioversion.

POST-RESUSCITATION CARE

Supportive therapy should be provided until there is recovery of function of vital organs. This may require provision of oxygen therapy, mechanical ventilation, inotropic/vasopressor infusion, renal support, parenteral nutrition and other therapy for several days or longer. However, the percentage of inspired oxygen should be reduced as soon as possible after resuscitation to achieve only normal levels of Pa_{O_2}. Hyperoxaemia, like hypoxaemia, should be avoided. Recovery of infants and children is usually slow because cardiorespiratory arrest is often secondary to prolonged global ischaemia or hypoxaemia, which implies that other organs sustained damage before cardiorespiratory arrest. Particular care should be taken to ensure adequate cerebral perfusion with well-oxygenated blood. Hyperventilation is not useful for this purpose.

Therapeutic hypothermia post resuscitation (32°C–34°C) up to 3 days may improve neurological outcome, but is controversial and may predispose to infection and coagulopathy. However, an inadvertently hypothermic patient (e.g. one nearly drowned in icy water), provided the temperature is above 33°C, should not initially be actively warmed. During therapeutic hypothermia, shivering should be prevented with sedation and/or neuromuscular blockade, seizures should be actively sought and treated with anticonvulsant and the cause of the CPA should be investigated and treated appropriately (e.g. sepsis or drug overdose). Hyperthermia should be aggressively treated, in all instances.

Complications of CPR should be sought, especially if secondary deterioration occurs. A chest X-ray should be obtained to check the position of the ETT, to exclude pneumothorax, lung collapse, contusion or aspiration, and to check the cardiac silhouette – although an echocardiographic examination is preferable to specifically check contractility and to exclude a pericardial effusion. Measurements of haemoglobin, pH, gas tensions, electrolytes and glucose are important.

CESSATION OF CARDIOPULMONARY RESUSCITATION

Long-term outcome from paediatric CPR is mediocre, but better if arrest is respiratory alone or if CPA occurs in hospital. The decision to cease CPR should be based on a number of factors including the duration and quality of resuscitation, response to treatment, pre-arrest status, remediable factors, likely outcome if ultimately successful, opinions of personnel familiar with the patient and, whenever appropriate, the informed wishes of the parents. In general, unless hypothermia or drug toxicity exists, survival to normality is unlikely if there has been a failure to respond to full competent CPR after 30 minutes and several doses of epinephrine. In the newborn, discontinuation of treatment is appropriate if CPR does not establish a spontaneous circulation within 10–15 minutes. In out-of-hospital arrest, adult termination-of-resuscitation

criteria may not be suitable for paediatric arrest since sensitivity for predicting death was 48% and specificity 93%.[22] Loss of grey–white matter differentiation or sulcal effacement on head computed tomography within only several hours of arrest, is associated with unfavourable neurological outcome.[23] Family members should be kept informed, allowed to be present or asked if they want to be present during resuscitation.

POST-RESUSCITATION STAFF MANAGEMENT

Unfortunately, CPA occurring in hospital is often unexpected; for example, when a moribund patient arrives unannounced in the emergency department, a patient's condition deteriorates rapidly on the ward or when a mishap occurs under anaesthesia. These situations test the readiness, training, abilities and skills of individuals and the organisation of the institution. Performance should be audited with a view to improvement. These events have significant psychological impact on individuals, and sensitive debriefing sessions should be encouraged.

Appendix I

Respiratory physiology symbols and normal values

SYMBOLS

Primary	Secondary symbols for gas phase
C Concentration of gas in blood	A Alveolar
F Fractional concentration in dry gas	B Barometric
f Frequency of respiration (breaths/min)	D Dead space
P Pressure or partial pressure	E Expired
Q Volume of blood	I Inspired
$\dot{Q}$ Volume of blood per unit time	L Lung
R Respiratory exchange ratio	T Tidal
S Saturation of haemoglobin with O_2	
$\dot{V}$ Volume of gas per unit time	*Secondary symbols for blood phase*
	a arterial
	c capillary
	ć end-capillary
	i ideal
	v venous
	$\bar{v}$ mixed venous

– Above any symbol denotes a mean value.
· Above any symbol denotes a value per unit time.

NORMAL VALUES

1. Blood
   (a) *Arterial*

pH	:	7.36–7.44	(H^+ = 44–36 nmol/L)
PaO	:	85–100 mm Hg	(11.3–13.3 kPa)
$PaCO_2$	:	36–44 mm Hg	(4.8–5.9 kPa)
O_2 content	:	20–21 vols %	(8.9–9.4 nmol/L)
CO_2 content	:	48–50 vols %	(21.6–22.5 nmol/L)

   (b) *Venous*

pH	:	7.34–7.42	(H^+ = 38–46 nmol/L)
PO_2	:	37–42 mm Hg	(5–5.6 kPa)
PCO_2	:	42–50 mm Hg	(5.6–6.7 kPa)
O_2 content	:	15–16 vols %	(6.7–7.2 mmol/L)
CO_2 content	:	52–54 vols %	(23.3–24.2 mmol/L)

2. Gases
   (a) *Inspired air*

O_2	:	20.93%	
PI_{O_2}	:	149 mm Hg	(19.9 kPa)
N_2	:	79.04%	
PI_{N_2}	:	563 mm Hg	(75 kPa)
CO_2	:	0.03%	

   (b) *Expired air*

O_2	:	16%–17%	
PE_{O_2}	:	113–121 mm Hg	(15–16 kPa)
N_2	:	80%	
PE_{N_2}	:	579 mm Hg	(77 kPa)
CO_2	:	3%–4%	
PE_{CO_2}	:	21–28 mm Hg	(2.8–3.7 kPa)

3. Ventilation: perfusion
   (a) *Alveolar–arterial oxygen gradient:*
   5–20 mm Hg (0.7–2.7 kPa) breathing air
   25–65 mm Hg (3.3–8.6 kPa) breathing 100% oxygen
   (b) *Venous admixture* ($\dot{Q}_S:\dot{Q}_T$): 5% of cardiac output
   (c) *Right to left physiological shunt*: 3% of cardiac output
   (d) *Anatomical dead space*: 2 mL/kg body weight
   (e) *Dead space: tidal volume ratio* ($V_D:V_T$): 0.25–0.4 or 33 + (Age/3) per cent
4. Lung volumes
   Approximate values in adults are listed. Values are less in smaller subjects and in females.

Tidal volume	:	400 mL or 6 mL/kg
Inspiratory capacity	:	3.6 L
Inspiratory reserve volume	:	3.1 L
Expiratory reserve volume	:	1.2 L
Functional residual capacity	:	2.4 L
Residual volume	:	1.2 L
Total lung capacity	:	6.0 L
Vital capacity	:	4.8 L

   or 2.5 L/sq m body surface *or* 2.5 L/m height in males
   2.0 L/sq m body surface *or* 2.0 L/m height in females
   or 65–75 mL/kg
5. Lung mechanics
   (a) *Peak expiratory flow rate* : 450–700 L/min (males)
   : 300–500 L/min (females)
   (b) *Forced expiratory volume in 1 s* (FEV_1) : 70%–83% of vital capacity
   (c) *Compliance* (approximate values)

		Static	*Dynamic*
(i) Lung compliance (CL)			
conscious (erect)	:	200 mL/cmH_2O	180 mL/cmH_2O
paralysed anaesthetised (supine)*	:	160 mL/cmH_2O	80 mL/cmH_2O
(ii) Chest wall compliance (CCW)	:	200 mL/cmH_2O	
(iii) Total compliance (CT):			
conscious (erect)	:	150 mL/cmH_2O	100 mL/cmH_2O
paralysed anaesthetised (supine)*	:	74 mL/cmH_2O	56 mL/cmH_2O

   (d) *Airways resistance*:
   conscious : 0.6–3.2 cmH_2O/L/s
   sedated, partially paralysed and ventilated : 5–10 H_2O/L/s
   (includes resistance of endotracheal tube and catheter mount)
   (e) *Work of breathing*: 0.3–0.5 kg m/min
   or oxygen consumption of 0.5–1 mL/L ventilation

*Compliance values would be lower for the sedated, partially paralysed, ventilated patient in the intensive care unit; that is, effective dynamic compliance = 40–50 mL/cmH_2O.

6. **Cardiovascular** — pressures in kPa are given within brackets

(a)	Cardiac index	:	2.5–3.6 L/min/m^2
(b)	Stroke volume	:	42–52 mL/m^2
(c)	Ejection fraction	:	0.55–0.75
(d)	End-diastolic volume	:	75 ± 15 mL/m^2
(e)	End-systolic volume	:	25 ± 8 mL/m^2
(f)	Left ventricular stroke work index	:	30–110 g-m/m^2
(g)	Left ventricular minute work index	:	1.8–6.6 kg-m/min/m^2
(h)	Oxygen consumption index	:	110–150 mL/L
(i)	Right atrial pressure	:	1–7 mm Hg (0.13–0.93)
(j)	Right ventricular systolic pressure	:	15–25 mm Hg (2.0–3.3)
(k)	Right ventricular diastolic pressure	:	0–8 (0–1)
(l)	Pulmonary artery systolic pressure	:	15–25 mm Hg (2.0–3.3)
(m)	Pulmonary artery diastolic pressure	:	8–15 mm Hg (1–2)
(n)	Pulmonary artery mean pressure	:	10–20 mm Hg (1.3–2.7)
(o)	Pulmonary capillary wedge pressure	:	6–15 mm Hg (0.8–2.0)
(p)	Systemic vascular resistance	:	770–1500 dyne-s/cm^5
		:	77–150 kPa-s/L
(q)	Pulmonary vascular resistance	:	20–120 dyne-s/cm^5
		:	2–12 kPa-s/L

Appendix II

Physiological equations

RESPIRATORY EQUATIONS

(a) *Oxygen consumption* (250 mL/min)
Oxygen consumption = amount of oxygen in inspired gas minus amount in expired gas

i.e. $\dot{V}O_2 = (\dot{V}I \times FI_{O_2}) - (\dot{V}E \times FE_{O_2})$

(b) *Carbon dioxide production* (200 mL/min)
Volume CO_2 eliminated in expired gas = expired gas volume × CO_2 concentration in mixed expired gas

i.e. $\dot{V}CO_2 = (\dot{V} \times F\bar{E}_{CO_2})$

As expired volume is made up of alveolar and dead space gas,

$$\dot{V}CO_2 = (\dot{V}A \times FA_{CO_2})(\dot{V}D \times FI_{CO_2})$$

As FI_{CO_2} is negligible, especially if there is no rebreathing,

$$\dot{V}CO_2 = \dot{V}A \times FA_{CO_2}$$

or $$FA_{CO_2} = \frac{\dot{V}_{CO_2}}{\dot{V}A}$$

or $$PA_{CO_2}\ (\text{mm Hg}) = \frac{\dot{V}_{CO_2}\ (\text{mL/min STPD})}{\dot{V}A\ (\text{L/min BTPS})} \times 0.863$$

or $$PA_{CO_2}\ (\text{kPa}) = \frac{\dot{V}_{CO_2}\ (\text{mmol/min})}{\dot{V}A\ (\text{L/min BTPS})} \times 2.561$$

STPD: Standard temperature (0°C) and pressure (760 mm Hg or 101.35 kPa) dry gas
BTPS: Body temperature and ambient pressure, saturated with water vapour

(c) *Physiological dead space*

Bohr's equation, $$\frac{V_D}{V_T} = \frac{PA_{CO_2} - P\bar{E}_{CO_2}}{PA_{CO_2}}$$

or $$\frac{V_D}{V_T} = \frac{Pa_{CO_2} - P\bar{E}_{CO_2}}{Pa_{CO_2}}$$

(d) *Alveolar oxygenation*

$$PA_{O_2} = PI_O - \frac{Pa_{CO_2}}{R}$$

where R is the respiratory quotient (normally 0.8).

$$PA_{O_2} = PI_{O_2} - Pa_{CO_2}\left(\frac{PI_{O_2} - P\bar{E}_{O_2}}{P\bar{E}_{CO_2}}\right)$$

or $$PA_{O_2} = PI_{O_2} - PA_{CO_2}\left(\frac{FI_{O_2} + 1 - FI_{O_2}}{R}\right)$$

when $FI_{O_2} = 1.0$ (patient breathing 100% oxygen),
then $PA_{O_2} = (PB - \text{saturated water vapour pressure}) - PA_{CO_2}$
$= (PB - 47) - Pa_{CO_2}$

(e) *Venous admixture*

(f) *Fractional inspired oxygen concentration*

$$FI_{O_2} = \frac{O_2 \text{ flow in L/min} + (\text{air flow in L/min} \times 0.21)}{\text{Total } O_2 + \text{air flow in L/min}}$$

(g) *Henderson–Hasselbalch equation*

$$pH = pKA + \log\frac{(HCO_3^-)}{CO_2}$$

$$pH = 6.1 + \log\frac{(HCO_3^- \text{ in mmol/L})}{(PCO_2 \text{ in mm Hg}) \times 0.03}$$

$$[H^+]\,\text{nmol/L} = 24 \times \frac{(PCO_2 \text{ in mm Hg})}{(HCO_3^- \text{ in mmol/L})}$$

$$[H^+]\,\text{nmol/L} = 180 \times \frac{(PCO_2 \text{ in kPa})}{(HCO_3^- \text{ in mmol/L})}$$

CARDIOVASCULAR EQUATIONS

(a) *Mean blood pressure* (BP) = DBP + ⅓ (SBP–DBP)

(b) *Rate pressure product* (RPP) = $P \times$ SBP

(c) *Body surface area* (BSA) in $m^2 = (Ht)^{0.725} \times (Wt)^{0.425} \times 71.84 \times 10^{-4}$

(d) **Cardiac index* (CI) $= \frac{CO}{BSA} = mL/min/m^2$

(e) *Stroke volume* (SV) $= \frac{CO}{P} = mL/beat$

(f) **Stroke volume index* (SVI) $= \frac{SV}{BSA} = mL/beat/m^2$

(g) **Left ventricular stroke work index* (LVSWI) = (BP–PCWP) (SVI) (0.0136) = g-m/m^2/beat

(h) *Systemic vascular resistance* (SVR) $= \frac{BP - RAP}{CO}$ resistance units

(Multiply × 79.9 to convert to absolute resistance units, dynes-s cm^{-5})

(i) *Pulmonary vascular resistance* (PVR) $= \frac{PAP - PCWP}{CO}$ resistance units

(Multiply × 79.9 to convert to absolute resistance units, dynes-s cm^{-5})

(j) *Left ventricular pre-ejection period* (PEP) = QS_2–LVET ms

(k) *Other systolic time index ratios* may easily be calculated:

$$\frac{1}{PEP^2} \quad \text{and} \quad \frac{PEP}{LVET}$$

*For interpatient comparisons and reference standards, the 'index' term, output normalised to body surface, may be used when:

SBP = systolic blood pressure in mm Hg
DBP = diastolic blood pressure in mm Hg
P = heart rate in beats/min
Ht = height in cm
Wt = weight in kg
CO = cardiac output in mL/min
PCWP = pulmonary capillary wedge pressure in mm Hg
RAP = right atrial pressure in mm Hg
PAP = mean pulmonary artery pressure in mm Hg
LVET = left ventricular ejection time in ms
QS_2 = total electromechanical systole in ms.

RENAL EQUATIONS

(a) *Standard creatinine clearance* (mL/min/1.73 m^2)

$$= \frac{\text{urine creatinine (mmol/L)}}{\text{serum creatinine (mmol/L)}} \times \text{urine volume (mL/min)} \times \frac{1.73}{\text{body surface area } (m^2)}$$

(b) *Per cent filtered Na^+ excreted*

$$= \frac{\text{urine } Na^+ \text{ (mmol/L)}}{\text{serum } Na^+ \text{ (mmol/L)}} \times \frac{\text{serum creatinine (mmol/L)}}{\text{urine creatinine (mmol/L)}} \times 100$$

(c) *Free water clearance* (mL/min)

$$= \text{urine volume (mL/min)} - \frac{\text{urine osmolality (mOsm/kg)}}{\text{plasma osmolality (mOsm/kg)}} \times \text{urine volume (mL/min)}$$

(d) *Additional calculated parameters*:

(i) $\frac{\text{urine}}{\text{plasma}}$ osmolality ratio

(ii) $\frac{\text{urine}}{\text{serum}}$ creatinine ratio

(iii) $\frac{\text{blood urea nitrogen}}{\text{serum creatinine}}$ ratio

(iv) $\frac{\text{urine}}{\text{plasma}}$ urea ratio

(v) Urinary Na^+ and K^+ excretion (mmol)

(vi) $\frac{\text{urinary } Na^+}{\text{urinary } K^+}$ ratio

Appendix III

Mortality/dysfunction risk scores and models

PAEDIATRIC RISK OF MORTALITY SCORE

Mortality risk assessment.

Parameter	Age limit	Ranges		Points
Systolic blood pressure		(mm Hg)	(kPa)	
	Infants	130–160	17.3–21.3	2
		55–65	7.3–8.7	2
		>160	>21.3	6
		40–54	5.3–7.2	6
		<40	<5.3	7
	Children	150–200	20–26.7	2
		65–75	8.7–10	2
		>200	>26.7	6
		50–64	6.7–8.5	6
		<50	<6.7	7
Diastolic blood pressure		(mm Hg)	(kPa)	
	All ages	>110	>14.6	6
Heart rate (beats/min)	Infants	>160		4
		<90		4
	Children	>150		4
		<80		4
Respiratory rate (breaths/min)	Infants	61–90		1
		>90		5
		Apnoea		5
	Children	51–70		1
		>70		5
		Apnoea		5
$Pa_{O_2} : Fi_{O_2}$ ratio		(mm Hg)	(kPa)	
	All ages	200–300	26.6–39.9	2
		<200	<26.6	3
$PaCO_2$		(torr [mm Hg])	(kPa)	
	All ages	51–65	6.8–8.7	1
		>65	>8.7	5
Pupillary reactions	All ages	Unequal or dilated		4
		Fixed and dilated		10
Prothrombin time (PT)/partial thromboplastin time (PTT)	All ages	1.5 times control		2
Total bilirubin (mg/dL)	>1 month	>3.5		6
Potassium (mEq/L)	All ages	3.0–3.5		1
		6.5–7.5		1
		<3.0		5
		>7.5		5
Calcium (mg/dL)	All ages	7.0–8.0		2
		12.0–15.0		2
		<7.0		6
		>15.0		6
Glucose (mg/dL)	All ages	40–60		4
		250–400		4
		<40		8
		>400		8
Bicarbonate (mEq/L)	All ages	<16		3
		>32		3

Infants: 0–1 year of age. Paediatric risk of mortality (PRISM) score = (systolic blood pressure points) + (diastolic blood pressure points) + (heart rate points) + (respiratory rate points) + (oxygenation points) + (Glasgow Coma Score points) + (pupillary reaction points) + (coagulation points) + (bilirubin points) + (potassium points) + (calcium points) + (glucose points) + (bicarbonate points).

SEPSIS-RELATED ORGAN FAILURE ASSESSMENT SCORE

Easy to calculate, describes the sequence of complications in a critically ill patient rather than predicting outcome.

Organ system	Measure
Respiration	$Pa_{O_2} : Fi_{O_2}$ ratio
Coagulation	Platelet count
Liver	Serum bilirubin
Cardiovascular	Hypotension
Central nervous system	Glasgow Coma Score
Renal	Serum creatinine or urine output

Measure	Finding		Points
$Pa_{O_2} : Fi_{O_2}$ ratio	(mm Hg)	(kPa)	
	≥400	≥53.2	0
	300–399	39.9–53.1	1
	200–299	26.6–39.8	2
	100–199	13.3–26.5	3
	<100	<13.3	4
Platelet count	≥1500/μL		0
	1000–149,999/μL		1
	500–99,999/μL		2
	200–49,999/μL		3
	<200/μL		4
Serum bilirubin	<1.2 mg/dL		0
	1.2–1.9 mg/dL		1
	2.0–5.9 mg/dL		2
	6.0–11.9 mg/dL		3
	≥12.0 mg/dL		4
Hypotension	(mm Hg)	(kPa)	
	Mean arterial pressure ≥70	≥9.3	0
	Mean arterial pressure <70 then (no pressor agents used)	<9.3	1
	Dobutamine any dose		2
	Dopamine ≤5 μg/kg/min		2
	Dopamine >5–15 μg/kg/min		3
	Dopamine >15 μg/kg/min		4
	Epinephrine ≤0.1 μg/kg/min		3
	Epinephrine >0.1 μg/kg/min		4
	Norepinephrine ≤0.1 μg/kg/min		3
	Norepinephrine >0.1 μg/kg/min		4
Glasgow Coma Score	15		0
	13–14		1
	10–12		2
	6–9		3
	3–5		4
Serum creatinine or urine output	Serum creatinine <1.2 mg/dL		0
	Serum creatinine 1.2–1.9 mg/dL		1
	Serum creatinine 2.0–3.4 mg/dL		2
	Serum creatinine 3.5–4.9 mg/dL		3
	Urine output 200–499 mL/day		3
	Serum creatinine >5.0 mg/dL		4
	Urine output <200 mL/day		4

Pa_{O_2} is in mm Hg/kPa and Fi_{O_2} in percentages, from 0.21 to 1.00. Adrenergic agents as administered for at least 1 hour with doses in μg/kg/min. A score of 0 indicates normal and a score of 4 indicates most abnormal. Data can be collected and the score calculated daily during the course of the admission. Interpretation: minimum total score: 0; maximum total score: 24. The higher the organ score, the greater is the organ dysfunction. The higher the total score, the greater is the multiorgan dysfunction.

MORTALITY RATE BY SEPSIS-RELATED ORGAN FAILURE ASSESSMENT SCORE[1]

Organ system	0	1	2	3	4
Respiratory	20%	27%	32%	46%	64%
Cardiovascular	22%	32%	55%	55%	55%
Coagulation	35%	35%	35%	64%	64%
CNS	32%	34%	50%	53%	56%
Renal	25%	40%	46%	56%	64%

CNS, Central nervous system.

LOGISTIC ORGAN DYSFUNCTION SYSTEM

Assess patients for severity of critical organ dysfunction. To predict the probability of death for the patient.

Data collection	During the first 24 h in the ICU
Data point	If not measured then it is assumed to be normal for scoring purposes If several measurements, use the most severe value

LOD score = (neurological score) + (cardiovascular score) + (renal score) + (pulmonary score) + (haematological score) + (hepatic score).
ICU, Intensive care unit.

NEUROLOGICAL SCORE

Glasgow coma score	Points
14–15	0
9–13	1
6–8	3
<6	5

Use lowest value. If sedated, estimate the score prior to sedation.

CARDIOVASCULAR SCORE

		Systolic BP		
Heart rate (beats/min)		(mm Hg)	(kPa)	Points
30–139	*and*	90–239	11.9–31.8	0
≥140	*or*	240–269	31.9–35.8	1
		70–89	9.3–11.8	1
		≥270	≥35.9	3
		40–69	5.3–9.2	3
<30	*or*	<40	<5.3	5

The most abnormal value for heart rate or systolic blood pressure, either minimum or maximum.

RENAL SCORE

Serum urea nitrogen (mg/dL)		Creatinine (mg/dL)		Urine output (L/d)	Points
<17	*and*	<1.20	*and*	0.75–9.99	0
17–27.99	*or*	1.2–1.59			1
28–55.99	*or*	≥1.60	*or*	≥10	3
				0.5–0.74	3
≥56					5
				<0.5	5

Highest value for urea nitrogen and for creatinine; if the urine output data are for less than a 24-hour period, adjust that value to 24 hours, assuming the same rate of excretion. On haemodialysis, use the value of urine output prior to initiating haemodialysis.

PULMONARY SCORE

On ventilation or continuous positive airway pressure?		Ratio (Pa_{O_2} [mm Hg]: Fi_{O_2})	Ratio (Pa_{O_2} [kPa]: Fi_{O_2})	Points
No				0
Yes	*and*	≥150	≥20	1
Yes	*and*	<150	<20	3

Respiratory support; use the lowest ratio of Pa_{O_2} to Fi_{O_2}.

HAEMATOLOGICAL SCORE

White blood cell count (10^9/L)		Platelet count (10^9/L)	Points
2.5–4.9/μL	*and*	≥50/μl	0
		≥50/μL	1
1–2.4/μL	*or*	<50/μL	1
<1/μL			3

Note: Most abnormal values for the white cell count are either minimum or maximum; minimum platelet count if several values are available.

HEPATIC SCORE[2]

Bilirubin		Prothrombin time	Points
<2.0 mg/dL (< 34.2 μmol/L)	*and*	≤3 s above standard (≥25% of standard)	0
≥2.0 mg/dL (≥34.2 μmol/L)	*or*	>3 s above standard (<25% of standard)	1

Highest value for bilirubin available. Highest value for prothrombin time in seconds.

MPM II, MORTALITY PROBABILITY MODELS[3,4]

Excluded
- Age less than 18 years
- Burn patients
- Coronary care patients
- Cardiac surgery patients
- (The scoring is either present or not present)

Definitions
- Coma or deep stupor at time of intensive care unit (ICU) admission
  - Not due to drug overdosage
  - If patient is on paralysing muscle relaxant, is awakening from anaesthesia or is heavily sedated, use your best judgement of the level of consciousness prior to sedation
  - *Coma*: no response to any stimulation; no twitching, no movements in extremities, no response to pain or command; Glasgow Coma Score 3
  - *Deep stupor*: decorticate or decerebrate posturing; posturing is spontaneous or in response to stimulation or deep pain; posturing is not in response to commands; Glasgow Coma Score 4 or 5

Heart rate at ICU admission
- Heart rate ≥150 beats/min within 1 hour before or after ICU admission

Systolic blood pressure at ICU admission
- Systolic blood pressure ≤90 mm Hg (11.9 kPa) within 1 hour before or after ICU admission

Chronic renal compromise or insufficiency
- Elevation of serum creatinine greater than 2 mg/dL and documented as chronic in the medical record
- If there is the acute diagnosis on chronic renal failure then record only 'yes' for acute renal failure

Cirrhosis
- History of heavy alcohol use with portal hypertension and varices
- Other causes of liver disease with evidence of portal hypertension and varices
- Biopsy confirmation of cirrhosis

Metastatic malignant neoplasm
- Stage IV carcinomas with distant metastases
- Do not include involvement only of regional lymph nodes
- Include if metastases are obvious by clinical assessment or confirmed by a pathology report
- Do not include if metastases is not obvious, or if the pathology report is not available at the time of ICU admission
- Acute haematological malignancies are included
- Chronic leukaemias are not included unless there are findings attributable to the disease or the patient is under active treatment for the leukaemia. Findings include sepsis, anaemia, stroke caused by clumping of white blood cells, tumour lysis syndrome with elevated uric acid following chemotherapy, pulmonary oedema or the lymphangiectatic form of acute respiratory distress syndrome

Acute renal failure
- Acute tubular necrosis or acute diagnosis on chronic renal failure
- Prerenal azotaemia is not included

Cardiac dysrhythmia
- Cardiac arrhythmia, paroxysmal tachycardia, fibrillation with rapid ventricular response, second- or third-degree heart block
- Do not include chronic and stable arrhythmias

Cerebrovascular incident
- Cerebral embolism, occlusion, cerebrovascular accident, stroke, brainstem infarction, cerebrovascular arteriovenous malformation (acute stroke or cerebrovascular haemorrhage, not chronic arteriovenous malformation)

Gastrointestinal (GI) bleeding
- Haematemesis, melaena
- A perforated ulcer does not necessarily indicate GI bleeding; may be identified by obvious 'coffee grounds' in the nasogastric tube
- A drop of haemoglobin by itself is not sufficient evidence of acute GI bleeding

Intracranial mass effect
- Intracranial mass (abscess, tumour, haemorrhage, subdural) as identified by computed tomography (CT) scan associated with any of the following: (1) midline shift; (2) obliteration or distortion of cerebral ventricles; (3) gross haemorrhage in cerebral ventricles or subarachnoid space; (4) visible mass greater than 4 cm; or (5) any mass that enhances with contrast media
- If the mass effect is known within 1 hour of ICU admission, it can be indicated as yes
- CT scanning is not mandated and is indicated only for patients with major neurological insult

Age in years
- Patient's age at last birthday

Cardiopulmonary resuscitation (CPR) within 24 hours prior to ICU admission
- CPR includes chest compression, defibrillation or cardiac massage
- Not affected by the location where the CPR was administered

Mechanical ventilation
- Patient is using a ventilator at the time of ICU admission or immediately thereafter

Medical or unscheduled surgery admission
- Do not include elective surgical patients (surgery scheduled at least 24 hours in advance) or pre-operative Swan–Ganz catheter insertion in elective surgery patients
