Acute respiratory distress syndrome

Andrew D Bersten, Shailesh Bihari

The acute respiratory distress syndrome (ARDS), also known by many pseudonyms such as 'DaNang lung', was first described in 1967 by Ashbaugh and colleagues as the 'acute onset of tachypnea, hypoxemia and loss of compliance after a variety of stimuli'.[1] Continued research examining the underlying mechanisms and management strategies is now translating into improved outcome.

DEFINITIONS

The ARDS Definition Task Force (the Berlin definition[2]) has recently revised the long-standing 1994 American-European Consensus Conference (AECC) definition (Table 33.1).[3] ARDS is now classified as mild, moderate and severe based on the Pa_{O_2}/Fi_{O_2} ratio (see Table 33.1). The broad term 'acute lung injury' (ALI), which referred to cases with a Pa_{O_2}/Fi_{O_2} ratio less than 300, has been replaced and many concerns addressed. A minimum positive end-expiratory pressure (PEEP) of 5 cm H_2O is specified, and chest radiograph criteria and exclusion of hydrostatic oedema clarified, including examples. The lung injury score (LIS),[4] which uses a four-point score attributed to ranges of Pa_{O_2}/Fi_{O_2} ratio, PEEP, respiratory system compliance and the number of quadrants involved on chest radiograph, has also been used to quantify severity of ARDS; however, as neither lung compliance nor dead space improved the predictive ability of the Berlin definition, the LIS may become less pertinent.

CHEST RADIOGRAPH AND CHEST COMPUTED TOMOGRAPHY IN ACUTE RESPIRATORY DISTRESS SYNDROME

The intent of chest imaging is to exclude opacities due to pleural effusion, nodules, masses, collapse and pleural thickening; the infiltrate must be bilateral and consistent with pulmonary oedema.[2] Autopsy and chest radiographs of ARDS show a uniform process affecting both lungs. However, chest computed tomography (CT)[5] has demonstrated marked heterogeneity of lung inflation in ARDS with a dorsal, dependent increase in lung density, and relatively normal inflation of ventral lung. In addition, CT frequently reveals previously undiagnosed pneumothorax, pneumomediastinum and pleural effusion. After the second week of mechanical ventilation, CT scans may demonstrate altered lung architecture and emphysematous cysts or pneumatoceles.

CT numbers or Hounsfield units can be assigned to each voxel (~2000 alveoli in a standard 10-mm slice).[5] These data can then be used to assess what proportion of a region of interest is non-aerated, poorly aerated, normally aerated, or hyperinflated. Whole-lung CT allows (a) reconstruction of the upper and lower lobes (the middle lobe is difficult to separate), (b) the same section of lung to be studied at different levels of inflation or PEEP (the lung also moves in a cepahalocaudad direction with respiration), and (c) a broader picture of the lung to be obtained (lung damage is heterogeneous in ARDS). However, whole-lung CT demands considerable exposure to ionising radiation, and different information, perhaps more pertinent to mechanical ventilation, is obtained from dynamic CT.

Clinical assessment of chest CT is discussed in Chapter 39, and CT findings in ARDS as discussed under Clinical management.

EPIDEMIOLOGY

Estimates of the incidence and outcome from ARDS vary widely due to differences in the definitions used, case-mix and local factors. Using the AECC definition, the Australian incidence was 34 per 100,000 for ALI and 28 per 100,000 for ARDS[6]; while US estimates were 79 and 59 per 100,000, respectively[7] – both much greater than many previous estimates. Recent data from 50 countries reports period prevalence of mild ARDS as 30.0%, moderate ARDS as 46.6%, and severe ARDS as 23.4%, respectively. ARDS represented 10.4% of intensive care unit (ICU) admissions and 23.4% of patients requiring mechanical ventilation. Clinical recognition of ARDS ranged from 51.3% in mild to 78.5% in severe ARDS.[8] However, the incidence of ARDS appears to be decreasing likely due to improvements in health care such as use of protective ventilation strategies, reduced transfusion-related acute lung injury ALI (TRALI) and better management of sepsis.[9]

For many years the mortality for ARDS was reported to be ~60%; data from 459 ICUs from 50 countries reports hospital mortality as 34.9% for those

ABSTRACT

Acute respiratory distress syndrome (ARDS) is an acute diffuse, inflammatory lung injury leading to increased pulmonary permeability, increased lung weight, loss of aerated lung tissue, hypoxaemia and bilateral radiographic opacities, associated with increased physiological dead space and decreased lung compliance which is not fully explained by cardiac failure or fluid overload. Patients with ARDS have a high rate of morbidity and mortality. Lung protective invasive mechanical ventilation with adequate positive end-expiratory pressure remains the cornerstone of management, although new therapies are being developed as underlying mechanisms and pathophysiology are better understood.

KEYWORDS

Acute respiratory distress syndrome
mechanical ventilation
positive end-expiratory pressure
fluid balance
ventilation-induced lung injury

Table 33.1 Criteria and classification of acute respiratory distress syndrome

	AECC DEFINITION*	BERLIN DEFINITION†
Onset	Acute (not defined) onset No risk factor formally defined	Within 7 days of a known risk factor (See Box 33.1)
Chest imaging	Bilateral opacities on chest radiograph	Bilateral opacities consistent with pulmonary oedema on either chest radiograph or CT
Pulmonary oedema	PAOP ≤18 mm Hg when measured or no clinical evidence of raised left atrial pressure	Non-hydrostatic oedema; not fully explained by heart failure or fluid overload Echocardiography or another objective measure may be required
Classification	ALI $Pa_{O_2}/Fi_{O_2} \leq -300$ ARDS $Pa_{O_2}/Fi_{O_2} \leq -200$	Mild $200 < Pa_{O_2}/Fi_{O_2} \leq 300$ Moderate $100 < Pa_{O_2}/Fi_{O_2} \leq 200$ Severe $Pa_{O_2}/Fi_{O_2} \leq 100$

*No minimum ventilatory setting defined for Pa_{O_2}/Fi_{O_2} data.

†Based on oxygenation measured on a minimum of 5 cm H_2O PEEP. For the mild classification only, oxygenation can also be assessed during non-invasive ventilation. For the moderate and severe classification, the patient must be receiving intubated ventilatory assistance.

with mild, 40.3% for moderate, and 46.1% for severe ARDS.[8] Particular diagnostic groups such as multiple trauma have a lower mortality rate than other causes of ARDS, and patients with ARDS who have chronic liver disease, non-pulmonary organ dysfunction, sepsis or age greater than 70 years (hazard ratio, 2.5) have a higher risk of death. Clinical trial outcomes report low mortality rates in the control arm in part due to the exclusion of patients with limited life expectancy; consequently, many factors need to be considered when assessing outcome prediction.

PULMONARY FUNCTION IN SURVIVORS

Respiratory function continues to improve after discontinuation of mechanical ventilation, and usually returns towards normal by 6–12 months.[10,11] Although a variety of abnormal pulmonary function tests may be found, impaired diffusing capacity is the most common. This is rarely symptomatic, but occasional patients have severe restrictive disease, and this is correlated with their cumulative LIS.[11]

QUALITY OF LIFE IN SURVIVORS

Compared with disease-matched ICU patients who do not develop ARDS, patients with ARDS have a more severe reduction in both pulmonary and general health-related quality of life.[12] Many patients have reduction in exercise tolerance that may be attributable to associated critical illness neuropathy and myopathy; nerve entrapment syndromes, contractures, postural hypotension, and heterotopic calcification may play a role in a minority.[10] When followed for 5 years in a young and severe cohort (median age 45 years) with relatively few prior co-morbidities, there was persistent functional impairment with little improvement after 12 months.[13] Depression, anxiety and post-traumatic stress disorder are also common (20%–50% of survivors). Finally, most survivors have cognitive impairments such as slowed mental processing, or impaired memory or concentration, and these correlate with the duration of ventilation, hyperglycaemia and variability in blood glucose, and the period and severity of desaturation less than 90%.[14,15] In an analysis of survivors of the ARDS Network Fluid and Catheter Trial (FACTT),[16] Mikkelsen and co-workers[17] found that over half the subjects suffered from cognitive dysfunction and from psychological disability, and that these parameters were associated with lower Pa_{O_2}, enrolment in the restrictive fluid arm, and hypoglycaemia. Taken together these data caution against permissive hypoxaemia as a strategy to reduce ventilator-induced lung injury (VILI), and suggest that quality of survival is an important additional outcome for clinical trials.

PATIENTS AT RISK FOR ACUTE RESPIRATORY DISTRESS SYNDROME

About one-third of critically ill patients exposed to either a direct or indirect risk factor (Box 33.1) develop ARDS, most within 6–48 hours. Multiple risk factors such as low pH, chronic alcohol abuse or chronic lung disease substantially increase the incidence of ARDS in at-risk patients. Diabetes reduces the risk of developing ARDS.[18]

FAT EMBOLISM SYNDROME

Fat embolism syndrome (FES) is most commonly associated with long bone and pelvic fractures, and is more frequent in closed fractures than open fractures. Patients with a single long bone fracture have a 1%–3% chance of developing FES, which increases with the number of fractures. Fat emboli usually result from fat

Box 33.1 Clinical risk factors for acute respiratory distress syndrome

DIRECT	INDIRECT
Pneumonia	Non-pulmonary sepsis
Aspiration of gastric contents	Multiple trauma
Lung contusion	Massive transfusion
Fat embolism	Pancreatitis
Near drowning	Cardiopulmonary bypass
Inhalational injury	
Reperfusion injury	

globules entering the bloodstream or via production of the toxic intermediaries of plasma-derived fat.

FES typically manifests 24–72 hours after the initial insult.[19] Affected patients develop a classic triad – hypoxaemia, neurological abnormalities and a petechial rash. Neurological abnormalities such as confusional state followed by an altered level of consciousness develop in the majority of patients. The characteristic petechial rash may be the last component of the triad to develop. It occurs in only 20%–50% of cases and is found most often on the head, neck, anterior thorax, axillae, and subconjunctiva.[20] The rash resolves in 5–7 days

Early immobilization of fractures reduces the incidence of FES, otherwise treatment is the same as for ARDS.

PATHOGENESIS

Although it is well accepted that diffuse alveolar damage with: (a) pulmonary oedema due to damage of the alveolocapillary barrier, (b) a complex inflammatory infiltrate and (c) surfactant dysfunction,[21] are essential components of ARDS, the sequence of events is uncertain and probably depends upon the precipitating insult and host response. For example, in endotoxin-induced lung injury, hypoxaemia and reduced lung compliance occur well before recruitment of neutrophils or an increase in lung weight due to an increase in permeability.[22] In addition, typical of early ARDS, surfactant turnover is dramatically increased prior to these changes. Furthermore, epithelial lining fluid sampled immediately following intubation in patients with ARDS has markedly increased concentrations of type III procollagen peptide,[23] suggestive of fibrosing alveolitis extremely early in the course of lung damage.

THE ALVEOLOCAPILLARY BARRIER

The normal lung consists of 300 million alveoli with alveolar gas separated from the pulmonary microcirculation by the extremely thin alveolocapillary barrier (0.1–0.2 μm thick). Since the endothelial pore size is 6.5–7.5 nm, and the epithelial pore size is almost one-tenth that at 0.5–0.9 nm, the epithelium is the major barrier to protein flux.[24] The surface area of the alveoli is estimated to be 50–100 m^2, which is made up predominantly of alveolar type I cells, with the metabolically active type II cells accounting for ~10% of the surface area. In turn, these cells are covered by the epithelial lining fluid with an estimated volume of 20 mL, ~10% of which is surfactant, the rest being filtered plasma water and low-molecular-weight proteins and a small number of cells, mainly alveolar macrophages and lymphocytes.

In ARDS the alveolocapillary barrier is damaged with bidirectional leakage of fluid and protein into the alveolus and leakage of surfactant proteins (SP) and alveolar cytokines into the plasma. Total protein content in bronchoalveolar lavage (BAL) fluid is 20–100 times that found in both healthy subjects and ventilated subjects without cardiorespiratory disease.[25,26] There is also disruption of the epithelial barrier, surfactant dysfunction and proliferation of alveolar type II cells as the progenitor of type I cells. Indirect causes of ARDS result in pulmonary endothelial injury, followed by recruitment of inflammatory cells and then epithelial damage, whereas direct causes of ARDS result in epithelial injury and secondary recruitment of inflammatory cells. The outcome of these processes must reflect a balance between repair and fibrosing alveolitis.

CELL TYPES INVOLVED

The large surface area of pulmonary epithelium and endothelium including the associated microcirculation, myofibroblasts, and both alveolar macrophages and recruited neutrophils are all important components of ALI. BAL fluid has a marked increase in cell count; alveolar macrophage numbers are increased about twofold, but as a fraction of the cell count falls from around 90% to 20%–40% of the cell count due to a greater increase in neutrophils from around 1% to 50%–80% of the cell count. In addition, microparticles, tiny vesicles potentially derived from most of these cell types, are found in both BAL fluid and blood and may play an important role in both lung damage and repair.[27] A temporal trend towards more normal neutrophil and alveolar macrophage ratios in BAL fluid is associated with survival.

NEUTROPHILS

Neutrophils are the most abundant cell type found in both the epithelial lining fluid (e.g. BAL fluid), and alveoli in histological specimens from early in the course of ARDS. Although neutrophil migration across the endothelium and then the epithelium does not cause injury, when activated, neutrophils are pro-inflammatory and pro-apoptotic, and release reactive oxygen species, cytokines, eicosanoids and a variety of proteases that may make an important contribution to basement membrane damage, increased permeability and direct cell damage. Following bone marrow

demargination, activated neutrophils adhere to the endothelium on their passage to the alveolus, and this may be accompanied by an early, transient leucopenia. Although neutrophils have an important role in host defence due to their bactericidal activity, there is a marked (50–1000-fold) increase in the release of cytotoxic compounds when they are activated by adherence to the endothelium, epithelium or contact with interstitial extracellular matrix proteins.[28] The factors involved in adhesion of neutrophils are complex and involve the integrin family of proteins, selectins and a number of adhesion molecules.

In models of ARDS, antibodies to adhesion molecules (e.g. CD11b/CD18 antibodies) ameliorate lung injury, suggesting a crucial and central role of this cell type. However, ARDS occurs in neutropenic patients, and was not more common when granulocyte colony-stimulating factor was administered to patients with pneumonia.[29] Clearly, other cell types play an important role, and neutrophil chemoattractants such as interleukin (IL)-8 must be present in the lung prior to neutrophil accumulation.

ALVEOLAR MACROPHAGES

Alveolar macrophages are the most common cell type normally found in BAL fluid, and together with interstitial macrophages play an important role in host defence and modulation of fibrosis. They are capable of releasing IL-6 and a host of mediators similar to the activated neutrophil, including tumor necrosis factor (TNF)-α and IL-8 in response to stretch,[30] and may amplify lung injury. Macrophages also release factors such as transforming growth factor (TGF)-α and platelet-derived growth factor (PDGF) that stimulate fibroblast proliferation, deposition of collagen and glycosaminoglycans, angiogenesis and lung fibrosis.

A study using different cell markers found that there appear to be different pools of alveolar macrophages termed the M1 and M2 phenotype.[31] The M1 phenotype is characterised as a resident alveolar macrophage that is pro-inflammatory, and the M2 phenotype appears to represent recruited monocytes and be central to lung repair and fibrosis depending upon timing, local milieu and cross talk with other cell types. This may account for the observation that ARDS survivors progressively increase alveolar macrophage number; however, any conclusion awaits further work examining alveolar macrophage phenotypes and clinical outcomes.

EPITHELIUM

Alveolar epithelial type II cells are extremely metabolically active; they manufacture and release surfactant, along with type I cells control alveolar water clearance through epithelial Na channels and Na^+/K^+ ATP-ase, express cytokines, which in turn interact with surfactant production, and are the progenitor of type I cells following injury. In response to both stretch and endotoxin, type II cells express IL-8 and TNF-α, with the latter cytokine augmenting Na^+, and hence water, egress from the alveolus.[32] Damage to the epithelium leads to dysfunctional surfactant release and impaired resolution of alveolar oedema which both reduces vectorial transport of Na^+ in part through down-regulation of ion transport genes, and up-regulates gene expression of Il-8, TNF-α, and IL-β.[33] Similarly, TGF-β acutely reduces transepithelial sodium transport by inducing endocytosis of epithelial sodium channel (ENaC) and plays a central role in lung fluid balance.[34]

Epithelial biomarkers include surfactant protein B (SP-B), which is predictive of ARDS,[35] and SP-D, and the receptor for advanced glycation end-products (RAGE), both of which have been associated with severity and outcome of ARDS.

ENDOTHELIUM

Pulmonary endothelial cells express a variety of adhesion molecules and cyclooxygenase (COX)-2, secrete endothelin and cytokines including IL-8,[36] stimulate procoagulant activity and 'cross talk' with the alveolar macrophages and type II cells. In addition to generalised endothelial activation, the endothelium is subject to mechanical stress both secondary to vascular pressure, and its association with the alveolus. Plasma levels of von Willebrand factor antigen are both predictive of and associated with outcomes from ARDS[37]; however, as it is synthesised by all vascular endothelial cells it is a non-specific biomarker. Similarly, plasma Angiopoietin-2 both predicts the onset of ALI in critically ill patients and has prognostic and pathogenetic significance.[38,39]

Microvascular thrombosis is common in ARDS, associated with inflammation, and contributes to pulmonary hypertension and wasted ventilation. Platelet aggregation contributes through release of thromboxane A_2, serotonin, lysosomal enzymes, and platelet-activating factor. Impaired fibrinolysis also contributes to these changes, and abnormal plasma levels of protein C and plasminogen activator inhibitor-1 are associated with outcome and organ failure in ARDS. Lung injury also leads to expression of the coagulation factor X on pulmonary epithelium, which appears to be a direct link between coagulation and pulmonary fibrosis.[40]

CHEMOKINES IN ACUTE RESPIRATORY DISTRESS SYNDROME

The expression and secretion of chemokines (chemoattractant cytokines) at sites of inflammation is a key proximal step in initiating the inflammatory cascade. IL-8-induced chemotaxis and activation of neutrophils are elevated in ARDS BAL fluid both within hours of the initiating insult and before recruitment of neutrophils, and in a manner that reflects subsequent morbidity and mortality. IL-8 antibodies prevent recruitment of neutrophils and protect the lung. Indeed, the recruitment and retention of neutrophils requires the

generation and maintenance of a localised chemotactic/haptotactic gradient.[41]

ION CHANNELS IN ACUTE RESPIRATORY DISTRESS SYNDROME

The transient receptor potential (TRP) ion channel superfamily is involved in sensing and transmission of a broad variety of external or internal stimuli, including mechanical stress.[42] TRP vanilloid (TRPV) 4 is expressed on the pulmonary endothelium, epithelium and macrophages. Activation of TRPV4 channels by shear forces,[43] stretch,[44] overinflation,[45] hypothermia,[44] increased hydrostatic pressure,[46] sudden increases in circulatory forces,[47,48] high intracapillary pressure,[44,46] and hypotonicity[49] leads to the rapid intracellular influx of calcium ions and leads to increased permeability of the alveolocapillary barrier through perturbations in cell morphology and disruption to the alveolar septal barrier[50] possibly via activation of matrix metalloproteinases[51] and calcium-activated K channels,[52] manifesting as lung injury.

MEDIATORS IN ACUTE RESPIRATORY DISTRESS SYNDROME[53]

Inflammation is usually a redundant process so that numerous mediators, including cytokines, chemokines, complement, reactive oxygen species, eicosanoids, platelet-activating factor, nitric oxide, proteases, growth factors and lysosomal enzymes, derived from a number of different cell types, play important roles in the pathophysiology of ARDS. As the alveolocapillary barrier becomes injured, these are no longer compartmentalised in the alveolus, and many of these proteins have been measured in blood as well as in the epithelial lining fluid. Care must be taken when interpreting these data, as immunological levels may not reflect biological activity, inhibitors or binding proteins may complex with the active protein or epitope and interfere with immunological detection, and the ultimate biological effect will depend upon a balance of pro-inflammatory and anti-inflammatory effects.

Of the pro-inflammatory mediators, TNF-α, IL-1β, IL–6, and IL-8 are the most important. However, even greater increases are found in their cognate receptors or antagonists such as the counter-regulatory cytokine IL-10, so that their biological impact is markedly reduced.[54] Blood or epithelial lining fluid levels are associated with mortality, but are rarely used clinically.

RESOLUTION OF ACUTE RESPIRATORY DISTRESS SYNDROME AND THE DEVELOPMENT OF FIBROSING ALVEOLITIS

Although histological evidence of fibrosing alveolitis (mesenchymal cells and new vessels in alveoli) is not usually found until at least 5 days following the onset of ARDS, elevated levels of type III procollagen peptide are found in the epithelial lining fluid soon after diagnosis[21]; both oedema fluid and plasma levels are associated with mortality.

Clinical resolution of ARDS usually occurs provided that both the underlying cause is promptly and effectively treated, and that appropriate supportive care is provided. Alveolar oedema resolves with active transport of Na^+ by the type II cells followed by passive clearance of water through transcellular aquaporin channels; repair of the alveolocapillary barrier is associated with improved outcome. Type II cells proliferate and cover the denuded epithelium before differentiating into type I cells.

Both host response and the clinical course of ARDS influence lung remodelling in ARDS. Cross-talk between type II cells and alveolar macrophages, probably the M2 phenotype, along with epithelial mesenchymal transition – a process where reactive oxygen species, hypoxia, TGF-β and mechanical stress lead to altered epithelial transcription – are central to interstitial responses. Epithelial cells assume characteristics of mesenchymal cells with loss of polarity, increased resistance to apoptosis, and increased migration (into the interstitium) where they lay down a fibrotic matrix.[55]

CLINICAL MANAGEMENT OF ACUTE RESPIRATORY DISTRESS SYNDROME

The factors leading to ARDS must be promptly and appropriately treated. This includes diagnosis and treatment of infection with drainage of collections and appropriate antimicrobial agents, recognition and rapid resuscitation from shock, splinting of fractures, and careful supportive care. Prevention of deep venous thrombosis, stress ulceration, nosocomial infection, and malnutrition, often with enteral nutrition, must all be considered.

Early mobilisation of mechanically ventilated patients accompanied by appropriate levels of analgesia and sedation is feasible and safe, and offers shorter duration of ventilation, reduced delirium, ICU and hospital length of stay, and improved mortality and functional outcomes.[56–58] However, two other randomised controlled trials[59,60] have not shown benefit, and care must be taken not to exacerbate lung injury with premature spontaneous effort which may result in unintended increases in both transpulmonary airway and transmural hydrostatic pressure,[61] and asynchrony. For example, use of neuromuscular blockers in the first 48 hours of mechanical ventilation in ARDS reduced mortality,[62] possibly through prevention or reduction of these factors.

MECHANICAL VENTILATION

Acute hypoxaemic respiratory failure,[63] and an increase in the work of breathing, usually mandates mechanical

Table 33.2 Pathophysiology of acute lung injury and adult respiratory distress syndrome

FEATURE	CAUSE(S)
Hypoxaemia	True shunt (perfusion of non-ventilated airspaces) Impaired hypoxic pulmonary vasoconstriction *V/Q* mismatch is a minor component
↑Dependent densities (CT)	Surfactant dysfunction alveolar instability
(Collapse/consolidation)	Exaggeration of normal compression of dependent lung due to ↑weight (↑lung water, inflammation)
↑Elastance (↓compliance)	Surfactant dysfunction (↑specific elastance) ↓Lung volume ('baby lung') ↑Chest wall elastance Fibrosing alveolitis (late)
↑Minute volume requirement	↑Alveolar dead space (VD_{phys} V_t often 0.4–0.7) ↑ V_{CO_2}
↑Work of breathing	↑Elastance ↑Minute volume requirement
Pulmonary hypertension	Pulmonary vasoconstriction (thromboxane A_2, endothelin) Pulmonary microvascular thrombosis Fibrosing alveolitis Positive end-expiratory pressure

CT, Computed tomography.

ventilation (Table 33.2). The role of non-invasive ventilation in ARDS is contentious; there are no large definitive studies, and although some groups report encouraging results, these are usually in patients with mild ARDS.[64] Failure of non invasive ventilation (NIV) is common, associated with greater complication rates and mortality, perhaps due to delayed intubation.[65–67] If non-invasive ventilation is considered in ARDS, it requires particular care (see Chapter 37).

The method and delivery of ventilatory support must take into account both the pathophysiology of ARDS and VILI. The ARDS Network randomised 861 ALI patients from 75 ICUs to receive either a tidal volume (V_T) of 12 or 6 mL/kg predicted body weight.[68] Mortality was reduced by 22%, from 40% to 31%, in the lower V_T group. There was a strict PEEP and Fi_{O_2} protocol, and patients were ventilated with assist-control ventilation to avoid excessive spontaneous V_T. Similar data with improved long-term survival are found in routine clinical practice[69]; however, it is the concept of lung protection rather than an exact V_T formula that is important.[70] As Hager and colleagues[71] found that lower V_T ventilation was protective across all quartiles of plateau pressure (P_{plat}) in the ARDS Network trial, with no safe upper limit of P_{plat}, it appears that the key variable is lower V_T rather than control of static airway pressure.

AVOIDANCE OF OVERSTRETCH AND INADEQUATE RECRUITMENT

The increase in dependent lung density found on chest CT, due to non-aerated and poorly aerated lung, reduces the volume of aerated lung available for tidal inflation (baby lung). Both PEEP and tidal recruitment will increase aeration of some of these air spaces, but a V_T that is not reduced in proportion to the reduction in aerated lung may lead to overstretch of aerated lung parenchyma and further diffuse alveolar damage. This is termed volutrauma, as increased airway pressure (P_{aw}) despite low V_T, due to decreased chest wall compliance, causes minimal damage compared with high V_T, high P_{aw} ventilation.[72] Atelectrauma refers to injury due to repeated opening and closing of air spaces during tidal inflation. Both volutrauma and atelectrauma result in alveolar inflammation and elevated alveolar cytokines (biotrauma), which may 'spill' into the systemic circulation.[73] However, as CT scans performed during ARDS Network protective ventilation show that tidal inflation occurs primarily in either normally aerated or overinflated compartments, with little tidal recruitment,[74] and PET-CT scans suggest that overinflation but not tidal recruitment is inflammatory,[75] overstretch appears to be the dominant mechanism causing VILI.

OVERSTRETCH

The normal lung is fully inflated at a transpulmonary pressure of ~25–30 cm H_2O. Consequently, a maximum P_{plat}, an estimate of the elastic distending pressure, of 30 cm H_2O has been recommended.[68] However, overinflation may occur at much lower elastic distending pressures (18–26 cm H_2O).[72,76]

The transpulmonary pressure may be lower than expected for a given P_{plat} in patients with a high chest

wall elastance (e.g. obesity, abdominal compartment syndrome, after abdominal or thoracic surgery). While placement of an oesophageal balloon (see Chapter 38) allows measurement of the transpulmonary pressure and may allow better titration of PEEP,[77] it must be correctly placed, have an adequate occlusion pressure ratio, and measurements are preferably performed in a semi-sitting position in order to lift the mediastinum off the oesophagus.

Finally, inspiratory muscle contraction through reduction of intrapleural pressure lowers P_{plat}, potentially avoiding simple detection of an excessive transpulmonary pressure. This is particularly common when pressure support ventilation is used as a primary mode of ventilatory support; V_T that would produce an unacceptably high P_{plat} during mechanical ventilation will produce the same volutrauma during a spontaneous or supported mode of ventilation, and should be avoided. Provided the same V_T is generated, spontaneous ventilation does not reduce VILI compared to controlled ventilation,[78] and may exacerbate it.[61]

Static or dynamic volume-pressure curves or quantitative chest CT can be used to infer overinflation, though chest CT cannot determine overstretch.[5] Consequently, unless particular expertise is available, V_T limitation is currently the most practical approach.

ADEQUATE PEEP

PEEP improves Pa_{O_2} by recruiting alveoli and increasing end-expiratory lung volume. Because PEEP may reduce cardiac output by impairing venous return, Suter and co-workers suggested that at best PEEP the oxygen delivery (oxygen content × flow) was highest, and that this coincided with greatest compliance.[79] PEEP is commonly titrated to a particular Pa_{O_2}/Fi_{O_2} ratio such as the ARDS Network protocol.[68] However, the amount of lung available for recruitment is extremely variable,[80] and does not differ comparing pulmonary with extrapulmonary ARDS.[81] Factors such as the duration, late ARDS being less recruitable, and phenotype influence whether PEEP leads to alveolar recruitment, overinflation or a balance of both. Based on chest imaging, ARDS can be subdivided into focal, intermediate and diffuse phenotypes, with progressive increase in the amount of recruitable lung.[82,83] Applying ARDS Network ventilation to focal ARDS (about ⅓ of most cohorts) leads to high lung stress, with increased cytokine release, which can be ameliorated by using lower levels of PEEP.[84]

The lower inflection point of a volume-pressure curve has been used to set PEEP; early studies suggested that this reflected recruitment of collapsed alveoli. However, in patients with ARDS, recruitment occurs well above the lower inflection point, often along the entire volume-pressure curve and above the upper inflection point.[85,86] Concurrently, there is frequently evidence of overstretching and hyperinflation on CT scans[41,87] or dynamic volume-pressure analysis.[76]

Meta-analysis of major clinical trials using protective V_T and comparing higher and lower PEEP scales[88] did not find an overall improvement in outcome with higher PEEP, although rescue therapies were required less often. However, patients with mild ARDS tended to have worse outcomes with higher PEEP, and those with moderate to severe ARDS had better outcomes.

These data suggest individual patients may benefit from a tailored approach. Although routine CT analysis has been advocated by some, it is cumbersome and has not been shown to influence outcome; non-invasive bedside alternatives are under investigation. Consequently, PEEP titration is often a compromise aiming to minimise both atelectrauma and volutrauma.[89] Reasonable approaches to PEEP titration include: (a) the use of a scale similar to the ARDS Network protocol, (b) titration of PEEP to Pa_{O_2} aiming for a PEEP of ~15 cm H_2O, or (c) measuring elastic mechanics at the bedside. Consistent with Suter's early observation,[79] both nadir elastance after a recruitment manoeuvre,[90] or minimal change in driving pressure[76] (see also Chapter 38), offer bedside methods to individualise PEEP.

In patients at risk for ARDS, prophylactic PEEP (8 cm H_2O) was not protective.[91]

Driving pressure

This is defined as the difference between the end-inspiratory plateau pressure and the total PEEP. In a meta-analysis of nine randomised controlled trials of protective ventilation strategies (lower V_T, lower Pplat, and higher PEEP), Amato and colleagues identified the driving pressure as the variable most robustly associated with improved outcome.[92] Although the driving pressure is an appealing and intuitive way of thinking about minimising lung stress, protocols examining this method need to be prospectively tested using patient-centred outcomes to exclude indirect association as the basis for these findings.

Recruitment manoeuvres and open lung ventilation

Open lung ventilation refers to an approach where the lung is maximally recruited, usually through application of higher PEEP, recruitment manoeuvres, and efforts to minimise derecruitment. In theory, increased lung volume will result in less tidal overinflation and improved outcome. However, despite alveolar recruitment with open lung ventilation, overinflation may occur in previously normally aerated lung.[93] The recruitment manoeuvre may be followed by a marked improvement in oxygenation; however, this is not a consistent finding, and hypotension may occur due to reduced venous return if there is inadequate fluid loading.

During a typical recruitment manoeuvre, a high level of continuous positive airway pressure (CPAP) (30–40 cm H_2O) is applied for 30–40 seconds in an apnoeic patient, followed by return to a lower level of PEEP and controlled ventilation. This may be

suboptimal; an alternative, for example, is a staircase recruitment manoeuvre where airway pressure is sequentially increased every 2 minutes, and then decreased until oxygenation deteriorates.[94] A number of small trials have shown improvement in oxygenation following recruitment manoeuvres; however, the largest clinical trial[95] failed to show an effect. Grasso and colleagues[96] found that recruitment manoeuvres were effective only early in ARDS and with lower levels of baseline PEEP, which probably explains the variable responses reported.

In addition to physical recruitment of alveoli, lung stretch above resting V_T is the most powerful physiological stimulus for release of pulmonary surfactant from type II cells. This is associated with a decrease in lung elastance and improved Pa_{O_2} in the isolated perfused lung,[97] and is a possible explanation for the improvement in oxygenation, recruited lung volume and elastance reported with addition of three sigh breaths in patients with ARDS.[98] Similarly, in models of lung injury, biologically variable or fractal V_T is associated with less lung damage with lower alveolar levels of IL-8,[99] improved oxygenation and lung elastance, and greater surfactant release.[100] These data caution against monotonous low V_T ventilation, and suggest that intermittent or variable lung stretch may reduce lung injury.

MODE OF VENTILATION

Non-invasive ventilation should not be routinely used in ARDS (see Chapter 37) and most patients require intubated mechanical ventilation. Following intubation, controlled ventilation allows immediate reduction in the work of breathing, and application of PEEP and a controlled Fi_{O_2}. Later in the clinical course, assisted or supported modes of ventilation may allow better patient-ventilator interaction (see Chapter 31), and possibly improved oxygenation through better $\dot{V}/\dot{Q}$ mismatch as a result of diaphragmatic contraction.[101] Withdrawal or weaning from mechanical ventilation is discussed in Chapter 31.

An advantage of assist-control ventilation (as used in the ARDS Network study) is that spontaneous effort generates a controlled V_T. However, the fall in airway pressure during triggered ventilation (e.g. assist control or supported ventilation) can result in worse lung injury than controlled ventilation in early ARDS, although a beneficial effect can be seen when the underlying lung injury is less severe.[102] This may be due to greater transpulmonary and transmural pressure changes, and heterogeneity of lung inflation. Care should also be taken with synchronised intermittent mandatory ventilation (SIMV), particularly if pressure support is added to SIMV, as excessive V_T may occur during supported breaths.

There is an increasing tendency to use pressure-controlled ventilation (PC) or pressure-regulated volume control (PRVC), as P_{pk} is lower than volume-controlled (VC) ventilation with a constant inspiratory flow pattern. However, the decelerating flow pattern of PC or PRVC means that most of the resistive pressure (P_{res}) during inspiration is dissipated by end inspiration, which is in contrast to VC with a constant inspiratory flow pattern where P_{res} is dissipated at end inspiration (see Fig. 31.2). Consequently, with PC and PRVC $P_{pk} \approx P_{plat}$ which is the same as P_{plat} during VC.[103] Both oxygenation, haemodynamic stability and mean airway pressure are no different between PC and VC, and a moderate-sized randomised study found no difference in outcome.[104] However, there may be differences in lung stress due to greater viscoelastic build-up with VC.[105]

Inverse ratio ventilation, often together with PC, has been used in ARDS. However, when $PEEP_i$ and total PEEP are taken into account, apart from a small decrease in $PaCO_2$, there are no advantages with inverse ratio ventilation. Mean airway pressure is higher with a greater risk of both haemodynamic consequences, and regional hyperinflation.[103] Consequently, an inspiratory to expiratory ratio greater than 1:1 is recommended.

A number of other modes of ventilation (see Chapter 31) including airway pressure release ventilation (APRV) and high-frequency oscillation (HFO) have been proposed for use in ARDS. Randomised clinical trials have not shown improved outcomes with APRV,[106] despite potential physiological benefits. The small V_T used with HFO, although appealing, may increase hospital mortality when compared with a ventilation strategy of low tidal volume and high PEEP.[107]

Use of venovenous extracorporeal membrane oxygenation (ECMO) has been investigated in patients with ARDS and shown to both increase survival and minimise severe disability, and to be cost effective.[108] However, caution must be taken in extrapolating these results, as almost a quarter of those considered for ECMO group did not receive it, and control patients were not transferred to the trial hospital. Further trials are underway and vv-ECMO is sometimes used as a rescue therapy (see Chapter 41).

TARGET BLOOD GASES

As discussed earlier, there are many variables that need to be considered when choosing target blood gases in ARDS. For example, if a patient also has a traumatic brain injury, it may be inappropriate to accept hypercapnia.

Oxygenation targets and Fi_{O_2}

There must be a compromise between the major determinants of oxygenation, including the extent of poorly or non-aerated lung, hypoxic pulmonary vasoconstriction and mixed venous oxygen saturation, and the target Pa_{O_2}. The association between cognitive impairment and arterial saturation (Sa_{O_2}) less than 90%[14] suggests that a $Sa_{O_2} \geq 90\%$, usually a $Pa_{O_2} > 60$ mm Hg, is a reasonable target. A recent trial reported lower ICU

mortality with target Pa_{O_2} values of 70–100 mm Hg versus values up to 150 mm Hg.[109] Because positive-pressure ventilation may reduce cardiac output, it is also important to consider tissue oxygenation.

In addition to PEEP, increased Fi_{O_2} is used to improve Sa_{O_2}. However, high Fi_{O_2} may also cause tissue injury, including diffuse alveolar damage. The balance between increased airway pressure and Fi_{O_2} is unknown, but high Fi_{O_2} is generally regarded as being less damaging.[110] In part this is because diffuse alveolar damage itself protects the lung against hyperoxia, perhaps through prior induction of scavengers for reactive oxygen species.[111] A reasonable compromise is to start ventilation at a Fi_{O_2} of 1 and to titrate down, aiming for a $Fi_{O_2} \leq 0.6$. In patients with extreme hypoxaemia, additional measures such as inhaled nitric oxide (iNO) and prone positioning may be tried, along with a lower Sa_{O_2} target.

Carbon dioxide target

Low V_T strategies will result in elevations in $PaCO_2$ unless minute ventilation is augmented by an increase in respiratory rate. The ARDS Network protocol aimed at normocapnia, with a maximum respiratory rate of 35, to minimise respiratory acidosis.[68] This exposes the lung to more repeated tidal stretch, and may result in dynamic hyperinflation due to a shortened expiratory time.[112] In addition, allowing the $PaCO_2$ to rise above normal may not be harmful in many patients.

If hypercapnic acidosis occurs slowly, intracellular acidosis is well compensated, and the associated increase in sympathetic tone may augment cardiac output and blood pressure. Although the respiratory acidosis may worsen pulmonary hypertension and induce myocardial arrhythmias, these effects are often small, particularly if there has been time for metabolic compensation. In addition, in an ischaemia-reperfusion model of ARDS, therapeutic hypercapnia reduced lung injury and apoptosis,[113] but was harmful in prolonged untreated pneumonia.[114]

Extracorporeal CO_2 removal technologies may facilitate further lowering of ventilator stretch, allowing dissection of the contribution of CO_2 and tidal stretch to lung injury or protection in ARDS. However, clinical studies of permissive hypercapnia and extracorporeal CO_2 removal technologies must be undertaken before they can be considered. Hypercapnia should be avoided in patients with or at risk from raised intracranial pressure.

NON-VENTILATOR MANAGEMENT

PRONE POSTURE

In patients with severe ARDS, early application of prolonged prone-positioning sessions significantly decreased 28- and 90-day mortality.[115] Notably, the study entry Pa_{O_2}/Fi_{O_2} ratio was less than 150, enrolment was within 36 hours of commencing mechanical ventilation, and the ICUs had more than 5 years of experience in managing ARDS patients with prone positioning. The mechanisms involved include recruitment of dorsal lung, with concurrent ventral collapse; however, perfusion is more evenly distributed leading to better $\dot{V}/\dot{Q}$ matching. While this study is supported by a meta-analysis,[116] a number of prior studies did not find clear evidence of benefit.[117,118] Moreover, the study did not control for lung heterogeneity (ARDS phenotype), or co-interventions (did not control or report fluid balance, or cumulative dose of catecholamines), and had baseline imbalances of neuromuscular blockers and a high rate of cardiac arrest. Consequently, the uptake of prone positioning remains sporadic; more studies are needed.

MANIPULATION OF THE PULMONARY CIRCULATION

iNO and aerosolised prostacyclin (PGI_2) may be used to reduce pulmonary shunt and right ventricular afterload by reducing pulmonary artery impedance. When hypoxic pulmonary vasoconstriction is active, there is redistribution of pulmonary blood flow away from the poorly ventilated dependent areas to more normally ventilated lung leading to an increase in Pa_{O_2}. Both iNO and PGI_2 are delivered to well-ventilated lung; both vasodilate the local pulmonary circulation and augment the effects of hypoxic pulmonary vasoconstriction. Intravenous almitrine is a selective pulmonary vasoconstrictor that reinforces hypoxic pulmonary vasoconstriction and, although this may improve oxygenation alone, there is a synergistic effect with iNO.

Inhaled NO or PGI_2 may also be used to reduce right ventricular afterload; however, a consequent increase in cardiac output is rare in ARDS. Intravenous PGI_2 will improve cardiac output in ARDS, though there is non-specific pulmonary vasodilation with increased blood flow through poorly ventilated lung zones, resulting in deterioration in oxygenation.

Inhaled nitric oxide

Nitric oxide is an endothelium-derived smooth muscle relaxant. It also has other important physiological roles including neurotransmission, host defence, platelet aggregation leucocyte adhesion and bronchodilation. Doses as low as 60 parts per billion iNO may improve oxygenation; however, commonly used doses in ARDS are 1–60 parts per million, with the higher doses required for reduction in pulmonary artery pressure. A rise in Pa_{O_2} exceeding 20% is generally regarded as a positive response; iNO should be continued at the minimum effective dose.

Inhaled NO may be delivered continuously or using intermittent inspiratory injection. Delivery is usually in the form of medical grade NO/N_2, and this should be adequately mixed to avoid delivery of variable NO concentrations. It is recommended that inspiratory NO

and NO_2 concentrations are measured, either by an electrochemical method or by chemiluminescence. The electrochemical method is accurate to 1 ppm, which is adequate for clinical use, and is less expensive. Local environmental levels of NO and NO_2 are low and predominantly influenced by atmospheric concentrations; however, it is still common practice to scavenge expired gas. Binding to haemoglobin in the pulmonary circulation rapidly inactivates NO, and systemic effects are reported only following high concentrations of iNO. Systemic methaemoglobin levels may be monitored, and are generally less than 5% during clinical use of iNO, but they should be compared with a baseline level. Nitric oxide may cause lung toxicity through combination with oxygen free radicals, and through metabolism of NO to NO_2; however, these do not appear to be major clinical problems. However, there are concerns about delayed resolution of pulmonary oedema with its usage.[119]

Only 40%–70% of patients with ARDS have improved oxygenation with iNO (responders), and this is likely due to active hypoxic pulmonary vasoconstriction in the remainder. Addition of IV almitrine can have an additive effect on oxygenation, and may improve the number of responders. Clinical trials[120] have shown no improvement in mortality or reversal of ARDS, and an increased risk of renal impairment. However, iNO transiently improves oxygenation (as compared with placebo or no iNO), which has been sustained beyond 12–24 hours in some trials. As constant dosing of iNO leads to both increased sensitivity and apparent tachyphylaxis,[121] subsequent investigation needs to consider different dose regimens. Currently iNO cannot be recommended for routine use in ARDS; however, in some patients with severe hypoxaemia, perhaps in combination with almitrine, iNO will provide temporary rescue.

Inhaled prostacyclin

PGI_2 (up to 50 ng/kg per minute) improves oxygenation as effectively as iNO in ARDS patients,[122] and may reduce pulmonary hypertension. It is continuously jet nebulised due to its short half-life (2–3 minutes). Potential advantages include increased surfactant release from stretched type II cells, avoidance of the potential complications of iNO, and minimal toxicity. However, PGI_2 is dissolved in an alkaline glycine buffer, which alone can result in airway inflammation, and the sticky nature of the aerosol can result in expiratory valve obstruction. Iloprost is a derivative of PGI_2 with similar activity, a longer duration of action, without an alkaline buffer. Neither agent has been shown to improve outcome in ARDS patients.

CONSERVATIVE FLUID BALANCE

Conservative fluid balance has been shown to decrease the length of mechanical ventilation when compared with liberal fluid balance in patients with ARDS,[16] although in a small number of patients who were followed up (30% of eligible survivors) it was associated with adverse neurocognitive outcome.[17] An intermittent approach between conservative and liberal fluid balance offers[123] solutions but has to be examined in larger prospective trials. A positive sodium balance is associated with respiratory dysfunction independent of fluid balance,[124] and future trials need to control for sodium balance in addition to fluid balance in patients with ARDS.

HIGH FLOW OXYGEN

Use of high flow humidified oxygen through nasal cannula (HFNC) has become common in patients with acute hypoxaemic respiratory failure. As the gas flow rate (15–60 L/min) is close to the subject's inspiratory flow rate, there is little dilution of the inspired oxygen fraction. Additional mechanisms include flow dependent continuous positive airway pressure with increased end-expiratory lung volume, and washout of upper airway carbon dioxide leading to decreased physiological dead space, with both contributing to reduce the work of breathing. Compared to standard oxygen or NIV, HFNC reduced intubation in patients with hypoxic respiratory failure.[125] However, as the rate of intubation was high (38%), caution should be used. The role in of HFNC in ARDS is uncertain and endotracheal intubation and lung protective ventilation should not be delayed.[126]

NEUROMUSCULAR BLOCKER

The ACURASYS trial in 2010 examined neuromuscular blockade in patients with severe, early ARDS and found that both the adjusted 90-day survival rate and time off the ventilator were greater in the cisatracurium group as compared with the placebo group.[62] This was despite the fact that variables commonly used to assess the propensity for VILI (e.g. plateau pressures and tidal volumes) did not differ significantly between the cisatracurium group and the placebo group, although reduced asynchrony and adverse effects attributable to triggering ventilation cannot be excluded.[61,127] These results have to be repeated, the possible mechanisms understood,[128] and concerns about long-term muscle weakness and the optimal duration of neuromuscular blocker also need to be addressed before it becomes a routine in the care of ARDS patients.

SURFACTANT REPLACEMENT THERAPY

Surfactant dysfunction is an important and early abnormality contributing to lung damage in ARDS.[21,129] Pulmonary surfactant reduces surface tension promoting alveolar stability, reducing work of breathing and lung water. In addition, surfactant has important roles in lung host defence. Reactive oxygen species, phospholipases and increased protein permeability lead to inhibition of surfactant function. In addition, composition is abnormal, and turnover markedly increased.

VILI is difficult to demonstrate without surfactant dysfunction.[129] Consequently, there has been considerable interest in exogenous surfactant replacement therapy.

Exogenous surfactant therapy has an established role in neonatal respiratory distress syndrome. In paediatric ARDS, particularly that due to direct lung injury, clinical trials have been promising. However, in adults results have been disappointing; subgroup analysis of recombinant SP-C-based surfactant administered intratracheally improved oxygenation in direct ARDS without an improvement in mortality.[130] However, subsequent research in this cohort failed to confirm these data, perhaps owing to inactivation of the surfactant during administration.[131]

GLUCOCORTICOIDS

Glucocorticoids may have a role in ARDS through their reduction of the intense inflammatory response and their potential to reduce fibroproliferation and collagen deposition, by faster degradation of fibroblast procollagen mRNA. Preventative steroids increase the incidence of ARDS and, although there may be a greater number of ventilator-free days and the possibility of a reduction in mortality,[132,133] neuromuscular complications, immunosuppression, superadded infection and higher blood glucose levels and increased mortality when steroids are administered more than 13 days after the onset of ARDS,[134] argue against their routine use.

OTHER PHARMACOLOGICAL THERAPIES

Numerous other therapies including cytokine antagonism, non-steroidal anti-inflammatory drugs, scavengers of reactive oxygen species, and lisofylline[135] have been trialled without success. The complex balance of inflammation and repair in ARDS, and the critical additional damage secondary to VILI, may explain these results. However, studies in less heterogeneous groups with minimisation of VILI using standardised ventilation protocols, together with a growing understanding of ARDS, offer potential pharmacological therapies. Many promising therapeutic options such as TRPV4 antagonism, hyperosmolar therapy recombinant human angiotensin converting enzyme 2 and stem cell therapy are under trials.

Pulmonary embolism

Sachin Gupta, Andrew R Davies

INTRODUCTION

Pulmonary embolism (PE) is a commonly considered but relatively uncommonly diagnosed condition in hospitalised patients. It is important to have an adequate understanding of the pathophysiology as well as a rapid and reliable strategy for investigation and management. This is particularly important in intensive care unit (ICU) patients where diagnosis can be difficult and PE may be life threatening. While admission rates for PE are rising, outcomes are improving overall.[1] However, mortality amongst haemodynamically unstable patients remains high.[1]

Early deaths in PE are usually the result of acute right ventricular (RV) failure and cardiogenic shock. After the first few days, mortality is less common and mostly determined by recurrent thromboembolic events and the underlying disease state.

AETIOLOGY

Deep venous thrombosis (DVT) and PE are components of a single disease termed venous thromboembolism (VTE). Embolisation of DVT to the pulmonary arteries leads to PE. The incidence of VTE in the population is about 1 in 1000 per year and is more common both with advancing age and in males.

Predisposing risk factors for VTE involve one or more components of Virchow triad: (1) venous stasis, (2) vein wall injury, and (3) hypercoagulability of blood. In addition to the main factors such as immobility (from any cause), surgery, trauma, malignancy, pregnancy, thrombophilia (see Box 34.1) and autoimmune disorders have also been associated with increased risk of PE.[2]

The term thrombophilia refers to any abnormality of blood coagulation that increases the risk of thrombosis, and can be heritable or acquired. Heritable thrombophilias are present in 5% of the population.[3] The most common of the heritable thrombophilias is activated protein C resistance, which is mediated by the factor V Leiden mutation. As most people with thrombophilia do not develop DVT or PE, and diagnosis of thrombophilia does not affect immediate and in most cases long-term management of these patients, investigation for thrombophilia should not be prioritised unless it changes management.[3] Autoimmune disorders are associated with high risk of PE and should be considered hypercoagulable disorders.[2]

Factor V Leiden mutation, oral contraceptive use, pregnancy, pueperium, obesity and minor leg injuries pose a higher risk of DVT as compared to PE, whereas pulmonary conditions like chronic obstructive pulmonary disease, sickle cell disease and pneumonia raise the risk of PE with little effect on risk of DVT.[4]

Most PE results from DVT in the lower limbs, pelvic veins or inferior vena cava (IVC), although thrombi can develop in the right atrium, right ventricle and upper limbs. Up to 40% of patients with DVT develop PE, although if the DVT is isolated to below the knee, then clinically obvious PE is rare. Between 2% and 4% of patients with VTE develop chronic pulmonary hypertension.[5]

PATHOPHYSIOLOGY

The effects of PE range from being incidental and clinically irrelevant to causing severe obstruction to the pulmonary circulation and sudden death. Pulmonary arterial obstruction and the subsequent release of vasoactive substances such as serotonin and thromboxane A_2 from platelets lead to elevated pulmonary vascular resistance and acute pulmonary hypertension.

Acute pulmonary hypertension increases RV afterload and RV wall tension which leads to RV dilatation and dysfunction with coronary ischaemia being a major contributing mechanism.[6] In massive PE, the combination of coronary ischaemia, RV systolic failure, paradoxical interventricular septal shift and pericardial constraint leads to left ventricular (LV) dysfunction and obstructive shock. In patients with underlying cardiorespiratory disease, a small PE can have profound consequences.

Pulmonary arterial obstruction causes a mismatch between lung ventilation and perfusion which leads to hypoxaemia. The ventilation of lung units that have reduced or no perfusion causes increased dead-space ventilation and an increase in the end-tidal to arterial

ABSTRACT

Pulmonary embolism is a commonly considered, uncommonly confirmed yet sometimes overlooked condition. Both clinical and objective parameters can be used to estimate pretest probability which improves detection. Computed tomography pulmonary angiogram (CTPA) scanning remains the mainstay of diagnosis. Echocardiography and biomarkers are important tools to stratify the risk of complications, while presence of haemodynamic compromise puts patients in the highest risk category. Even though treatment carries significant risk of bleeding, undertreatment may lead to death or significant long-term disability. Newer oral anticoagulants have simplified longer-term management and treatment monitoring. Catheter-directed thrombolysis and lower dose fibrinolysis have the potential to reduce bleeding without compromising patient outcomes in carefully chosen patients. Other supportive therapies include haemodynamic support focused on right ventricular function.

CO_2 gradient. Alveolar hyperventilation also occurs leading to hypocapnia. Increased right atrial pressure can open a patent foramen ovale, which may result in right-to-left shunting manifested as either refractory hypoxaemia or paradoxical (arterial) embolisation commonly to the brain leading to cerebral infarction.

CLINICAL PRESENTATION

PE is relatively uncommon in critically ill patients despite the frequent presence of risk factors for VTE. However, when PE does occur the diagnosis is frequently overlooked or is difficult to confirm because several more prevalent cardiopulmonary diseases, including heart failure, pneumonia and chronic lung diseases, have similar clinical features. Up to one in six patients have the diagnosis made more than 10 days after symptom onset.[7]

Clinical assessment should raise the suspicion of PE but is neither sensitive nor specific enough to reliably confirm or exclude the diagnosis on its own. Clinical decision rules (CDRs) have been developed, some based entirely on objective parameters such as the combination of symptoms, signs and risk factors (Geneva, Pisa, Charlotte, and Pulmonary Embolism Rule-out Criteria [PERC]) and others still requiring clinician's judgement regarding whether PE is more likely than alternative diagnoses (Wells score) in addition to the objective criteria. The most widely reported of these are the Wells score and the Geneva score.[8] Even though CDRs provide accurate and reproducible determinations of probability for use in a diagnostic strategy, empirical clinical assessment may carry similar sensitivity and specificity, especially when prevalence of PE is higher.[9] However, CDRs may modestly increase the yield of computed tomographic pulmonary angiogram (CTPA).[10] With either strategy, patients can have their probability determined as unlikely (in whom PE can be safely ruled out with a negative D-dimer result) or likely (in whom an imaging test is required and in whom prompt anticoagulant therapy should be considered). The differential diagnoses are listed in Box 34.2.

SYMPTOMS

Dyspnoea, pleuritic chest pain, and haemoptysis are the classic symptoms of PE. Most patients will have at least one of these symptoms, with dyspnoea being the most common. The combination of pleuritic chest pain and haemoptysis reflects a late presentation where pulmonary infarction has occurred. If syncope occurs, and there is no other obvious cause, it is likely that this is a massive PE. A family history of venous thrombosis is itself a risk factor regardless of the presence of an inherited thrombophilia.

PHYSICAL SIGNS

Physical signs can be absent, but the most frequent sign is tachypnoea. Others include tachycardia, fever and signs of RV dysfunction (raised jugular venous pressure, parasternal heave and loud pulmonary component of the second heart sound). In massive PE, signs may include hypotension, pale mottled skin and peripheral or even central cyanosis. It is important to examine for signs of DVT particularly in the legs.

INVESTIGATIONS

The diagnosis of PE requires a high level of clinical suspicion and the appropriate use of investigations. The aim of these investigations is to confirm or exclude the presence of PE but also to stratify treatment to aid planning management. The optimal investigation strategy depends upon the individual patient and institution; however, multidetector CTPA scanning is now the imaging test of first choice. A suggested investigation algorithm is shown in Fig. 34.1.

D-DIMER

The serum D-dimer level, which becomes elevated when acute thrombus formation occurs, is useful for exclusion of VTE, particularly when it is normal and combined with a low-risk clinical assessment.[11] Because of its sensitivity, negative D-dimer tests, particularly using enzyme-linked immunosorbent assays (ELISA), enzyme-linked immunofluorescence assays (ELFAs) and latex quantitative assays, are highly predictive of the absence of both DVT and PE.

A high D-dimer concentration is also an independent predictive factor associated with mortality.[12] Age adjusted D-dimer cut off (defined as age in years × 10 in patients above 50 years of age) increases the number of low-to-intermediate probability patients (revised Geneva score <5 or Wells Score </= 4) in whom PE can be safely ruled out.[13] Unfortunately, D-dimer levels are often elevated in ICU patients for reasons including infection, inflammation, cancer, surgery and trauma, acute coronary syndrome, stroke, peripheral artery disease or ruptured aneurysm. D-dimer tests should be used with caution in patients who are elderly (as the upper limit of normal increases with age), who have prolonged symptoms and who are already receiving therapeutic anticoagulant therapy. In addition, reporting units and performance of the assay used by the laboratory need to be considered when using D-dimer cut offs to rule out PE.[14]

BIOMARKERS

Although of little use for confirming or excluding the diagnosis, biomarkers can assist in risk stratification of patients with diagnosed PE.[15] Below cut-off levels of established biomarkers such as troponin, brain natriuretic peptide (BNP) and N-terminal pro BNP (NT-pro-BNP) can help stratify patients into a low-risk category.

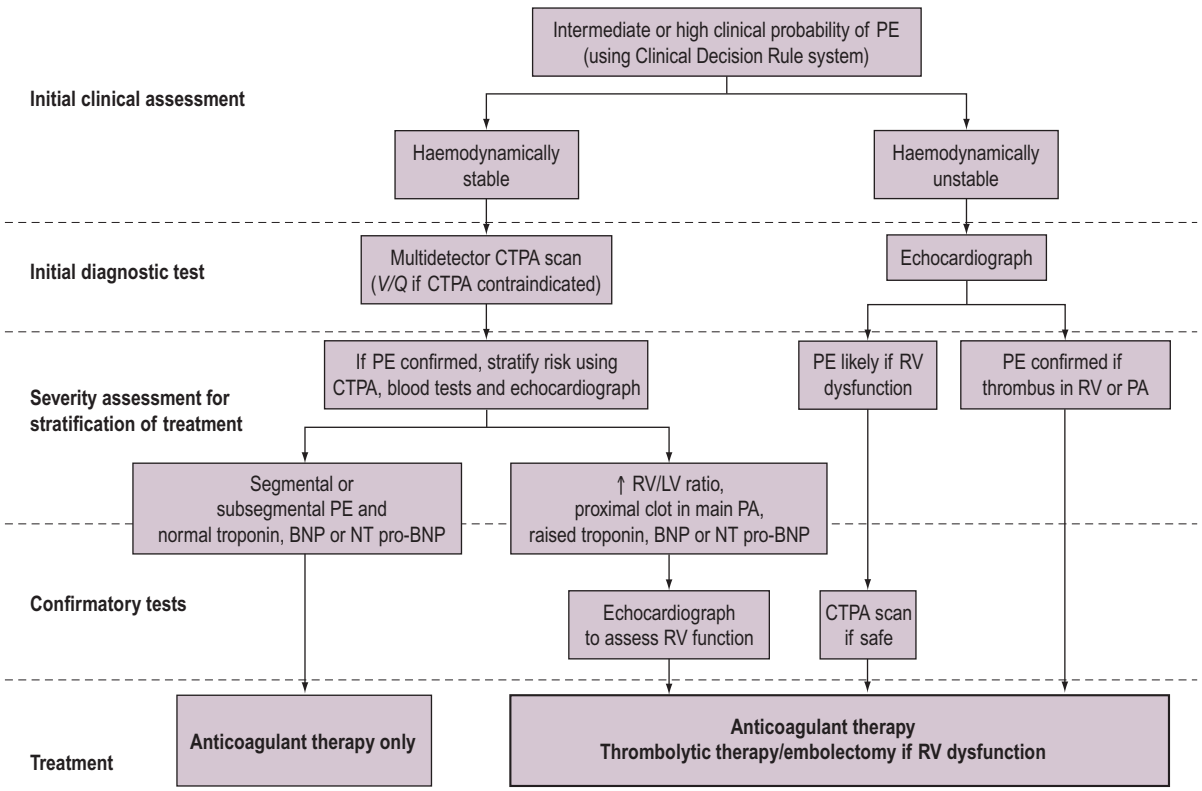

Figure 34.1 Suggested investigation and treatment algorithm for pulmonary embolism (PE). *BNP*, Brain natriuretic peptide; *CTPA*, computed tomographic pulmonary angiography; *IVC*, inferior vena cava; *NT pro-BNP*, N-terminal pro BNP; *PA*, pulmonary artery; *RV*, right ventricular; *RV/LV*, right ventricle/left ventricle; *V/Q*, ventilation/perfusion scan.

Admission troponin levels may be falsely low in some patients who present early, so the troponin level at 8 hours is a better marker for risk stratification for these patients.[16] Heart fatty acid binding protein (H-FABP) is a cytoplasmic protein which appears in the circulation as early as 90 minutes after myocardial injury and is an emerging biomarker for predicting adverse outcomes after PE.[17] These biomarkers should be used in conjunction with other tests investigating for the presence of RV dysfunction (echocardiography or CTPA) to stratify these patients, as none of these biomarkers alone can separate patients with low risk from those with higher risk of death or PE-related complications with an acceptable degree of certainty.[18]

ARTERIAL BLOOD GASES

A normal arterial blood gas profile does not exclude the diagnosis of PE; however, hypoxaemia (with a widened alveolar-arterial oxygen gradient), hypocapnia and an increased end-tidal CO_2 gradient should raise the suspicion of PE, even if these are common findings in critically ill patients for other reasons. Metabolic acidosis may be present if shock from a large PE occurs. Capnography may evolve into a useful tool to rule out PE in patients with positive D-dimer tests but at present the method and optimal cut offs are unclear.[19]

ELECTROCARDIOGRAPH

A normal electrocardiograph (ECG) is found in about one-third of patients. Apart from sinus tachycardia (which is non-specific), the most frequent ECG abnormalities are non-specific S–T depression and T-wave inversion in leads V1–V4, right bundle branch block, S1Q3T3 pattern (deep S-wave in lead I and a Q-wave and inverted T-wave in lead III) and S-T segment elevation in lead AVR, reflecting right heart strain. These ECG abnormalities and the presence of atrial fibrillation are associated with a higher risk of adverse outcomes.[20] The ECG is also useful in excluding acute myocardial infarction and pericarditis. Presence of T-wave inversion in both lead III and V1 increases the likelihood of PE as compared to acute coronary syndrome.[21]

CHEST X-RAY

The chest X-ray is often normal or only slightly abnormal with non-specific signs such as cardiac enlargement, pleural effusion, elevated hemidiaphragm, atelectasis and localised infiltrates. More specific findings, including focal oligaemia, a peripheral wedge-shaped density above the diaphragm (Hampton hump) and an enlarged right descending pulmonary artery (Palla sign), are uncommon and may be difficult for non-radiologists to identify.[22] The chest X-ray is also useful in identifying an alternative diagnosis such as pneumothorax, pneumonia, acute pulmonary oedema, rib fracture and pleural effusion.

CONFIRMATORY IMAGING TESTS INCLUDING CTPA SCAN

Imaging is required in any patient with a high or likely clinical probability. As the technology has improved, CTPA scanning, especially the multidetector scanner (MD-CTPA),[23] has now largely replaced lung ventilation-perfusion (V/Q) scanning as the cost-effective and clinically reliable imaging procedure of choice in patients with suspected PE.[24] This is because the CTPA scan has the advantages of greater diagnostic accuracy, ready availability at most hospitals, more rapid image acquisition time, and the possibility of making an alternative diagnosis. High-resolution images to the level of segmental and in some cases subsegmental pulmonary arteries can be obtained in a short time period (often a single breath-hold). When compared with conventional angiography it appears reliable, with excellent sensitivity, specificity and accuracy.[25] It is therefore recommended that the CTPA scan should be the principal imaging test for patients with high and moderate probability of PE.

Although inconclusive CTPA scans occur in around 10%, a negative CTPA result means that withholding anticoagulant therapy is safe.[26] An emerging problem of CTPA scanning, however, is the increased detection (around 10%) of small peripheral emboli in subsegmental pulmonary arteries due to increased visualisation of these arteries. The clinical significance of these findings in critically ill patients is unknown; however, these are usually unlikely to lead to a poor outcome if left untreated, unless the patient has co-existing DVT, cancer or is symptomatic.

The CTPA scan can also be used to assess the severity of PE. An increased RV/LV ratio, high thrombus load and central location of the clot are associated with worse clinical outcomes. Increased RV/LV ratio is the most significant marker of severity of PE.[27] Severity stratification is further increased by combining CTPA scanning with other tests such as troponin,[10] BNP or NT-Pro-BNP.[15] CTPA scanning may also identify the causative DVT in the veins of the legs, pelvis and abdomen or detect alternative or additional diagnoses such as a pulmonary mass, pneumonia, emphysema, pneumothorax, pleural effusion or mediastinal adenopathy (Fig. 34.2).

Despite the increased use of the CTPA scan, the planar and SPECT V/Q scan retain a role when CTPA is either unavailable or contraindicated (e.g. significant renal impairment, anaphylaxis to intravenous contrast or pregnancy).[28] SPECT V/Q has equivalent diagnostic yield to CTPA, with lower radiation dose, despite improvements in technology progressively reducing the radiation dose of CTPA. Planar V/Q scanning is

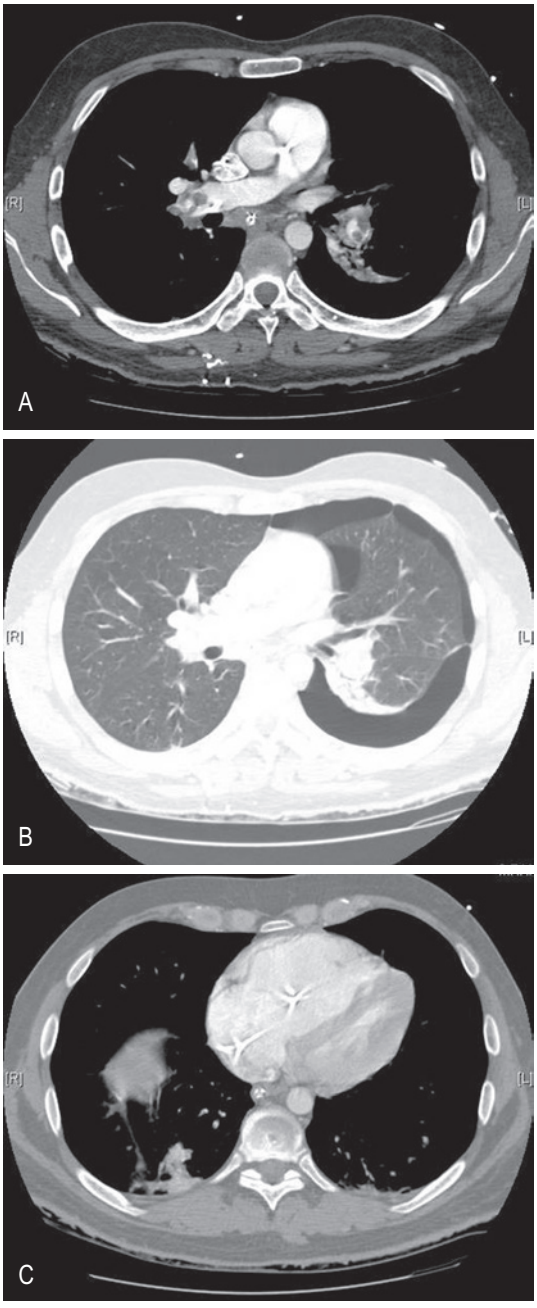

Figure 34.2 Computed tomography (CT) scanning and pulmonary embolism. Three CT images from the same patient demonstrating the ability of CT to detect pulmonary emboli, assess severity and confirm additional diagnoses. (a) (mediastinal window): filling defects in the right pulmonary artery and inferior branch of the left pulmonary artery. A pulmonary artery catheter is also in situ. (b) (lung window): a left pneumothorax with pleural adhesions, and a small area of left-sided posterior consolidation. (c) (mediastinal window): dilatation of the right ventricle relative to the left ventricle.

inferior to both SPECT V/Q and CTPA in diagnostic yield.[29] V/Q scanning also allows quantification of regional blood flow within the lungs which may be required in the assessment of chronic thromboembolic pulmonary hypertension.

PE may also be diagnosed by using a combination of real time magnetic resonance angiography (MRA) and contrast enhanced MRA, which seems to have highest diagnostic yield amongst MRI techniques. While lack of radiation and nephrotoxic intravenous contrast are obvious advantages, significant numbers of low quality images and poor sensitivity for subsegmental PE remain a problem, restricting wider use of this modality.[30]

ECHOCARDIOGRAPHY

Because of its portability, echocardiography has the greatest usefulness in critically ill patients with probable PE. Many patients with PE have an echocardiographic abnormality, the most common being RV dilatation, RV hypokinesis, paradoxical interventricular septal motion towards the LV, tricuspid regurgitation and pulmonary hypertension. The pattern of RV hypokinesis with apical sparing (McConnell sign) reflects tethering of the RV apex to the hyperdynamic LV and was considered pathognomonic for PE, although it can occur in other conditions such as RV infarction.[31] Pulmonary acceleration time less than 60 ms with maximum tricuspid regurgitate pressure of less than 60 mmHg (60/60 sign) may be more sensitive for diagnosing PE in patients without underlying cardiorespiratory comorbidities but needs a more detailed echocardiography assessment.[32] The presence of RV dysfunction correlates with mortality.[33] However, it must be noted that a negative echocardiography does not exclude PE.

Transthoracic echocardiography will also allow estimation of pulmonary arterial pressure, identification of intracardiac thrombi (which usually requires surgical embolectomy) and aids in differential diagnosis by raising suspicion of aortic dissection and excluding pericardial tamponade. Transoesophageal echocardiography has the additional benefit of directly identifying embolus in the proximal pulmonary arteries which is common in patients with haemodynamically significant PE.

Echocardiography has its best application in haemodynamically unstable patients where it can be rapidly brought to the patient. If the patient has RV dilatation and hypokinesis in the right clinical setting, PE is extremely likely.

DIAGNOSIS OF DEEP VENOUS THROMBOSIS USING ULTRASOUND

Doppler ultrasound has been recommended to search for DVT in the leg veins from where over 90% of

emboli originate. If a leg DVT is confirmed, anticoagulation is required unless the DVT is entirely below the knee where the associated morbidity is low. Ultrasound is highly accurate in symptomatic or proximal DVT, although in asymptomatic patients ultrasound is much less likely to find DVT, meaning the absence of DVT does not exclude PE. The best use of ultrasound is when a CTPA scan is contraindicated.[34] Proximal compression ultrasound (CUS) with four-point compression (bilateral femoral vein at the saphenofemoral junction and bilateral popliteal veins) has excellent specificity for diagnosis of PE in the right clinical setting and hence is useful for ruling in the diagnosis in patients in whom CTPA is contraindicated or carries a significant risk of harm (e.g. pregnancy, allergy to intravenous contrast or renal dysfunction).[35]

INVESTIGATION STRATEGY IN HAEMODYNAMICALLY STABLE PATIENTS

- A CTPA scan is the preferred initial test. If positive, the patient should be stratified into high or moderate risk. The presence of clot within pulmonary arteries confirms the diagnosis of PE.
- An echocardiograph should then be considered to assess RV dysfunction for high-risk patients who have:
  - Clot within proximal pulmonary arteries
  - Raised RV/LV ratio (i.e. >0.9–1.0)
  - Raised troponin (repeated at 8 hours if not elevated on admission), BNP or NT-pro-BNP.
- If a CTPA scan is not possible (contraindicated or unavailable), an alternative investigation such as a *V*/*Q* scan, MRA or ultrasound should be considered.
- None of these tests excludes PE but a negative result in a haemodynamically stable patient means that the outcome without anticoagulation is unlikely to be poor.

INVESTIGATION STRATEGY IN HAEMODYNAMICALLY UNSTABLE PATIENTS

- An echocardiograph (transoesophageal if patient is intubated in absence of contraindications) should be the first test performed.
- If the patient has acute RV dilatation with systolic dysfunction and visible embolus, PE is confirmed.
- If there is RV dilatation with or without systolic dysfunction but no visible embolus, then a CTPA scan is required depending on how unstable the patient is.
- If there is no RV dilatation, the haemodynamic instability is unlikely to be due to PE (although this cannot be excluded completely). Finding an alternative diagnosis is the priority.
- If echocardiography is not readily available, a CTPA scan should be performed unless a proximal CUS can expediently confirm a DVT. Absence of a DVT on proximal CUS is insufficient to rule out PE.

MANAGEMENT

MANAGEMENT PRINCIPLES

Once PE has been confirmed, patients at all levels of severity should receive anticoagulation with either unfractionated or low-molecular-weight heparin (LMWH), or newer oral anticoagulants (NOACs), to prevent further embolisation. In more severe cases of PE, however, the key principle is embolus destruction to maximise a more rapid effect on relief of RV dysfunction. To assist in planning management it is important to grade the severity of PE. Prediction models based on clinical findings at diagnosis may be useful for the prognostic assessment of patients with acute PE. The PE severity index is the most extensively validated prognostic clinical score[36] and a simplified version of this has been developed.[37] The place of these indices in critical illness is yet to be determined and it may be that a combination of a predictive scoring system with a combination of imaging for RV dysfunction and cardiac laboratory biomarkers is the most useful.[38]

MASSIVE PULMONARY EMBOLISM (HAEMODYNAMICALLY UNSTABLE)

Patients with PE and hypotension have a high risk of death despite treatment. If cardiopulmonary resuscitation is required the risk is even higher. These patients have the most to benefit from a strategy that includes attempts at urgent embolus destruction (with thrombolytic therapy or embolectomy), concurrent haemodynamic support and prevention of further embolisation.

SUBMASSIVE PULMONARY EMBOLISM (HAEMODYNAMICALLY UNSTABLE WITH EVIDENCE OF RIGHT VENTRICULAR DYSFUNCTION)

Patients with PE and evidence of RV dysfunction have higher mortality (around 15%) and recurrence rates than those with normal RV function.[33] They also develop shock and RV thrombi more frequently. These patients require prevention of further embolisation but also warrant strong consideration of embolus destruction using thrombolytic therapy. Thrombolytic therapy in these patients has been shown to reduce haemodynamic decompensation and mortality at the cost of increased risk of intracranial haemorrhage and major extracranial bleeding, especially in elderly patients.[39,40] Consideration should be given to low-dose thrombolysis or catheter-based techniques.[41–43]

MILD PULMONARY EMBOLISM (HAEMODYNAMICALLY STABLE WITH NO RIGHT VENTRICULAR DYSFUNCTION)

Patients with PE who have normal blood pressure, normal RV function (determined by echocardiography or CTPA scan) and non-elevated cardiac biomarkers

have a low risk of death or recurrence. The predominant management goal is prevention of further embolisation using anticoagulant therapy, as treatment focused on embolus destruction is unlikely to confer additional benefits.

In summary, the major principles of management are therefore

- Prevention of further embolisation (for massive, submassive and mild PE)
- Embolus destruction (for massive and submassive PE)
- Concurrent haemodynamic support (for massive PE).

A suggested management strategy is outlined in Fig. 34.1.

PREVENTION OF FURTHER EMBOLISATION

ANTICOAGULANT THERAPY

Heparin has been known to prevent recurrence and reduce the mortality from PE for over 45 years. LMWHs are as effective and safe as unfractionated heparin (UFH)[44] and may even be better.[45] LMWHs offer several advantages over UFH, including a longer half-life, increased bioavailability, a more predictable dose-response and fewer requirements for monitoring and dose adjustments. They should be readily used in the stable patient with PE.

UFH should be used in patients with renal impairment and following thrombolytic therapy or embolectomy as it can be easily and rapidly reversed. Intravenous UFH should be administered after a bolus and initial monitoring should be with 6-hourly activated partial thromboplastin time (APTT) testing. Since subtherapeutic levels of anticoagulant therapy increase the risk of recurrence, it is important to achieve therapeutic heparinisation rapidly. Weight-based dosing of heparin should be used, as target anticoagulation levels are reached sooner.[46] It is noteworthy that in the context of thrombolysis UFH infusion should be withheld for 12 hours if twice-daily LMWH was being used prior to thrombolysis; or for 24 hours if using once-daily LMWH. If a patient is on UFH infusion prior to thrombolysis, UFH should be stopped during streptokinase or urokinase infusion but can continue during rtPA infusion.[38]

The predominant complications of both UFH and LMWHs are bleeding related. These include bleeding peptic ulcer, stroke, retroperitoneal haematoma and postsurgical wound haemorrhage. Heparin-induced thrombotic thrombocytopenia syndrome (HITTS) can also occur. Bleeding complications and HITTS appear to be less common when LMWHs are being used. A number of conditions are considered to be relative contraindications to anticoagulant therapy. These include active peptic ulceration, recent surgery, recent trauma and recent cerebral haemorrhage. In each individual patient the risk-to-benefit ratio (taking into account the severity of the PE) should be considered before anticoagulation is withheld from the patient.

Oral anticoagulants should be started as soon as possible so that LMWH or UFH can eventually be ceased. For warfarin, this is generally when the international normalised ratio is greater than 2.0. Although warfarin (a vitamin K antagonist [VKA]) has been commonly used as the long-standing anticoagulant of choice, adverse events leading to hospitalisation remain common.[47] NOACs, namely factor Xa antagonists (rivaroxaban, apixaban, edoxaban) and direct thrombin inhibitors (dabigatran), are increasingly being used for treatment of PE. These have advantage of more rapid onset of action, predictable anticoagulant effects and no need for routine laboratory monitoring. Both direct thrombin inhibitors and factor Xa antagonists have been shown to be as efficacious as LMWH-VKA combination in patients with non-massive PE with a lower risk of bleeding.[48] In addition, rivaroxaban and apixaban do not require a heparin lead-in period as opposed to edoxaban and dabigatran, which need at least 5 days of heparin lead-in. While there is no proven advantage of one NOAC over another, pharmacokinetics, severity of disease, individual patient characteristics and preferences should be considered carefully when choosing between these agents. Amongst NOACs, higher severity of disease may favour agents with overlap with heparin while mild to moderate renal impairment may favour factor Xa antagonists over dabigatran. However, severe renal impairment or doubts about compliance favours VKAs, as treatment can be monitored. Recent approval of a reversal agent for dabigatran (idarucizumab) and emerging reversal agents for factor Xa antagonists (andexanet alfa) may help in management of bleeding complications in patients on NOACs.[49,50]

INFERIOR VENA CAVA FILTER

IVC filters are another method used to prevent further embolisation. These can be permanent, temporary (needing removal in a few days) or retrievable (can be left in situ for longer). IVC filters are indicated for patients in whom anticoagulation is contraindicated and those who experience recurrent PE despite adequate anticoagulation.[38] They do not have a role in patients with massive or submassive PE who have undergone open surgical embolectomy or thrombolysis[38] and they do not offer any further benefit if added to therapeutic anticoagulation.[51] Insertion is usually performed percutaneously in a radiology department but it can be done at the bedside. They lower early recurrence rates but increase long-term DVT recurrence rates.[52] Newer retrievable designs may be more efficacious and safe if removed at the appropriate time. If not removed, complications related to these filters may nullify their immediate benefits in the longer term.[53]

Absolute indications include:

- New or recurrent PE despite anticoagulation
- Contraindications to anticoagulation
- Complications resulting from anticoagulation.

EMBOLUS DESTRUCTION

THROMBOLYTIC THERAPY

Intravenous thrombolytic drugs result in dramatic and immediate haemodynamic improvement in some patients by dissolving the embolus and rapidly reducing pulmonary arterial obstruction. Experimental studies, clinical observations and randomised trials have consistently demonstrated the favourable effects of thrombolytic therapy on angiographic, haemodynamic and scintigraphic parameters of patients with acute PE, although comparisons with patients who received heparin have essentially revealed similar degrees of embolus resolution after a few days to a week.

The only randomised trial to date that enrolled patients with massive PE with shock was terminated early, as all the four patients in the anticoagulation arm died while all four patients in the thrombolysis arm survived.[54] A recent meta-analysis concluded that thrombolysis reduced mortality in patients with intermediate-to-high risk PE at the cost of increased risk of major bleeding and intracranial bleeding especially in patients aged greater than 65 years.[40]

It is therefore recommended that once the diagnosis of massive PE has been confirmed, thrombolytic therapy should be given without delay unless there is a clear contraindication.[38] Around 90% of patients should respond to thrombolytic therapy.[55] The clinical benefits and relative underuse of this therapy have been recently highlighted using observational data.[56]

For patients with submassive PE, the benefits of thrombolysis in terms of improvement in haemodynamics and possible lower risk of adverse events like poor functional capacity at 90 days post thrombolysis should be carefully balanced with the increased risk of bleeding.[57] Consideration should be given to low-dose thrombolysis or catheter-based techniques.[41–43] The decision to use thrombolysis for patients with intracardiac thrombi needs to be similarly individualised. Even though thrombolysis has been recommended in recent guidelines, propensity score-matched analysis of data from a large PE specific registry did not support use of reperfusion treatment over anticoagulation with a higher risk of recurrence in the reperfusion treatment arm.[58]

There is a large array of thrombolytic drugs with few comparative studies. Although there may be slight differences between thrombolytic drugs, the choice of drug is less important than the choice to give thrombolytic therapy at all. Suggested doses are recommended in Table 34.1 and can be administered through either a peripheral or a central venous catheter. In contrast to acute myocardial infarction and stroke, thrombolytic therapy may be useful in PE when given up to 14 days after symptoms begin.[59] Once the thrombolytic therapy has been administered, heparin should be commenced.

Table 34.1 Recommended doses of thrombolytic drugs for pulmonary embolism

Urokinase	4400 units/kg bolus (over 10 minutes) followed by 4400 units/kg per hour for 12 hours
Streptokinase	250,000 unit bolus (over 15 minutes) followed by 100,000 units/hour for 24 hours
Alteplase	10 mg bolus followed by 90 mg over 2 hours
Reteplase	10 unit boluses 30 minutes apart

Haemorrhagic complications are not uncommon and can significantly affect patient morbidity; however, it is difficult to predict those patients who are at the highest risk for bleeding. Major clinically significant bleeding can occur in up to 10% of patients, although cerebral haemorrhage is fortunately uncommon (0.9%).[60] Recent surgery is not an absolute contraindication and patients should have their individualised risks and the benefits weighed up; in shocked patients with massive PE, the balance appears to be in favour of thrombolytic therapy for almost all patients.

If bleeding occurs the thrombolytic therapy should be ceased and fresh frozen plasma and cryoprecipitate can be given to replace coagulation factors.

SURGICAL EMBOLECTOMY

The merit of surgical pulmonary embolectomy, which has traditionally been seen as a life-saving option for moribund patients with massive PE, has been questioned since the advent of reliable thrombolytic therapy. Embolectomy surgery results vary widely and there has traditionally been an associated perioperative mortality of 25%–50%. There is little reliable evidence comparing embolectomy and thrombolytic therapy. Mortality rates have been found to be lower when using a surgical approach combining rapid diagnosis, prompt surgical intervention and a high frequency of concurrent IVC filter placement.[61]

Surgical embolectomy should therefore be strongly considered in patients with PE and hypotension who have absolute contraindications to thrombolytic therapy or if thrombolytic therapy has failed.[38] Embolectomy may also be useful when patients have free-floating intracardiac thrombus and a large patent foramen ovale.[62]

PERCUTANEOUS EMBOLECTOMY

Percutaneous pulmonary embolectomy methods include either embolus fragmentation and aspiration

techniques or catheter-directed fibrinolysis techniques, including ultrasound-accelerated fibrinolysis, wherein high frequency, low power ultrasound is used to loosen the fibrin strands, increasing penetration of fibrinolytic agent.[63] Amongst catheter-based techniques ultrasound-assisted thrombolysis has been shown to improve RV function without increased risk of bleeding in patients with intermediate risk PE.[43] As the safety profile of catheter-based techniques improves they should be considered more commonly in patients with intermediate risk to high-risk PE who can be safely transferred to the radiology department in centres where requisite expertise is available.[42]

CONCURRENT HAEMODYNAMIC SUPPORT

Shocked patients with PE (massive PE) need urgent haemodynamic support in addition to attempts at embolus destruction and prevention of further embolisation.

INTRAVENOUS FLUIDS

Volume loading can improve haemodynamic status in patients with massive PE, although if excessive then fluid therapy may worsen RV function which can in turn affect LV function and become detrimental.[64] Cautious administration of small amounts of intravenous fluid should occur.

VASOPRESSORS

Ischaemia in the coronary circulation is an important factor in the haemodynamic instability of massive PE.[6] Embolus destruction (with thrombolytic therapy or embolectomy) should have the greatest effect on ischaemia reduction. However, elevation of the blood pressure and reduction in pulmonary and RV pressures may also be helpful, based on the rationale that the RV coronary perfusion pressure (RVCPP) can be severely impaired in massive PE.

RVCPP is estimated by the formula:

$$\text{RVCPP} = \text{MAP} - \text{RVPm} \quad (34.1)$$

where MAP is the mean arterial pressure and RVPm is the mean RV pressure, all in mmHg.

RVPm can then be estimated by the formula:

$$\text{RVPm} = \text{CVP} + 1/3\,(\text{PAPs} - \text{CVP}) \quad (34.2)$$

where CVP is the central venous pressure and PAPs is the systolic pulmonary arterial pressure, all in mmHg.

When RVCPP falls as low as 30 mm Hg (4 kPa) (normal being around 70–80 mm Hg [9.31–10.64 kPa]), RV myocardial blood flow falls substantially and this contributes significantly to severe RV failure and shock. Efforts to elevate the MAP or reduce the PAPs should increase the RVCPP and therefore improve coronary blood flow to relieve ischaemia. Haemodynamic support for the shock state due to massive PE should therefore predominantly involve vasopressor drugs, as these will predominantly increase MAP and therefore RVCPP.

Norepinephrine (noradrenaline) is preferred to a pure alpha agonist such as phenylephrine as cardiac output and RV myocardial blood flow effects are greater owing to the added beta-adrenoceptor agonist action. Dopamine, epinephrine (adrenaline) and vasopressin are reasonable alternatives to norepinephrine.

Although systemic vasodilators might improve the measured cardiac output in massive PE, they may be harmful overall as the MAP will either fall or remain constant at best and therefore the RVCPP will not increase. Isoprenaline, dobutamine, nitroglycerin, nitroprusside or milrinone should be considered only if the MAP is adequate and treatment is focused on cardiac output or pulmonary artery pressure.

Extracorporeal membrane oxygenation (ECMO) is an alternative form of haemodynamic support that may be available in more specialised institutions.[65] It should be considered for patients with PE who have had cardiopulmonary arrest or have very severe shock.

SELECTIVE PULMONARY VASODILATORS

Inhaled nitric oxide may be useful in patients with massive PE by selectively decreasing pulmonary arterial pressure with minimal effect on systemic haemodynamics. It may also assist in the severely hypoxaemic patient. Inhaled prostacyclin is an alternative.[66]

OTHER SUPPORTIVE MANAGEMENT

Oxygen should be supplemented to target adequate oxygen saturation. High flows may be required because of hyperventilation and the increased dead space. Intubation and mechanical ventilation are often necessary in patients with massive PE.

If chest pain is prominent, morphine should be administered. To guide resuscitation, it is useful to have at least a central venous catheter particularly before thrombolytic therapy is given. Although there is increased risk of bleeding owing to the concurrent administration of thrombolytic therapy and/or anticoagulant therapy in these patients, this is probably outweighed by the importance of secure venous access and monitoring of the circulation in patients with haemodynamic compromise due to PE.

PREVENTION

Prophylaxis is probably the most important management aspect of VTE. All ICU patients should have an adequate assessment as to whether prophylaxis is warranted, although most should receive it using pharmacological thromboprophylaxis.[67] Careful attention to the intervention and dose is required as omission of prophylaxis[68] and failure of prophylaxis[69] are common.

LMWHs have challenged traditional prophylaxis with fixed low-dose subcutaneous UFH such that both

are suggested alternatives for the prevention of VTE in critically ill patients.[67] Both therapies seem comparable for prophylaxis of DVT; however, rates of PE and HITTS were lower in a recent large study.[70]

Mechanical approaches (including graduated-compression stockings and intermittent pneumatic compression devices)[71] seem best utilised in patients who are bleeding or at major risk of bleeding. When bleeding risk decreases, pharmacological thromboprophylaxis should be commenced.

Acute severe asthma

David V Tuxen, Mark Hew

Acute severe asthma is a medical emergency associated with a significant morbidity and mortality. Many of the adverse outcomes are attributed to underestimation of severity with delayed and/or inadequate treatment[1-3] and are potentially preventable.

The worldwide prevalence of asthma varies widely and continues to change. Between 1993 and 2003, the prevalence of asthma increased in low-to-middle income countries but stabilised in high-prevalence countries.[4] Australia, New Zealand and the United Kingdom continue to have amongst the highest incidences.[4] In Australia, 10% have asthma as a long-term condition. In previous decades, many countries, including Australia, have achieved reductions in hospital presentations and admissions,[5,6] reduced intensive care admissions and reduced overall asthma mortality.[5,6] Improved intensive care asthma management has resulted in fewer requirements for mechanical ventilation and decreasing mechanical ventilation mortality (Fig. 35.1).[5,6] These changes have resulted in the group of asthma patients who require mechanical ventilation having more severe asthma, that is, more refractory to treatment and more difficult to manage.[7,8] Despite reducing admissions, significant and potentially preventable mortality continues to occur in those patients who do require intensive care or mechanical ventilation.[7,9,10]

The previous reduction in asthma mortality has been attributed to widespread guideline dissemination, better community management of asthma,[1,2] increasing use of inhaled corticosteroids[3] and other preventative measures, such as action plans. However, in 2015, almost half of the asthma patients in Australia still had uncontrolled asthma, forming a cohort at risk of exacerbations. Gains from improved community management appear to have stalled.[11] At the same time, mortality rates in Australia due to asthma have not fallen further in the last 10 years. An audit of asthma deaths[12] reported to the coroner suggests that social and behavioural determinants may have contributed to these deaths as much as severe asthma biology. Fundamental systemic changes[13] may need to be applied to asthma care in order to address these patient factors and deliver further improvements in asthma control, severe exacerbation risk and mortality rates. Similar conclusions have been reached following a national enquiry[14] into asthma deaths in the United Kingdom.

CLINICAL DEFINITION

Asthma is now defined by a history of respiratory symptoms such as wheeze, shortness of breath, chest tightness and cough that vary over time and in intensity, together with variable expiratory airflow limitation.[15] Asthma is usually characterised by airway inflammation. It is now recognised that asthma is a heterogeneous disease, and distinct inflammatory phenotypes[16] have been described. Exacerbations of asthma are characterised by increasing dyspnoea, cough, wheeze, chest tightness and decreased expiratory air flow. Status asthmaticus has had varying definitions. However, for practical purposes, any patient not responding to initial doses of nebulised bronchodilators should be considered to have status asthmaticus.[17]

'Difficult' (as opposed to 'severe') asthma is another term in which patients can present with mild, moderate or severe asthmatic symptoms. Characteristics include: (a) discordance between symptoms and objective markers of asthma, such as lung function or arterial blood gases, (b) severe asthma despite treatment that should be effective, and (c) a disconnection between patient expectations and effective outcomes.[18] Commonly, there is poor compliance, psychosocial adversity and secondary gain with continued symptoms. Significant anxiety and social and adverse family circumstances frequently co-exist. Differential diagnoses include hyperventilation syndromes, vocal cord dysfunction, chronic obstructive pulmonary disease (COPD) or lack of adherence to treatments (estimated to occur in two-thirds of patients presenting). An alternative description includes poor perceivers or over-reactors. These patients are difficult because sometimes they present with severe life-threatening asthma, yet experience would suggest this to be preventable if the usual medication were taken.

ABSTRACT

Intensive care admissions for asthma are decreasing but admitted patients have more severe asthma that is refractory to treatment and more difficult to ventilate. Acute severe asthma is a life-threatening medical emergency. Underestimation of severity and undertreatment remain the biggest contributors to asthma mortality.

The treatment of life-threatening asthma has many pitfalls that can increase the morbidity and mortality if not well managed. Intravenous and continuous nebulised salbutamol can cause significant lactic acidosis, which can increase dyspnoea and fatigue. Mechanical ventilation can easily cause excessive dynamic hyperinflation leading to hypotension and pneumothorax. Mechanical ventilation needs low initial Ve, minute ventilation less than 115 mL/kg per minute (8 L/min) and Pplat less than 25 mm Hg. In very severe asthma, excessive dynamic hyperinflation can lead to cardio-respiratory collapse. Neuromuscular blocking agents and heavy sedation can lead to severe necrotising myopathy. Mortality risk is increased following a requirement for intensive care and patients require treatment including inhaled steroids, a management plan and careful follow-up.

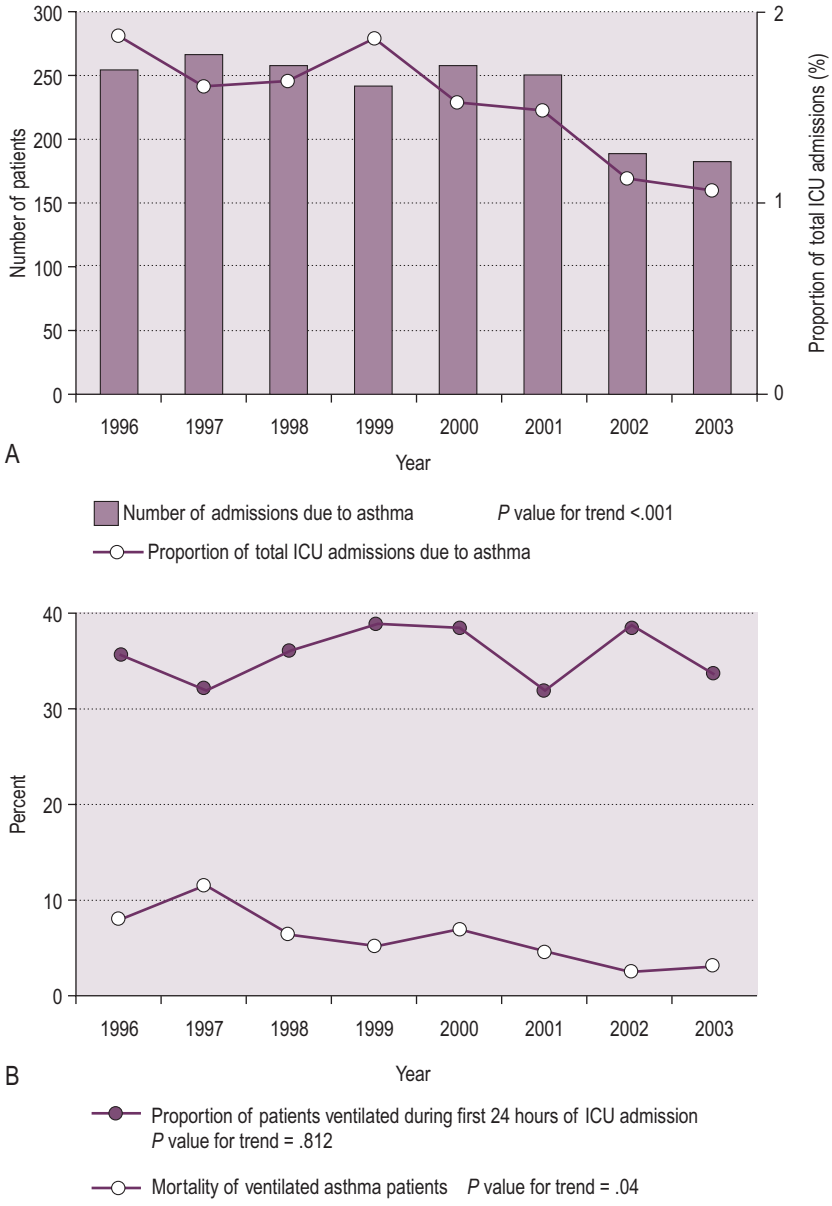

Figure 35.1 Intensive care unit (ICU) admissions (A), mechanical ventilation and mortality (B) due to asthma in Australia from 1996 to 2003. *(Modified from Stow P, Pilcher D, Wilson J, et al. Improved outcomes from acute severe asthma in Australian intensive care units (1996–2003).* Thorax. *2007;62(10):842–847.)*

AETIOLOGY

The pathogenesis of asthma reflects a complex interaction between environmental and genetic influences. In developed nations, a reduced exposure to childhood infections and changes in dietary patterns may alter gut, respiratory and skin bacterial composition and diversity (the microbiome), which then increases risk for developing allergic diseases including asthma.[19] This may be mediated through effects on T cell inflammatory gene transcription, which promote activation towards a T helper 2 phenotype, driving the allergic inflammatory response.[20] Such epigenetic changes have been found in asthma patients, and impair their responsiveness to corticosteroid therapy.[21] These persistent changes also may be passed on to subsequent generations, thus explaining the continuing rise in allergic disease prevalence.[20]

Immunoglobulin-E-dependent mechanisms appear to be important in generating the characteristic state

of airway inflammation and bronchial hyperreactivity with the allergens in the local environment dictating the specificity of the antibody response.[22] In addition to atopic asthma, an asthma phenotype that increases the risk of exacerbations is eosinophilic asthma, which is defined either by blood or sputum eosinophilia, and elevated exhaled nitric oxide.[16] Asthma co-morbidities,[23] such as obesity and chronic rhinosinusitis, also predispose to exacerbations. Triggers of acute asthma can be non-specific (cold air, exercise, atmospheric pollutants), specific allergens (housemite, pollen, animal danders), modifiers of airway control (aspirin, beta blockers), or stress or emotion. No precipitant can be identified in over 30% of patients.

A wide range of risk factors for life-threatening asthmatic episodes and/or the need for mechanical ventilation are now recognised. First is *underestimation of severity*, with delayed and/or inadequate treatment by managing doctors and/or the patient.[1-3] Second is *patient behaviour factors*, which are associated with the requirement for intensive care[24] and mechanical ventilation are smoking (and illicit drugs),[24] poor treatment compliance and prior treatment with beta agonists without inhaled steroids.[7,25] Low socioeconomic status has also been recognised as a risk factor, as has ethnic minority status.[26] Third is *genetic polymorphism* (the IL4RA*576R allele), which is now recognised as a significant factor related to fatal or near-fatal asthma attacks.[8,27] Other functional factors linked to severe asthma attacks include airway remodelling, down-regulation of β-receptors, and lack of steroid responsiveness.[8] Diminished perception of dyspnoea in some patients with acute severe asthma leads to delayed interventions.[8,28]

PATHOPHYSIOLOGY

The postmortem airway pathology of patients who die from acute asthma includes bronchial wall thickening from oedema and inflammatory cell infiltrate, hypertrophy and hyperplasia of bronchial smooth muscle and submucosal glands, deposition of collagen beneath the epithelial basement membrane and prominent intraluminal secretions. These secretions may narrow or occlude the small airways, and postmortem studies frequently report extensive plugging and atelectasis.[29,30] When interpreting the latter findings it is important to remember that during life in very severe asthma the lungs are hyperinflated close to total lung capacity (TLC) by maximal inspiratory effort, and to beyond TLC during mechanical ventilation. At this time, radiological atelectasis is rare, suggesting that most airways are communicating at these high lung volumes, even if airways are very narrowed. Only at death does the prolonged apnoea allow lung deflation, widespread airway closure and alveolar gas absorption to give the postmortem appearance of extensive complete occlusion that was not present to the same degree during life.

In some deaths bronchial mucus is absent; in these cases airway obstruction may be mainly due to intense smooth bronchoconstriction. This observation may account for two patterns of progression of asthma:

1. Acute severe asthma is the more common group (80%–90%), with progression of symptoms over many hours or days, often with a background of poor control and recurrent presentations. Most patients in this group are female, with upper respiratory infections frequent triggers; it responds more slowly to treatment, which may reflect greater contribution from mucous inspissation and chronic bronchial wall inflammation with eosinophilia.[28,31]
2. 'Hyperacute', 'fulminating', 'asphyxic' or 'sudden onset' severe asthma is where the interval between onset of symptoms and intubation is less than 3 hours.[28,31-33] This presentation is less common (approximately 10%–20% of life threatening presentations), tends to occur in younger patients with relatively normal lung function but high bronchial reactivity, and the majority of patients are male. Massive respiratory allergen exposure, cold air or exercise and psychosocial stress are the most frequent triggers.[28] Although patients in this group are less common, 'thunderstorm asthma', due to massive production and distribution of rye-grass micro particles triggered during a thunderstorm, can occasionally result in overwhelming numbers of patients exclusively in this group presenting within a 24-hour period.[34] This group characteristically has neutrophilic inflammation, typically responds quickly to bronchodilators and is thought to be mainly due to bronchial smooth muscle contraction.

The characteristic pathology of asthma leads to increased airway resistance and dynamic pulmonary hyperinflation. This has a number of consequences:

- *Increased work of breathing* results from increased airway resistance and reduced pulmonary compliance as a result of high lung volumes. When asthma is severe, dynamic hyperinflation (DHI) may bring the lung volume close to TLC.[34] This causes a severe mechanical disadvantage of inspiratory muscles with diaphragm flattening and results in a large inspiratory muscle effort affecting a small change in inspiratory pressure. The final outcome can be respiratory muscle failure with insufficient alveolar ventilation and consequent hypercapnia.[35]
- *Ventilation–perfusion mismatch* is the result of airway narrowing and closure. This leads to impaired gas exchange and increases the minute ventilation requirement, further adding to the work of breathing.[35]
- *Adverse cardiopulmonary interactions* are seen when the marked changes in lung volume and pleural pressure impact on the function of both left and

right ventricles.[36,37] Spontaneous breathing during acute asthma can generate inspiratory pressures as low as –35 cm H_2O.[36,37] This increases venous return to the right ventricle (RV) and increases RV volume during inspiration. However, increased RV afterload as a result of hypoxic pulmonary vasoconstriction, acidosis and increased lung volume,[36,37] and increased pulmonary capacitance decrease return to the left ventricle (LV). These negative intrapleural pressures also cause increased LV afterload,[36,37] and increased RV afterload with septal shift reduces LV volume[36,37] further reducing LV output during inspiration. Pulsus paradoxus is the most direct result of these cardiopulmonary interactions in severe asthma. This is a decrease in systolic blood pressure during inspiration of greater than 10 mm Hg (1.33 kPa), typically 15–25 mm Hg (2–3.33 kPa), normal ≤5 mm Hg (0.66 kPa). The degree of pulsus paradoxus may not correlate with the severity of asthma as it may be reduced by inspiratory muscle weakness or fatigue.

CLINICAL FEATURES AND ASSESSMENT OF SEVERITY

The symptoms of asthma are well known and include wheeze, cough, dyspnoea and chest discomfort or tightness. Triage and assessment of severity of the acute asthma attack are crucial. Underestimation or non-measurement of asthma severity is associated with increased mortality.[38] Assessment has two key features: assessment of initial severity (Box 35.1) and ongoing assessment of response to treatment.

HISTORY

Any history of prior intubation and mechanical ventilation for asthma is a predictor for life-threatening asthma.[38] A history of poor asthma control, multiple recent medical presentations for asthma and poor response to prior treatments are recognised risk factors. Other risk factors are listed above (see section 'Aetiology').

PHYSICAL EXAMINATION

The general appearance and level of distress can be an important indicator of severity (Table 35.1). The use of accessory muscles, suprasternal retraction, markedly diminished breath sounds or a silent chest, central cyanosis, the inability to speak, a disturbance in the level of consciousness, upright posture and diaphoresis all suggest a severe attack. A respiratory rate greater than 30/min, pulse rate greater than 120/min and pulsus paradoxus of greater than 15 mm Hg (2 kPa) are associated with severe asthma, though their absence does not preclude life-threatening asthma. Patients with

Box 35.1 Key points

1. Asthma prevalence in the community is increasing but admissions to hospital and intensive care are decreasing.
2. Acute severe asthma is a lifethreatening medical emergency both on presentation and during mechanical ventilation.
3. Underestimation of severity and undertreatment are the biggest contributors to asthma mortality.
4. Patients who do require mechanical ventilation have more severe asthma refractory to treatment and are more difficult to ventilate.
5. Intravenous and continuous nebulised salbutamol can cause significant lactic acidosis.
6. Mechanical ventilation can easily cause excessive dynamic hyperinflation leading to hypotension and pneumothorax.
7. Mechanical ventilation needs careful regulation with initial V_e <115 mL/kg per minute (8 L/min) and P_{plat} <25 mm Hg (3.32 kPa).
8. Very severe dynamic hyperinflation can lead to cardiorespiratory collapse diagnosed by an apnoea test.
9. Neuromuscular-blocking agents and heavy sedation can lead to severe necrotising myopathy.
10. Following intensive care, asthma requires full treatment including inhaled steroids, a management plan and careful follow-up.

Table 35.1 Assessment of asthma severity

	MILD	MODERATE	SEVERE
Conscious state	Alert, relaxed	Anxious, difficulty sleeping	Agitated, delirious
Speech	Sentences	Phrases	Words
Accessory muscles	Nil	Mild	Significant sitting upright
Wheeze	Moderate	Loud	Loud or silent
Pulse rate (BPM)	<100	100–120	>120
Peak expiratory flow (% predicted)	>80%	60%–80%	<60%
$PaCO_2$ (mm Hg) (kPa)	<45 (5.98)	<45 (5.98)	>45 (5.98)

Pulsus paradoxus when present indicates severe asthma; however, it is an unreliable test.

BPM, Beats per minute.

diminished perception of dyspnoea may mask severe asthma and lead to underestimation of severity.[28]

VENTILATORY FUNCTION TESTS

The patient may not be able to perform these due to breathlessness. However, FEV_1 and peak expiratory flow rate (PEFR) are useful indicators of severity and response to treatment when done serially. An FEV_1 less than 1.0 L or PEFR less than 100 L/min indicates very severe asthma at significant risk of requiring mechanical ventilation. In some patients forced expiration may worsen symptoms; these measurements should cease if this occurs.

PULSE OXIMETRY

Pulse oximetry is usually readily available and provides a rapid assessment of oxygenation. It is also very valuable in regulation oxygen therapy, both for avoiding hypoxia (SpO2 >90%)[39] and for avoiding potential side effects of hyperoxia (SpO2 <95%).[40] Of course, pulse oximetry cannot assess arterial $PaCO_2$ or acid-base state, therefore it does not replace the need for blood gases.

ARTERIAL BLOOD GASES

Arterial hypoxaemia is almost invariably present in a patient with severe asthma breathing room air though it usually responds well to low-level oxygen supplementation (28%–35%).[39] Blood gases should not delay initiation of treatment, and are not required in mild asthma or moderate asthma that is responding well to treatment. They are very important in severe asthma, or moderate asthma with inadequate treatment response. The $PaCO_2$ is an important measure of severity and, if hypercapnia is present, an important guide to treatment response. Venous blood gases have had increasing use in place of arterial blood gases. Such blood gases will usually determine the upper limit of $PaCO_2$ and the lower limit of pH; however, there is insufficient agreement between venous and arterial PCO2 measurements to determine the degree of hypercapnia in obstructive airways disease.[41] We therefore recommend arterial blood gas measurement in the assessment of acute severe asthma, where initial and follow-up PCO2 levels inform critical treatment decisions.

Ventilation is initially increased in an acute attack leading to hypocapnia and a respiratory alkalosis.[39] As the asthmatic attack worsens, the work of breathing, V/Q mismatch and adverse cardiopulmonary interactions all increase, and the minute ventilation required to maintain the same alveolar ventilation and $PaCO_2$ increases. Eventually the patient is incapable of meeting this demand and the $PaCO_2$ rises. The presence of hypercarbic acidosis is associated with a FEV_1 of less than 20% predicted and reliably indicates that asthma is severe. A metabolic acidosis may also be present, and this is most commonly due to lactic acidosis associated with intravenous or continuous nebulised beta agonists.[42,43]

CHEST X-RAY

Chest X-rays are not generally helpful in assessing severity and are not routinely indicated. A chest X-ray should be performed when asthma is severe or refractory to treatment, when barotrauma or lower respiratory tract infection is suspected or when the diagnosis is in doubt. It is not required in milder attacks that respond well to treatment.

ASSESSMENT OF TREATMENT RESPONSE

Repeated evaluation of the patient's response to treatment is a valuable tool in assessing severity of acute asthma. The response to the first 2 hours of treatment is an important predictor of outcome.[44] Adverse events are associated with underestimation of severity, inadequate observation after initial assessment and under treatment. Ongoing evaluation of response to therapy is critical. This evaluation should include repeated assessments of: (1) appearance and physical indicators of severity (see Table 35.1); (2) objective measurements – FEV1 or PEFR, heart rate, respiratory rate, pulsus paradoxus; (3) SpO2 and oxygen requirements; and (4) progress of $PaCO_2$ or metabolic acidosis if present on blood gases.

Admission to intensive care is preferred if the above criteria suggest severe asthma. Indications for immediate admission to intensive care include respiratory arrest, altered mental status, dysrhythmias or associated myocardial ischaemia.

DIFFERENTIAL DIAGNOSIS

The diagnosis of asthma is usually obvious. However, wheeze and dyspnoea may be caused by other illnesses, including left ventricular failure, aspiration, upper airway obstruction, inhaled foreign body, pulmonary embolism or hyperventilation syndromes. Wheeze and dyspnoea arising in hospitalised patients who were not admitted with asthma are less likely to be due to asthma. Clues to another or additional diagnosis include: (1) no past history of asthma; (2) sudden onset following vomiting or food intake; (3) focal or asymmetrical chest auscultation findings; (4) risk factors for thromboembolism; and (5) onset during hospitalisation when admitted with another condition.

MANAGEMENT

ESTABLISHED TREATMENTS

Initial therapy of acute severe asthma should include the following.

OXYGEN

Hypoxaemia contributes to life-threatening events that complicate acute severe asthma.[45] Current guidelines[46] recommend supplemental oxygen should be titrated to achieve a SpO2 94%–98% but clinicians should consider the risk of oxygen-induced increasing hypercapnia with co-existing chronic air-flow limitation or pre-existing chronic hypercapnia. This phenomenon was not believed to be relevant to the majority of patients with acute asthma; however, there is now emerging evidence that hyperoxia may be harmful to a more widespread group[47] by releasing pulmonary hypoxic vasoconstriction, worsening V/Q matching and increasing hypercapnia. A previous trial[40] showed a decrease in $PaCO_2$ in a group receiving 28% O_2 and an increase in $PaCO_2$ in a group receiving 100% FiO_2. A more recent trial[48] demonstrated patients receiving oxygen titrated to achieve target SpO_2 of 93%–95% had lower transcutaneous CO_2 levels after 1 hour than those receiving 8 L O_2/min by mask.

BETA AGONISTS

Short-acting beta agonists remain the first-line bronchodilator therapy of choice.[46,49] Agents include salbutamol (albuterol), terbutaline, isoproterenol (isoprenaline) and epinephrine (adrenaline). Salbutamol is generally the agent of first choice as it has relative β_2-selectivity, with decreased β_1-mediated cardiac toxicity. Long-acting beta agonists, such as salmeterol, have no role in status asthmaticus owing to the slow onset of action and association with fatalities in this setting.[17] Beta agonists cause bronchodilatation by stimulation of β_2-receptors on airway smooth muscle and may reduce bronchial mucosal oedema.

The standard approach is to start with nebulised salbutamol in high and repeated doses. The typical adult dose is 5–10 mg (in 2.5 to 5.0 mL diluent volume) every 2–4 hours, but more frequent doses with a higher total dose are often required in severe asthma. It should be noted that less than 10% of the nebulised drug reaches the lung even under ideal conditions.[50] Continuous nebulisation appears to be superior to intermittent doses and is commonly used at the beginning of treatment in severe asthma.[17,51] The nebuliser should be driven by oxygen with the flow at 10–12 L/min and a reservoir volume of 2–4 mL so as to produce particles in the desired 1–3 µm range.[52] The total dose should be modulated by response to treatment and the level of toxic side effects.

Beta agonists can also be delivered by metered dose inhaler (MDI). There are data to suggest that in non-intubated patients MDIs combined with a spacing device are as effective as or more effective than nebulisers and are cheaper to use.[53] In intubated patients both nebulisers and MDIs have been used effectively.[54] Two-thirds of acutely presenting patients will respond well to inhaled beta agonists[55] irrespective of the method of administration. The remaining one-third are refractory even to high doses and usually require longer periods of intense treatment including multiple other agents.

Intravenous beta agonists remain controversial. There is no clear evidence of benefit[56] and significant side effects. Despite this, intravenous beta agonists have a theoretical benefit of additional access to lung units with severe air-flow obstruction and poor nebulised drug delivery, and some studies have demonstrated improved response when intravenous beta agonist is used.[57] Intravenous beta agonists continue to be considered if the patient is not responding to continuous nebulisation.[58] The typical dose is 5–20 µg/min, but doses greater than 10 µg/min should be used for the first 4–6 hours because of side effects, which should be monitored closely. Salbutamol 100–250 µg may also be given intravenously to non-intubated patients in extremis or delivered down an endotracheal tube should there be no time to gain intravenous access.

Side effects of beta agonists include tachycardia, dysrhythmias, hypertension, hypotension, tremor, hypokalaemia, worsening of ventilation–perfusion mismatch and hyperglycaemia,[59] but the most common side effect of parenteral beta agonists, also occasionally seen with continuous nebulised beta agonists, is lactic acidosis. This occurs in over 70% of patients with intravenous agonists; it has an onset within 2–4 hours of commencing an infusion or following an intravenous statim dose; the levels may reach 4–12 mmol/L; and may significantly add to a respiratory acidosis and respiratory distress.[43,60,61] Parenteral infusions should be initially limited to 10 µg/min and statim doses should not exceed 250 µg. Serum bicarbonate and lactate should be regularly monitored. If lactic acidosis becomes significant, the salbutamol infusion should be reduced or ceased. Lactic acidosis will generally resolve within 4–6 hours of infusion cessation and is seldom a problem with infusions in place for more than 24 hours.

Long-term high-dose beta-agonist use has been associated with increased mortality,[62] but whether high-dose beta agonists are a marker of disease severity, an indicator of suboptimal inhaled steroids or a direct cause of death is unclear. These concerns do not apply in the treatment of the acute asthma attack.

ANTICHOLINERGICS

Anticholinergics cause bronchodilatation by decreasing parasympathetic-mediated cholinergic bronchomotor tone. Ipratropium bromide is the most commonly used anticholinergic for asthma and is a quaternary derivative of atropine. Although some conclude there is insufficient evidence,[63] a number of studies and meta-analyses suggest clear additional benefit and few side effects when ipratropium bromide is added to the beta-agonist regimen.[64,65] Ipratropium is now widely used as first-line therapy for acute severe asthma in conjunction with beta-agonist

therapy. Preservative-induced bronchoconstriction has been reported in a few patients and can be prevented by using preservative-free solutions.[66] The bronchodilatation effect of ipratropium bromide appeared to be maximal with a dose of 250 µg when studied in children between 9 and 17 years of age. The optimal dose is not known in adults.[67] A reasonable regimen is ipatropium bromide 500 mcg nebulised 4–6 hourly for 24–48 hours with a frequency reduction thereafter.

CORTICOSTEROIDS

The role of corticosteroids in the acute asthma attack has been well established. Systemic steroids should be considered in all but mild exacerbations of asthma.[68] Their benefits include increased β-responsiveness of airway smooth muscle, decreased inflammatory cell response and decreased mucus secretion. Early treatment with corticosteroids has been shown to decrease the likelihood of hospitalisation and decrease the mortality rate from acute asthma. Systematic reviews[68,69] suggest that effects commence within 6–12 hours, that oral is as effective as intravenous and that there is little evidence of benefit for initial daily doses exceeding 800 mg/day of hydrocortisone (160 mg/day methylprednisolone) given in four divided doses.

Inhaled steroids have established long-term benefit and are believed to be a major factor in asthma mortality reduction.[1-3] Although some believe there is insufficient evidence,[63] there are data that inhaled steroids may also have a role during an acute attack[70,71] and it appears reasonable to use them routinely from day 1 as they may also enable more rapid dose reduction of parenteral steroids, potentially reducing side effects.

Parenteral corticosteroid dose reductions should commence after 1–3 days according to the severity of the attack, the degree of chronic inflammation and the response to treatment and should be converted to a reducing dose of oral steroids within 4–7 days (e.g. oral prednisolone starting at 40–60 mg/day).

Side effects of corticosteroids include hyperglycaemia, hypokalaemia, hypertension, acute psychosis and myopathy,[72,73] though they are usually well tolerated acutely. The immunosuppressive effects can increase the risk of infections including *Legionella*, *Pneumocystis jiroveci* and varicella[74,75] especially when the patient is on long-term corticosteroids. Allergic reactions including anaphylaxis have been reported with the use of most corticosteroid preparations.

MAGNESIUM SULPHATE

Magnesium sulphate is postulated to block calcium channels, and possibly acetylcholine release at the neuromuscular junction, leading to smooth muscle relaxation and bronchodilatation. It appeared to be well tolerated in early studies, and a number of some prospective randomised, double-blind trials of adding intravenous or nebulised magnesium sulphate to conventional therapy in adults with acute asthma were performed. Some showed benefit whereas others showed none.

The most recent Cochrane reviews[76,77] on this topic suggest that intravenous magnesium is useful for adults with acute severe asthma, although evidence for benefit in children is less clear. If given, recommended doses for adults are 5–10 mmol (1.25–2.5 g, 2.5–5.0 mL of 50% solution) given slowly over 20 minutes, but doses up to 40 mmol (10 g) can be given.[78] Side effects include hypotension, flushing, sedation, weakness, areflexia, respiratory depression and cardiac arrhythmias seen at higher serum levels (>5 mmol/dL or 12 mg/dL). Serum concentrations should be measured if repeated or high doses are used.

AMINOPHYLLINE

There have been conflicting reports regarding the efficacy of aminophylline in acute asthma ranging from no benefit to improved lung function and improved outcome. However, it is accepted that aminophylline is an inferior bronchodilator, with a narrow therapeutic range and frequent side effects[79] including headache, nausea, vomiting and restlessness, with cardiac arrhythmias and convulsions that can occur at serum levels above 200 µmol/L (40 mg/L). A Cochrane meta-analysis[80] identified no patient subgroup in which aminophylline was beneficial.

As a result, aminophylline is not a first-line treatment.[46,49,63] Aminophylline may be given to patients with acute asthma who are not showing a favourable response to full treatment with first-line agents. Careful administration and monitoring are required with an initial loading dose of 3 mg/kg (maximum 6 mg/kg, omitted if the patient is already taking oral theophylline) and an infusion of 0.5 mg/kg per hour. This should be reduced in patients with cirrhosis, cardiac failure or chronic obstructive airways disease and in patients taking cimetidine, erythromycin or antiviral vaccines. Drug levels should be taken after a loading dose (if given), and then 24 hours later aiming for a level of 30–80 µmol/L (5–12 mg/L). Levels should be repeated daily thereafter until stability has been achieved. The duration should be based on the response to treatment.

NON-ESTABLISHED TREATMENTS

A number of other therapies have reported benefit in acute severe asthma, but their role in addition to full standard therapy has not been clearly established and they are not advocated for routine use. However, these modes of therapy can be considered in the patient who is in extremis or remaining severe despite conventional treatment.

EPINEPHRINE

Epinephrine has some theoretical advantages over pure β_2-agonists in that its additional α-agonist actions

of vasoconstriction and mucosal shrinkage may improve airway calibre. However, in practice, nebulised epinephrine has not been shown to confer any advantage over nebulised β_2-agonists and is not recommended because of its cardiac side effects.[67] It may be tried in the patient who is failing to respond to conventional treatment. The nebulised dose is 2–4 mg in 2–4 mL (1% solution, 0.05 mL/kg) 1- to 4-hourly. Epinephrine by infusion may avert mechanical ventilation in very severe cases, but should be used with caution with electrocardiogram monitoring and preferably with central venous access. An initial intravenous dose of 0.1 mg (1 ml of 1:10,000 epinephrine) can be given slowly over 3–5 minutes. This may be followed by a continuous infusion of 1–10 μg/min, which is weaned when the acute attack subsides.[81]

The one situation where adrenaline is indicated is when acute severe bronchospasm is suspected to be caused by anaphylaxis. Intramuscular epinephrine should be administered immediately at a dose of 0.3–0.5 mg (0.3–0.5 mL of 1:1000 epinephrine), repeated if necessary 1–2 times over 5–10 minutes. If there is no improvement, consider intravenous epinephrine as above.

HELIOX

Inhalation of a helium:oxygen mixture reduces gas density and turbulence with reduced air-flow resistance. The most effective gas mixture is 70% helium (30% oxygen) and the minimum concentration likely to provide benefit is 60% helium. The work of breathing is decreased and pulmonary access of inhaled bronchodilators may be improved.[82] Small case series and reports have suggested benefit from heliox; randomised, prospective trials have both positive and negative results.[83] Meta-analyses[84,85] have shown trends towards improved aspects of lung function but insufficient evidence to recommend use of heliox in severe asthma. However, it otherwise appears safe and may be tried in critical asthma to avert intubation or during difficult mechanical ventilation provided the patient can tolerate 30%–40% O_2.

ANAESTHETIC AGENTS

Ketamine, a dissociative anaesthetic agent, has been used in severe asthma. It may cause bronchodilatation by both sympathomimetic potentiation and a direct effect on airway smooth muscle.[86] Small case series have suggested some benefit, although a small, randomised, controlled trial found no benefit with ketamine in the treatment of acute severe asthma[87] – ketamine may be a useful induction agent for endotracheal intubation (dose 0.5–1 mg/kg up to 2 mg/kg) as it may ameliorate the bronchoconstrictor response to intubation. It has been used as a continuous infusion in the dose range of 0.2–1 mg/kg per hour[87] to treat refractory asthma. Side effects include increased bronchial secretions, a hyperdynamic cardiovascular response and hallucinations; the hallucinations can be reduced with concomitant benzodiazepines.

The volatile inhalational agents including halothane, isoflurane and enflurane have been used in mechanically ventilated patients with severe asthma.[88] Clinical data are limited to small case-series, and side effects include direct myocardial depression, arrhythmias and hypotension.[89] The volatile anaesthetic agents should be used with great care and usually only as a prelude to or during invasive ventilation. An anaesthetic machine or custom-fitted ventilator is required for safe administration.

LEUKOTRIENE ANTAGONISTS

Leukotriene antagonists have shown benefit in chronic asthma[90] and there is some evidence of benefit in acute asthma.[91] There is insufficient evidence and the benefits were of insufficient magnitude to recommend these agents for acute severe asthma.[63]

BRONCHOALVEOLAR LAVAGE

Bronchoalveolar lavage has been used in severe refractory asthma to clear mucous plugging during mechanical ventilation.[92] It may have a role in ventilated patients with resistant mucus impaction, but it is rarely used.

THERAPIES NOT RECOMMENDED

Antibiotics are not routinely indicated[93] unless there is clear evidence of infection. Antihistamines are not effective. Inhaled mucolytics have been shown to have no benefit and may worsen air-flow obstruction. Sedation is unsafe in acute asthma. There is a clear association between their use and avoidable deaths.[94] Patients with severe asthma should not be sedated unless being intubated and ventilated, or in carefully monitored circumstances.

VENTILATION IN ASTHMA

DYNAMIC HYPERINFLATION

In all degrees of air-flow obstruction, slow expiratory air flow results in incomplete exhalation of gas during normal expiratory times. Gas is trapped in the lungs by the arrival of the next breath and the lungs are unable to return their normal passive relaxation volume (functional residual capacity [FRC]). Incomplete exhalation of each successive breath causes progressive accumulation of trapped gas called DHI (Fig. 35.2),[95] which continues until an equilibrium point is reached where the exhaled volume increases to match the inspired volume.[95] This equilibrium occurs because increasing lung volume increases small airway calibre and lung elastic recoil pressure, both of which improve expiratory air flow and allow the inspired tidal volume to be exhaled in the expiratory time available. There are three primary determinants of this equilibrium point: the volume inspired (V_t), the time for expiration

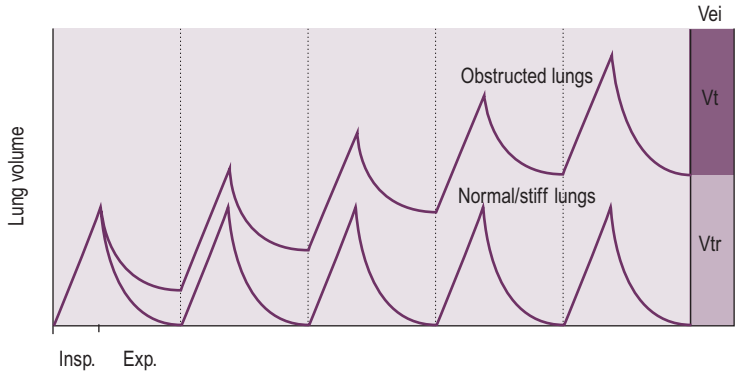

Figure 35.2 Dynamic hyperinflation. The volume history of normal or acutely injured lungs compared with that of obstructed lungs when commenced on controlled mechanical ventilation. This shows initial lung volume to be at the passive relaxation volume of the respiratory system or functional residual capacity. *Exp,* Expiratory time period; *Insp,* inspiratory time period; *Vei,* volume of the lung above functional residual capacity at the end of inspiration; *Vt,* tidal volume; *Vtr,* volume of gas trapped above functional residual capacity by the occurrence of the next breath.

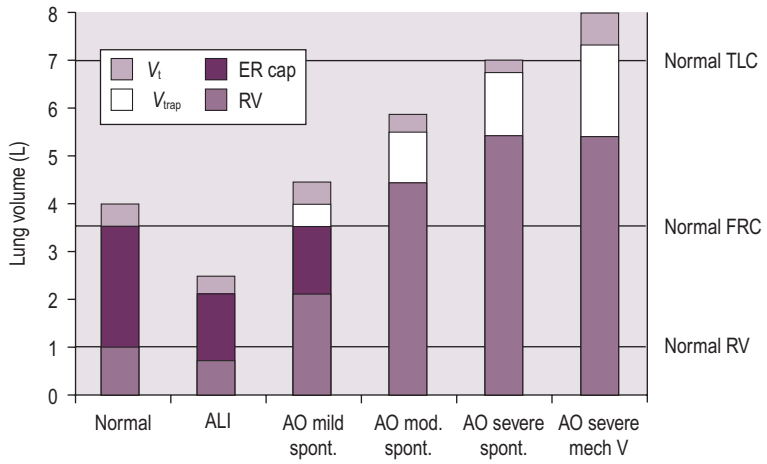

Figure 35.3 Comparison of lung volumes in patients with normal lungs, acute lung injury (ALI), and mild, moderate and severe air-flow obstruction (AO). Severe AO is shown during both spontaneous ventilation (spont) and mechanical ventilation (mech V). Functional residual capacity (FRC) is the static lung volume at the end of expiratory flow (60–90 seconds in severe AO). Expiratory reserve capacity (ER cap) is the additional gas expired with expiratory effort after FRC has been reached. Residual volume (RV) is the minimum lung volume possible after prolonged expiration and maximum expiratory effort. V_{trap} is the gas trapped by dynamic hyperinflation during tidal ventilation. *TLC*, Total lung capacity.

(t_e, which depends on both the ventilator rate or cycle time and the inspiratory flow or inspiratory time, t_i) and, of course, the severity of air-flow obstruction (the time constant of the lung). The first two determinants are controlled by the ventilator settings and compound to the minute ventilation (V_e) making this the most important determinant of DHI.

Gas trapped at the end of expiration exerts a positive pressure on the alveoli; this pressure is intrinsic positive end-expiratory pressure ($PEEP_i$) or auto-PEEP.[95,96] During expiration, sequential closure of the most severely obstructed airways occurs with only the less obstructed airways remaining in communication with the central airway at the end of tidal expiration.[97] As a consequence, measured $PEEP_i$ underestimates the true magnitude of $PEEP_i$ and is recognised as being insensitive to changes in severity.[97]

In mild air-flow obstruction, this process is adaptive as it allows the desired minute ventilation, which could not be achieved at FRC, to be achieved at a higher lung volume (Fig. 35.3, 'mild AO'). As asthma becomes more severe (see Fig. 35.3, 'mod AO') the static FRC that would be reached with a long expiratory time is elevated above the normal FRC by airway closure (static hyperinflation) and DHI further increases lung volume to a level where work of breathing is increased by lower lung compliance and respiratory muscles become less efficient from shortening and mechanical

disadvantage. At this level, some degree of dyspnoea is expected. When asthma is severe enough to risk requiring mechanical ventilation, static hyperinflation may increase FRC by 50%[98] and very little DHI is required to reach TLC (see Fig. 35.3, 'severe AO'). In this circumstance, the minute ventilation required to maintain normocapnia would cause hyperinflation beyond normal TLC. During spontaneous ventilation, the patient with severe asthma is unable to exceed TLC (see Fig. 35.3), has a much lower maximum minute ventilation capacity and as a result must become hypercapnic even at maximum respiratory effort with no fatigue.[99] When mechanical ventilation is commenced, increased tidal volume and rate delivery is easily able to increase minute ventilation and DHI well beyond normal TLC (see Fig. 35.3).[95] The consequences of this are commonly hypotension (due to increased intrathoracic pressure and decreased venous return) and barotrauma.[95,99–101]

NON-INVASIVE VENTILATION

Non-invasive ventilation (NIV) has been widely used for a variety of respiratory problems. In severe asthma there are a number of potential benefits. Externally applied PEEP may help overcome $PEEP_i$ due to gas trapping, and thus reduce the inspiratory threshold work of breathing. Augmentation of inspiration with NIV may further decrease the work of inspiration and increase tidal volume and minute ventilation. If tidal volume is increased with a shorter inspiratory time, then increased minute ventilation can occur without a proportional increase in DHI. Both inspiratory augmentation and PEEP may facilitate airspace opening, thus reducing V/Q mismatch.[102,103]

The role of NIV is well established in COPD where a number of randomised trials have shown benefit.[104,105] Although there have been no large randomised trials in acute asthma, there is increasing evidence of benefit from NIV for this indication with all studies reporting a positive outcome.[106,107] Non-randomised studies have reported improvements in respiratory acidosis and respiratory rate following the introduction of NIV, and low requirements for invasive ventilation. In small prospectively randomised studies of acute asthma, Soroksky et al.[107] showed better lung function and decreased hospitalisation rate, and Gupta et al.[108] found accelerated improvement in lung function, decreased inhaled bronchodilator requirement and shortened intensive care unit and hospital stay. In a retrospective cohort study, Murase et al.[98] found that NIV reduced the rate of endotracheal intubation from 18% (9/50) to 3.5% (2/57, $P = .01$).

There have been multiple reviews of NIV for acute severe asthma[109–112] including a Cochrane review[113] All concluded there is limited evidence for some benefits, insufficient data to be conclusive and that larger trials are needed. Where opinions were given, all recommended use of NIV in selected patients with asthma.[109–112] Indications for use are: (1) moderate to severe dyspnoea or respiratory distress, (2) hypercapnic acidosis and (3) respiratory rate greater than 25, accessory muscle use or paradoxical breathing. Contraindications to NIV include cardiac or respiratory arrest, a decreased conscious state, severe upper gastrointestinal bleeding, haemodynamic instability, facial trauma or surgery, inability to protect the airway and clear secretions and high risk of aspiration.

Nasal masks are usually not suitable in acute respiratory failure and full-face masks fitted to achieve comfort and a reliable seal are usually best.

NIV should be commenced with 5 cm H_2O continuous positive airway pressure (CPAP) (expiratory positive airway pressure 5 cm H_2O) and 8–10 cm H_2O pressure support (inspiratory positive airway pressure [IPAP] 13–15 cm H_2O). The aim is a respiratory rate less than 25 breaths/min and an exhaled tidal volume of 7 mL/kg. CPAP may be increased to 7 or 10 cm H_2O if there is difficulty initiating inspiration, or pressure support may be increased if tidal volume is low or respiratory rate remains high. It is not possible to reliably achieve total pressures (IPAP) greater than 20 cm H_2O. NIV should be undertaken in an area familiar with its use and where close observation is available.

Complications of NIV include nasal bridge ulceration, mask discomfort, nasal congestion, gastric insufflation, aspiration, hypotension and pneumothorax.[112] However, hypotension and pneumothorax are uncommon compared with their risk during mechanical ventilation. A recent uncontrolled series[114] suggest NIV is safe in this situation if conducted under careful supervision in a monitored environment.

INVASIVE VENTILATION

Invasive mechanical ventilation in acute severe asthma may be life saving, but can be associated with significant morbidity and mortality (Fig. 35.4).[100] Institution of invasive ventilation with endotracheal intubation carries the risk of inadvertent pulmonary hyperinflation[95,96,100] and potential aggravation of bronchospasm and a significant part of the morbidity and mortality has been attributed to pulmonary hyperinflation.[95,96,100] Despite these risks, the incidence of mechanical ventilation for asthma is decreasing and mortality of patients ventilated for asthma is also decreasing in some series (see Figs 35.1 and 35.4).[5,6]

The decision to intubate depends on both the clinical status of the patient and the natural history of the type of asthma present. Hyperacute asthma may present with marked hypercapnia ($PaCO_2$ >60 mm Hg [7.98 kPa]) due to mechanical limitations of ventilation as a result of DHI. Such patients may not initially be fatigued and may respond rapidly to treatment, thereby avoiding mechanical ventilation. Acute severe asthma that has been progressing for days may have

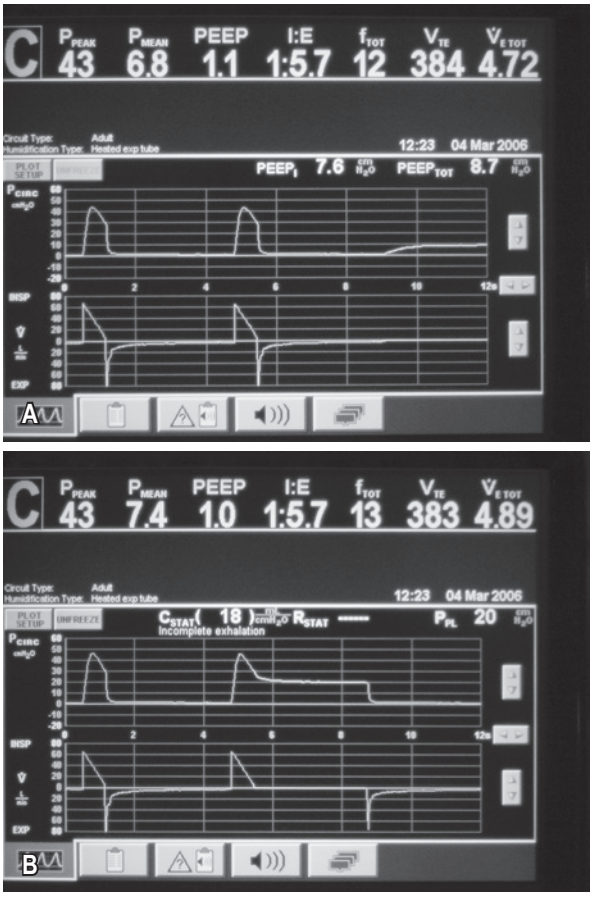

Figure 35.4 (a) The ventilator circuit pressure and flow traces versus time during controlled ventilation of a patient with severe air-flow obstruction. Note the use of a low rate, low V_t, a high inspiratory flow rate (V_i 80 L/min) and hence a short inspiratory time (t_e <1 second). This causes a high peak airway pressure but allows a long expiratory time (>4 seconds). Expiratory flow is low throughout expiration and appears close to baseline at the onset of the next breath (second on screen). Suggesting minimal gas trapping but when an intrinsic positive end-expiratory pressure ($PEEP_i$) manoeuvre is done (end-expiratory pause) these is a surprising degree of $PEEP_i$ present (7.6 cm H_2O). (b) The ventilator circuit pressure and flow traces versus time during controlled ventilation of the same patient in part a. When a P_{plat} manoeuvre is done (end-inspiratory pause) the P_{plat} is safe (20 cm H_2O) with this ventilator pattern despite the degree of PEEPi present. Note the low P_{plat} despite the high peak airway pressure.

less hypercapnia but will often respond poorly to treatment. The $PaCO_2$ may rise despite maximal treatment owing to fatigue and the patient may require intubation at a lower $PaCO_2$. The general principles are to use NIV early but to avoid mechanical ventilation if it is safe to do so.

The decision to intubate is based primarily on the degree of respiratory distress as assessed by an experienced clinician and the patient themselves. A patient with a high $PaCO_2$ (e.g. >70 mm Hg [9.31 kPa]) who is dyspnoeic but not distressed and who may respond to full treatment over a few hours needs close observation but not immediate intubation. Patients are often able to tolerate hypercapnia without requiring invasive ventilation.[115] A patient with a lower $PaCO_2$ (e.g. 50–60 mm Hg [6.66–7.98 kPa]) who has been unwell for days, and who has a deteriorating status despite treatment and significant respiratory distress, is likely to need intubation. A patient who complains of respiratory exhaustion is likely to need intubation. Absolute indications for intubation include cardiac or respiratory arrest, severe hypoxia or rapid deterioration of conscious state.[17,59]

Once the decision to intubate has been made, a safe option is to perform rapid sequence intubation using the orotracheal approach. As large as possible endotracheal tube should be used to reduce the work of breathing and to reduce the risk of tube occlusion by the tenacious secretions that often occur with asthma. Once the endotracheal tube is in place, slow hand ventilation (8–10 breaths/min) should maintain oxygenation until the ventilator can be connected.

INITIAL VENTILATOR SETTINGS

The principles of initial mechanical ventilation are to avoid excessive DHI[95,99–101,116] and to avoid excessive hypoventilation (Fig. 35.5) by commencing with a minute ventilation less than 115 mL/kg per minute (<8 L/min in a 70 kg patient) best achieved with a tidal volume of 5–7 mL/kg, a respiratory rate of 10–12 breaths/min and a short inspiratory time to ensure an expiratory time ≥4 seconds.[95,99–101,116] This degree of hypoventilation will usually result in hypercapnic acidosis and continued respiratory distress necessitating heavy sedation, and sometimes requires 1–2 bolus doses of a neuromuscular-blocking agent (NMBA).

The use of volume-controlled ventilation is most established for this ventilatory pattern. In volume control, a high inspiratory flow rate (70–100 L/min) is required to achieve a short inspiratory time. This will result in a high peak airway pressure (PIP), but this will lower DHI and P_{plat} and reduce barotrauma compared with lower inspiratory flow rates[95,100] Pressure-controlled or assisted modes have been used[117] without adverse consequences. The theoretical advantage of a safe pressure limit in pressure modes is offset by the fact that equilibrium with the set safe pressure cannot be reached during the short inspiratory times required, and thus either a higher pressure must be set or more than necessary hypoventilation may occur. It is not clear whether one mode is superior to the other.

If significant hypotension occurs this should be treated by reducing the respiratory rate, (thereby reducing DHI) and volume loading.

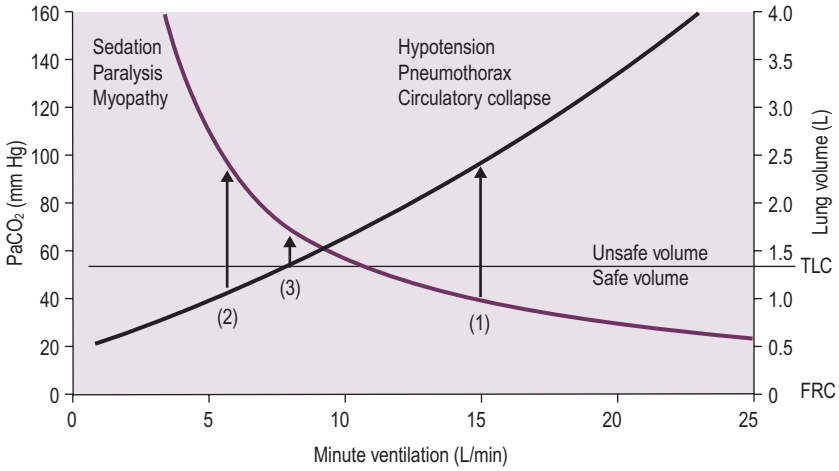

Figure 35.5 The effects of minute ventilation on $PaCO_2$ and end-inspiratory lung volume above functional residual capacity (FRC) in a typical patient with severe asthma. (1) The minute ventilation required for normocapnia; (2) profound hypoventilation; and (3) optimal hypoventilation. *TLC*, Total lung capacity.

POSITIVE END-EXPIRATORY PRESSURE

The role of extrinsic PEEP during mechanical ventilation of the patient with severe asthma requires careful consideration. During spontaneous breathing, CPAP has been shown to facilitate the initiation of the next breath and reduce the work of breathing in many patients with severe air-flow obstruction. However, during the initial controlled hypoventilation when there is an excessive level of PEEPi and DHI, and the work of breathing is not an issue, early work has shown that extrinsic PEEP will further increase lung volumes. As this conferred no benefit and risk of detriment, it has been recommended that extrinsic PEEP should not be used.[101] More recently, some research has suggested that low-level PEEP may improve the distribution of ventilation (as does hyperinflation) and reduce $PaCO_2$,[118] and one study[119] has found that extrinsic PEEP may paradoxically reduce hyperinflation in some patients ventilated with air-flow obstruction. The uncertain benefit and unpredictable responses to PEEP in these latter studies continue to suggest that extrinsic PEEP should not be routinely used during controlled ventilation for severe air-flow obstruction.[101]

ASSESSMENT OF DYNAMIC HYPERINFLATION

Once mechanical ventilation has started, the degree of DHI should be assessed by measurement of *plateau airway pressure* (P_{plat}). This is the airway pressure after transient expiratory occlusion at the end of inspiration. This may be achieved by an end-inspiratory hold function on most current ventilators, which delays the commencement of the next breath (see Fig. 35.4a), or by applying a 0.5 s 'plateau', which does not delay the onset of the next breath. The latter should be applied for a single breath only as application for several breaths in a row will decrease expiratory time and progressively increase DHI. This is the most easily measured estimate of average alveolar pressure at the end of inspiration and is directly proportional to the degree of hyperinflation and should be maintained at less than 25 cm H_2O.[95,100]

In patients with severe asthma, P_{plat} of 25 cm H_2O correlated with an average end-inspiratory lung volume of less than 20 mL/kg (1.4 L in a 70 kg patient, see Figs 35.2 and 35.3) above FRC. This has been shown to be a good predictor of complications during mechanical ventilation[100] and to correlate with a total lung volume at TLC.[99]

$PEEP_i$ is the airway pressure during occlusion of expiratory flow at the end of expiration (see Fig. 35.4b). This is also an automated end-inspiratory hold function on most current ventilators. However, this measurement is known to underestimate true $PEEP_i$, as a consequence of small-airway closure during expiration resulting in many higher-pressure alveoli not communicating with the central airway at the end of expiration.[97] Because of this, $PEEP_i$ can be used to show the presence of DHI but is not recommended to regulate the mechanical ventilation. Ideally, $PEEP_i$ should be less than 12 cm H_2O, although the exact safe level is unknown.

Assessment of the change in blood pressure and central venous pressure should be made during a period of transient ventilator disconnection (1–2 minutes) or transient ventilator rate reduction (4–6 breaths/min for 2–4 minutes). If DHI has been suppressing circulation then a significant increase in blood pressure and reduction in central venous pressure will occur.

ADJUSTMENT OF VENTILATION

Ventilatory patterns with excessive minute ventilation risk hypotension and barotrauma, and are associated with a high mortality. The use of profound hypoventilation will guarantee avoidance of these complications,

but usually necessitates heavy sedation and neuromuscular blockade (see Fig. 34.5). This, in association with parenteral steroids, has a high probability of myopathy,[72,120,121] which may cause severe prolonged disability. To minimise the risk of both these complications, DHI should be carefully assessed and the minimum amount of hypoventilation used to achieve a safe level of DHI (see Fig. 35.5) in association with less sedation and minimal or no use of NMBA.

Ventilation should be adjusted based on assessment of DHI, not on $PaCO_2$ or pH. If P_{plat} is greater than 25 cm H_2O or circulatory suppression is present, the ventilator rate should be reduced.[95,122] If P_{plat} is low, ventilation can be liberalised by increasing the ventilator rate or reducing sedation and allowing spontaneous ventilation. Hypercapnia is usually present but is well tolerated[123] and does not appear to depress cardiac function. There is no evidence of benefit from sodium bicarbonate, but it may reduce acidaemia-induced respiratory distress, and it may be given if the pH is less than 7.1.

When air-flow obstruction improves (decreasing P_{plat} and $PEEP_i$), sedation may be decreased, ventilator rate reduced and spontaneous ventilation assisted with pressure support ventilation. Pressure support of 10–16 cm H_2O may be used. Once spontaneous ventilation has commenced and when DHI is no longer critical, 3–7 cm H_2O CPAP may be introduced to assist ventilator triggering and reduce the work of breathing.

COMPLICATIONS OF INVASIVE VENTILATION IN ASTHMA

Hypotension may be caused by sedation, DHI, pneumothoraces or arrhythmias.[95,100] Hypovolaemia may be a contributory factor but is rarely a cause. Hypotension may be mild or life threatening.[124] Hypotension due to DHI may be diagnosed by the recovery of blood pressure during apnoea of 60 seconds (the 'apnoea test')[124] or by a longer period of low ventilator rate (4–6 breaths/min for 2–4 minutes). If this occurs, ventilation should be continued at a lower rate.

Circulatory arrest with apparent electromechanical dissociation (EMD) is a recognised complication that may occur within 10 minutes of intubation, and can lead to death or severe cerebral ischaemic injury if not managed correctly.[124–126] Standard mechanical ventilation recommendations (minute ventilation 115 mL/kg per minute) have been estimated to be safe for 80% of patients requiring mechanical ventilation for acute severe asthma, with the remaining 20% requiring a small to moderate reduction in minute ventilation to return DHI to a safe level.[100] A small percentage of patients with unusually severe asthma can rapidly develop excessive DHI during initial uncontrolled mechanical ventilation leading to EMD, sometimes despite 'safe' levels of minute ventilation. If the cause of this is not immediately recognised, it can lead to prolonged and unnecessary cardiopulmonary resuscitation, unsafe procedures (e.g. intercostal vascular access needles or pericardial taps) and can risk cerebral injury and death.[124–126] When this occurs, immediate disconnection from ventilation for 60–90 seconds (the 'apnoea test', above) or profound hypoventilation (2–3 breaths/min)[59] will diagnose and improve this situation. An even smaller percentage of patients may remain hypotensive despite profound hypoventilation with marked hypercapnia, fluid loading and inotropes. These patients may require heliox delivered by the mechanical ventilator[127] or extracorporeal membrane oxygenation.[126,128–130]

Pneumothoraces were common before the advent of protective ventilatory strategies. DHI during mechanical ventilation was probably the major causative factor involved.[95,100] Pneumothoraces may also occur in association with subclavian central venous catheter insertion and as a consequence of intercostal needle insertion for suspected tension pneumothorax during circulatory arrest (above). Asthma continues to remain one of the three most common conditions (with acute respiratory distress syndrome [ARDS] and interstitial lung disease) associated with barotrauma during mechanical ventilation with a risk rate of 6.3% compared with an overall risk rate of 2.9% for all mechanically ventilated patients.[131] The presence of severe air-flow obstruction prevents lung collapse and favours gas loss through the ruptured alveoli, with the result that tension is almost always present in the pneumothorax. Once a unilateral tension pneumothorax is present, this will necessarily reduce ventilation to that lung and redistribute ventilation to the contralateral lung, thereby further increasing DHI in the second lung, and bilateral tension pneumothoraces may result with severe adverse consequences.

As soon as a tension pneumothorax is suspected, the ventilator rate should be immediately reduced to decrease the risk to the second lung. Clinical diagnosis of a tension pneumothorax can be difficult as the lungs in severe asthma are already overexpanded and hyper-resonant with poor air entry. An urgent chest X-ray is always advisable for confirmation prior to intercostal catheter insertion unless severe hypotension is present. Intercostal catheters should always be inserted by blunt dissection. If intercostal needles are inserted for suspected pneumothorax, an intercostal catheter should always be inserted soon thereafter because if a tension pneumothorax was not present it is highly likely to present after the intercostal needles.

Acute necrotising myopathy is a serious complication that may occur in patients who are invasively ventilated for asthma and receive NMBA or very deep sedation.[72,120,121,132,133] It is characterised by weakness with electromyographic evidence of myopathy and increased serum creatine kinase levels. Muscle biopsy reveals two patterns: myonecrosis with muscle cell vacuolisation or predominant type II fibre atrophy.[72,132] Recovery can be slow with prolonged weaning from

mechanical ventilation and the need for rehabilitation. Incomplete recovery after 12 months has been reported in a few patients.[133,134] The aetiology of the myopathy appears to be a combination of the effects of corticosteroids and NMBA with the duration of paralysis a strong predictor of myopathy.[133,134] The type of NMBA used seems to make no difference to the incidence of myopathy.[132] Effective paralysis by deep sedation without the use of NMBAs also confers the risk of severe weakness in this patient group.[134] Gehlbach et al.[10] found that the risk factors for prolonged mechanical ventilation were female gender, the use of NMBAs, the requirement for inhaled corticosteroids prior to admission and a high illness severity score (APACHE II). The relative contributions of corticosteroids versus NMBAs in the causation of myopathy are unclear. It seems wise to minimise the dose of parenteral corticosteroids with early introduction of nebulised agents, to minimise or avoid NMBAs if possible and to minimise deep sedation.

MORTALITY, LONG-TERM OUTCOME AND FOLLOW-UP

Prior to the year 2000,[60] there was a high overall mortality of 12.4% for patients requiring mechanical ventilation for asthma with a progressive reduction in reported mortality during that period (Fig. 35.6). A selection of reports[5,7,9,10,25] published since 2000 have shown continued reduction in overall mortality (see Fig. 35.6) but with mortalities as high as 21% still occurring in one series.[9] The largest and most comprehensive recent series[5] reported 1899 patients admitted to 22 Australian intensive care units over an 8-year period (1996–2003). This series reported a requirement for mechanical ventilation for 36% of patients admitted with severe asthma and a progressive reduction in annual mortality of the ventilated patients from 10% to 3% over the 8-year period.

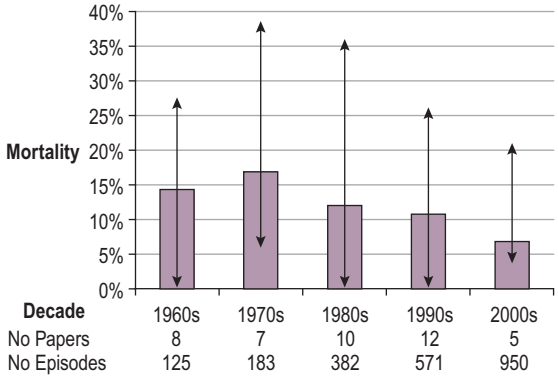

Figure 35.6 Comparison of reported mortality associated with the mechanical ventilation of patients with severe asthma over the last five decades. Mortality shown as mean with minimum and maximum mortality within the reported series for that decade.

The need for invasive ventilation increases the risk of death,[5,9] and survivors of these near-fatal episodes of asthma have an increased risk of intensive care readmission and an increased risk of death after hospital discharge.[38,135] For these reasons, patients who have an episode of asthma severe enough to require hospitalisation – particularly intensive care admission – need careful follow-up. This should include active identification and avoidance of precipitants, aggressive bronchodilator therapy including inhaled steroids, regular medical review, regular measurement of lung function, management plans for a deteriorating status and ready access to emergency services. Patients with difficult asthma may benefit from detailed psychological and sometimes speech therapy assessment.[18]

Pneumonia

Kai Man Chan, Charles David Gomersall

The management of pneumonia is based on four findings and premises:

- Pneumonia is associated with a wide range of largely non-specific clinical features.
- Pneumonia can be caused by over 100 organisms.
- The relationship between specific clinical features and aetiological organism is insufficiently strong to allow a clinical diagnosis of the causative organism.[1,2]
- Early administration of appropriate antibiotics is important.[1,3]

The net result is that the differential diagnosis is wide and treatment should be started before the aetiological agent is known. The differential diagnosis and the likely causative organisms can be narrowed by using epidemiological clues, the most important of which are whether the pneumonia is community acquired or hospital acquired, and whether the patient is immunocompromised. Note that the flora and antibiotic resistance patterns vary between countries, hospitals and even intensive care units (ICU) and this must be taken into account.

COMMUNITY-ACQUIRED PNEUMONIA

Evidence-based guidelines have been issued by the UK National Institute for Health and Care Excellence (NICE, www.nice.org.uk/guidance/cg191) and the British Thoracic Society.[3] A summary of overlap and differences between the guideline is given at https://www.brit-thoracic.org.uk/document-library/clinical-information/pneumonia/adult-pneumonia/annotated-bts-cap-guideline-summary-of-recommendations/.

DEFINITION

An acute infection of the pulmonary parenchyma associated with at least some symptoms of acute infection, accompanied by an acute infiltrate on a chest X-ray (CXR) or auscultatory findings consistent with pneumonia (e.g. altered breath sounds, localised crackles) in a patient not hospitalised prior to the onset of symptoms.

The overall incidence is 3–40 per 1000 inhabitants per year with 40%–60% requiring hospital admission. Overall, 10% of patients are admitted to ICU. The overall mortality of hospitalised patient is approximately 10%.[4]

AETIOLOGY

Table 36.1 gives possible aetiological agents based on epidemiological clues. *Streptococcus pneumoniae* is the most commonly isolated organism. The next most common bacterial pathogens in patients admitted to ICU are: *Legionella* spp., *Haemophilus influenzae,* Enterobacteriaceae spp., *Staphylococcus aureus* and *Pseudomonas* spp.[8]

CLINICAL PRESENTATION

Pneumonia produces both systemic and respiratory manifestations. Common clinical findings include fever, sweats, rigors, cough, sputum production, pleuritic chest pain, dyspnoea, tachypnoea, pleural rub and inspiratory crackles. Classic signs of consolidation occur in less than 25% of cases. Multiorgan dysfunction or failure may occur depending on the type and severity of pneumonia.

The diagnosis of pneumonia may be more difficult in the elderly. Although the vast majority of elderly patients with pneumonia have respiratory symptoms and signs, over 50% may also have non-respiratory symptoms and over one-third may have no systemic signs of infection.

INVESTIGATIONS[4,5]

Investigations should not delay the administration of antibiotics, as a delay is associated with an increase in mortality.[1] Important investigations include:

1. Imaging: CXR usually shows infiltrates but may be normal in 25%–30% of patients with pneumonia. Lung ultrasound appears to be similarly or more sensitive,[9,10] but computed tomography (CT) is the most sensitive.
2. Arterial blood gases or oximetry.

ABSTRACT

Pneumonia should be treated urgently, prior to the identification of the causative organism. The choice of antimicrobial is therefore empirical initially, and is based on epidemiological clues, the most important of which are whether pneumonia is community or hospital acquired and whether the patient is immunocompromised. Recent changes in the management of chest infections include: the increasing recognition that invasive pulmonary aspergillosis may occur in critically ill patients without overt severe immunocompromise, decreased emphasis on routine use of invasive sampling of respiratory specimens, shorter duration of antibiotic therapy, procalcitonin-guided duration of antibiotic therapy and the use of a polymerase chain reaction to identify causative organisms.

KEYWORDS

Pneumonia
empyema
pleural effusion
antibiotics
bacterial infection
fungal infection
viral infection
immunocompromise
tuberculosis

Table 36.1 Possible aetiological agents based on epidemiological clues

EXPOSURE TO ANIMALS	
Handling turkeys, chickens, ducks or psittacine birds or their excreta	*Chlamydia psittaci*
Exposure to birds in countries in which avian flu has been identified in birds	Influenza A H5N1, H7N9, H5N6
Handling infected parturient cats, cattle, goats or sheep or their hides	*Coxiella burneti*
Handling infected wool	*Bacillus anthracis*
Handling infected cattle, pigs, goats or sheep or their milk	*Brucella* spp.
Insect bite. Transmission from rodents and wild animals (e.g. rabbits) to laboratory workers, farmers and hunters	*Francisella tularensis*
Insect bites or scratches. Transmission from infected rodents or cats to laboratory workers and hunters	*Yersinia pestis*
Contact with infected horses (very rare)	*Pseudomonas mallei*
Exposure to mice or mice droppings	Hantavirus
GEOGRAPHICAL FACTORS	
Immigration from or residence in countries with high prevalence of TB	*M. tuberculosis*
N. America. Contact with infected bats or birds or their excreta. Excavation in endemic areas	*Histoplasma capsulatum*
Southwest United States	*Coccidiodes* spp., *Hantavirus*
United States. Inhalation of spores from soil	*Blastomyces dermatitidis*
Middle East or contact with confirmed Middle East respiratory syndrome (MERS) case or exposure to camels	*MERS coronavirus*
Asia, Pacific, Caribbean, N. Australia. Contact with local animals or contaminated skin abrasions	*Burkholderia pseudomallei*
HOST FACTORS	
Diabetic ketoacidosis	*Strep. pneumoniae, S. aureus*
Alcoholism	*Strep. pneumoniae, S. aureus, Klebsiella pneumoniae,* oral anaerobes, *M. tuberculosis, Acinetobacter* spp.
Chronic obstructive pulmonary disease or smoking	*Strep. pneumoniae, Haemophilus influenzae, Moraxella catarrhalis, Chlamydia pneumoniae, Legionella* spp., *Pseudomonas aeruginosa*
Sickle cell disease	*Strep. pneumoniae*
Pneumonia complicating whooping cough	*Bordatella pertussis*
Pneumonia complicating influenza	*Strep. pneumoniae, S. aureus, CA-MRSA*
Pneumonia severe enough to necessitate artificial ventilation	*Strep. pneumoniae, Legionella* spp. *S. aureus, Haemophilus influenzae, Mycoplasma pneumoniae,* enteric gram-negative bacilli, *Chlamydia pneumoniae, Mycobacterium tuberculosis,* viral infection, endemic fungi
Nursing home residency	Treat as healthcare associated pneumonia
Poor dental hygiene	Anaerobes
Suspected large volume aspiration	Oral anaerobes, Gram-negative enteric bacteria
Structural disease of lung (e.g. bronchiectasis, cystic fibrosis)	*Pseudomonas aeruginosa, Burkholderia cepacia, S. aureus*

Table 36.1 Possible aetiological agents based on epidemiological clues—cont'd

Lung abscess	Community acquired methicillin resistant *S. aureus*, oral anaerobes, endemic fungi, *M. tuberculosis*, atypical mycobacteria
Endobronchial obstruction	Anaerobes, *Strep. pneumoniae, H. influenzae, S. aureus*
Intravenous drug addict	*S. aureus, CA-MRSA,* anaerobes, *M. tuberculosis, Strep. pneumoniae*
End-stage renal failure	*CA-MRSA*
OTHERS	
Epidemic	*Mycoplasma pneumoniae,* influenza virus (H1N1, H3N2, influenza B), parainfluenza
Air-conditioning cooling towers, hot tubs or hotel or cruise ship stay in previous 2 weeks	*Legionella pneumophilia*
Presentation of a cluster of cases over a very short period of time	Bioterrorist agents: *Bacillus anthracis, Franciscella tularensis, Yersinia pestis*

See references 1, 5–7.

3. Full blood count.
4. Serum creatinine, urea and electrolytes.
5. Liver function tests.
6. Blood cultures (×2) prior to the administration of antimicrobials.
7. Sputum (if immediately available) for urgent Gram stain and culture. The usefulness of sputum tests remains debatable because of contamination by upper respiratory tract commensals. However, a single or predominant organism on a Gram stain of a fresh sample or a heavy growth on culture of purulent sputum is likely to be the organism responsible. The finding of many polymorphonuclear cells (PMN) with no bacteria in a patient who has not already received antibiotics can reliably exclude infection by most ordinary bacterial pathogens.

   Specimens should be obtained by deep cough and be grossly purulent. Ideally, the specimen should be obtained before treatment with antimicrobials – if this does not delay administration of antibiotics – and be transported to the laboratory immediately for prompt processing to minimise the chance of missing fastidious organisms (e.g. *Strep. pneumoniae*). Acceptable specimens (in patients with normal or raised white blood cell [WBC] counts) should contain less than 25 PMN per low power field (LPF) and less than 10–25 squamous epithelial cells (SEC)/LPF or less than 10 PMN per SEC. These criteria should not be used for *Mycobacteria* and *Legionella* infection.

   Certain organisms are virtually always pathogens when recovered from respiratory secretions (Table 36.2).

   Patients with risk factors for tuberculosis (TB) (see Table 36.6), particularly those with cough for more than 1 month, other common symptoms of TB and suggestive radiographic changes should have sputum examined for *M. tuberculosis*.

   Sputum cannot be processed for culture for anaerobes due to contamination by the endogenous anaerobic flora of the upper respiratory tract. In addition to the factors listed in Table 36.1, foul smelling sputum, lung abscess and empyema should raise suspicion of anaerobic infection.
8. Aspiration of pleural fluid for Gram stain, culture, protein, lactate dehydrogenase (LDH), pH and leukocyte count – all patients with a pleural effusion less than 1 cm thick on a lateral decubitus CXR or less than 2–2.5 cm on CT.
9. Urinary *Legionella* antigen. This test is specific (>95%). In patients with severe Legionnaires disease sensitivity is 88%–100% for *L. pneumophilia* serogroup 1 (the most commonly reported cause of legionella infection). A positive result is virtually diagnostic of *Legionella* infection, but a negative result does not exclude it. In areas where other

Table 36.2 Organisms that are virtually always pathogens when recovered from respiratory secretions

Legionella
Chlamydia
Tuberculosis
Influenza, para-influenza virus, respiratory syncytial virus, adenovirus, hantavirus, SARS coronavirus
Stronglyloides stercoralis
Toxoplasma gondi
Histoplasma capsulatum
Coccidiodes immitis
Blastomycoses dermatitidis
Cryptococcus neoformans

Legionella species are more common (e.g. South Australia), this test is less helpful.

10. Urinary pneumococcal antigen has moderate sensitivity (50%–80%) and high specificity (>90%).
11. Polymerase chain reaction (PCR) for *Mycoplasma pneumoniae* and *Chlamydophilia*. PCR assays are more sensitive than culture for *Mycoplasma* and *Chlamydophilia* species and at least as sensitive for *Legionella*.[9] PCR assays also detect Legionella strains other than serogroup 1. The British Thoracic Society guidelines[3] recommend PCR of the lower respiratory tract sample or, if unavailable, a throat swab for the diagnosis of Mycoplasma pneumonia. PCR for *Chlamydophilia* should be performed when invasive respiratory samples are collected from patients with severe community-acquired pneumonia (CAP).
12. HIV serological status.

Other investigations should be considered in patients with risk factors for infection with unusual organisms. Bronchoalveolar lavage may be useful in immunocompromised patients, those who fail to respond to antibiotics or those in whom sputum samples cannot be obtained.[11]

Molecular diagnosis (e.g. PCR-based methods) has the advantages of a quick result (within 3 hours), enhanced sensitivity, independence of organism viability and hence previous antibiotics and the theoretical possibility for determining antimicrobial susceptibility.[9] For example, PCR for pneumococcus is positive in 62% of blood samples from adult patients with confirmed or probable pneumococcal pneumonia,[11] while blood cultures are positive in only 37%. It is most useful when performed on specimens from a normally sterile site. In respiratory specimens, PCR testing may increase the sensitivity of detection, but false positive results from upper respiratory tract contamination and lower respiratory tract colonisation may occur.

MANAGEMENT

GENERAL SUPPORTIVE MEASURES

A general approach should be made to organ support with an emphasis on correcting hypoxia. The use of nasal high-flow oxygen was associated with a lower 90-day mortality (compared to patients treated with non-invasive ventilation) in a randomised controlled trial of patients with acute respiratory failure, of whom 80% had pneumonia.[12] However, there was no difference in the primary outcome (need for intubation) and these data should be considered hypothesis-generating only.

ANTIMICROBIAL REGIMES

Increased mortality among those who do not receive empiric antibiotics that cover the infecting pathogen(s) is well documented.[13] Each unit should have its own regimens tailored to the local flora and antibiotic resistance patterns. In the absence of such regimens, the regimen outlined in Fig. 36.1 may be helpful. This should be modified in the light of risk factors

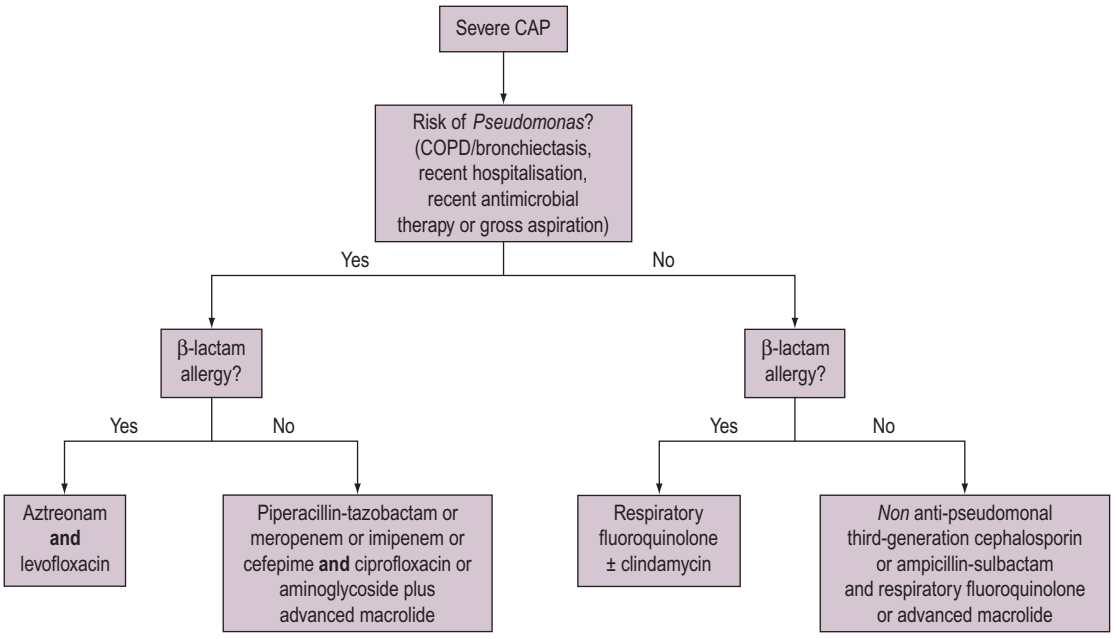

Figure 36.1 Antibiotic regimes for treatment of severe community acquired pneumonia (CAP) in critically ill patients.[5,8] Respiratory fluoroquinolones include moxifloxacin and levofloxacin. Advanced macrolides include azithromycin and clarithromycin. Non–anti-pseudomonal third-generation cephalosporins include cefotaxime and ceftriaxone. *COPD*, Chronic obstructive pulmonary disease.

(see Table 36.1). Quinolones may be less appropriate in areas with a high prevalence of TB as their use may mask concurrent TB infection. Patients infected with Panton-Valentine Leukocidin toxin-producing *S. aureus* (most community-acquired MRSA and some MSSA) may benefit from antimicrobials that also reduce toxin production (e.g. linezolid, rifampicin or clindamycin).[13] Antimicrobials should be administered to patients with sepsis within 1 hour of diagnosis.[14] There is controversy regarding the de-escalation of empiric therapy based on microbiological findings.[4,5] Changing to narrower spectrum antimicrobial cover may result in inadequate treatment of the 5%–38% of patients with polymicrobial infection. Increasing evidence demonstrates improved outcome with combination antimicrobial, including a macrolide, compared to monotherapy, particularly in severely ill patients with bacteraemic pneumococcal pneumonia.[15,16] The odds ratio of death was 1.5 to 6 for monotherapy compared to combination therapy.[4] A recent meta-analysis showed a trend towards an improved outcome when a beta-lactam was combined with a macrolide rather than a fluoroquinolone.[16] For the treatment of drug-resistant *Strep. pneumoniae* the regimes in Table 36.2 are probably suitable for isolates with a penicillin minimum inhibitory concentration (MIC) less than 4 mg/L.[5] If the MIC is ≥4 mg/L an antipneumococcal fluoroquinolone, vancomycin, teicoplanin or linezolid should be given.[4]

DURATION OF THERAPY

There are no clinical trials that have specifically addressed this issue. Courses as short as 5 days may be sufficient.[17] NICE guidelines recommend 7- to 10-day courses for patients with moderate or severe pneumonia. Short courses may be suboptimal for patients with bacteraemic *S. aureus* pneumonia, meningitis or endocarditis complicating pneumonia or infection with less common organisms (e.g. *Burkholderia pseudomallei* or fungi) or *Pseudomonas aeruginosa*. Procalcitonin may be useful to guide antibiotic therapy, allowing a reduction in antibiotic duration without an adverse effect on mortality in both CAP[18] and sepsis, and septic shock.[19]

CORTICOSTEROIDS

Limited data suggest that the administration of steroids (methylprednisolone 30 mg/day for 7 days) may decrease the risk of acute respiratory distress syndrome, reduce hospital and ICU stay and time to stability, but has no effect on mortality.[20] Routine use is not recommended by NICE.

RESPONSE TO THERAPY[5,6,21]

A response is usually seen within 1–3 days of starting therapy; this can be assessed on the basis of respiratory symptoms, fever, oxygenation, WBC count, bacteriology, CXR changes, C-reactive protein reduction and procalcitonin reduction. The average time to defervescence varies with organism, severity and patient age (7 days in elderly patients, 2.5 days in young patients with pneumococcal pneumonia, 6–7 days in bacteraemic patients with pneumococcal pneumonia, 1–2 days in patients with *M. pneumoniae* pneumonia and 5 days in patients with *Legionella* pneumonia). Both blood and sputum cultures are usually negative within 24–48 hours of treatment, although *P. aeruginosa* and *M. pneumoniae* may persist in the sputum despite effective therapy. CXR changes lag behind clinical changes with the speed of change depending on the organism, the severity of illness, the age of the patient and the presence of co-morbid illnesses. The CXRs of most young or middle-aged patients with bacteraemic pneumococcal pneumonia are clear by 4 weeks but resolution is slower in elderly patients and patients with underlying illness, extensive pneumonia on presentation or *Legionella pneumophilia* pneumonia.

If the patient fails to respond, consider the following questions:

- Has the patient got pneumonia?
- Are there host factors which explain the failure (e.g. obstruction of bronchus by a foreign body or tumour, inadequate host response)?
- Has a complication developed (e.g. empyema, superinfection, bronchiolitis obliterans organising pneumonia, metastatic abscess)?
- Is the right drug being given in an adequate dose by the right route?
- Is the organism resistant to the drug being given?
- Are there other organisms?
- Is the fever a drug fever?

Useful investigations include CT of the chest, thoracocentesis, bronchoalveolar lavage (Table 36.3) and transbronchial or open lung biopsy.

PREDICTION OF ADVERSE OUTCOME AND ADMISSION TO INTENSIVE CARE UNIT

The CURB65 score can be used to risk-stratify patients. Patients with three or more of the following features have a greater than 15% mortality risk: new confusion or abbreviated mental test score ≤8; urea greater than 7 mmol/L (blood urea nitrogen >19.6 mg/dL); low blood pressure, diastolic ≤60 mm Hg or systolic ≤90 mm Hg; age ≥65 years.

Viral pneumonia

Viral infection is common in patients with CAP. Estimates suggest that it occurs in approximately 25% of patients hospitalised with pneumonia. The most commonly identified viruses are influenza, rhinovirus and respiratory syncytial virus (RSV). Although viral and bacterial pneumonia have a similar short-term mortality, dual infection with both bacteria and virus is associated with a higher mortality (odds ratio 2:1).[22] The diagnosis is based on reverse transcriptase PCR of nasal or lower respiratory tract aspirates.

Table 36.3 Procedure for obtaining microbiological samples using bronchoscopy and protected specimen brushing and/or bronchoalveolar lavage

Infection control	In patients suspected of having a disease which is transmitted by the airborne route (e.g. tuberculosis): • the risk of transmission should be carefully weighed against the benefits of bronchoscopy, which may generate large numbers of airborne particles. • perform bronchoscopy in a negative-pressure isolation room • consider the use of a muscle relaxant in ventilated patients, to prevent coughing • staff should wear personal protective equipment which should include a fit-tested negative-pressure respirator (N95, FFP2 or above) as a minimum. Use of a powered air-purifying respirator should be considered
General recommendations	Suction through the endotracheal tube should be performed before bronchoscopy Avoid suction or injection through the working channel of the bronchoscope Perform protected specimen brushing before bronchoalveolar lavage
Ventilated patients	Set Fio_2 at 1.0 Set peak pressure alarm at a level that allows adequate ventilation Titrate ventilator settings against exhaled tidal volume Consider neuromuscular blockade in addition to sedation in patients at high risk of complications who are undergoing prolonged bronchoscopy
Protected specimen brushing (PSB)	Sample the consolidated segment of lung at subsegmental level If purulent secretions are not seen advance the brush until it can no longer be seen but avoid wedging it in a peripheral position Move brush back and forth and rotate it several times
Bronchoalveolar lavage (BAL)	Wedge tip of bronchoscope into a subsegment of the consolidated segment of lung Inject, aspirate and collect 20 mL of sterile isotonic saline. Do not use this sample for quantitative microbiology or identification of intracellular organisms. It can be used for other microbiological analysis Inject, aspirate and collect additional aliquots of 20–60 mL The total volume of saline injected should be 60–200 mL
Complications	Hypoxaemia (possibly less with smaller BAL volumes) Arrhythmia Transient worsening in pulmonary infiltrates Bleeding (particularly following PSB) Fever (more common after BAL)
Positive results	>5% of cells in cytocentrifuge preparations of BAL fluid contain intracellular bacteria OR $\geq 10^3$ colony forming units/mL in PSB specimen OR $\geq 10^4$ colony forming units/mL in BAL fluid

Meduri GU, Chastre J. The standardization of bronchoscopic techniques for ventilator-associated pneumonia. *Chest*. 1992;102(5 S1):557S–564S.

Influenza pneumonia is typically preceded by a prodrome of fever, chills, sore throat, myalgia and non-productive cough. CXR usually shows bilateral infiltrates. Multiorgan failure may occur, but the pattern of organ failure appears to vary between strains. A complicated course is more common in the elderly and very young, and those with chronic medical conditions.[23] Oseltamivir is recommended for critically ill patients although there is no direct evidence of outcome benefit. Glucocorticoids do not appear to be useful[21] and may prolong viral replication. Bacterial superinfection should be considered, with Gram-positive cocci being most frequently isolated.[22] Droplet and contact precautions should be followed routinely. Airborne precautions are recommended where aerosol-generating procedures are frequent.

Rhinovirus infection is difficult to distinguish from influenza, although a cough may be less common, and septic shock is a less common presentation to the ICU. Patients with severe infection (requiring mechanical ventilation or with septic shock) are more likely to be immunocompromised than patients with influenza. Mortality in the two groups is similar (approximately 50% in one series).[24]

RSV tends to present with wheezes, crackles and a pneumonic infiltrate in adults, but it is difficult to distinguish it from other viral infections on clinical grounds. There is no established therapy. Ribavirin and palivizumab have been used in immunocompromised patients. The use of corticosteroids to treat wheezing is controversial. Droplet and contact precautions should be adopted.[23,25]

Hospital-acquired pneumonia and ventilator-associated pneumonia

Hospital-acquired pneumonia (HAP) is defined as pneumonia with an onset occurring after 48 hours of hospital admission.[26] It occurs in 0.5%–5% of hospitalised patients, with a higher incidence in certain groups (e.g. postoperative patients and patients in ICU). Diagnosis may be difficult as many non-infectious conditions (e.g. atelectasis, pulmonary embolus, aspiration, heart failure, pulmonary haemorrhage and cancer) can cause chest infiltrates. Identification of the organism responsible is even more difficult than in patients with community-acquired pneumonia due to the high incidence of oropharyngeal colonisation by Gram-negative bacteria. Blood cultures are only positive in about 6% of cases of HAP. Ventilator-associated pneumonia (VAP) is pneumonia arising after 48 hours of invasive mechanical ventilation. The reported incidence of VAP is 10%–20% for those who receive mechanical ventilation for more than 48 hours.[23] The previously used term 'healthcare-associated pneumonia' is now obsolete in the latest Infectious Diseases Society of America (IDSA)/American Thoracic Society (ATS) hospital acquired pneumonia (HAP)/ventilator associated pneumonia (VAP) guidelines.[26]

PATHOGENESIS

HAP/VAP is thought to result from microaspiration of bacteria colonising the upper respiratory tract. Other routes of infection include macroaspiration of gastric contents, inhaled aerosols, haematogenous spread, spread from pleural space and direct inoculation from ICU personnel.

CLINICAL DIAGNOSIS

Diagnosis is based on the findings of new or progressive chest infiltrates plus either clinical features with simple laboratory investigations or the results of quantitative microbiology. In clinical terms, pneumonia is diagnosed by the finding of a new infiltrate or a change in an infiltrate on chest radiograph, and the growth of pathogenic organisms from sputum plus one of the following: WBC count greater than 12×10^5/L, core temperature ≥38.3°C or purulent sputum.

INVESTIGATIONS

These are broadly similar to those required in community-acquired pneumonia

- CXR: although studies using a histological diagnosis as the gold standard have demonstrated that pneumonia may be present despite a normal CXR, most definitions of HAP/VAP require the presence of new persistent infiltrates on a CXR.
- Respiratory secretions: considerable controversy surrounds the issue of whether invasive sampling of respiratory secretions is necessary, and whether quantitative culture improves diagnostic accuracy. Whether invasive (bronchoscopic BAL, protected specimen brushing or blind bronchial miniBAL, see Table 36.3) or non-invasive (tracheal aspirates) sampling is used, empiric broad-spectrum antibiotics should be started while results are awaited. The results of microbiological analysis of specimens are used to either stop antibiotics or narrow the spectrum.[26] Using histopathology as reference standard, tracheal aspirate using semi-quantitative culture has higher sensitivity but lower specificity compared to quantitative tracheal aspirate ($\geq 10^5$ colony-forming unit [CFU]/mL) or BAL ($\geq 10^4$ CFU/mL). Quantitative BAL and quantitative tracheal aspirate have similar sensitivity (approximately 50%) and specificity (approximately 80%). A meta-analysis of randomised trials shows that sampling sites and culture techniques do not affect clinical outcomes, such as the duration of mechanical ventilation, the ICU length of stay or mortality.[26] The latest IDSA/ATS guidelines[26] favour the use of non-invasive sampling with semi-quantitative culture for the diagnosis of VAP *(weak recommendation, low quality of evidence)*. While tracheal aspirates may predominantly reflect the organisms colonising the upper airway, they may be useful in indicating which organisms are not responsible for the pneumonia, thus allowing the antimicrobial cover to be narrowed.[26] This interpretation is based on the premise that the predominant route of infection is via the upper respiratory tract. From this it can be assumed that if the organism is not present in the upper respiratory tract, the probability of it being present in the lung parenchyma is low. Certain organisms are virtually always pathogens when recovered from respiratory secretions (see Table 36.2). Of note, the respiratory specimens should be processed within 2 hours if kept at room temperature and within 24 hours if kept at 4°C.
- Blood cultures: Blood cultures should be taken from all patients with HAP/VAP. Although only 8%–20% VAP patients are bacteraemic, bacteraemia is associated with a worse prognosis. Of note, at least 25% of positive blood cultures in patients with suspected VAP are from non-pulmonary source of sepsis, with important implications in antimicrobials treatment and source control.
- Newer techniques such as PCR/electrospray ionisation-mass spectrometry show promise as methods to provide rapid detection of microbiological pathogens in blood cultures and respiratory specimens.[27]

MANAGEMENT

Management is based on the finding that early treatment with antimicrobials that cover all likely pathogens results in a reduction in morbidity and mortality.[3]

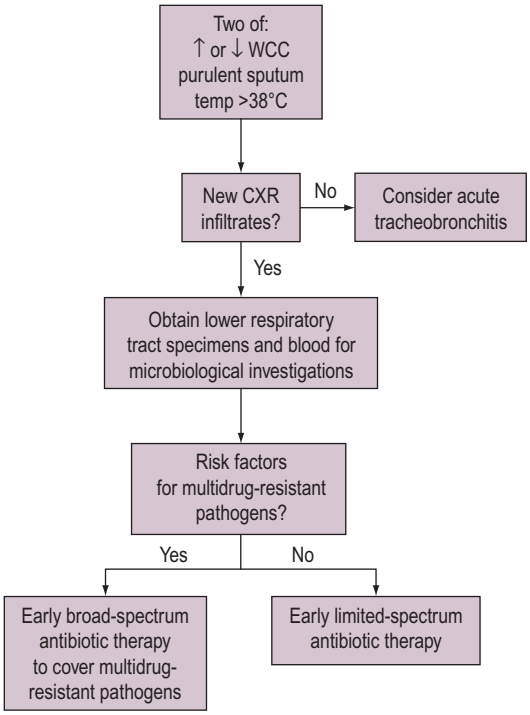

Figure 36.2 An outline of initial management of HAP/VAP based on a non-invasive clinical approach. *CXR*, Chest x-ray; *HAP*, hospital-acquired pneumonia; *VAP*, ventilator-associated pneumonia.

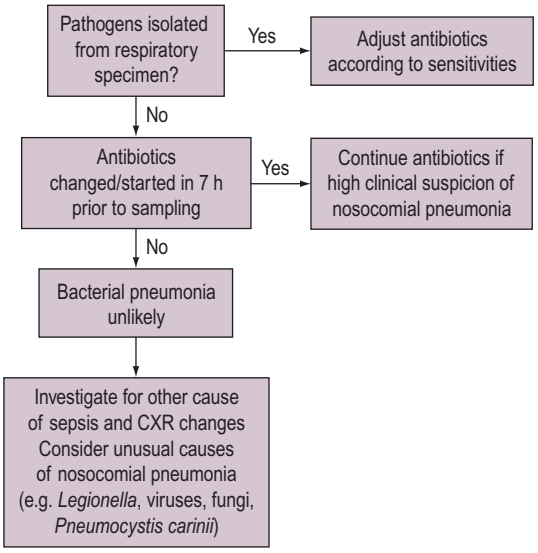

Figure 36.3 Subsequent management of nosocomial pneumonia based on a non-invasive clinical approach. *CSR*, Chest x-ray.

The initial selection of antimicrobials is based on risk factors for multidrug resistant (MDR) organisms and the local ICU/hospital antibiogram (Fig. 36.2, Table 36.4). *S. aureus*, *P. aeruginosa* and other Gram-negative bacilli should be covered in all empirical therapies *(strong recommendation, low-quality evidence)*. The results of microbiological investigations are used to narrow antimicrobial cover later. Treatment should be reassessed after 2–3 days or sooner if the patient deteriorates (Fig. 36.3).

DURATION OF THERAPY

Current IDSA/ATS guidelines[26] recommend 7 days rather than 8–15 days of antimicrobial treatment for both VAP and HAP *(strong recommendation, moderate-quality evidence)*. Systematic reviews confirmed no difference in important clinical outcomes such as mortality, length of stay and duration of mechanical ventilation. Short-course antibiotics increase 28-day antibiotic-free days and decrease recurrent VAP due to MDR organisms. There is concern in VAP caused by non-glucose fermenting Gram-negative bacilli (*Pseudomonas sp.* and *Acinetobacter sp.*) that 8-day therapies may have more recurrent infection when compared to 15-day therapies.[28] Although this finding is not universal, caution should be applied when considering short courses of antibiotics for non-glucose fermenting Gram-negative bacilli. Serial measurement of procalcitonin can be used to guide the duration of antibiotics,[19] but it is uncertain whether this can decrease antibiotic exposure in settings when a short-course of 7-day antibiotics is used.

RESPONSE TO THERAPY

Clinical improvement is usually not apparent for 48–72 hours and therapy should not be changed in this time. The CXR is of limited value for assessing response: initial deterioration is common and improvement often lags behind clinical response. However a rapidly deteriorating CXR pattern with a less than 50% increase in size of infiltrate in 48 hours, new cavitation or a significant new pleural effusion should raise concern. If a patient fails to respond, consider the diagnosis, host factors (e.g. immunosuppressed, debilitated), bacterial factors (e.g. virulent organism) and therapeutic factors (e.g. wrong drug, inadequate dose). Review the antibiotics and repeat cultures. It may be useful to broaden the antimicrobial cover while waiting for the results of investigations. Consider invasive sampling of respiratory secretions, CT or ultrasound of the chest (to look for an empyema or abscess), another source of infection, an open lung biopsy to establish diagnosis and aetiology, or the administration of steroids.

Mortality and morbidity attributable to ventilator-associated pneumonia

Substantial morbidity and mortality associated with VAP has previously been reported.[23] However, causal

Table 36.4 Recommended initial empiric treatment for nosocomial pneumonia

SITUATION	ANTIBIOTICS
No risk factors for multidrug-resistant pathogens	Piperacillin-tazobactam 4.5 g q6h *or* cefepime 2 g q8h *or* Levofloxacin 750 mg q24h *or* meropenam 1 g q8h, imipenam 500 mg q6h
Risk factors for multidrug-resistant organisms: • Prior intravenous antimicrobial therapy within 90 days • Hospitalisation for ≥5 days prior to onset of VAP • Septic shock at time of VAP • ARDS preceding VAP • Acute renal replacement therapy prior to VAP onset *or* • High frequency of antibiotic resistance in the local ICU/hospital antibiogram • >10%–20% *Staph aureus* isolates being resistant to methicillin • >10% of Gram-negative isolates being resistant to an agent considered for monotherapy) *or* Immunosuppression *or* Bronchiectasis *or* Cystic fibrosis	One of: Antipseudomonal cephalosporin (e.g. cefepime 2g q8h, ceftazidime 2g q8h) *or* Antipseudomonal carbapenem (e.g. meropenem 1 g q8h or imipenem-cilastin 500 mg q8h) *or* ß-lactam/ß-lactamase inhibitor (e.g. piperacillin-tazobactam 4.5g q6h, cefoperazone-sulbactam 2 g q8h) *or* Monobactam (aztreonam 2 g q8h) *PLUS* one of: Aminoglycoside 15–20 mg/kg q24h or Antipseudomonal quinolone (e.g. levofloxacin 750 mg q24h, ciprofloxacin 400 mg q8h) PLUS one of the following for patients at high risk of methicillin-resistant *Staphylococcus aureus* (MRSA) infection: Linezolid 600 mg q12h or vancomycin load 25–30 mg/kg, 15 mg/kg q12–8h

The use of dual therapy in susceptible Gram-negative isolates is not well supported by evidence but it does reduce the probability that the pathogen is resistant to the drugs being given. If an extended spectrum β lactamase-producing strain or an *Acinetobacter* spp. is suspected, a carbapenem should be given. If *Legionella pneumophilia* is suspected, use a quinolone. The risk factor for MDR HAP, MRSA HAP/VAP, MDR pseudomonas HAP/VAP was prior use of intravenous antibiotics within 90 days.

ARDS, Acute respiratory distress syndrome; *HAP*, hospital-associated pneumonia; *ICU*, intensive care unit; *MDR*, multidrug resistant; *MRSA*, methicillin-resistant *Staphylococcus aureus*; *VAP*, ventilator-associated pneumonia.

American Thoracic Society and Infectious Diseases Society of America. Guidelines for the management of adults with hospital-acquired, ventilator-associated, and healthcare associated pneumonia. *Am J Respir Crit Care Med*. 2005;171:388–416.

inference is difficult to be established. It should be noted that patients who developed VAP tended to be more severely ill and at a higher risk of death, not only at the time of ICU admission, but also throughout the course of their illness. While VAP is associated with a significantly longer ICU length of stay (mean of 6.1 days; 95% CI: 5.32–6.87), mechanical ventilation and increased health care cost,[23] recent studies suggest that mortality directly attributable to VAP is small.[25,26] While the attributable mortality for VAP was 4.4% on the 30th day of ICU and 5.9% on the 60th day, mortality directly due to the effect of VAP was found to be 1% and 1.5%, respectively, after controlling the evolution of severity of illness.[26] In another meta-analysis using pooled individual patients' data from 24 randomised controlled trials of VAP prevention, the attributable mortality of VAP was 13%. After using competing analysis, the increased risk of dying in ICU was concluded to be merely due to the results of prolonging ICU length of stay rather than a direct effect on VAP on mortality.[29]

PREVENTION

Several guidelines for prevention of VAP and HAP have been published, but these vary in the advice given. A consensus summary, based on literature review followed by a Delphi approach, is given in Table 36.5.[30]

TUBERCULOSIS

The main risk factors are listed in Table 36.6. Typical clinical features include fever, sweating, weight loss, lassitude, anorexia, cough productive of mucoid or purulent sputum, haemoptysis, chest wall pain, dyspnoea, localised wheeze and apical crackles. Patients

Table 36.5 Consensus strategies for prevention of ventilator-associated pneumonia

Positioning	Nurse in semirecumbent position (≥30 degrees)
Minimise duration of invasive mechanical ventilation	Assess daily for readiness to wean using spontaneous awakening trials and spontaneous breathing trials Facilitate use of non-invasive ventilation
Suctioning	Use subglottic suctioning in patients expected to be intubated for >72 h Use closed endotracheal suctioning and change catheters only as needed. Use standard precautions while suctioning respiratory tract secretions Avoid non-essential tracheal suctioning
Ventilator circuit	Change ventilator circuits only when damaged or soiled. Remove condensate from circuits, keeping circuit closed during removal and making sure condensate does not drain towards patient Change heat and moisture exchangers every 5–7 days or if clinically indicated
General care	Oral care at least 6 times per day, with chlorhexidine at least twice per day Use an early mobilisation protocol Avoid gastric overdistension
General infection control measures	Perform hand hygiene Avoid use of prophylactic systemic antimicrobials

Table 36.6 Risk factors for pulmonary tuberculosis

Living in or originating from a developing country
Age (<5 yrs, middle-aged and elderly men)
Alcoholism and/or drug addiction
HIV infection
Diabetes mellitus
Lodging house dwellers
Immunosuppression
Close contact with smear positive patients
Silicosis
Poverty and/or malnutrition
Previous gastrectomy
Smoking

may also present with unresolved pneumonia, pleural effusions, spontaneous pneumothorax and hoarseness, or with enlarged cervical nodes or other manifestations of extrapulmonary disease. In the most recent (retrospective) study, the in-hospital mortality for all patients with TB requiring ICU admission was 25.9%, but in those requiring mechanical ventilation it rose to 50%.[31] The presentation and management of TB in HIV-positive patients is different (see later).

INVESTIGATION OF PULMONARY TUBERCULOSIS[32]

IDENTIFICATION OF MYCOBACTERIA

Multiple[33,34] sputum samples should be collected, preferably on different days, for fluorescent microscopy for acid-fast bacilli (AFB) and culture. If sputum is not available, bronchial washings taken at bronchoscopy and gastric lavage or aspirate samples should be obtained. Gastric aspirates need to be neutralised immediately on collection. Bronchoscopy and transbronchial biopsy may be useful in patients with suspected TB but who have a negative sputum smear. Pleural biopsy is often helpful and mediastinoscopy is occasionally needed in patients with mediastinal lymphadenopathy. Part of any biopsy specimen should always be sent for culture. The Xpert MTB/RIF gene probe system is able to simultaneously identify the presence of *M. tuberculosis* and rifampicin resistance. As rifampicin is strongly associated with isoniazid resistance, the system can give a strong indication of multidrug resistance. In sputum samples, the system has a sensitivity of approximately 90% (compared to 65% for a single AFB smear) with a specificity of 99%. Sensitivity (67%) is lower in smear-negative patients and patients with HIV (approximately 80%).[33]

CHEST X-RAY

A normal CXR almost excludes TB (except in HIV infected patients) but endobronchial lesions may not be apparent, and early apical lesions can be missed. Common appearances include patchy/nodular shadowing in the upper zones (often bilateral), cavitation, calcification, hilar or mediastinal lymphadenopathy (may cause segmental or lobar collapse), pleural effusion, tuberculomas (dense round or oval shadows) and diffuse fine nodular shadowing throughout the lung fields in miliary TB. Inactivity of disease cannot be inferred from the CXR alone. This requires three negative sputum samples *and* failure of any lesion seen on CXR to progress. CXR appearances in HIV-positive patients with TB differ from non–HIV-infected patients.

TREATMENT OF PULMONARY TUBERCULOSIS[34,35]

The decision to initiate anti-TB treatment should be based on the level of clinical suspicion, the results of the AFB smear or the gene probe, and sometimes mycobacterial culture. If the initial clinical suspicion is strong and the patient is seriously ill attributable to possible TB, treatment should be initiated promptly, sometimes before the result of the AFB smear. Subsequent positivity of the AFB smear or the gene probe provides support for the continuation of treatment. Combination chemotherapy consisting of four drugs is necessary for maximal efficacy. Treatment is divided into the initial phase and the continuation phase. The most commonly used initial regimen consists of 8 weeks of rifampicin 600 mg daily (450 mg for patients <50 kg), isoniazid 300 mg daily, pyrazinamide 2 g daily (1.5 g for patients <50 kg) and ethambutol 15 mg/kg daily as an initial phase treatment. Ethambutol should only be used in patients who have reasonable visual acuity and who are able to appreciate and report visual disturbances. This excludes patients who require sedation. Visual acuity and colour perception must be assessed (if ethambutol is to be used) and liver and renal function checked before treatment is started. Steroids are recommended for children with endobronchial disease and, possibly, for patients with TB pleural effusions. Pyridoxine 10 mg daily should be given to prevent isoniazid-induced neuropathy to those at increased risk (e.g. patients with diabetes mellitus, chronic renal failure or malnutrition, or alcoholic or HIV-positive patients). A negative AFB smear should not delay initial treatment if clinical suspicion remains high. Supporting features included chronic cough, weight loss, characteristic CXR findings, emigration from a high incidence country, no other immediate diagnosis and a positive tuberculin test.

INFECTION CONTROL

Patients admitted to an ICU with infectious TB or suspected of having active pulmonary TB should be managed in an isolation room with special ventilation characteristics, including negative pressure. Patients should be considered infectious if they are coughing or undergoing cough-inducing procedures, or if they have positive AFB smears and they are not on or have just started chemotherapy, or have a poor clinical or bacteriological response to chemotherapy.[35,36] Patients with non–drug-resistant TB should be non-infectious after 2 weeks of treatment that includes rifampicin and isoniazid.[35] As TB is spread through aerosols it is probably appropriate to isolate patients who are intubated, even if only their bronchial washings are smear positive. Staff caring for patients for patients who are smear positive should wear personal protective equipment including a fit-tested negative-pressure respirator (N95, FFP2 or higher). The use of a powered air-purifying respirator should be considered when bronchoscopy is being performed, particularly if the patient has not received effective treatment, is smear positive and if the bronchoscopy is being carried out in a room with less than 12 air changes per hour.[36]

PNEUMONIA IN THE IMMUNOCOMPROMISED

The lungs are amongst the most frequent target organs for infectious complications in the immunocompromised. The incidence of pneumonia is highest amongst patients with haematological malignancies, bone marrow transplant (BMT) recipients and patients with AIDS.

The speed of progression of pneumonia, the CXR changes (Table 36.7) and the type of immune defect provide clues to the aetiology. Bacterial pneumonias progress rapidly (1–2 days), while fungal and protozoal pneumonias are less fulminant (several days to a week or more). Viral pneumonias are usually not fulminant, but on occasion they may develop quite rapidly. Bronchoscopy is a major component of the investigation of these patients. Empiric management based on CXR appearances is outlined in Table 36.6. There is some evidence that early non-invasive ventilation may reduce the need for intubation amongst immunocompromised patients with fever and bilateral infiltrates,[37] but it did not reduce the need for intubation nor the mortality in patients with haematological malignancy or solid-organ transplants.[38]

PNEUMOCYSTIS JIROVECI PNEUMONIA[39]

Most cases occur in patients with HIV who are not receiving HIV care or who have advanced immunosuppression, or in patients with other causes of immunosuppression (e.g. haematological malignancy). The onset is usually insidious with dry cough, dyspnoea and fever on a background of fatigue and weight loss. Crackles in the chest are rare. A rise in LDH is common but non-specific. Approximately 15% of patients have a concurrent cause for respiratory failure (e.g. Kaposi sarcoma, TB, bacterial pneumonia). Useful investigations are:

1. CXR: classical appearance is diffuse bilateral perihilar interstitial shadowing, but in the early stages this is very subtle and easily missed. The initial CXR is normal in 10%. In a further 10% the changes are atypical with focal consolidation or coarse patchy shadowing. None of the changes are specific for pneumocystis jiroveci pneumonia (PCP) and may be seen in other lung diseases associated with AIDS. Pleural effusions, hilar or mediastinal lymphadenopathy are unusual in PCP, but are common in mycobacterial infection, Kaposi's sarcoma or lymphoma.

Table 36.7 Causes of CXR changes and empiric treatment of pneumonia in the immunocompromised

CHEST X-RAY APPEARANCE	CAUSES	EMPIRIC TREATMENT FOR SUSPECTED PNEUMONIA
Diffuse infiltrate	Cytomegalovirus (CMV) and other herpes viruses Pneumocystis carinii Bacteria Aspergillus (advanced) Cryptococcus (uncommon) Non-infectious causes (e.g. drug reaction, non-specific interstitial pneumonitis, radiation pneumonitis [uncommon], malignancy, leucoagglutinin reaction, heart failure secondary to cardiotoxic chemotherapy)	Broad-spectrum antibiotics for at least 48 h (e.g. third-generation cephalosporin and aminoglycoside). Cotrimoxazole. Lung biopsy or lavage within 48 h or full 2-week course of cotrimoxazole (depends on patient tolerance of invasive procedure)
Focal infiltrate	Gram-negative rods Staph aureus Aspergillus Cryptococcus Nocardia Mucor Pneumocystis carinii (uncommon) Tuberculosis Legionella Non-infectious causes (e.g. malignancy, nonspecific interstitial pneumonitis, radiation pneumonitis)	Broad-spectrum antibiotics. If response seen continue treatment for 2 weeks If disease progresses lung biopsy/aspirate within 48–72 h or empiric trial of anti-fungal ± macrolide

2. Induced sputum. In this technique the patient inhales nebulised hypertonic saline from an ultrasonic nebuliser. This provokes bronchorrhoea and the patient coughs up material containing cysts and trophozoites. This is time consuming and requires meticulous technique, and is less sensitive than bronchoscopy but less invasive. The possibility of concurrent TB should be considered and steps taken to minimise the risk of spread of infection.
3. Bronchoscopy with bronchoalveolar lavage leads to the diagnosis in over 90% of cases. Specimens should be sent for cytology. PCR is a sensitive method of detecting PCP but may not be able to distinguish colonisation from infection. The role of PCR in diagnosing PCP is mainly limited to non-HIV patients, in whom conventional microscopy and staining of induced sputum and BAL has a lower sensitivity than in HIV patients.[12]

Anti-pneumocystis treatment should be started as soon as the diagnosis is suspected. Treatment should not be delayed to obtain specimens as organisms persist in specimens for days to weeks after effective treatment is initiated. The treatment of choice is trimethoprim plus sulphamethoxazole (co-trimoxazole) 20 mg/kg per day + 100 mg/kg per day for 3 weeks. In patients with HIV infection, give adjunctive steroids as soon as possible and within 72 hours: prednisolone 40 mg orally twice daily for 5 days followed by 20 mg twice daily for 5 days and then 20 mg/day until the end of PCP treatment. Side effects of cotrimoxazole are common (nausea, vomiting, skin rash, myelotoxicity, nephrotoxicity, hepatotoxicity). The dose should be reduced by 25% if the WBC count falls. Patients who are intolerant of cotrimoxazole should be treated with:

- Pentamidine 4 mg/kg per day intravenously or
- Primaquine with clindamycin

Response to treatment is usually excellent, with a response time of 4–7 days. If the patient deteriorates or fails to improve by 8 days of treatment: consider (re-) bronchoscopy (is the diagnosis correct?), treat co-pathogens and consider a short course of high-dose intravenous methylprednisolone and/or diuretics (patients often fluid overloaded). Approximately 70% of patients with HIV-related PCP, but only 40% of patients with non–HIV-related PCP, who require mechanical ventilation survive to hospital discharge.[40]

Antiretroviral therapy should be initiated, when possible, in patients who are not already receiving it and who present with HIV-related PCP, within 2 weeks of the diagnosis of PCP. Although this may precipitate paradoxical immune reconstitution inflammatory syndrome, the syndrome is rarely life threatening and early antiretroviral therapy is associated with better outcomes (Guidelines for Prevention and Treatment of Opportunistic Infections in HIV-Infected Adults and Adolescents).

For more detailed advice on management of patients with HIV-associated PCP go to https://aidsinfo.nih.gov/guidelines.

BACTERIAL PNEUMONIA[41]

This is the most common cause of acute respiratory failure in HIV-positive patients. Bacterial pneumonia is more common in HIV-infected patients than in the general population and tends to be more severe. *Strep. pneumoniae, H. influenza, Pseudomonas aeruginosa* and *S. aureus* are the most common organisms. *Nocardia* and Gram negatives should also be considered. Atypical pathogens (e.g. *Legionella*) are rare. The response to appropriate antibiotics is usually good but may require protracted courses of antibiotics because of the high tendency to relapse. Patients with severe immunodeficiency ($CD4^+$ T lymphocyte count <100/μL) and a history of *Pseudomonas* infection or bronchiectasis or neutropenia should receive antibiotics that cover *P. aeruginosa* as well as other Gram negatives. The possibility of concurrent PCP or TB should be excluded.

TUBERCULOSIS

TB may be the initial presentation of AIDS, particularly in sub-Saharan Africa. The pattern of TB in HIV patients depends on the degree of immunosuppression. In patients with $CD4^+$ T lymphocytes greater than 200 cells/μL the clinical presentation is similar to TB in non–HIV-infected patients although extrapulmonary disease is more common. In patients with $CD4^+$ T lymphocytes less than 200 cells/μL, extrapulmonary disease (pleuritis, pericarditis, meningitis) is common. Severely immunocompromised patients ($CD4^+$ T lymphocytes <100 cells/μL) may present with severe systemic disease with high fever and rapid progression sepsis. In these patients, lower and middle lobe disease is more common; miliary disease is common; and cavitation is less common. Sputum smears and culture may be positive even with a normal CXR.

Response to treatment is usually rapid. Initial treatment should be the same as non–HIV-infected patients, except in those receiving antiretrovirals. Management of TB in in these patients is complex due to numerous drug interactions, and consultation with an expert in treatment HIV-related TB should be strongly considered. The National Institutes of Health guidelines for doses of first-line drugs are given at https://aidsinfo.nih.gov/guidelines/html/4/adult-and-adolescent-oi-prevention-and-treatment-guidelines/356/tb-drug-dosing.

CYTOMEGALOVIRUS (CMV) PNEUMONITIS[42,43]

The risk of infection is highest following haematological stem cell transplantation, followed by lung transplantation, pancreas transplantation and then liver, heart and renal transplantation and advanced AIDS. If both the recipient and the donor are seronegative then the risk of both infection and disease are negligible. If the recipient is seropositive, the risk of infection is approximately 70% but the risk of disease is only 20%, regardless of the serostatus of the donor. However, if the recipient is seronegative and the donor is seropositive the risk of disease is 70%. If steroid pulses and antilymphocyte globulin are given for the treatment of acute rejection, the risk of developing disease is markedly increased. Infection may be the result of primary infection or reactivation of latent infection. It is clinically important, but often difficult, to distinguish between CMV infection and CMV disease, and a definitive diagnosis can only be made histologically. Quantitative PCR can be used to quantify viral load in blood and BAL fluid, which will aid the distinction. Treatment consists of intravenous ganciclovir for at least 14 days. Foscarnet can be used if ganciclovir fails.

FUNGAL PNEUMONIA

Fungi are rare but important causes of pneumonia. They can be divided into two main groups based on the immune response required to combat infection with these organisms. Histoplasma, blastomycosis, coccidioidomycosis, paracoccidioidomycosis and cryptococcus require specific cell-mediated immunity for their control and thus, in contrast to infections, which are controlled by phagocytic activity, the diseases caused by these organisms can occur in otherwise healthy individuals, although they cause much more severe illness in patients with impaired cell-mediated immunity (e.g. patients infected with HIV, and organ transplant recipients). With the exception of cryptococcus, these organisms are rarely seen outside North America. Aspergillus and mucor spores are killed by non-immune phagocytes, so these fungi rarely result in clinical illness in patients with normal neutrophil numbers and function.

CANDIDIASIS

Primary *Candida* pneumonia (i.e. isolated lung infection) is uncommon[44–46] and the isolation of *Candida* from respiratory secretions most commonly reflects benign colonisation of the airway. Where it is associated with infection, pulmonary lesions are usually only one manifestation of disseminated candidiasis. Echinocandins are the recommended first-line treatment in the critically ill.

INVASIVE ASPERGILLOSIS[47]

Invasive aspergillosis was previously believed to be almost exclusively associated with severe immunocompromise. However, recent data suggest that the majority of cases in the ICU are not severely immunocompromised, with chronic obstructive pulmonary disease and decompensated liver disease being significant patient risk factors. Exposure to construction, demolition or renovation work is an important environmental risk factor. Definitive diagnosis requires both histological evidence of acute-angle branching,

Table 36.8 Diagnostic criteria for putative invasive pulmonary aspergillosis

CRITERIA			
Aspergillus isolate AND	Positive isolate from respiratory tract specimen		
Clinical features At least one feature AND	Fever refractory to ≥3 days' appropriate antibiotic therapy Unexplained recurrence of fever, while still on antibiotics after a defervescence of ≥48 h Pleuritic chest pain Dyspnoea Haemoptysis Worsening respiratory failure despite appropriate antibiotics and ventilatory support		
Imaging AND	Abnormal chest X-ray or CT scan of lungs		
Risk factors or invasive cultures	Neutropaenia before or on ICU admission Malignancy treated with cytotoxic agents Glucocorticoid treatment (prednisolone >20 mg/day or equivalent) Immunodeficiency	OR	Semi-quantitative Aspergillus +ve culture of BAL fluid (+ or ++), without bacterial growth together with +ve smear showing branching hyphae

BAL, Bronchoalveolar lavage; *CT*, computed tomography; *ICU*, intensive care unit.

septated non-pigmented hyphae measuring 2–4 µm in width, and cultures yielding *Aspergillus* species from biopsy specimens of involved organs, but this is rarely practical in critically ill patients. The new diagnostic category, putative invasive pulmonary aspergillosis (Table 36.8) provides a more useful guide for clinicians caring for critically ill patients. The criteria have a 61% specificity and 92% sensitivity for invasive pulmonary aspergillosis. Recovery of *Aspergillus* species from respiratory secretions in immunocompromised, but not immunocompetent, patients may indicate invasive disease with a positive predictive value as high as 80%–90% in patients with leukaemia or BMT recipients. Galactomannan antigen detection has high specificity for invasive pulmonary aspergillosis in both serum and BAL fluid, but has much greater sensitivity in BAL fluid.

Early intravenous treatment is important. First-line therapy is voriaconazole. Liposomal amphotericin is an alternative and echinocandins can be used as salvage therapy.[48]

PARAPNEUMONIC EFFUSION

This may be an uncomplicated effusion that resolves with appropriate treatment of the underlying pneumonia, or a complicated effusion that develops into an empyema unless drained. Complicated effusions tend to develop 7–14 days after initial fluid formation. They are characterised by increasing pleural fluid volume, continued fever and pleural fluid with low pH (<7.2) and high LDH concentration (>1000 IU/L),[49] which contains a large number of neutrophils and may reveal organisms on Gram staining or culture.

EMPYEMA[49]

DEFINITION

Collection of pus in the pleural space

AETIOLOGY

This most commonly follows bacterial pneumonia and parapneumonic effusion. Other causes include bronchial carcinoma, oesophageal rupture, extension of subdiaphragmatic infection, chest trauma, mediastinitis and infections of the thoracic or cervical spine. Anaerobic bacteria, usually streptococci or Gram-negative rods are responsible for 76% of cases.

DIAGNOSIS

The diagnosis should be considered in all patients with a pleural effusion and pneumonia or unexplained sepsis. Failure of clinical improvement within a few days in a patient with pneumonia should prompt investigation to identify a pleural effusion. Imaging should include a CXR ± ultrasound. Ultrasound may reveal loculated effusions that are obscured by consolidation on the CXR. CT scanning may reveal loculations, show features indicative of infection, demonstrate the underlying cause and distinguish between an abscess and an empyema. The diagnosis is confirmed by the aspiration of pus. In the absence of pus, measure the pleural fluid pH and LDH. A pH <7.2 or LDH >1000 IU/L are predictive of complicated parapneumonic effusions that require drainage. Pleural fluid taken at the time of pleurocentesis should be sent for culture. Fluid from drains gives unreliable results.

TREATMENT

The mainstay of treatment is image-guided drainage. There is controversy regarding the optimal drain size. The traditional belief is that small-bore catheters are ineffective for drainage of thick pus or in the presence of extensive septation within the empyema, but there a few data to provide guidance. Routine flushing of the drain (e.g. 20 mL normal saline every 6 hours) reduces the risk of drain occlusion. The adequacy of drainage should be monitored with repeated thoracic CT. Any undrained loculations should be treated by the use of larger or additional drains. Intrapleural-tissue-plasminogen-activator and DNase may be beneficial in patients with more advanced disease, but are not routinely indicated in patients with early empyema. Failure to achieve complete drainage or failure to improve should prompt a referral to a thoracic surgeon. Antibiotics have only an adjunctive role. Broad-spectrum antibiotic regimes with anaerobic cover should be used until the results of microbiological analysis of the aspirated pus are available.

Non-invasive ventilation

Graeme J Duke, Andrew D Bersten

Non-invasive ventilation (NIV) is a valuable therapeutic option in the management of acute and chronic respiratory failure – for certain diagnoses it is the preferred option. The application of NIV predates the introduction of laryngoscopy (early 1900s) and the widespread use of positive-pressure mechanical ventilation (MV) via an endotracheal tube in the 1950s.[1] The clinical benefit of NIV in acute respiratory failure (ARF) was first publicised in 1936.[2]

NIV is defined as ventilatory support without an (invasive) endotracheal airway. NIV should be considered as standard therapy in the early management of rapidly reversible ARF,[3,4] and in domiciliary management of chronic respiratory failure due to obstructive sleep apnoea (OSA) and neuromuscular disease.

NIV may be achieved either through the delivery of positive pressure to the airway (P_{ao}) or the application of a negative-pressure generator to the chest ('chest box' or cuirass) or body ('iron lung'). A conceptual framework is shown in Fig. 37.1.

Negative-pressure generators may be used for the management of acute or chronic respiratory disease.[5] Major limitations to the use of negative-pressure generators include the induction of OSA, lack of fractional inspired oxygen (Fi_{O_2}) control, equipment bulk and size.[6] However, external negative-pressure generators suit some patients with chronic respiratory failure, particularly as there is no oral or nasal prosthesis.

This chapter deals primarily with the use of positive-pressure NIV to treat ARF. The clinical efficacy of NIV depends upon: (1) the ventilatory mode selected and (2) the nature and severity of the underlying respiratory pathophysiology.[7,8] Correctly applied NIV reduces morbidity and mortality, whereas incorrect or inappropriate application may delay definitive therapy and adversely affect the outcome.[9] The physiological rationale for NIV will assist the clinician in understanding the indications and benefits, and predict the side effects of each mode of NIV.

PHYSIOLOGY OF NON-INVASIVE VENTILATION

Several important aspects regarding ventilatory support are discussed in Chapter 31, and this chapter will focus on those aspects specific to NIV.

The physiological benefits of NIV are similar to those of invasive ventilatory support. NIV can reverse many of the adverse physiological and mechanical derangements associated with ARF, through a combination of:

- augmentation of alveolar ventilation (V_A) to reverse respiratory acidosis and hypercarbia
- alveolar recruitment and increased Fi_{O_2} to reverse hypoxia
- reduction in work of breathing (W_{mus}) to reduce or prevent respiratory muscle insufficiency
- stabilisation of the chest wall in the presence of chest trauma or surgery
- reduction in left ventricular (LV) afterload that may lead to improved cardiac function
- reduction of right ventricular (RV) afterload and improved RV function.[10]

In brief, the respiratory effort (pressure–volume work) required to achieve a desired minute volume (V_E) may be viewed as the summation of the individual forces that must be overcome to generate inspiratory flow, namely: elastic work (or 'stretch'; W_{el}), flow-resistive work (air-flow obstruction; W_{res}) and threshold work. Intrinsic positive end-expiratory pressure (PEEPi) and dynamic hyperinflation are absent in the healthy lung, but are common in the presence of tachypnoea or expiratory airflow obstruction. During flow limitation, PEEPi impedes the onset (triggering) of inspiratory support modes (inspiratory positive airway pressure [IPAP] and pressure support ventilation [PSV]). Threshold load (PEEPi) must be counterbalanced by additional inspiratory effort before inspiratory flow can commence. External PEEP (CPAP) that matches PEEPi will aid in reducing this component of elastic work W_{el}.

Since the volume component is constant the equation of motion can be written as:

$$P_{mus} = P_{el} + P_{res} \quad (37.1)$$

(See Chapter 31, for more detailed explanation.)

With the addition of a device for ventilatory support, the respiratory muscle effort (P_{mus}) required by the patient is equivalent to the difference between the applied P_{ao} and the total work required to maintain V_E:

ABSTRACT

Non-invasive ventilation (NIV) has been successfully applied in patients with acute respiratory failure (ARF) caused by cardiogenic pulmonary oedema (CPO), chronic obstructive pulmonary disease (COPD) and chronic respiratory failure due to sleep apnoea and neuromuscular disorders. NIV should be considered as standard therapy for respiratory support in these patients before considering invasive mechanical ventilation. Continuous positive airway pressure (CPAP) alone appears to be beneficial in ARF due to CPO and COPD with threshold load. Bilevel (or pressure support ventilation with CPAP) is beneficial in patients with hypercapnic ARF secondary to respiratory muscle insufficiency, high inspiratory workloads or reduced alveolar ventilation. NIV does not appear to benefit patients with severe pneumonia, acute respiratory distress syndrome or postoperative respiratory failure. Its role in ARF due to pneumonia in immune-compromised subjects, acute asthma and blunt chest trauma remains unclear.

KEYWORDS

Non-invasive ventilation
acute respiratory failure

CPAP
BiPAP

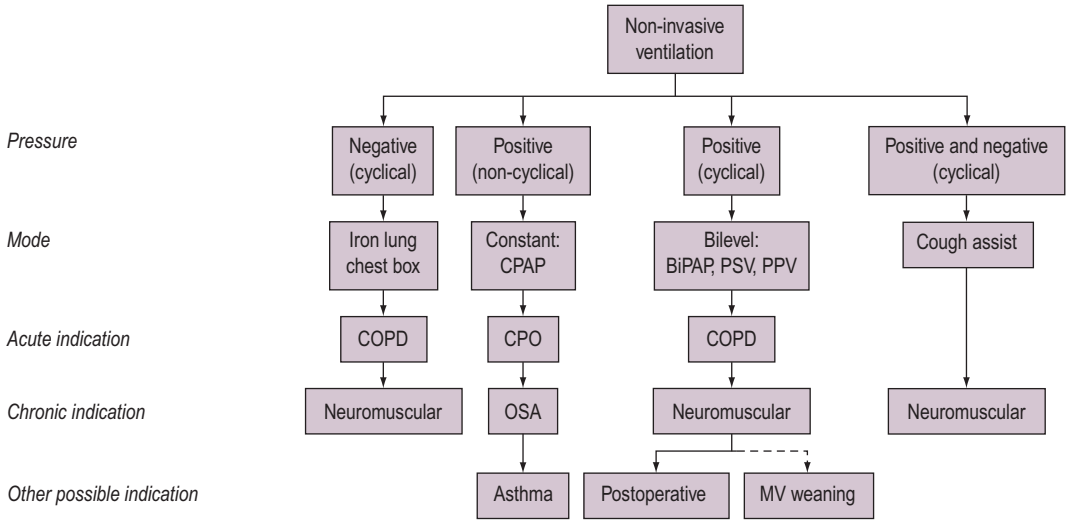

Figure 37.1 Conceptual non-invasive ventilation paradigm. *BiPAP*, Biphasic positive airway pressure; *CPAP*, continuous positive airway pressure; *COPD*, chronic obstructive pulmonary disease; *CPO*, cardiogenic pulmonary oedema; *MV*, mechanical ventilation; *OSA*, obstructive sleep apnoea; *PPV*, positive-pressure ventilation; *PSV*, pressure support ventilation.

$$P_{mus} = (P_{el} + P_{res}) - P_{ao} \quad (37.2)$$

This relationship may be rearranged into its individual components, as follows:

$$P_{mus} + P_{ao} = E \bullet V + R \bullet \dot{V} + \text{PEEPi} \quad (37.3)$$

where E is the respiratory elastance (inverse of compliance), V is the volume of gas, R is the respiratory and circuit flow resistance, $\dot{V}$ is the inspiratory flow rate and PEEPi is the intrinsic PEEP.

It is important to remember that breathing via a circuit will create additional air-flow resistance (R) adding to breathing work (P_{mus}), and thus attention to circuit design is important (see below).

Respiratory failure occurs when the forces opposing inspiration – namely elastic (P_{el}), resistive (P_{res}) and threshold (PEEPi) work – exceed the respiratory muscle effort (P_{mus}) required to maintain V_E. Hypermetabolic states (e.g. trauma, sepsis) increase basal V_E, whereas pulmonary and chest wall diseases increase respiratory workload and neuromuscular disease impairs respiratory muscle effort. NIV may prevent respiratory failure by counterbalancing the increased respiratory workload and/or reducing respiratory muscle effort, and thus maintain V_A.

Any invasive MV mode may be delivered non-invasively, and four are commonly described in clinical research: CPAP, PSV, bilevel or biphasic positive airway pressure (BiPAP) and pressure- or volume-limited intermittent positive-pressure ventilation. Other modes under investigation include high-frequency and proportional assist ventilation.

All NIV modalities utilise semiclosed or closed circuits and are thus capable of reliably delivering high Fi_{O_2}. This is an important mechanism by which NIV improves oxygenation, independently of other mechanisms discussed below.

CONTINUOUS POSITIVE AIRWAY PRESSURE

CPAP is a form of NIV because it provides respiratory support even though the P_{ao} applied is constant throughout the respiratory cycle. This mode addresses a number of the objectives of ventilatory support, namely:

- reduction in the work of breathing by:
  - alveolar recruitment and reduction in elastic work
  - reducing threshold load created in the presence of PEEPi
- reversing hypoxia through the delivery of high Fi_{O_2}, alveolar recruitment, and the reduction of intrapulmonary shunt
- reduction of LV transmural pressure (afterload).[10,11]

INSPIRATORY POSITIVE AIRWAY PRESSURE AND PRESSURE SUPPORT VENTILATION

Positive inspiratory airway pressure without expiratory pressure (e.g. PSV or IPAP), provides respiratory support by reducing both the elastic and the resistive components of respiratory work resulting in:

- augmentation of tidal volume (V_E) and minute volume (V_E) and reduction in $PaCO_2$
- reduction in P_{mus} with diminished, or the prevention of, respiratory muscle insufficiency
- induction of pulmonary surfactant release through alveolar inflation above resting tidal volume.[12]

Bilevel positive airway pressure allows separate settings for inspiratory (IPAP) and expiratory (EPAP) airway pressure levels; it is equivalent to PSV plus CPAP.[13] Respiratory frequency is usually patient-dependent but may be mechanically time cycled and independent of patient effort.

CONTROLLED VENTILATION

NIV may also be administered as volume- or pressure-limited MV applied via a mask (instead of an endotracheal airway).

PATIENT–VENTILATOR INTERACTION

This is discussed in Chapter 31, and subdivided into: (1) triggering of inspiration, (2) inspiration and (3) cessation of inspiration. Asynchrony is a common cause of NIV failure arising from gas leaks due to poor mask fit.[14] Mask leaks interfere with the ability to sense the end of expiration because there is continued 'expiratory' gas flow.

NON-INVASIVE VENTILATION EQUIPMENT

Equipment design varies according to NIV mode and purpose (e.g. critical care or domiciliary setting), and significant variations in performance characteristics have been documented.[1,15] The important characteristics of an efficient NIV circuit include:

- high gas flow to match peak inspiratory air flow – high flows may be generated by a pressurised gas supply, a gas turbine or a jet venturi mechanism: a device providing continuous flow imposes less circuit work than a demand flow device
- an expiratory (threshold) resistor capable of maintaining the desired PEEP, yet offering a low resistance to expiratory flow to reduce fluctuations in the delivered P_{ao} – this may be a threshold resistor or flow resistor; the optimal position for the expiratory valve is as close to the patient's airway as possible
- short wide-bore tubing to reduce turbulence and flow resistance
- a flow or pressure sensor to identify inspiratory effort and facilitate triggering of the predetermined inspiratory pressure support (e.g. PSV or IPAP)
- ability to control and deliver a wide range of Fi_{O_2}
- other desirable features include the humidification, pressure-relief safety valves, battery back-up, apnoea back-up support, acoustic suppression and monitoring of volume and P_{ao}. These are important for management of ARF and less important for domiciliary (long-term) NIV devices.

Several varieties of mask design are also available and the optimal configuration depends upon the purpose and mode of NIV, patient anatomy, and preference. These include intranasal, nasal, and oronasal, full-face and helmet (full-head) masks. Desirable features of a mask include lightweight and transparent materials affording a comfortable airtight seal, minimal dead space, and separate inspiratory and expiratory ports to minimise air-flow turbulence[15] and rebreathing.[16] In lung model studies, expiratory ports over the nasal bridge reduce dead space,[17] which may prove to be clinically advantageous. Orofacial masks have a lower dead space than full-face masks or helmet designs,[18] but a higher risk of air leak.[14]

Mask discomfort, arising from the mask seal, air leaks, humidification or claustrophobia, are common causes of non-compliance. Masks that cover nose and mouth tend to produce more reliable and constant P_{ao} because they are unaffected by mouth breathing – a common problem in the critically ill patient. Nasal masks are less restrictive on the patient's ability to talk, eat/drink and expectorate, and therefore gain higher compliance in long-term and domiciliary applications. To effectively compensate for air leaks, nasal masks should be used with circuits capable of rapidly augmenting and delivering high gas flow (>100 L/min).

Fibreoptic bronchoscopy can be safely performed during NIV,[19-21] using a full-face mask with at least two ports. One of these can be modified to provide a simple valve for insertion of the bronchoscope, and the other used for NIV. Provided there is adequate flow reserve during suction, this can be performed during any mode of NIV. This technique may allow both diagnostic and therapeutic bronchoscopic intervention without intubation even in critically ill patients.

COMPLICATIONS AND ASSESSMENT OF EFFICACY

Contraindications and complications specific to NIV are listed in Box 37.1. Acutely unwell patients requiring NIV should be managed in a critical care ward, or similar area with appropriately trained on-site medical and nursing staff. Although availability of sophisticated, portable non-invasive ventilators makes it easy to provide NIV in any environment, its benefits may diminish outside the critical care environment.[22,23]

The reversal of hypoxia and the reduction in respiratory effort is commonly observed with the commencement of NIV, yet they are a poor guide to the efficacy of NIV. More reliable clinical measures of NIV efficacy include the reversal of hypercarbia, a sustained improvement in respiratory function and outcomes, such as a reduction in intubation, nosocomial pneumonia and mortality.

Box 37.1 Contraindications and complications of non-invasive ventilation

Contraindications
- Respiratory arrest
- Unprotected airway (coma, sedation)
- Upper airway obstruction
- Inability to clear secretions
- Untreated pneumothorax
- Marked haemodynamic instability

Complications
- Mask discomfort, patient intolerance
- Facial or ocular abrasions
- Nasal congestion, sinus pain
- Oronasal dryness
- ↑ Intraocular pressure (particularly in patients with glaucoma)
- ↑ Intracranial pressure (particularly in patients with neurotrauma)
- ↓ Blood pressure (if hypovolaemic)
- Aspiration pneumonia (rare)
- Aerophagy and gastric distension (uncommon; routine gastric decompression is unnecessary)

NON-INVASIVE VENTILATION AND ACUTE RESPIRATORY FAILURE

CARDIOGENIC PULMONARY OEDEMA

Cardiogenic pulmonary oedema (CPO) is a common cause of severe reversible ARF. Since the 1930s, the therapeutic benefits of all modes of NIV, particularly CPAP have been well documented.[24-26] CPO leads to an increase in elastic workload (P_{el}) and, to a lesser extent, resistive workload (P_{res}), an increase in lung water and impaired surfactant function. CPAP reverses hypoxia, recruits alveoli and reduces intrapulmonary shunt and LV afterload. The redistribution of extravascular lung water from alveoli to the interstitial space is aided by the recruitment of alveoli and improved surfactant function.

Over 30 prospective, randomised, controlled trials of NIV in CPO have consistently demonstrated physiological improvements in hypoxic and hypercapnic respiratory failure, and a significant reduction in the need for intubation (relative risk 95% confidence interval [RR 95% CI]), duration of respiratory support, hospital length of stay, and improved survival (RR 95% CI = 0.44–0.92).[22,24]

NIV should be considered part of standard therapy for CPO.[1,22] The optimal mode of NIV in CPO appears to be CPAP.[27] The optimal P_{ao} level remains to be resolved, although 10 cm H_2O appeared to be safe and effective in the majority of subjects. The addition of a differential inspiratory pressure (e.g. IPAP and PSV) may be as effective as CPAP in avoiding (95% CI, RR = 0.33–0.86) intubation without survival benefit[28,29] and may increase the rate of myocardial infarction (95% CI, RR = 0.92–2.42).[24]

Benefits appear to be greater in those with acute coronary syndrome as the primary aetiology.[24] CPAP reduces preload and afterload[10,11,30] and myocardial catecholamine release,[31] whereas the cyclical P_{ao} (of bilevel NIV) may cause fluctuation in the preload and afterload during respiration.

ACUTE RESPIRATORY FAILURE IN CHRONIC OBSTRUCTIVE PULMONARY DISEASE

Chronic obstructive pulmonary disease (COPD) patients have an elevated resistive work (P_{res}), often coupled with an elevated basal V_E and elastic work (P_{el}) as a result of the pre-existing parenchymal damage. Threshold load (PEEPi) is frequently present as a consequence of air-flow obstruction, and is exacerbated during ARF by further increases in P_{res} and the respiratory rate. Reversible ARF is a common complication of COPD.

The importance of NIV in hypercapnic ARF is now supported by at least 14 well-performed prospective, randomised, controlled studies[32,33] in more than 600 patients. Most investigators reported a low prevalence of side effects and a significant decrease in intubation rates and in-hospital mortality. A meta-analysis of NIV trials reveals significant reductions in mortality (95% CI, RR = 0.35–0.76) and the need for intubation (95% CI, RR = 0.33–0.53) – the number of patients needed to treat to avoid one intubation or death being as few as 4 and 10, respectively.[33] Risk reduction appears to be proportional to the severity of respiratory acidosis.[35] The incidence of nosocomial pneumonia is lower with NIV[34,35] and this may explain some of the survival benefit associated with NIV.

Current evidence supports the use of NIV in hypercapnic ARF as standard therapy in COPD subjects.[34] This is supported by several respiratory medicine societies.[22,32,36]

All modes of NIV appear to have a role but the optimal mode and pressure settings remain unresolved.[22] Patients with ARF arising predominantly from reversible air-flow obstruction (P_{res}) and/or threshold load are likely to respond to CPAP alone. Hypercapnic patients often experience reduced alveolar ventilation or respiratory muscle insufficiency and are likely to benefit from the addition of inspiratory support (PSV or IPAP).

A trial of NIV is indicated by the presence of respiratory acidosis (pH <7.37) or persistent breathlessness.[33] It is poorly tolerated in those without acidosis.

Inspiratory support (usually 5–20 cm H_2O) should be titrated to improve V_E as indicated by an improvement in tidal volume and pH, and a reduction in respiratory rate and/or $PaCO_2$. Low levels of CPAP or EPAP (4–8 cm H_2O) are usually required to counterbalance threshold load and trigger inspiratory support. Clinical observation and judgement are required to

titrate this to a level that minimises the effort required to trigger inspiratory support (PSV or IPAP). Fi_{O_2} is titrated to reverse hypoxia.

Early predictors of NIV success in COPD patients include improvements in pH and $PaCO_2$ (but not Pa_{O_2}) within the first 1–2 hours of therapy.[33,37] Predictors of NIV failure include persistent mask intolerance, severe acidosis (pH <7.25), tachypnoea (>35/min), impaired conscious state and poor clinical response to initial therapy. The bedside care plan should address management should the trial of NIV fail. Mask intolerance, nursing workload and failure rates are greater during NIV for COPD than those reported in CPO. These patients benefit from a critical care setting where expertise and equipment are available, and where reported outcomes appear better.[23,33]

While reported success rates are high (70%–90%), NIV failure (requiring intubation) appears to increase with the severity of respiratory acidosis. For the poorly compliant patient, reassurance and explanation together with a trial of different size and/or type of mask or initiation with lower-pressure settings, plus brief periods of NIV will sometimes assist. Low-dose anxiolytic drugs may be beneficial where anxiety is a recurrent precipitant of dyspnoea, but should be used with caution because of their respiratory depressant side effects.

Late failure (>48 hours) occurs in 10%–20% of patients[38] despite an initial improvement with NIV. This group of patients has a high mortality risk.[37] Whether this reflects the severity of the underlying disease or the delayed initiation of MV remains unclear.

ASTHMA

Asthma is an acute inflammatory lung disease that increases resistive (P_{res}) and threshold (PEEPi) respiratory work. Clinical improvement[39-41] and physiological improvement[42,43] has been demonstrated in acute asthmatics with the application of CPAP and bilevel NIV.

The role of NIV in the management of acute asthma, and thus the optimal mode and pressure settings, remains to be clarified. Nebulised drugs can be effectively delivered even in the presence of a high-flow NIV circuit.[44] Controlled clinical studies with robust end-points are awaited.[39] Low-level CPAP (5 cm H_2O) may be effective in moderate to severe asthma unresponsive to steroids and continuous inhaled bronchodilators. Mask intolerance is the most frequent cause of NIV failure. NIV must be delivered in a high-acuity environment where the appropriately skilled staff members are immediately available should the patient require urgent intubation.

ACUTE RESPIRATORY DISTRESS SYNDROME

Like CPO, acute respiratory distress syndrome (ARDS) leads to an increase in elastic workload (P_{el}) and, to a lesser extent, resistive workload (P_{res}) arising from an increase in alveolar–capillary permeability, the release of inflammatory mediators and impaired surfactant function. Even though PEEP is beneficial in ARDS, and NIV has a lower prevalence of nosocomial pneumonia,[34,35] current data do not support the routine use of NIV in ARDS, non-CPO or undifferentiated hypoxaemic ARF.[45,46]

Despite numerous publications reporting the successful use of NIV in the setting of community-acquired pneumonia[47] (without COPD) and other forms of ARDS, the failure rate remains high.[45-51] This may reflect the differences in duration, severity, and the pathophysiology of pneumonia and ARDS compared with CPO. Apparent benefit may be due to the inclusion of subjects with CPO[49] or COPD[52,53] – subgroups that benefit from NIV.

PNEUMONIA IN THE IMMUNOCOMPROMISED PATIENT

MV is associated with high morbidity and mortality in immunocompromised patients with hypoxic respiratory failure.[54-56] These patients may benefit from an early trial NIV,[57] although early evidence for improved survival is not supported by a recent large randomised trial.[58] Whether NIV benefits this group by reducing unnecessary exposure to a high-morbidity therapy (MV)[34] or by identifying responders (with a rapidly reversible form of ARF) remains unclear. It seems reasonable, based on the current evidence, to offer NIV to these patients[22,56] with a clear plan for patient management should the trial of NIV fail.

POSTOPERATIVE AND POST-TRAUMATIC ACUTE RESPIRATORY FAILURE

ARF in postoperative and trauma patients may arise from a number of reversible pathological processes associated with increases in elastic workload (P_{el}) and impaired respiratory muscle function (P_{mus}), including dependent atelectasis, impaired chest-wall mechanics, poor cough, nosocomial infection, aspiration pneumonitis and non-respiratory trauma or sepsis.

Mask CPAP consistently improves intermediate physiological parameters (e.g. oxygenation and respiratory rate) and may reduce the risk of intubation in general surgical[59] and cardiothoracic patients[60,61] with mild postoperative hypoxic respiratory failure, but evidence for a survival benefit is lacking,[62] particularly when high rates of failure are reported in the control groups of favourable trials. NIV may improve survival in certain subgroups, such as postoperative lung resection,[61] but many of these patients have underlying COPD, and extrapolation of these results to non-COPD patients awaits further study.

Mask CPAP has been shown to be superior to MV in patients with isolated severe chest trauma,[63,64] but

the benefit of CPAP plus PSV remains unclear. NIV is contraindicated in the presence of neurotrauma, intracranial hypertension, facial trauma or the presence of an undrained pneumothorax.

NON-INVASIVE VENTILATION-ASSISTED WEANING

Since NIV is effective in reducing the need for intubation and MV, it has been postulated that NIV may reduce the risk of failed extubation. Therefore NIV has been recommended to expedite early weaning from MV[65] or as rescue therapy following failed[66] or accidental extubation. The putative advantages relate to a reduction in the duration and the risks of MV (e.g. nosocomial pneumonia).

For COPD patients there appears to be a survival benefit,[67,68] but it cannot be recommended in the non-COPD group where reported failure (intubation) rates are unacceptably high,[69] NIV offers no benefit[18,70,71] and mortality risk may be higher.[68] Thus NIV is a post-extubation rescue therapy for COPD patients, but it is not a substitute for weaning strategies to the risk of extubation failure.[69]

HIGH-FLOW INTRANASAL OXYGEN THERAPY

High-flow intranasal oxygen therapy (HFNO) systems deliver humidified oxygen at high flows (up to 60 L/min) via nasal cannula, with or without a pressure seal. Humidification improves patient tolerance and high flows create low levels of CPAP in the hypopharynx, reduce dead space and improve lung volumes.[70] This form of therapy is useful in neonates (see Chapter 107). Its benefit and role in adult ARF are less clear. HFNO consistently improves oxygenation but failure (intubation) is frequent and improved survival remains controversial.[71]

NON-INVASIVE VENTILATION AND CHRONIC RESPIRATORY DISEASE

NIV is an important modality for the long-term treatment of severe chronic respiratory failure associated with obstructive and central sleep apnoea syndromes[22,72] and chronic hypoventilation syndromes associated with extrapulmonary disease, such as neuromuscular disease,[73] and thoracic deformities,[74] COPD with hypercapnia[75] and cystic fibrosis (CF).[76,77]

These patients may require short-term respiratory support during an acute illness or as an aid to perioperative care in a critical care environment. NIV (plus minitracheostomy for secretion removal) may improve outcome compared with intubation and MV,[78] but failure rates appear to be higher.[79] Diagnosis of these underlying disorders during admission for the treatment of severe ARF should prompt referral and assessment for long-term NIV.

NON-INVASIVE VENTILATION AND SLEEP APNOEA SYNDROMES

Moderate or severe OSA results in nocturnal hypoventilation and episodic hypoxia that can lead to pulmonary and systemic hypertension, cardiac failure, plus daytime hypercapnia and somnolence.[80,81] Many of these complications can be arrested or reversed through the appropriate use of nocturnal CPAP.[22,72,80] Patients with suspected sleep apnoea require accurate assessment by a respiratory physician, including sleep studies, prior to the routine use of domiciliary CPAP. Bilevel or controlled ventilation is required when there is inadequate central respiratory drive or increased elastic work. In many patients, respiratory drive will improve and they can then be managed with CPAP after a period of bilevel or controlled ventilation.

Intercurrent illness, surgery or the use of sedatives and opioid analgesics, will increase the frequency and duration of hypopnoea, apnoea and hypoxia. CPAP should be available even for those patients who do not require admission to a critical care ward.

NON-INVASIVE VENTILATION AND CHRONIC HYPOVENTILATION SYNDROMES

Domiciliary NIV (predominantly using inspiratory support modes or NIPPV) should be considered in all patients presenting with severe chronic respiratory failure due to neuromuscular disease.[78,83-86] Early referral and consideration of domiciliary NIV are recommended because of improved outcomes and quality of life.[83] As mentioned earlier, there are recent data to support NIV in CF[77] and chronic hypercapnic COPD patients.[75]

Assessment of these patients for domiciliary NIV includes respiratory function tests, blood gas analysis and sleep studies, together with trials of NIV modes and pressure settings. In general, indications for long-term NIV include the demonstration of symptomatic respiratory failure, daytime hypercapnia and a significantly reduced (<20% predicted) vital capacity. The use of nocturnal or intermittent NIV has been shown to improve daytime respiratory and cardiac function,[83] to improve exercise endurance, to slow the progression of respiratory dysfunction and to reduce the frequency of hospitalisation.[78,86]

Respiratory monitoring

Andrew D Bersten

History and respiratory examination are particularly important in the critically ill patient. Particular attention should be directed at the respiratory rate (f), the most poorly documented vital sign, the quantity and nature of sputum, and evidence of excessive inspiratory and/or expiratory pleural pressure changes and effort, which include accessory muscle use, tracheal tug, supraclavicular and intercostal indrawing, paradoxical abdominal movement (which is suggestive of diaphragmatic fatigue),[1] and pulsus paradoxus. During spontaneous ventilation, an excessive fall in blood pressure during inspiration (>10 mm Hg) is found both in low-output states such as cardiac tamponade, cardiogenic shock, pulmonary embolism, hypovolaemic shock, and in acute respiratory failure. The fall in pleural pressure during spontaneous inspiration has a curvilinear relationship with the fall in blood pressure. However, as there is marked variation between individuals,[2] pulsus paradoxus is most useful in following trends. A reduction in the degree of paradox may reflect improvement with a fall in the negative pleural pressure needed for ventilation, or may reflect respiratory muscle insufficiency, and an inability to generate the same negative pleural pressure.

Additional information can be gained from blood gases and pulse oximetry (see Chapter 18), and capnography, ventilatory pressures, and waveform analysis in patients receiving respiratory assistance. This chapter will focus on tests of respiratory function that are directly relevant to critically ill patients.

MONITORING GAS EXCHANGE

OXYGENATION

This is reviewed in Chapter 18, and is only briefly discussed here. Hypoxaemia may be due to a low partial pressure of inspired O_2 (rare), hypoventilation, diffusion impairment (rare), ventilation-perfusion ($\dot{V}/\dot{Q}$) mismatch, and shunt. Inert gas analysis has been used to quantitate $\dot{V}/\dot{Q}$ mismatch, and has demonstrated that hypoxaemia in acute respiratory distress syndrome (ARDS) is predominantly due to alveoli that are perfused but not ventilated (shunt),[3] consistent with computed tomography (CT) scan evidence of increased dependent lung density. The alveolar gas equation is a common but less accurate method to assess hypoxaemia:

$$(38.1)\quad P\mathrm{A}_{\mathrm{O}_2} = \text{inspired } P_{\mathrm{O}_2} - \mathrm{PaCO}_2 \text{ respiratory quotient}$$

where $P\mathrm{A}_{\mathrm{O}_2}$ is the alveolar PO_2, and this is usually simplified to:

$$(38.2)\quad P\mathrm{A}_{\mathrm{O}_2} = (760 - 47) \times F\mathrm{i}_{\mathrm{O}_2} - \mathrm{PaCO}_2/0.8$$

where 760 is atmospheric pressure in mm Hg, and 47 is the saturated vapour pressure of water at 37°C, since gas at the alveolus is fully humidified. The normal $P\mathrm{A}_{\mathrm{O}_2}$ to $P\mathrm{a}_{\mathrm{O}_2}$ gradient is less than 15 mm Hg, but increases to 25 mm Hg in the elderly. This normal A–a gradient is due to some venous admixture through the lungs, and a small right-to-left shunt through both the bronchial veins, and the thebesian veins of the coronary circulation. This equation removes hypercarbia as a direct cause of hypoxaemia, and an increase in the A–a gradient will usually be due to $\dot{V}/\dot{Q}$ mismatch or right-to-left shunt. A commonly used alternative measure of hypoxaemia is the $P\mathrm{a}_{\mathrm{O}_2}/F\mathrm{i}_{\mathrm{O}_2}$ ratio. However, this does not account for the effect of a raised $PaCO_2$, and both measures are influenced by a number of factors (e.g. cardiac output, Hb, $F\mathrm{i}_{\mathrm{O}_2}$) in addition to the extent of venous admixture, which may be estimated from the intrapulmonary shunt equation:

$$(38.3)\quad \dot{Q}_s/\dot{Q}_t = \mathrm{Cc}'_{\mathrm{O}_2} - \mathrm{Ca}_{\mathrm{O}_2} / \mathrm{Cc}'_{\mathrm{O}_2} - \mathrm{Cv}_{\mathrm{O}_2}$$

where $\dot{Q}_s$ is the intrapulmonary shunt blood flow, $\dot{Q}_t$ is the total pulmonary blood flow, $\mathrm{Cc}'_{\mathrm{O}_2}$ is the end-capillary O_2 content calculated from the $P\mathrm{A}_{\mathrm{O}_2}$, and $\mathrm{Ca}_{\mathrm{O}_2}$ and $\mathrm{Cv}_{\mathrm{O}_2}$ are the O_2 contents of arterial and mixed venous blood, respectively.

CARBON DIOXIDE

$PaCO_2$ is determined by alveolar ventilation ($\dot{V}_A$), and CO_2 production ($\dot{V}_{\mathrm{CO}_2}$):

$$(38.4)\quad P\mathrm{a}_{\mathrm{CO}_2}\ (\text{mm Hg}) = \dot{V}_{\mathrm{CO}_2}\ (\text{mL/min STPD}) \times 0.863/\dot{V}_{\mathrm{A}}\ (\text{L/min BTPS})$$

ABSTRACT

Respiratory monitoring can usefully assist clinical assessment of patients requiring respiratory support. Pulse oximetry is almost universally available, and continuously monitored. Capnography should be used to confirm endotracheal or tracheostomy placement, and to continuously monitor tube position during ventilatory assistance; however, arterial blood gases are still required when the absolute value of $PaCO_2$ is needed. In combination with an understanding of the methodology, various measures of respiratory mechanics including plateau pressure (Pplat), intrinsic PEEP (PEEPi), and respiratory system compliance and resistance, and observation of respiratory waveforms both help adjust ventilator support, reduce asynchrony and monitor responses to treatment. The clinical role of bedside measures of stress and strain remain uncertain.

where $\dot{V}_A$ is the minute ventilation ($\dot{V}_E$) minus the wasted or dead space ventilation ($\dot{V}_D$). The modified Bohr equation (assuming $PA_{CO_2} = PaCO_2$) calculates the proportion of the V_T that is wasted ventilation (i.e. physiological dead space; V_{Dphys}):

$$(38.5) \qquad V_{Dphys}/V_T = PaCO_2 - P\bar{E}_{CO_2}/PaCO_2$$

where $P\bar{E}_{CO_2}$ is the mixed expired P_{CO_2}, and V_{Dphys} is composed of anatomical dead space (V_{Danat}) and alveolar dead space (V_{Dalv}) – notionally due to alveoli that are ventilated but not perfused. Normally V_{Dalv} is minimal and V_{Danat} comprises 30% of V_T. Since the volume of an endotracheal tube is less than the mouth or nose, and pharynx, intubation may reduce V_{Danat}; however, when the connection from the endotracheal tube is taken into account, there is little change in dead space. Positive-pressure ventilation increases dead space by distension of the airways increasing V_{Danat}, and through a tendency to increase alveoli that are ventilated but not perfused. In patients with ARDS, marked increases in V_{Dalv} lead to marked increases in the V_{Dphys}/V_T ratio (exceeding 0.6), which is an independent prognostic factor.[4]

CAPNOGRAPHY

Capnography measures and displays exhaled CO_2 throughout the respiratory cycle, with sampling usually by a mainstream sensor as side-stream systems tend to become blocked by secretions. However, when capnography is used in non-intubated patients, side-stream sampling is commonly used (e.g. modified nasal cannulae). Infrared spectroscopy measures the fraction of energy absorbed and converts this to a percentage of CO_2 exhaled. During expiration, the capnogram initially reads no CO_2, but as anatomical dead space is exhaled there is a rise in the exhaled CO_2 to a plateau, which falls to 0% CO_2 with the onset of inspiration. In patients with significant respiratory disease, a plateau may never be achieved. The end-tidal CO_2 (PE'_{CO_2}) is the value at the end of the plateau, and is normally only slightly less than the $PaCO_2$. However, this gradient will increase when alveolar dead space (V_{Dalv}) increases, such as low cardiac output, pulmonary embolism and elevated alveolar pressure. Consequently, the PE'_{CO_2} may not reflect $PaCO_2$ in critically ill patients. Nevertheless, in a stable patient the gradient will be fairly constant, and can be used to guide $\dot{V}_E$ during transport,[5] and when other factors including the adequacy of minute ventilation are unchanged, then sudden changes in the PE'_{CO_2} may provide an early signal. Indeed, PE'_{CO_2} directly correlates with cardiac output, and PE'_{CO_2} monitoring has been used to assess adequacy of cardiopulmonary resuscitation, and its prognosis.[6]

The presence of exhaled CO_2 confirms endotracheal tube placement, and is recommended even when the tube is seen to pass through the vocal cords,[7] since clinical assessment is not always reliable. Simple colorimetric devices may be used for this purpose. However, detection of expired CO_2 is not infallible[7] as false positives can rarely occur following ingestion of carbonated liquids, and false negatives may be due to extremely low pulmonary blood flow, or very large alveolar dead space such as pulmonary embolus or severe asthma. Capnography is also recommended during transport,[8] in all patients receiving intubated ventilator support,[9] and should be available for every anaesthetised patient.[10]

Sidestream capnography should also be considered during conscious sedation, as this is associated with reduced hypoxaemic episodes, and in morbidly obese patients or those receiving significant parenteral opiates in the intensive care unit (ICU).[11] Supplemental oxygen in these circumstances is routine but also reduces the sensitivity of pulse oximetry to detect ventilator problems.

GAS TRANSFER (DIFFUSING CAPACITY)

This is a test of the transfer of a gas, typically carbon monoxide (CO), across the alveolocapillary barrier. The transfer factor is calculated as:

$$(38.6) \qquad \text{volume of CO taken up}/(PA_{CO} - Pc_{CO})$$

and, as CO is so completely taken up by Hb, Pc_{CO} is taken as zero. This test is usually performed as an outpatient, is not usually measured in ICU, and diffusion abnormality is rarely a cause of hypoxaemia. The transfer factor is often corrected for lung volume since diseases such as emphysema and pulmonary fibrosis may affect both lung volume and diffusion. In chronic heart failure, diffusing capacity is reduced and correlates with exercise performance and chronic heart failure (CHF) severity and prognosis due to a reduction in the volume of alveolar tissue and amount of blood participating in gas exchange.[12]

LUNG VOLUME AND CAPACITIES

The tidal volume (V_T) is the volume of gas inspired and expired with each breath, and the volume at end expiration and zero positive end-expiratory pressure (PEEP) is the functional residual capacity (FRC); the end-expiratory lung volume (EELV) is the volume at end-expiration at a specified PEEP so that at PEEP 0 cm H_2O FRC is equal to EELV (Fig. 38.1). The residual volume (RV) is the FRC minus the expiratory reserve volume (ERV). If a maximum inspiratory effort is made from FRC, this is termed a vital capacity (VC) manoeuvre when the total lung capacity (TLC) is reached. Clinically, the most important of these are the FRC, EELV, V_T and VC, and the latter two are easily measured using a spirometer or integrated from flow.

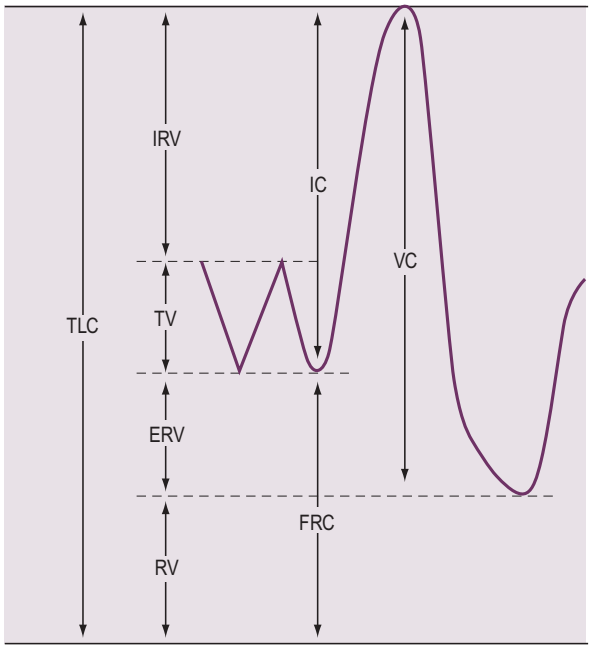

Figure 38.1 Lung volumes and capacities. *ERV*, Expiratory reserve volume; *FRC*, functional residual capacity; *IC*, inspiratory capacity; *IRV*, inspiratory reserve volume; *RV*, residual volume; *TLC*, total lung capacity; *TV*, tidal volume; *VC*, vital capacity.

TIDAL VOLUME

Minute volume is composed of f and V_T – normally ~17 breaths/min and ~400 mL, respectively, in adults.[13] Rapid shallow breathing is common in patients with respiratory distress, and in those failing weaning. Although the f/V_T ratio greater than 100 was initially shown to be highly predictive of weaning failure,[14] subsequent studies have reported varying results.

VITAL CAPACITY

At TLC, inspiratory muscle forces are counterbalanced by elastic recoil of the lung and chest wall (CW). Both these parameters and the size of the lung, which varies with body size and gender (Box 38.1), determine TLC. Vital capacity, the difference between TLC and FRC, is also reduced by factors that reduce FRC (e.g. increased abdominal CW elastance and premature airway closure in chronic obstructive pulmonary disease [COPD]). The normal VC is ~70 mL/kg; although reduction to 12–15 mL/kg has been suggested as an indication for mechanical ventilation, many other factors need to be considered, including the patient's general condition, the strength of the expiratory muscles, glottic function, and the response to non-invasive ventilation. Indeed, many chronically weak patients are able to manage at home with extremely low VC with the assistance of non-invasive ventilation.

Box 38.1 Factors that decrease vital capacity

Decreased muscle strength
- Myopathy
- Neuropathy
- Spinal cord injury

Increased lung elastance
- Pulmonary oedema
- Atelectasis
- Pulmonary fibrosis
- Loss of lung tissue

Increased chest wall elastance
- Pleural effusion
- Haemothorax
- Pneumothorax
- Kyphoscoliosis
- Obesity
- Ascites

Reduced functional residual capacity
- Atelectasis
- Premature airway closure (e.g. chronic obstructive pulmonary disease)

END-EXPIRATORY LUNG VOLUME

Direct measurement of EELV is rare in the ICU. Anatomical rather than functional estimates of EELV can be derived from CT scan, and while this remains a research standard it is not used clinically due to logistics. Techniques such as nitrogen or oxygen washout[15] are becoming available on modern ventilators but concerns regarding accuracy limit their use to changes in EELV greater than 200 mL.[16] When EELV is less than the closing volume, the lung volume at which airway closure is present during expiration, there is a marked increase in $\dot{V}/\dot{Q}$ mismatch. Consequently, PEEP is commonly used to elevate EELV. Increases in lung volume above resting lung volume can also be directly measured from a prolonged expiration to atmospheric pressure using either a spirometer or integration of flow,[17] or by repeated EELV measurements.[18] FRC is decreased in ARDS and pulmonary oedema, in patients with abdominal distension, and following abdominal and thoracic surgery. Increased FRC places the diaphragm at a mechanical disadvantage, and is seen with severe air-flow limitation and dynamic overinflation, and when there is loss of elastic recoil (e.g. emphysema).

ELECTRICAL IMPEDANCE TOMOGRAPHY

Electrical impedance tomography (EIT) uses impedance variation (as gas is a poor conductor) derived from multiple CW electrodes to monitor regional tidal ventilation. This is usually performed following a recruitment manoeuvre or change in PEEP setting.[19] Care must be taken to differentiate the diaphragm from collapsed lung, as the diaphragm moves cephalad both during

expiration and at lower lung volumes. EIT can be calibrated to volume, and used to examine changes in EELV but not FRC itself. PEEP may be adjusted to these changes and to indices of heterogeneity of ventilation. Automated summary analyses are being developed which may help assess variables such as the balance between non-aerated and overdistended lung.[20] Other developments include the assessment of lung perfusion and regional pulmonary function testing; however, clinical trials are needed prior with the potential to influence patient care to widespread use.

MEASUREMENT OF LUNG MECHANICS

The forces the respiratory muscles must overcome during breathing are the elastic recoil of the lung and CW, and airway and tissue resistance. During controlled mechanical ventilation, the ventilatory pressures reflect the work done to overcome these forces; however, during partial ventilatory support, the pressure at the airway opening reflects both these forces and those generated by the respiratory muscles. Estimates of respiratory mechanics are often readily available, and can assist titration of ventilatory support.

ELASTIC PROPERTIES OF LUNG AND CHEST WALL

The respiratory system (RS) is composed of the lung (L) and CW, which is comprised of the rib cage and abdomen. Although it is often convenient to consider RS mechanics as implying information about the lung, abnormal CW compliance can markedly influence these measurements.[21–25]

The pressure gradient across the lung (P_L) that generates gas flow is equal to the difference between the pressure at the airway opening (P_{ao}) and the mean pleural pressure (P_{pl}), which is estimated as the oesophageal pressure (P_{es}):

$$P_L = P_{ao} - P_{es} \quad (38.7)$$

Although the P_{es} is not always an accurate measure of the absolute P_{pl}, the change in P_{es} reflects the change in P_{pl}. However, this requires an appropriately positioned and functioning oesophageal balloon. In spontaneously breathing subjects, a thin latex balloon sealed over a catheter is introduced into the lower third of the oesophagus and P_{es} and P_{ao} measured simultaneously during an end-expiratory airway occlusion. A well-positioned oesophageal balloon will have a ratio of $\Delta P_{es}/\Delta P_{ao}$ of ~1.[26] This technique is reliable in supine, intubated spontaneously breathing patients[27] and in paralysed subjects it appears that a similar pressure change, induced by manual rib cage pressure,[28] can be used to verify oesophageal balloon function.

CW mechanics are derived from P_{es} referenced to atmospheric pressure and, in ventilated relaxed subjects, RS mechanics are derived from P_{ao} referenced to atmospheric pressure. It is not surprising then that $P_{RS} = P_L + P_{CW}$. Finally, abdominal mechanics can be estimated as either intravesical or intragastric pressure. However, despite these provisos, useful information can be obtained from RS mechanics.

Measuring the slope of the V–P relationship of the lung or RS allows a simple estimate of the elastic properties of the lung. Since the E_{RS} is directly related to its components ($E_{RS} = E_L + E_{CW}$), it is preferred to compliance, which is inversely related: $1/C_{RS} = 1/C_L + 1/C_{CW}$. The normal E_{RS} is 10–15 cm H_2O/L and the normal C_{RS} is 60–100 mL/cm H_2O in ventilated patients.

POSITIVE END-EXPIRATORY PRESSURE-TITRATION USING TRANSPULMONARY PRESSURE

Using a V_T of 6 m/kg pbw in patients with ARDS, PEEP-titration to achieve an end-expiratory transpulmonary pressure (Ptp; PEEP – oesophageal pressure) based on a Ptp Fi_{O_2} scale resulted in higher PEEP and plateau pressure (Pplat) levels, with both improved oxygenation, and Crs compared with conventional PEEP-titration[29] (ARDSnet protocol).[30] There was a trend to improved mortality but the trial was small (n = 61), and clinical outcomes, not physiologic data, should drive decision making; comparing V_T of 6 versus 12 mL/kg pbw oxygenation was worse in the lower V_T, lower-mortality group for the first 3 days.[30] However, there continues to be strong interest in using transpulmonary pressure to guide mechanical ventilation in ARDS.[31]

MEASUREMENT OF ELASTANCE

Elastance and resistance are frequency dependent, and respiratory mechanics depend upon the volume and volume history of the lung.[32] With increasing frequency of breathing, total RS resistance falls and elastance increases, and this is particularly obvious in patients with air-flow obstruction.[33,34] Consequently, these factors must be taken into account when interpreting respiratory mechanics. In a passively ventilated subject, P_{ao} is the sum of: (1) the pressure required to overcome airway, endotracheal tube and circuit resistance (P_{res}), (2) the elastic pressure required to expand the lung and CW (P_{el}), (3) the elastic recoil pressure at end expiration or total PEEP (P_o), and (4) the inertial pressure required to generate gas flow (P_{inert}):

$$P_{ao} = P_{el} + P_{res} + P_o + P_{inert} \quad (38.8)$$

Since the elastance (E) is equal to $\Delta P/\Delta V$, with the resistance (R) equal to $\Delta P/\Delta \dot{V}$, and ignoring the inertance,[35] this can be rewritten as the single-compartment equation of motion:

$$P_{ao} = E_{RS}V + R_{RS}\Delta\dot{V} + P_o \quad (38.9)$$

Elastance can then be measured using either static techniques, where cessation of gas flow allows dissipation of P_{res}, or dynamic techniques, where flow is not interrupted.

END-INSPIRATORY OCCLUSION METHOD

The simplest estimate of E_{RS} can be made using a rapid end-inspiratory airway occlusion during a constant flow breath, provided that the respiratory muscles are relaxed (Fig. 38.2). If a plateau is introduced at end inspiration, there is a sudden initial pressure drop due to dissipation of flow resistance ($P_{pk} - P_1$) followed by a slower, secondary pressure drop to a plateau ($P_{dif} = P_1 - P_2$) due to stress relaxation. At least 1–2 seconds are taken for this plateau to be achieved, and P_2 is often called the plateau pressure; however, if P_{plat} is measured too soon it will lie somewhere between P_1 and P_2.

Stress adaptation

Stress relaxation of the RS is due to both tissue viscoelasticity and time constant inequalities of the RS (pendelluft). In the normal lung, pendelluft has a minimal contribution to stress relaxation.[36] However, heterogeneity of regional resistance and elastance can markedly influence stress relaxation.[37] Pulmonary surfactant and its contribution to changes in surface tension, parenchymal factors including elastic fibres in the lung, contractile elements such as the alveolar duct muscle and changes in pulmonary blood volume have all been implicated in the viscoelastic properties of the lung. In the abnormal lung, it is difficult to separate either of these factors or the role of pendelluft in stress adaptation. However, pendelluft may contribute to lung injury in ARDS during triggered or supported ventilation.[38]

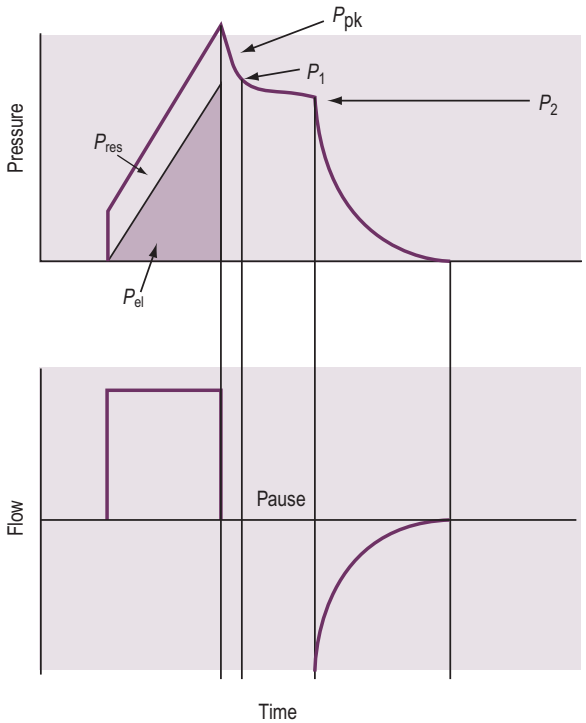

Figure 38.2 Schematic diagram of a volume-controlled breath with constant inspiratory flow. A period of no inspiratory gas flow has been interposed before expiration (pause) to illustrate dissipation of lung resistance as airways resistance (fall from P_{pk} to P_1) and tissue resistance (fall from P_1 to P_2). The inspiratory pressure due to the elastic properties of the respiratory system is illustrated in the top panel as the filled area (P_{el}), and the lung resistive pressure is labeled as P_{res}. (See text for more detail.)

Calculation of respiratory mechanics

Returning to Fig. 38.2, it is now simple to estimate RS resistance and elastance from P_{ao}. The static elastance ($E_{rs,st}$) and the dynamic elastance ($E_{rs,dyn}$) are calculated as:

$$E_{rs,st} = (P_2 - P_o)/V_T \quad (38.10)$$

$$E_{rs,dyn} = (P_1 - P_o)/V_T \quad (38.11)$$

where P_o is the total PEEP (extrinsic plus intrinsic PEEP). The difference between $P_{el,dyn}$ and $P_{el,st}$ is the effective recoil pressure of the RS during mechanical ventilation. Consequently, additional work is performed during inspiration to overcome stress adaptation, and this is stored and dissipated during expiration. This contributes to the hysteresis seen in dynamic volume-pressure curves during mechanical ventilation, and to the generation of expiratory flow. This latter component may be important in patients with air-flow obstruction since the imposition of a pause at end inspiration results in a 32% dissipation of the total energy loss within the RS.[39]

THE STATIC VOLUME–PRESSURE CURVE

The quasistatic volume–pressure (V–P) curve is infrequently performed, and the relevance of a measurement performed on a single occasion is questionable when lung mechanics are not constant. Various techniques have been described, but the overall concept is that incremental volume and pressure points are made after a sufficient period of no flow has allowed P_{res} to be dissipated. This allows definition of a sigmoidal-shaped curve with upper and lower inflection points, and a mid-section with relatively linear V–P relations, allowing inflation elastance to be measured as this slope at a given lung volume. If similar measures are made during deflation, a deflation curve and its hysteresis can also be described.

The V–P curve provides an advantage over an end-inspiratory elastance as, with the latter, it is not possible to know which part of the V–P curve is being measured. Consequently, this 'chord' elastance may span either inflection point, yielding a falsely high

figure. The upper inflection point represents a sudden decrease in elastance with increasing volume, and this has been interpreted as lung overdistention. The lower inflection point represents a sudden decrease in elastance with increased volume, and this has been interpreted as recruitment of atelectatic air spaces. Ventilation between these two inflection points should minimise both shearing forces secondary to repetitive collapse and reopening of alveoli, and overstretch of alveoli. However, this interpretation of the V–P curve has been questioned. In patients with ARDS, recruitment occurs well above the lower inflection point, along the entire V–P curve and above the upper inflection point.[40,41] An alternative interpretation is that the lower inflection point represents a zone of rapid recruitment, and that the upper inflection point is due to a reduced rate of recruitment.[42]

Conventionally the static V–P curve has been measured in paralysed ventilated patients with the 'supersyringe' method.[43] In a paralysed patient, the RS is progressively inflated from FRC in 100 mL steps up to ~1700 mL or a predefined pressure limit. After each step, sufficient time is allowed for a well-defined plateau to become apparent (using a pause of 3–6 seconds). The effects of temperature, humidity, gas compression and ongoing gas exchange during the manoeuvre need to be taken into account,[44,45] and the volume history standardised before it is performed. Many patients become hypoxaemic following disconnection from the ventilator during the 60 seconds or so without PEEP. An alternative is to randomly insert a range of single-volume inflations, followed by a prolonged pause,[46] during normal mechanical ventilation at 0 cm H_2O PEEP. Advantages include simplicity, the patient is not disconnected from the ventilator, the volume history is the same for each measurement and gas exchange during the measurement is negligible. However, again, many patients will become hypoxaemic due to prolonged periods without PEEP (this procedure may take ~15 minutes), particularly following a small-volume breath. Finally, an automated low-flow V–P curve method allowing subtraction of P_{res} is available on some ventilators, takes around 20 seconds to perform, and correlates well with the static occlusion technique.[47,48]

THE DYNAMIC VOLUME–PRESSURE CURVE

Dynamic P_{ao}, $\dot{V}$ and V are displayed by many ventilators, but the volume signal is not referenced to FRC and the signals are not readily available for quantitative analysis. However, $\dot{V}$ is readily measured with a heated pneumotachograph, and volume can then be derived by simple integration. If P_{ao} is also collected, it is relatively simple to measure dynamic mechanics.

The dynamic V–P curve appears to show hysteresis, due to the effects of airway and tissue resistance; however, during tidal breathing even the static V–P does not show hysteresis.[49] In contrast to static V–P relations, dynamic mechanics are collected during normal ventilation so they do not interfere with patient care, and they provide a 'functional' description of respiratory mechanics. Indeed, the 'effective' alveolar distending pressure is more accurately $P_{el,dyn}$, not $P_{el,st}$. Since dynamic mechanics are potentially continuous, they could also be used to servo-control ventilatory strategies.

There are a number of ways to analyse dynamic V–P data. A line can be drawn between no-flow points at end inspiration and end expiration to determine elastance; however, this is relatively inaccurate as it is based on two points that can be hard to exactly identify. Multiple linear regression analysis is now the technique most commonly employed. The patient does not need to be paralysed,[50] provided the respiratory muscles are not active during ventilation. The signal can also be split to allow analysis of inspiratory and expiratory mechanics.

Provided the model fit is acceptable, elastance and resistance are accurately and reproducibly calculated using the single compartment equation of motion:

$$P_{ao} = E_{RS}V + R_{RS}\Delta\dot{V} + P_o \quad (38.12)$$

Static intrinsic PEEP ($PEEP_i$) is accurately calculated, as $P_o - PEEP_e$, when compared with either an end-expiratory airway occlusion method[51] or by direct measurement of end-expiratory alveolar pressure.[52] However, the single compartment model only approximates the RS, and frequency and volume dependence of the derived mechanics are observed.

Changes in elastance during tidal breathing can be modelled with the stress index derived from power analysis of the P_{ao}–t curve ($P_{ao} = a^t + c$),[53] and addition of a volume-dependent term to the equation of motion[15,54]:

$$P_{ao} = (E_1 + E_2V)V + R_{RS}\Delta\dot{V} + P_o \quad (38.13)$$

$$E_{rs} = E_1 + E_2V \quad (38.14)$$

Since power analysis requires a constant inspiratory $\dot{V}$ pattern to discount resistive effects, it is not as versatile as the volume-dependent technique, which models resistance and can be applied to any inspiratory $\dot{V}$ pattern. Both measures correlate highly with each other, suggesting they measure the same parameter.

High stress, and possibly overinflation, is inferred when the stress index is greater than 1.1 and when the volume-dependent elastance increases, which may be quantified:

$$\%E_2 = 100E_2V/E_{rs} \quad (38.15)$$

A stress index below 0.9 and a negative volume dependence (negative $\%E_2$) suggest significant atelectasis during tidal breathing. Provided both V_T and

$\dot{V}$ are constant, the change in driving pressure, either $P_{pk} - PEEP_{tot}$ or $P_1 - PEEP_{tot}$ 20–30 minutes following a change in PEEP, is highly correlated with $\%E_2$.[15] Using the 95% predictive interval for these data, an increase in $\Delta P > 2$ cm H_2O, consistent with a significant increase in elastance, suggests high stress and overinflation. Similarly, the lowest E_{rs} during PEEP titration targets the best balance between recruitment and overinflation, and may be superior to the stress index or $\%E_2$ in laboratory models.[55]

Both the stress index and volume-dependent elastance also vary with stress relaxation, and high stress may not mean overinflation; in COPD, bullous lung disease is due to a loss of lung tissue and elastic recoil. This may be measured on CT as hyperaerated; however, the associated wall stress may be high or low depending upon the degree of inflation.

INTERPRETATION OF ELASTANCE

Elastance may be increased due to a reduction in lung volume or to an increase in specific elastance, the product of E and FRC. Small body size, female gender, lung resection and reduced aerated lung volume (e.g. ARDS) are important factors in reducing effective lung volume. Specific elastance is increased in ARDS, pulmonary oedema and pulmonary fibrosis.

MEASUREMENT OF THE RESISTANCE OF THE LUNG AND CHEST WALL

Lung resistance (R_L) is the sum of airway (R_{aw}) and tissue resistance (R_{ti}). Resistance is flow-, volume- and frequency-dependent, and R_L decreases as f increases. It is also important to compare measurements at similar lung volumes since there is a hyperbolic relation between lung volume and R. This is particularly obvious in ARDS, where the incremental administration of PEEP can result in a decrease in R_{aw} due to concurrent recruitment and an increase in lung volume. Indeed, although the absolute values are increased, when corrected for EELV R_L, R_{aw} and R_{ti} are unchanged in ARDS,[17] although specific R_{ti} did increase with PEEP.[21] Finally, since gas flow may be a mixture of laminar and turbulent flow, resistance is often flow-dependent.

END-INSPIRATORY OCCLUSION TECHNIQUE

The total inspiratory R_{aw}, including the endotracheal tube and associated ventilatory apparatus, can be calculated in a relaxed patient following an inspiratory pause (see Fig. 38.2) as:

$$R_{aw} = (P_{pk} - P_1)/\dot{V} \quad (38.16)$$

and R_L calculated by using P_2 instead of P_1. Since the endotracheal tube and apparatus will make a significant contribution to R_{aw}, it is best to measure P_{ao} distal to the endotracheal tube with an intratracheal catheter. An alternative approach is to calculate and subtract endotracheal tube resistance using the Rohrer equation ($R = K_1 + K_2\dot{V}$),[56] and this is now automatically included in some ventilators. However, as in vivo endotracheal tube resistance is often greater than in vitro resistance[57] due to the effect of secretions and interaction with the tracheal wall, these corrections may be inaccurate. Despite these provisos, this simple measure of resistance, or the P_{pk} to P_{plat} difference at a constant $\dot{V}$, can be clinically useful in both the diagnosis and monitoring of air-flow obstruction.[58]

DYNAMIC TECHNIQUES

Total, inspiratory and expiratory R can also be estimated, using either multiple linear regression analysis or from linear interpolation of the V–P curve at a constant volume. However, this latter technique assumes a constant elastance during tidal inflation, and may be inaccurate because it relies on only two measurements. Finally, an average expiratory R can be calculated from the time constant (τ) derived from passive expiration if the E is known, since:

$$\tau = R/E \quad (38.17)$$

However, the lung does not empty as a single compartment in patients with air-flow obstruction, and E is assumed to be constant over the tidal expiration.

OTHER MEASUREMENT TECHNIQUES

The interrupter technique consists of a series of short (100–200 ms) interruptions to relaxed expiration by a pneumatic valve.[59] This results in an expiratory plateau in P_{ao} following equilibration with alveolar pressure. From the V, P and $\dot{V}$ data, the expiratory elastance and the expiratory P–$\dot{V}$ relationship are measured. This technique does not make assumptions about the behaviour of the RS and can identify dynamic air-flow limitation.

Assuming that the RS behaves linearly, it can be analysed following a forced-flow oscillation at the airway opening.[60] The resultant pressure waveform depends upon the impedance of the RS, which can be analysed following Fourier analysis of the P and $\dot{V}$ waveforms into resistance and reactance. This will then allow measurement of R_{aw}, R_{ti}, E_{rs} and inertance, and information can be gained regarding small airways disease by examining R_{aw} at different oscillatory frequencies.

FORCED EXPIRATORY FLOW

Maximum expiratory flow rates from TLC, the forced vital capacity (FVC), the forced expiratory volume in the first second of expiration (FEV_1) and the peak expiratory flow rate (PEFR) are commonly measured in cooperative subjects with a spirometer or flow meter. The PEFR is cheap but is relatively effort-dependent, and is less specific and reliable than the FEV_1. It is most useful for office or home use. The normal PEFR

is 450–700 L/min in males and 300–500 L/min in females. It is reduced with obstructive diseases and gross muscle weakness.

The FEV_1 is usually expressed as a ratio of the FVC since both may be reduced in restrictive disease, with a normal ratio. The FEV_1 is normally 50–60 mL/kg and 70%–83% of FVC. In asthma and COPD, the FEV_1 is reduced out of proportion to the FVC to a ratio less than 70%.

MEASUREMENT OF INTRINSIC POSITIVE END-EXPIRATORY PRESSURE

$PEEP_i$ (1) may have unrecognised haemodynamic consequences,[61] (2) adds an elastic load to inspiratory work during assisted and supported ventilatory modes, which may be reduced by application of small amounts of $PEEP_e$,[62] and (3) reflects dynamic hyperinflation with the consequent risks of barotrauma[63] and right heart failure. If $PEEP_i$ is not taken into account during calculation of chord compliance, an incorrect denominator is used, which may result in gross error.[64] As automated measures of mechanics do not account for $PEEP_i$, estimates of elastance must be corrected.

The two most commonly described techniques for measuring $PEEP_i$ are end-expiratory airway occlusion in a relaxed subject and the fall in oesophageal pressure during inspiration prior to initiation of inspiratory $\dot{V}$. However, these are not really comparable measures since static and dynamic $PEEP_i$, respectively, are measured. Static $PEEP_i$ is measured as the plateau P_{ao} that is reached following an end-expiratory occlusion; typically a plateau is reached in ~5 seconds, but this will be shorter in ARDS and longer in severe COPD. With the cessation of gas flow, alveolar pressure equilibrates with P_{ao}. Since the lung is composed of non-homogeneous units, this will represent the average static $PEEP_i$. All respiratory effort must be absent since muscle pressure will increase end-expiratory P_{ao}. End expiration must be accurately identified. This is most easily done by the ventilator itself either using an end-expiratory hold manoeuvre or by using the next inspiration, the onset of which is concurrent with expiratory valve closure, to close a valve that directs inspiratory flow to atmosphere and seals the circuit. Static $PEEP_i$ is a surrogate measure of dynamic hyperinflation, and this volume may be directly measured using a spirometer[61] or a pneumotachograph[15] during a prolonged expiration.

Dynamic $PEEP_i$ is measured as the pressure change required to initiate inflation. In ventilated subjects, this will be the change in P_{ao} prior to initiation of inspiratory $\dot{V}$,[62] and in spontaneously breathing subjects the change in oesophageal[60] or transdiaphragmatic[65] pressure from their end-expiratory relaxation values prior to inspiratory $\dot{V}$. Measurement of dynamic $PEEP_i$ in spontaneously breathing subjects is not particularly straightforward. The changes in pressure are small and influenced by cardiogenic oscillations, which are preferably filtered out.[66] Furthermore, dynamic $PEEP_i$ is not constant, with breath-to-breath variation probably due to variation in the extent of dynamic hyperinflation. Many patients with air-flow obstruction have an active expiration that 'falsely' increases $PEEP_i$, at least with respect to its elastic load since cessation of active expiration does not require work.[67] Consequently, it is preferable to concurrently measure intragastric pressure as a measure of active expiration.

Finally, $PEEP_i$ can be measured as P_o from dynamic P, V and $\dot{V}$ data in ventilated subjects. This is thought to be a measure of dynamic $PEEP_i$ since static $PEEP_i$ systematically yields a slightly greater result,[51] with similar discrepancies reported between other dynamic measures of $PEEP_i$ and static $PEEP_i$.[68,69] This systematic difference correlates with, and is thought to be due to, the viscoelastic properties and regional time constant inequalities of the RS.[68] This has clinical significance as, although matching dynamic $PEEP_i$ with $PEEP_e$ reduces respiratory work through a decrease in elastic load,[62] it does not counterbalance these forces.

PATIENT–VENTILATOR ASYNCHRONY

Asynchrony between the patient and ventilator is more common than usually recognised during both intubated and non-invasive ventilatory support, and is often due to patient effort failing to trigger the ventilator. Clinical findings include agitation and anxiety, tachycardia, tachypnoea, and increased work of breathing. Careful observation of the patient–ventilator interaction, including waveforms, can be used to further identify and help match ventilatory assistance to neural drive.[70] (See also Chapter 31.)

INSPIRATION

TRIGGERING OF INSPIRATION

Ineffective respiratory efforts are best detected from the P_{es} waveform; however, this is rarely monitored. Ineffective triggering due to $PEEP_i$ may be detected from the expiratory $\dot{V}$ waveforms as an abrupt decrease in $\dot{V}$ at either the onset of inspiratory muscle activity or relaxation of the expiratory muscles. Monitoring of P_{ao} is less sensitive unless the circuit expiratory resistance is increased (e.g. heat and moisture exchanger [HME] or poorly functioning expiratory valve) so that small changes in expiratory $\dot{V}$ are reflected in P_{ao}. Sensing P_{ao} at the Y-piece may not offer any advantage, as the pressure signal needs to travel the same distance, usually via separate gas tubing to the ventilator expiratory block. Inadequate sensitivity may also lead to ineffective triggering with similar but more obvious waveform effects.

Autotriggering, a triggered assisted or supported breath without patient effort, may occur owing to

excessively low trigger threshold or to P_{ao} or $\dot{V}$ distortion, as commonly seen with large cardiogenic oscillations, hiccups, condensate in tubing or a circuit leak. Again, waveform analysis may help detect and manage the problem; for example, it may be necessary to reduce trigger sensitivity to prevent cardiogenic oscillations from being detected as inspiratory effort.

INSPIRATION

During an assisted volume control breath, P_{ao} may fall, often seen as a scalloped shape, if there is excessive inspiratory muscle effort as seen in $\dot{V}$ starvation. Expiratory muscle effort, as may be seen with an excessive V_T or prolonged inspiratory time (T_i), leads to a rise in P_{ao}. During an assisted pressure control breath or during pressure support, changes in patient effort are detected from the $\dot{V}$ waveform. Finally, excessively rapid development of the set delivered pressure, a rapid rise time, may be detected by an overshoot in P_{ao}; an excessively long rise time will be seen as a rounded inspiratory $\dot{V}$ profile, similar to that seen with continued inspiratory muscle effort.

CESSATION OF INSPIRATION

Mismatch of the mechanical and neural T_i can be detected from waveform changes at the cessation of inspiration.

Mechanical T_i shorter than neural T_i

There will be prolonged inspiratory muscle effort during early expiration; if this leads to a sufficient fall in P_{ao} or $\dot{V}$, an early triggered breath follows. During pressure-cycled ventilation this will lead to a second small I_T breath due to the high baseline lung volume, but in assist volume control P_{ao} will be excessive. Typically this is seen with a stiff RS, $PEEP_i$ or inadequate pressure support.

Mechanical T_i longer than neural T_i

This leads to features of passive inflation such as a linear increase in P_{ao} during assist volume control ventilation; during pressure-cycled ventilation there may be an increase in P_{ao} due to loss of inspiratory effort, or an unexplained fall in $\dot{V}$.

EXPIRATION

Changes in P_{ao} during expiration are usually small unless expiratory circuit resistance is abnormally high. However, in patients with expiratory flow limitation, the expiratory $\dot{V}$ waveform shows a typical 'tick' pattern; there is a rapid spike in expiratory flow due to dynamic compression of large conducting airways at the beginning of expiration, and this is followed by low, slowly declining expiratory $\dot{V}$ due to high $\dot{V}$ expiratory resistance. When $PEEP_i$ is present, the expiratory $\dot{V}$ fails to cease prior to the inspiratory trigger; however, this may be difficult to detect due to the poor fidelity present on most commercial ventilators.

MONITORING NEUROMUSCULAR FUNCTION

INSPIRATORY OCCLUSION PRESSURE

The pressure 100 ms (P_{100} or $P_{0.1}$) after a random occlusion timed at the beginning of inspiration is a measure of respiratory drive. There is a large range of normal values (1.5–5 cm H_2O), but it is reproducible in an individual patient. In ventilated patients, the $P_{0.1}$ correlates with the work of breathing during pressure support ventilation, and changes in the same direction as $PEEP_e$ is increased if work is reduced.[71] Consequently, $P_{0.1}$ may prove to be a useful method of titrating $PEEP_e$ in patients with dynamic hyperinflation; however, this is not valid when flow triggering is used.

MAXIMUM MOUTH PRESSURES

Maximum inspiratory (MIP) and expiratory (MEP) mouth pressures can be used to estimate the power of the respiratory muscles. MIP is usually measured in ventilated patients using a unidirectional expiratory valve for ~20 seconds.[72] This ensures the procedure is performed from a low lung volume and does not require patient cooperation. However, despite this the results are quite variable.[73] Normal values vary with age and gender; young females may exceed ~–90 cm H_2O, and young males ~–130 cm H_2O. A MIP <–20 cm H_2O is predictive of weaning failure; however, this is associated with too many false positives and negatives to be useful.[13] MEP may be useful in myopathic patients with expiratory muscle weakness. Transdiaphragmatic pressure is assessed using an oesophageal and gastric balloon to measure the pressure in these two cavities.

WORK OF BREATHING

The work of breathing (W_B) is the sum of elastic work (W_{el}), flow-resistive work (W_{res}) and inertial work (negligible), and can be estimated from V–P data during spontaneous or assisted ventilation. An oesophageal balloon is used to examine changes in pleural pressure, $\dot{V}$ is measured with a pneumotachograph, and volume is derived as its integral. Although conceptually W_B is the inspiratory area of a V–P loop, this needs to be referenced to the CW V–P curve, and the appropriate area measured from a Campbell diagram.[74]

The normal W_B is ~0.5 J/L of $\dot{V}_E$, and this may be significantly increased in patients with acute respiratory failure, and by additional work imposed by ventilatory apparatus including the endotracheal tube and connector, humidifier and ventilator circuit.[75] The consequences of a large increase in W_B may include an increase in the $\dot{V}O_2$ attributable to breathing ($\dot{V}O_{2resp}$), respiratory muscle insufficiency, CO_2 retention and acute respiratory failure. However, W_B is rarely measured outside of research projects since

the Campbell diagram is a relatively tedious approach. Simplifications have been used, but these are not as accurate, and W_B only estimates energy expenditure during muscle shortening with relatively poor correlation with $\dot{V}O_{2resp}$.[76] Consequently, the pressure-time product (PTP), which does correlate with $\dot{V}O_{2resp}$,[77] is more commonly measured.[10]

PRESSURE–TIME PRODUCT

PTP is usually calculated from the oesophageal pressure-time integral during inspiration. In mechanically ventilated patients, the oesophageal pressure during assisted breathing is compared with that during a controlled breath, or that pressure calculated from the CW elastance and lung volume.[10] However, the early correlation of $\dot{V}O_{2resp}$ with PTP used the transdiaphragmatic pressure in spontaneously breathing subjects.[74] Using either technique, importantly, the effort expended before $\dot{V}$ occurs due to $PEEP_i$ is measured, probably accounting for the better correlation of $\dot{V}O_{2resp}$ with PTP than W_B.[74] Although incremental pressure support ventilation may reduce PTP in COPD patients, the effect can be variable with some patients also showing evidence of expiratory muscle activity due to delayed sensing of neural expiration.[10]

ELECTRICAL ACTIVITY OF THE DIAPHRAGM

Using a modified nasogastric tube, electrical activity of the diaphragm (EAdi) can be monitored, and used to drive neutrally assisted ventilation.[78] While EAdi and transdiaphragmatic pressure (Pdi) usually show a strong correlation, suggesting that EAdi could replace the need for P_{es} monitoring in some circumstances, electromechanical uncoupling may occur when the diaphragm is placed under mechanical disadvantage such as the presence of PEEPi.[31] During triggered ventilation, EAdi may help diagnose and manage asynchrony, and this technique offers assistance diagnosing and managing neuromuscular disorders, particularly those with minimal peripheral muscle manifestations.

ULTRASOUND

Lung ultrasound is covered in Chapter 40. Ultrasound can also be used to measure diaphragm thickness at the zone of apposition, and fractional thickening is predictive of weaning trial outcome.[79]

Chest imaging

Simon PG Padley, Patrick MT Wong

RADIOLOGICAL TECHNIQUES

Of the imaging techniques available for investigating patients in the intensive care unit (ICU), the chest radiograph remains the most important, with ultrasound being utilised in a selected group of patients. High-resolution and computed tomography (CT) allow further investigation of these patients in certain situations.

CHEST RADIOGRAPHY

The views of the chest most frequently performed in the ambulant patient are the erect posteroanterior (PA) and lateral projections, taken with the patient breath-holding at total lung capacity. While portable or mobile chest radiography, as undertaken on an ICU, has the obvious advantage that the examination can be done without moving the patient from the ward, there are many disadvantages. These include:

- shorter focus–film distance causing magnification
- limited X-ray output necessitating long exposure times with resultant movement blurring
- difficulties with satisfactory patient positioning.

COMPUTED TOMOGRAPHY

CT relies on differing absorption of X-rays by tissues with constituents of differing atomic number, so slight differences in X-ray absorption can be interpreted to produce a cross-sectional image. The components of a CT scanner are an X-ray tube, which rotates around the patient, and an array of X-ray detectors opposite the tube.

Spiral (also known as volume or helical) scanning entails sustained patient exposure by the rotating X-ray tube during continuous movement of the examination couch through the CT gantry aperture. In this way, a continuous data set or 'spiral' of information may be acquired in a single breath-hold.

INTRAVENOUS CONTRAST ENHANCEMENT

The inherent high contrast on CT between vessels and surrounding air in the lung, and vessels and surrounding fat within the mediastinum reduces the need for intravenous contrast enhancement in most instances. However, in some circumstances, for example to aid the distinction between hilar vessels and a soft-tissue mass or to detect a pulmonary artery embolus, contrast is required. The timing of the injection of contrast media depends on the technical attributes of the CT scanner. Rapid scanning protocols with automated injectors tend to improve contrast enhancement of vascular structures at the expense of enhancement of solid lesions because of the rapidity of scanning. Timing of image acquisition is vital for accurate diagnosis of pulmonary embolism. However, when examining inflammatory lesions such as the reaction around an empyema, it may be necessary to delay scanning by 60 seconds to allow contrast to diffuse into the extravascular space.

CLINICAL APPLICATIONS OF HIGH-RESOLUTION COMPUTED TOMOGRAPHY IN THE INTENSIVE CARE UNIT PATIENT

High-resolution computed tomography (HRCT) is increasingly being used to confirm the impression of an abnormality seen on a chest radiograph. HRCT may also be used to achieve a histospecific diagnosis in some patients with obvious but non-specific radiographic abnormalities. Furthermore, HRCT has provided a number of useful insights into chest disease in the severely ill patient in an ICU setting.

High-resolution computed tomography in uncomplicated acute respiratory distress syndrome[1]

- HRCT reveals that the apparently homogeneous opacification apparent on the chest radiograph has an anterior-to-posterior graded increase in density – an appearance referred to as a gravitational gradient (Fig. 39.1).
- HRCT demonstrates early dilatation of the smaller airways within areas of ground-glass density, an appearance that suggests development of fibrosis, and may prompt anti-inflammatory treatment.
- HRCT demonstrates that a shift from the supine to the prone position results in redistribution of

ABSTRACT

This chapter discusses an approach to chest imaging useful for intensivists. An approach to plain film interpretation is described. Common intensive care conditions are presented with a focus on important imaging considerations.

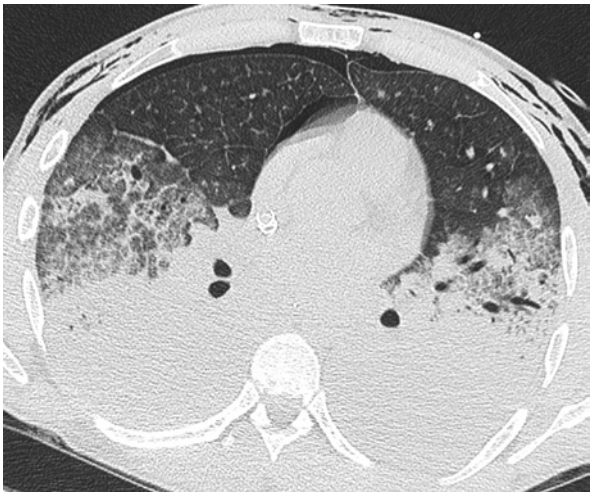

Figure 39.1 Computed tomography of a patient with acute respiratory distress syndrome. Note the marked anterior-to-posterior-density gradient. The anterior lung is of almost normal density, becoming of ground-glass attenuation in the mid part of the lung before fading into consolidation posteriorly. There are small pneumothoraces bilaterally and surgical emphysema.

the previously dependent dense parenchymal opacification to the now dependent anterior lung, a phenomenon that may be accompanied by improvements in patient oxygenation.

High-resolution computed tomography of complications of acute respiratory distress syndrome

- Infection is common in acute respiratory distress syndrome (ARDS). Diagnosis may be difficult. Radiographically there may be a lack of specific findings, often due to superimposition of changes attributable to ARDS. This is a particular problem in the critically ill patient when the usual indicators of pneumonia are also unreliable. Although the diagnosis may still be in question following HRCT, associated pneumonic changes such as abscess formation, empyema and mediastinal disease, as well as development of non-dependent areas of consolidation, are all useful pointers to superadded infection (see Fig. 39.1).
- Barotrauma – mediastinal and interstitial emphysema, as well as pneumothorax, are all increasingly common at higher levels of peak end-expiratory pressure (PEEP). The incidence of barotrauma has been reported to be as high as 50%.
- HRCT allows the exact location of loculated air collections to be defined.

NORMAL RADIOGRAPHIC ANATOMY

THE MEDIASTINUM, CENTRAL AIRWAYS AND HILAR STRUCTURES

Appreciation of abnormality requires a sound grasp of normal radiological anatomy. The mediastinum is delimited by the lungs on each side, the thoracic inlet above, the diaphragm below and the vertebral column posteriorly. Because the various structures that make up the mediastinum are superimposed on each other on the chest radiograph, they cannot be separately identified. Key points include:

- Only the outline of the mediastinum and the air-containing trachea and bronchi (and sometimes oesophagus) are clearly seen on a normal chest radiograph.
- The right superior mediastinal border is formed by the right brachiocephalic vein and superior vena cava (SVC), and becomes less distinct as it reaches the thoracic inlet. The right side of the superior mediastinum can appear to be considerably widened in patients with an abundance of mediastinal fat.
- The left mediastinal border above the aortic arch is the result of summation of the left carotid and left subclavian arteries together with the left brachiocephalic and jugular veins.
- The left cardiac border comprises the left atrial appendage, which merges inferiorly with the left ventricle. The silhouette of the heart should always be sharply outlined. Any blurring of the border is due to loss of immediately adjacent aerated lung, usually by collapse or consolidation.
- The density of the heart shadow to the left and right of the vertebral column should be identical and any difference indicates pathology (e.g. an area of consolidation or a mass in a lower lobe).
- The trachea and main bronchi should be visible through the upper and middle mediastinum.
- In older individuals, the trachea may be displaced by a dilated aortic arch. In approximately 60% of normal subjects, the right wall of the trachea (the right paratracheal stripe) can be identified as a line of uniform thickness (less than 4 mm in width); when it is visible it excludes the presence of an adjacent space-occupying lesion, most usually lymphadenopathy.
- The carinal angle is usually less than 80 degrees. Splaying of the carina is an insensitive sign of subcarinal disease, either in the form of massive subcarinal lymphadenopathy, or a markedly enlarged left atrium.
- The origins of the lobar bronchi, where they are projected over the mediastinal shadow, can usually be identified but the segmental bronchi within the lungs are not generally seen on plain radiography.

- Normal hilar shadows on a chest radiograph represent the summation of the pulmonary arteries and veins.
- The hila are approximately the same size and the left hilum normally lies between 0.5 cm and 1.5 cm above the level of the right hilum. The size and shape of the hila show remarkable variation in normal individuals, making subtle abnormalities difficult to identify.

THE PULMONARY FISSURES, VESSELS AND BRONCHI

The two lungs are separated by the four layers of pleura behind and in front of the mediastinum. The resulting posterior and anterior junction lines are often visible on chest radiographs as nearly vertical stripes, the posterior junction line lying higher than the anterior.

The upper and lower lobes of the left lung are separated by the major (or oblique) fissure. The upper, middle and lower lobes of the right lung are separated by the major fissure and the minor (horizontal or transverse) fissure. The minor fissure is visible in over half of normal PA chest radiographs. The major fissures are not visible on a frontal radiograph and are inconstantly identifiable on lateral radiographs. In a few individuals, fissures are incompletely developed – a point familiar to thoracic surgeons performing a lobectomy because of incomplete cleavage between lobes. Accessory fissures are occasionally seen.

All of the branching structures seen within normal lungs on a chest radiograph represent pulmonary arteries or veins. It is often impossible to distinguish arteries from veins in the lung periphery. On a chest radiograph taken in the erect position, there is a gradual increase in the diameter of the vessels, at equidistant points from the hilum, travelling from lung apex to base; this gravity-dependent effect disappears if the patient is supine or in cardiac failure.

THE DIAPHRAGM AND THORACIC CAGE

The interface between aerated lung and the diaphragm is sharp and the highest point of each dome is normally medial to the midclavicular line. The right dome of the diaphragm is higher than the left by up to 2 cm in the erect position unless the left dome is elevated by air in the stomach (Fig. 39.2).

Filling-in or blunting of these costophrenic angles usually represents pleural disease, either pleural thickening or an effusion.

Figure 39.2 Erect chest radiograph of a patient with a pneumoperitoneum demonstrating the normal thickness in position of the hemidiaphragms. The right lies slightly higher than the left.

POSITIONING OF TUBES AND LINES[3]

CENTRAL VENOUS CATHETERS

The end of a central venous catheter (CVC) needs to be intrathoracic, and is ideally in the SVC. CVCs may be introduced via an antecubital, subclavian or jugular vein. Subclavian venous puncture carries a risk of pneumothorax and mediastinal haematoma. Rarely, perforation of the subclavian vein leads to fluid collecting in the mediastinum or pleura. All catheters have a potential risk of coiling, misplacement, knotting and fracture (Fig. 39.3). The tip should not abut the vessel wall at an obtuse angle.

PULMONARY ARTERY FLOTATION CATHETERS

Ideally, the end of the catheter should be maintained less than 5–8 cm (2–3 inches) beyond the bifurcation of the main pulmonary artery in either the right or left pulmonary artery (see Fig. 39.3). When the pulmonary artery occlusion pressure is measured, the balloon is inflated, and the flow of blood carries the catheter tip peripherally, to an occluded position. After the measurement has been made, the balloon is deflated and the catheter returns to a central position; otherwise, there is a risk of pulmonary infarction. The inflation balloon is radiolucent. The balloon should normally be kept deflated.

NASOGASTRIC TUBES

These should reach the stomach but may coil in the oesophagus or occasionally are inserted into the tracheobronchial tree (Fig. 39.4).

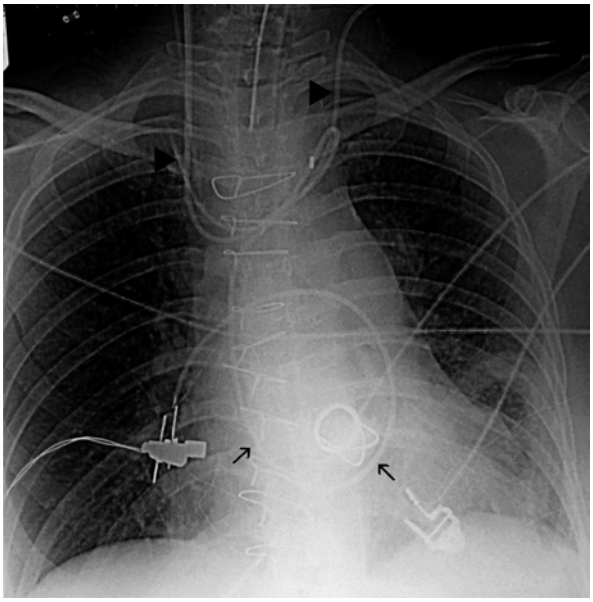

Figure 39.3 Intensive care unit patient with multiple tubes and lines in place. The endotracheal tube tip position is satisfactory, and there are sternotomy wires, an intra-aortic balloon pump (radiopaque tip in the proximal descending aorta) and a prosthetic heart valve. The central line inserted into the left internal jugular vein passes into the right internal jugular vein. The Swan–Ganz catheter, which has been inserted via the right internal jugular vein, loops into the left brachiocephalic vein, before taking a satisfactory course through the cardiac chambers *(black arrows)*.

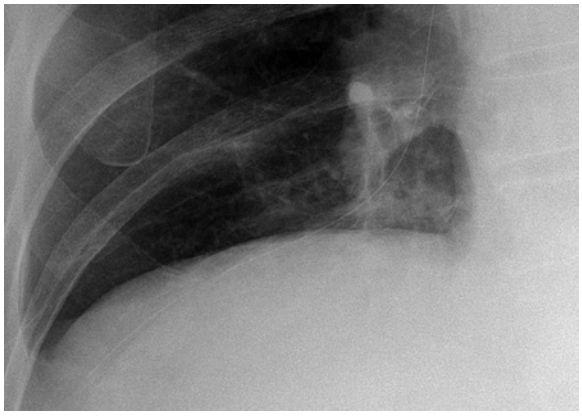

Figure 39.4 Misplaced nasogastric tube.

ENDOTRACHEAL TUBES

Extension and flexion of the neck may make the tip of an endotracheal tube move by as much as 5 cm. With the neck in neutral position, the tip of the tube should ideally be about 4–5 cm above the carina. A tube that is inserted too far usually passes into the right bronchus, with the risk of non-ventilation or collapse of the left lung (Fig. 39.5).

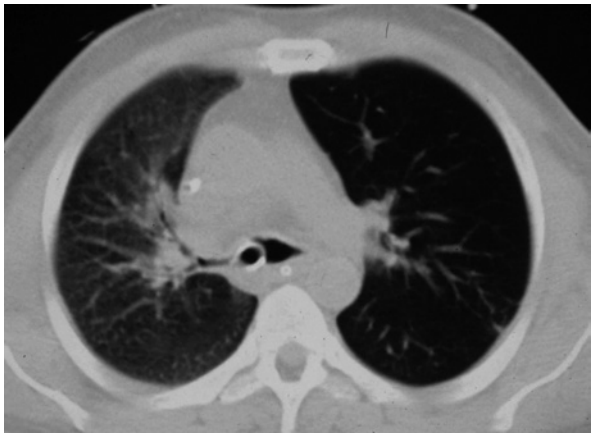

Figure 39.5 Endotracheal tube inserted into the right main bronchus as demonstrated on computed tomography. This image, obtained in expiration, demonstrates air trapping in the left lung.

TRACHEOSTOMY TUBES

The tube tip should be situated centrally in the airway at the level of T_3. Acute complications of tracheostomy include pneumothorax, pneumomediastinum and subcutaneous emphysema. Long-term complications include tracheal ulceration, stenosis and perforation.

PLEURAL TUBES

These are used to treat pleural effusions and pneumothoraces. A radiopaque line usually runs along pleural tubes and is interrupted where there are side holes. It is important to check that all the side holes are within the thorax. Tracks may remain on the chest X-ray following removal of chest tubes, causing tubular or ring shadows. When doubt remains about tube position, then CT scanning should be considered (Fig. 39.6).

MEDIASTINAL DRAINS

These are usually present following sternotomy. Apart from their position, they look like pleural tubes.

INTRA-AORTIC BALLOON PUMP

These are used in patients with cardiogenic shock, often following cardiac surgery. The ideal position of the catheter tip is just distal to the origin

Figure 39.6 Computed tomography scan demonstrating bilateral pneumothoraces in a patient with acute respiratory distress syndrome. Note is made of bilateral chest drains.

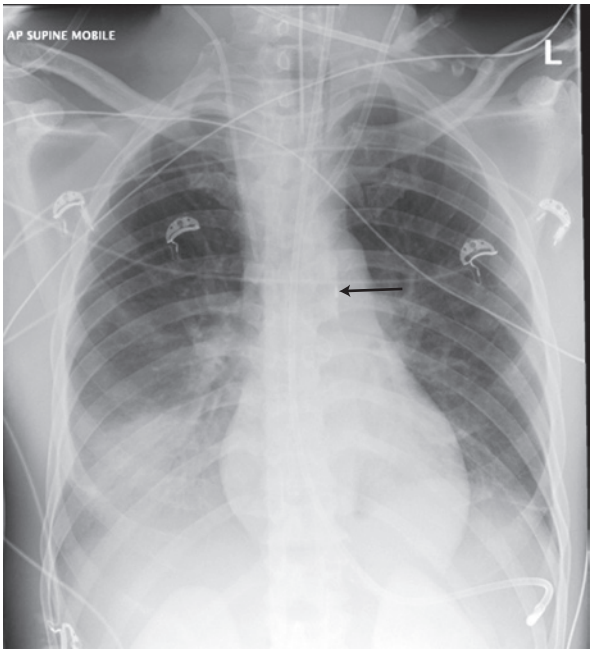

Figure 39.7 Intra-aortic balloon pump. The tip *(arrow)* is seen appropriately positioned in the proximal descending aorta. The patient suffered septic cardiomyopathy due to multilobar pneumococcal pneumonia.

of the left subclavian artery (Fig. 39.7). If the catheter tip is advanced too far it may occlude the left subclavian artery, and if it is too distal the balloon may occlude branches of the abdominal aorta. The intra-aortic balloon pump may be visible only by its radiopaque tip.

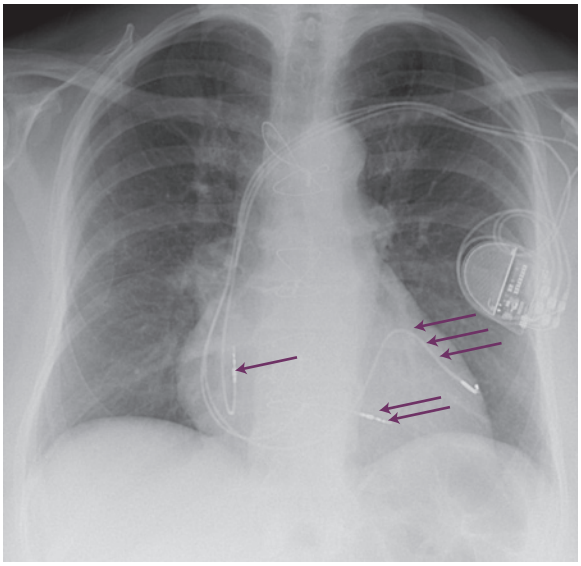

Figure 39.8 Biventricular pacemaker. Note the right atrial lead *(arrow)*, right ventricular lead *(double arrows)* and coronary sinus lead *(triple arrows)*.

PACEMAKERS

These may be permanent or temporary (Fig. 39.8). Temporary epicardial wires are sometimes inserted during cardiac surgery, and may be seen as thin, almost hair-like metallic opacities overlying the heart. Temporary pacing electrodes are usually inserted transvenously via a subclavian or jugular vein. If a patient is not being paced properly, a chest radiograph may reveal that the position of the electrode tip is unstable, or that a fracture in the wire has occurred.

EXTRACORPOREAL MEMBRANE OXYGENATION

Extracorporeal membrane oxygenation (ECMO) cannulae are large bore, and can be classified as veno-venous or veno-arterial based on line location.

Veno-venous ECMO: the venous drainage cannula should be placed in the proximal SVC or inferior vena cava (IVC) and return cannula should be placed in the right atrium (Fig. 39.9). Veno-arterial ECMO: the venous drainage cannula should be placed in the right atrium, distal IVC or SVC and the return cannula should be within the aorta or its branches (Fig. 39.10).

Line-associated complications include venous tear, arterial pseudoaneurysm, haemorrhage and thrombosis, which can be identified on CT. Systemic complications include thrombosis, pulmonary or systemic emboli (including ischaemic stroke), disseminated intravascular coagulation, systemic haemorrhage and especially intracranial haemorrhage (Fig. 39.11).

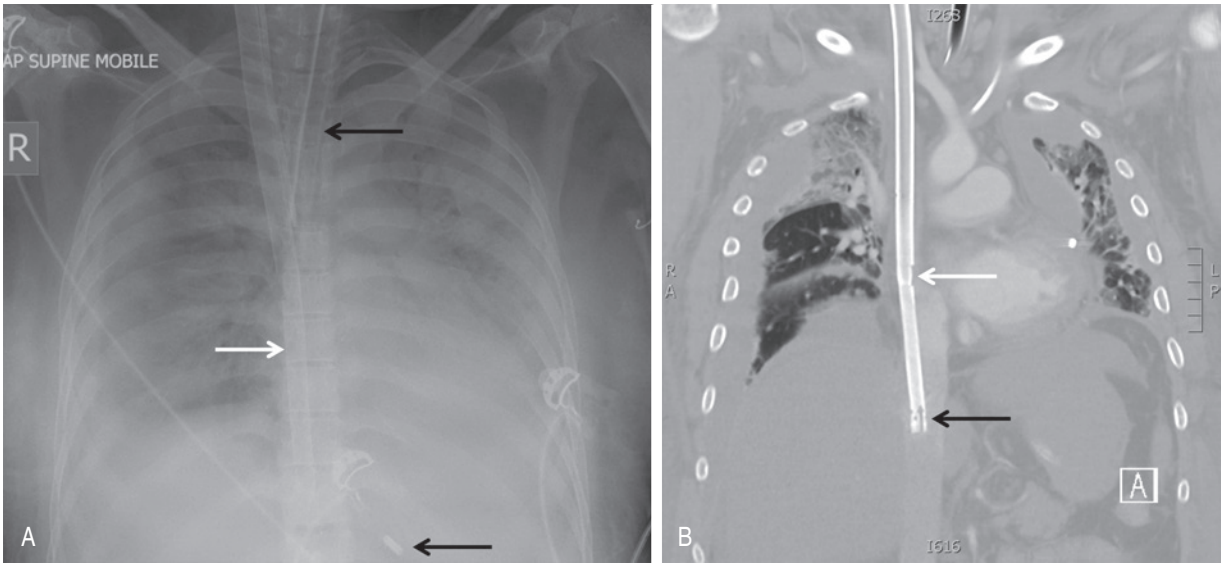

Figure 39.9 (a) Chest radiograph of an adult male patient with acute respiratory distress syndrome demonstrating the single puncture dual lumen venovenous-extracorporeal membrane oxygenation Avalon catheter in situ *(white arrow)*. The draining and returning holes cannot be demonstrated on plain radiographs. Endotracheal and nasogastric tubes are also in situ *(black arrows)*. (b) Maximum intensity projection (MIP) coronal images on lungs windows demonstrate the position of the Avalon cannula inserted via the right internal jugular vein (RIJV), the holes of the draining lumen *(black arrow)* and the hole of the return lumen *(white arrow)*.

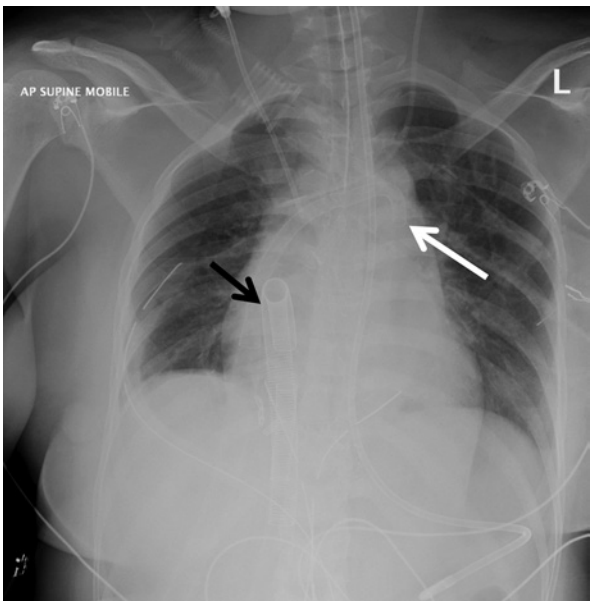

Figure 39.10 Venoarterial-extracorporeal membrane oxygenation in a patient with massive pulmonary embolism. The drainage cannula is in the right atrium *(black arrow)*. The return cannula is in the proximal descending aorta *(white arrow)*.

Figure 39.11 Unenhanced axial computed tomography head image of a 71-year-old male on venoarterial-extracorporeal membrane oxygenation post aortic aneurysm repair. There is a large intraparenchymal, subarachnoid and intraventricular haemorrhage.

RADIOGRAPHIC SIGNS OF PATHOLOGY

CONSOLIDATION

Consolidation, or synonymously air space shadowing, is due to opacification of the air-containing spaces of the lung, usually without a change in volume of the affected area. It is not possible to tell what the air space filling is due to in the absence of a clinical history, except perhaps for shadowing due to cardiogenic alveolar oedema, when there will be associated signs of cardiac failure. Typical features of all forms of consolidation (Fig. 39.12) include:

- ill-defined margins, except where it directly abuts a pleural surface
- sharply demarcated by fissures
- loss of vascular markings
- air bronchograms – the bronchi, usually invisible, may become apparent in negative contrast to the air space opacification
- acinar opacities, due to individual acini or secondary pulmonary lobules being opacified but still surrounded by normally aerated lung, usually seen at the periphery of a more confluent area of consolidation, and 0.5–1 cm in diameter
- ground-glass opacification, when consolidation has caused only partial filling of the air spaces
- silhouette sign – consolidation abutting a soft-tissue structure causes the silhouette of that structure to be lost.

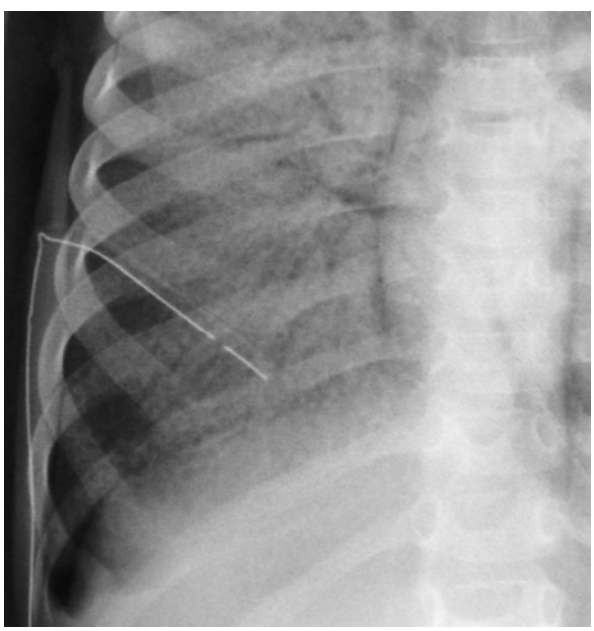

Figure 39.12 Close-up view of an area of consolidation adjacent to the right heart border, which is obscured. Air bronchograms can be identified passing through this area. A chest tube is in situ.

When an area of consolidation undergoes necrosis, due to either infection or infarction, then liquefaction may result, and if there is either a gas-forming organism or communication with the bronchial tree, then an air-fluid level may develop in addition to cavity formation.

The radiographic signs of a lobar consolidation are similar to those of lobar collapse (see section on Collapse, below), with the exception that there is no volume loss.

COLLAPSE

When there is partial or complete volume loss in a lung or lobe, this is referred to as collapse or atelectasis, implying a diminished volume of air in the lung with associated reduction of lung volume. There are several different mechanisms for lung or lobar collapse, for example relaxation or passive collapse, when fluid or air accumulates in the pleural space; cicatrisation collapse, when volume loss is associated with pulmonary fibrosis; adhesive collapse, as in ARDS; and resorption collapse, as in bronchial obstruction.

The radiographic appearance in pulmonary collapse depends upon a number of factors. These include the mechanism of collapse, the extent of collapse, the presence or absence of consolidation in the affected lung and the pre-existing state of the pleura. This latter factor includes the presence of underlying pleural tethering or thickening and the presence of pleural fluid.

The direct signs of collapse include:

- displacement of interlobar fissures
- loss of aeration resulting in increased density or the presence of the silhouette sign
- crowding of vessels and bronchi.

The indirect signs of collapse include:

- elevation of the hemidiaphragm, especially with lower lobe collapse
- mediastinal displacement, especially in upper lobe collapse
- hilar displacement, where the hilum is elevated in upper lobe collapse and depressed in lower lobe collapse
- compensatory hyperinflation of remaining normal lung, resulting in increased transradiancy or herniation across the midline from the normal side
- crowding of the ribs reflecting diminished overall volume of the affected hemithorax.

COMPLETE LUNG COLLAPSE

Complete collapse (Fig. 39.13) will cause complete opacification of the hemithorax, with displacement of the mediastinum to the affected side and elevation of the hemidiaphragm. Compensatory hyperinflation of the contralateral lung with herniation across

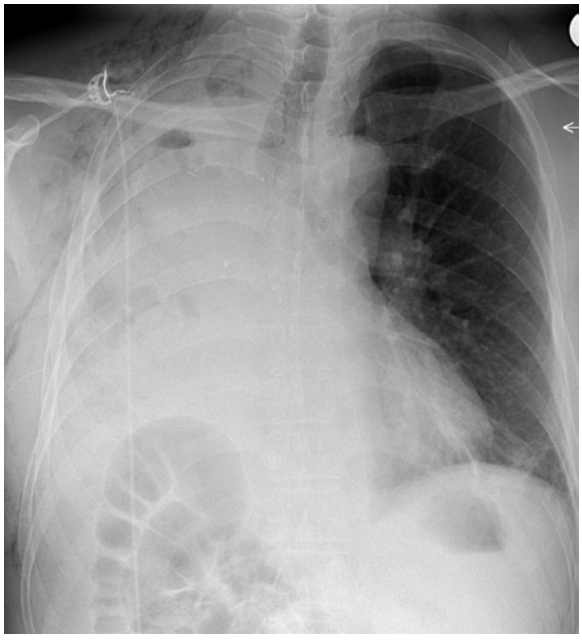

Figure 39.13 Complete lung collapse. There was an obstructing tumour in the right main bronchus. The right hemithorax is opaque, the mediastinum has shifted and the trachea is deviated to the right.

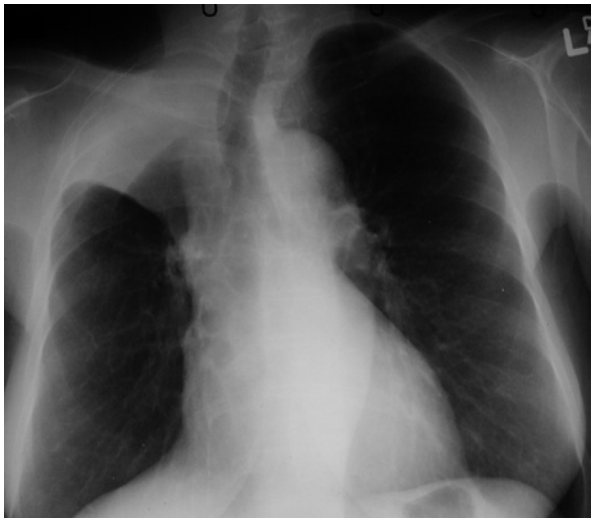

Figure 39.14 Right upper lobe collapse. The horizontal fissure has become elevated and the right upper lobe has become a wedge-shaped density extending from the hilum to the right lung apex. There is evidence of volume loss with shift of the trachea to the right side.

the midline may be apparent. Herniation may occur in the retrosternal space, anterior to the ascending aorta, or may be posterior to the heart.

INDIVIDUAL OR COMBINED LOBAR COLLAPSE

In any situation, some or all of the signs may be present.

Right upper lobe collapse (Fig. 39.14)

- Horizontal fissure moves upwards and medially towards the superior mediastinum.
- Trachea deviates to the right.
- Compensatory hyperinflation of the right middle and lower lobes.

Middle lobe collapse (Fig. 39.15)

- Horizontal fissure and lower half of the oblique fissure move towards each other – best seen on the lateral projection.
- Frontal radiograph changes may be subtle, with obscuration of the right heart border.
- Indirect signs of volume loss are rarely obvious.

Right lower lobe collapse

- There is partial depression of the horizontal fissure.
- There is triangular opacity of the collapsed lower lobe on the frontal projection, usually obscuring the diaphragm but preserving the right heart border.

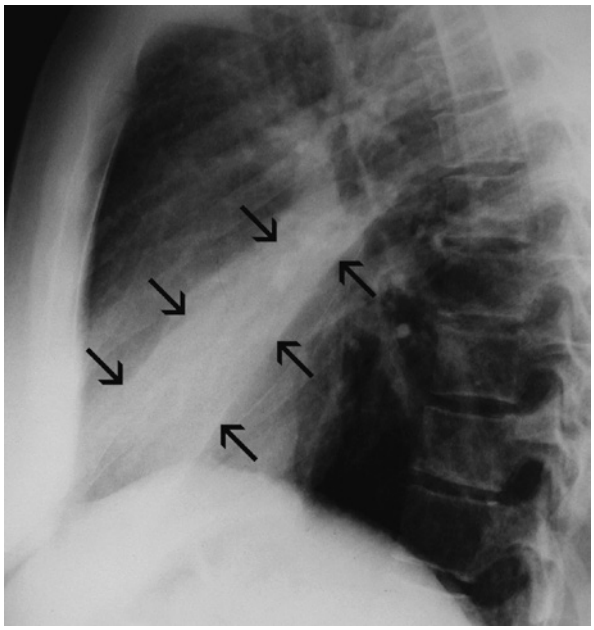

Figure 39.15 Middle lobe collapse. The horizontal fissure is depressed and demarcates the collapsed middle lobe as a wedge-shaped density best demonstrated on the lateral *(arrows)*.

- Eventually a completely collapsed lower lobe may be so small that it flattens and merges with the mediastinum, producing a thin, wedge-shaped shadow.

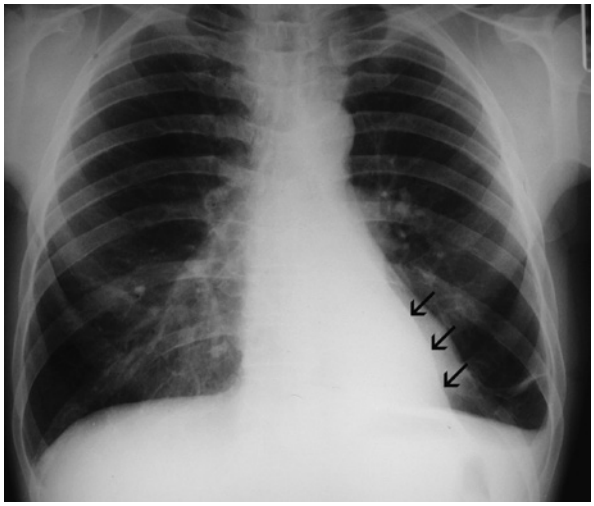

Figure 39.16 Left lower lobe collapse. The left lower lobe has become a wedge-shaped density behind the heart, forming a double left heart border *(arrows)*. The left hilar vessel to the lower lobe has disappeared as a result of collapse.

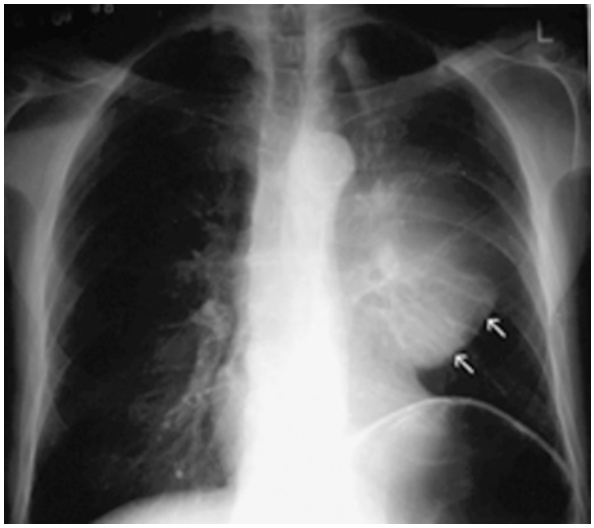

Figure 39.17 Left upper lobe collapse. A hazy opacity extends from the hilum towards the left lung apex. It is sharply demarcated inferiorly and laterally *(white arrows)* owing to the presence of a large tumour at the left hilum, which is obstructing the left upper lobe bronchus. Note the signs of volume loss, particularly the elevation of the left hemidiaphragm.

Left lower lobe collapse (Fig. 39.16)

- Collapsed lobe may be obscured by the heart and a penetrated view may be required.
- Mediastinal structures and the diaphragm adjacent to the non-aerated lobe are obscured.
- Extreme volume loss may cause the lobe to be so small as to be invisible as a separate opacity.
- There is loss of lower lobe artery silhouette at the hilum.

Lingula collapse

- Is often involved in collapse of the left upper lobe.
- May collapse individually, leading to focal blurring of the central left heart border.
- Radiographic features are similar to those of middle lobe collapse.

Left upper lobe collapse (Fig. 39.17)

- Lateral view demonstrates anterior displacement of the entire oblique fissure, oriented almost parallel to the anterior chest wall, demarcating the posterior surface of the upper lobe as an elongated opacity extending from the apex almost reaching the diaphragm and lying anterior to the hilum.
- Eventually the upper lobe retracts posteriorly and loses contact with the anterior chest wall.
- Frontal radiograph demonstrates an ill-defined hazy opacity in the upper, mid and sometimes lower zones, with loss of hilar clarity.
- Hilum is often elevated, and the trachea deviated to the left.

COMBINED COLLAPSE

Right lower and middle lobe collapse is the most common pairing since a lesion may occur in the bronchus intermedius. The appearances are similar to right lower lobe collapse except that the horizontal fissure is not apparent, and the opacification reaches the lateral chest wall on the frontal radiograph, and similarly extends to the anterior chest wall on the lateral view.

Right upper and middle lobe collapse is much less common because of the distance between the origins of their bronchi, and can generally be taken to imply the presence of more than one lesion. This combination will produce appearances almost identical to those of left upper lobe collapse (see Fig. 39.17). On occasion, isolated right upper lobe collapse will also produce appearances that are identical to left upper lobe collapse.

UNILATERAL INCREASED TRANSRADIANCY

The commonest causes are technical and include:

- patient rotation
- poor beam centring
- offset grid.

Pathological causes include:

- chest wall changes
- mastectomy

- congenital unilateral absence of pectoral muscles, known as Poland syndrome
- reduced vascularity when interruption or significant reduction in the blood supply to one lung may cause that lung to be of increased transradiancy
- lung hyperexpansion due to air trapping or asymmetric emphysema.

When there is relative increased transradiancy of one hemithorax for which there is no obvious cause, then the possibility of generalised increase in radiopacity of the opposite side should be considered – for example, the posterior layering of a pleural effusion in a supine patient. Usually hypertransradiancy due to technical factors can be identified by comparison of the soft tissues around the shoulder girdle, and particularly over the axillae.

ABNORMALITIES OF THE MEDIASTINUM

Pneumomediastinum or mediastinal emphysema is the presence of air between the tissue planes of the mediastinum (see section on Injuries to the mediastinum). Chest radiography may show vertical translucent streaks in the mediastinum, representing air separating the soft-tissue planes. The air may extend up into the neck and over the chest wall, causing subcutaneous emphysema, and also over the diaphragm. The mediastinal pleura may be displaced laterally and then be visible as a thin stripe alongside the mediastinum.

Acute mediastinitis is usually due to perforation of the oesophagus, pharynx or trachea and chest radiograph usually shows widening of the mediastinum and pneumomediastinum.

Mediastinal haemorrhage may occur from venous or arterial bleeding. The mediastinum appears widened, and blood may be seen tracking over the lung apices. It is imperative to identify a life-threatening cause such as aortic rupture.

Aortic dissection or aneurysmal dilatation may also cause widening of the mediastinal silhouette on chest radiography (Fig. 39.18).

Figure 39.18 Aortic dissection. Coronal computed tomographic image showing intimal flap in the descending aorta.

PLEURAL FLUID

The most dependent recess of the pleural space is the posterior costophrenic angle and this is where a small effusion will tend to collect. As little as a few millilitres of fluid may be detected using decubitus views with a horizontal beam, ultrasound or CT. Larger volumes of fluid eventually fill in the costophrenic angle on the frontal view, and with increasing fluid a homogeneous opacity spreads upwards, obscuring the lung base (Fig. 39.19). The fluid usually demonstrates a concave upper edge, higher laterally than medially, and obscures the diaphragm. Fluid may track into the fissures. A massive effusion may cause complete opacification of a hemithorax with passive atelectasis. The space-occupying effect of the effusion may push the mediastinum towards the opposite side, especially when the lung does not collapse significantly. Effusions in a supine patient redistribute into the

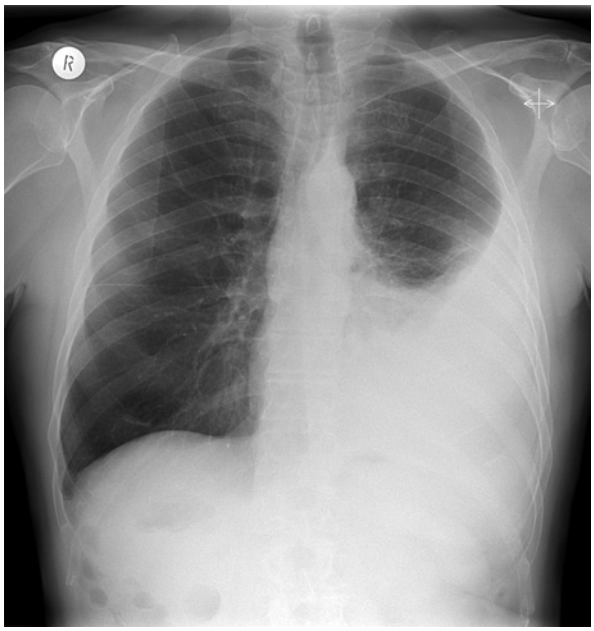

Figure 39.19 Left pleural effusion. There is a typical configuration of the left upper border, a meniscus extending up the lateral chest wall.

paravertebral sulcus and produce an even increased density throughout that hemithorax.

Lamellar effusions are shallow collections between the lung surface and the visceral pleura, sometimes sparing the costophrenic angle, and occur early in heart failure.

Subpulmonary effusions accumulate between the diaphragm and undersurface of a lung, mimicking elevation of the hemidiaphragm, altering the diaphragmatic contour so the apex moves more laterally than usual. When left-sided, there is increased distance between the gastric air bubble and lung base.

Fluid may become loculated in the interlobar fissures and is most frequently seen in heart failure. Loculated interlobar effusions may disappear rapidly and are sometimes known as pulmonary pseudotumours.

Differentiation between a simple effusion and a complicated parapneumonic effusion or an empyema usually requires thoracentesis. Loculation is best demonstrated with ultrasound.

PNEUMOTHORAX

In an erect patient, air will usually collect at the apex (Fig. 39.20). The lung retracts towards the hilum and on a frontal chest film the sharp white line of the visceral pleura will be visible, separated from the chest wall by the radiolucent pleural space, which is devoid of lung markings. This should not be confused with a skin fold, which mostly occurs in supine or recumbent patients. The lung usually remains aerated, although perfusion is reduced in proportion to ventilation and therefore the radiodensity of the partially collapsed lung remains relatively normal. A large pneumothorax may lead to complete retraction of the lung, with some mediastinal shift towards the normal side. Since it is a medical emergency, tension pneumothorax is often treated before a chest radiograph is obtained. However, if a radiograph is taken in this situation it will show marked displacement of the mediastinum. Radiographically the lung may be squashed against the mediastinum or herniate across the midline, and the ipsilateral hemidiaphragm may be depressed. A supine pneumothorax may produce increased transradiancy towards the diaphragm, and a deep sulcus sign.

COMPLICATIONS OF PNEUMOTHORAX

Pleural adhesions may limit the distribution of a pneumothorax and result in a loculated or encysted pneumothorax (see Fig. 39.6). The usual appearance is an ovoid air collection adjacent to the chest wall, and it may be radiographically indistinguishable from a thin-walled subpleural pulmonary cyst or bulla. Pleural adhesions are occasionally seen as line shadows

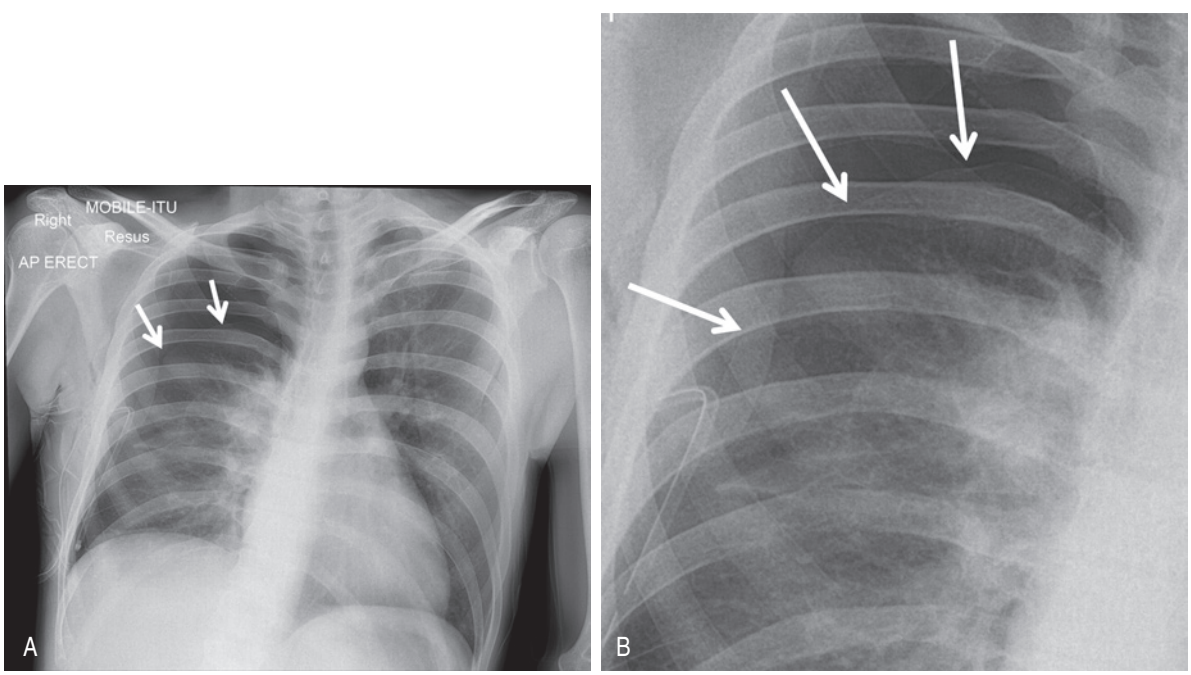

Figure 39.20 Pneumothorax. (a) This patient, with underlying lung abnormality, has developed a pneumothorax. The fine white line that represents the visceral pleura delineates the edge of the lung *(arrows)*. (b) Close-up of the pleural line. Note how there are no vascular markings beyond this point.

stretching between the two pleural layers, preventing relaxation of the underlying lung. Rupture of an adhesion may produce a haemopneumothorax. Collapse or consolidation of a lobe or lung in association with a pneumothorax is important because it may delay re-expansion of the lung.

Since the normal pleural space contains a small volume of fluid, blunting of the costophrenic angle by a short fluid level is commonly seen in a pneumothorax. In a small pneumothorax this fluid level may be the most obvious radiological sign. A larger fluid level usually signifies a complication and represents exudate, pus or blood, depending on the aetiology of the pneumothorax. A hydropneumothorax is a pneumothorax containing a significant amount of fluid (Fig. 39.21). On a radiograph obtained with a horizontal beam, a fluid level is evident. A hydro- or pyopneumothorax may arise as a result of a bronchopleural fistula, and may be a complication of surgery, tumour or infection.

PULMONARY EMBOLISM

CT has excellent reported sensitivity and specificity for the detection of pulmonary embolus down to the segmental level.[3] Pulmonary emboli are identified as filling defects in the contrast opacified pulmonary arteries (Fig. 39.22). CT pulmonary angiography (CTPA) also allows evaluation of clot burden, right heart strain and pulmonary infarction. In addition, even with a negative study, CTPA also allows other diagnoses to be made that explain the symptoms of chest pain or dyspnoea.

TRAUMA AND THE INTENSIVE CARE UNIT PATIENT

SKELETAL INJURY

Following trauma, rib fractures are common and may be single, multiple, unilateral or bilateral. In cases of

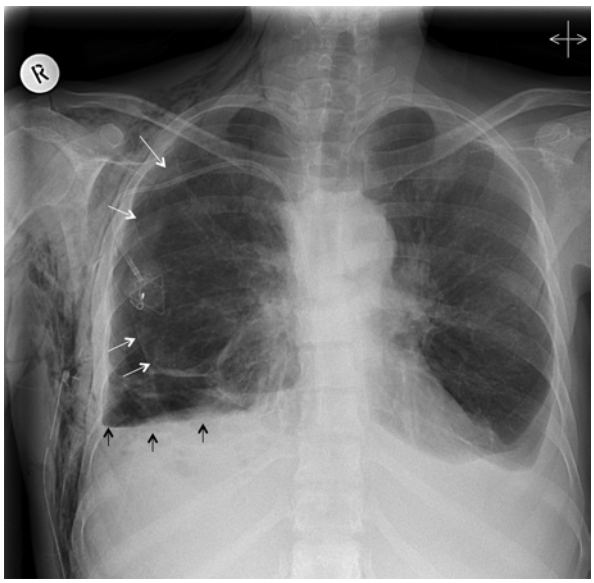

Figure 39.21 Hydropneumothorax post biopsy. There is a thin white line due to pneumothorax *(white arrows)* associated with an air-fluid level *(black arrows)* due to fluid. The intercostal catheter has dislodged into the chest wall, causing surgical emphysema.

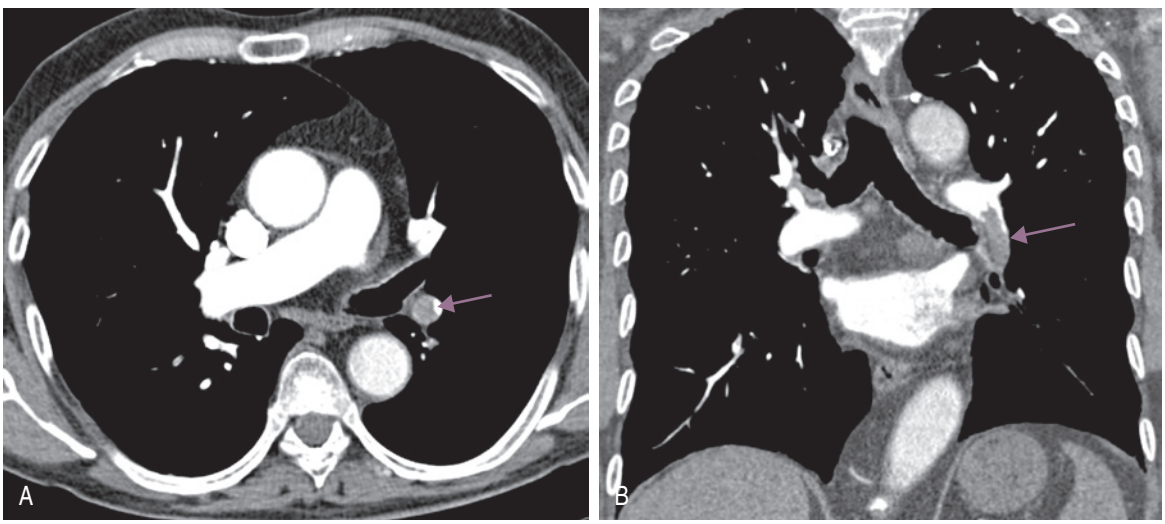

Figure 39.22 Pulmonary embolism: (a) axial and (b) coronal computed tomographic image of an embolus in the left lower lobe pulmonary artery *(arrows)*.

chest trauma, the chest X-ray is more important in detecting a complication of rib fracture than the fracture itself. Fracture of one of the first three ribs is often associated with major intrathoracic injury, and fracture of the lower three ribs may be associated with important hepatic, splenic or renal injury. Complications of rib fracture include a flail segment, pneumothorax, haemothorax and subcutaneous emphysema. A flail segment is usually apparent clinically and radiologically. The fractured ends of ribs may penetrate underlying pleura and lung and cause a pneumothorax, haemothorax, haemopneumothorax or intrapulmonary haemorrhage. Air may also escape into the chest wall and cause subcutaneous emphysema. Fractures of the sternum usually require a lateral film or CT for visualisation. Fractures of the thoracic spine may be associated with a paraspinal shadow, which represents haematoma. Fractures of the clavicle may be associated with injury to the subclavian vessels or brachial plexus, and posterior dislocation of the clavicle at the sternoclavicular joint may cause injury to the trachea, oesophagus, great vessels or nerves of the superior mediastinum.[4]

DIAPHRAGMATIC INJURY[5]

Laceration of the diaphragm may result from penetrating or non-penetrating trauma to the chest or abdomen. Rupture of the left hemidiaphragm is encountered more frequently in clinical practice than rupture on the right (Fig. 39.23). The typical plain film appearance is of obscuration of the affected hemidiaphragm and increased shadowing in the ipsilateral hemithorax due to herniation of stomach, omentum, bowel or solid viscera, although such herniation may be delayed. Ultrasound may demonstrate diaphragmatic laceration and free fluid in both the pleura and peritoneum. Barium studies may be useful to confirm herniation of stomach or bowel into the chest.

PLEURAL INJURY[6-8]

Pneumothorax may be a complication of rib fracture, and is then usually associated with a haemothorax. If no ribs are fractured, pneumothorax is secondary to a pneumomediastinum, pulmonary laceration or penetrating chest injury. Pneumothorax due to a penetrating injury is liable to develop increased pressure, resulting in a tension pneumothorax, which may require emergency decompression. Haemothorax may also occur with or without rib fractures, and is due to laceration of intercostal or pleural vessels. If a pneumothorax is also present, a fluid level will be seen on a horizontal-beam film. Pleural effusion may also result from trauma. Open injuries to the pleura are prone to infection and development of an empyema.

INJURIES TO THE LUNG[6-8]

Pulmonary contusion is due to haemorrhagic exudation into the alveoli and interstitial spaces and appears as patchy, non-segmental consolidation within the first

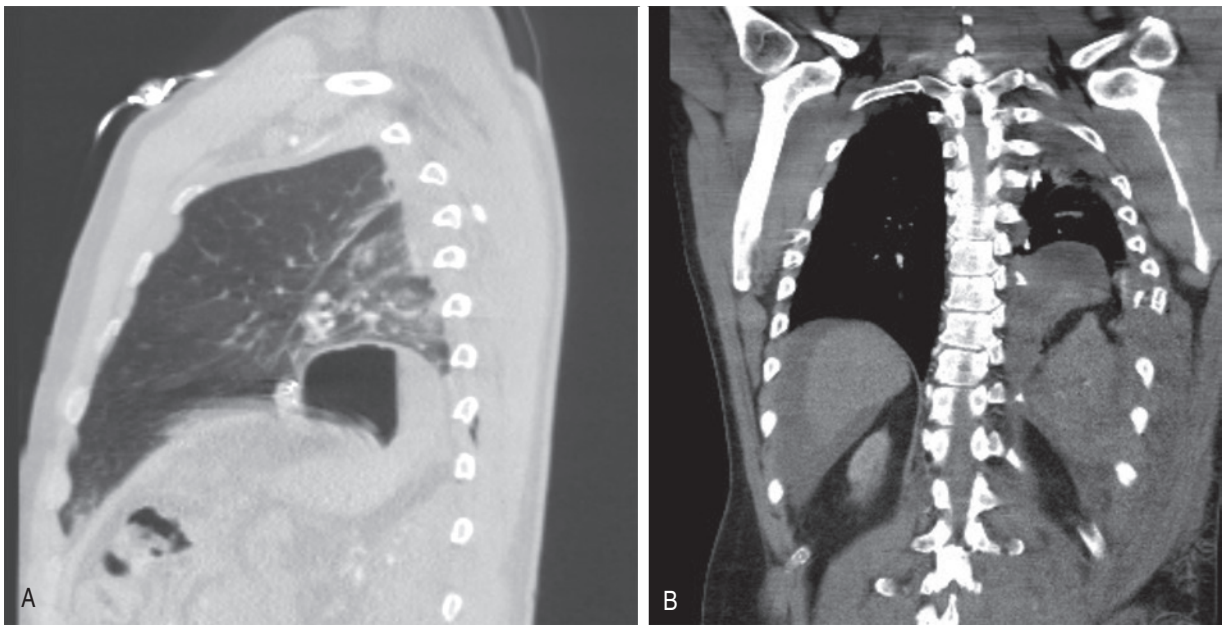

Figure 39.23 Traumatic diaphragmatic hernia on computed tomography. Axial lung windows demonstrate the stomach is above the diaphragm. The defect is best seen on the coronal soft tissue reformats.

few hours of penetrating or non-penetrating trauma. There is usually improvement within 2 days and clearance within 3–4 days. Pulmonary lacerations may be obscured by pulmonary contusion, but, as this resolves, the laceration will become evident. If filled with blood it appears as a homogeneous round opacity, and if partly filled with blood it may show a fluid level (Fig. 39.24). Such pulmonary haematomas or blood cysts gradually decrease in size, but may take a few months to resolve completely. Fat embolism is a rare complication of multiple fractures, with poorly defined nodular opacities throughout both lungs, which resolve within a few days.

INJURIES TO THE TRACHEA AND BRONCHI[9,10]

Laceration or rupture of a major airway is an uncommon result of severe chest trauma. Fracture of the first three ribs and mediastinal emphysema and pneumothorax may also be evident. The injury is usually in the trachea just above the carina, or in a main bronchus just distal to the carina. If the bronchial sheath is preserved there may be no immediate signs or symptoms, but tracheostenosis or bronchiectasis may occur later. CT may be helpful in diagnosis, but bronchoscopy is the best diagnostic method in the acute stage.

INJURIES TO THE MEDIASTINUM[11,12]

Pneumomediastinum and mediastinal emphysema, discussed in the section, Abnormalities of the mediastinum, are the presence of air between the tissue planes of the mediastinum. Air may reach here as a result of pulmonary interstitial emphysema, perforation of the oesophagus, trachea or bronchus, or from a penetrating chest injury. Pulmonary interstitial emphysema is a result of alveolar wall rupture due to high intra-alveolar pressure, and may occur during violent coughing, severe asthma or crush injuries, or be due to positive-pressure ventilation. Air dissects centrally along the perivascular sheath to reach the mediastinum. Rarely, air may dissect into the mediastinum from a pneumoperitoneum. A pneumomediastinum may extend beyond the thoracic inlet into the neck, and over the chest wall. Pneumothorax is a common complication of pneumomediastinum, but the converse rarely occurs. Pneumomediastinum usually produces vertical translucent streaks in the mediastinum. This represents gas separating and outlining the soft-tissue planes and structures of the mediastinum. Gas shadows may extend up into the neck, or dissect extrapleurally over the diaphragm, or extend into the soft-tissue planes of the chest wall, causing subcutaneous emphysema. The mediastinal pleura may be displaced laterally, and become visible as a linear soft-tissue shadow parallel to the mediastinum. If mediastinal air collects beneath the pericardium the central part of the diaphragm may be visible, producing the 'continuous diaphragm' sign. Mediastinal haemorrhage may result from penetrating or non-penetrating trauma, and be due to venous or arterial bleeding. Many cases are probably unrecognised, as clinical and radiographic signs are absent. Important causes include automobile accidents, aortic rupture and dissection, and introduction of CVCs. There is usually bilateral mediastinal widening, but a localised haematoma may occur.

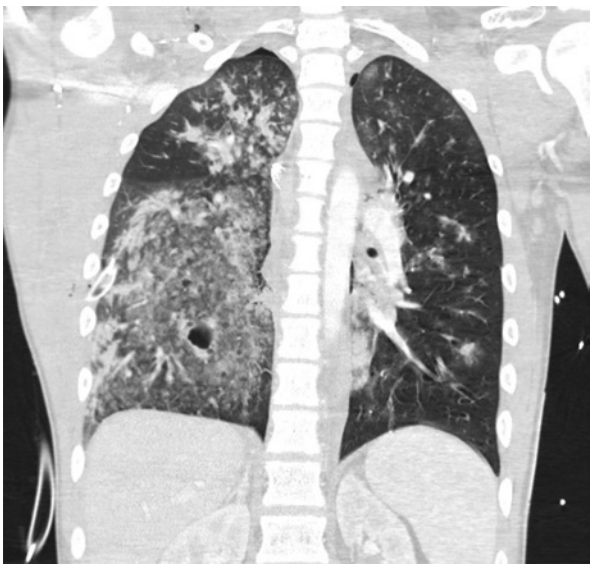

Figure 39.24 Pulmonary contusion. Computed tomography shows diffuse ground-glass opacity of the right lung, and there is also a laceration causing a traumatic pneumatocele (air cyst) of the right lower lobe.

ACUTE AORTIC INJURY

Aortic rupture (Fig. 39.25) is usually the result of an automobile accident. Most non-fatal aortic tears occur at the aortic isthmus, the site of the ligamentum arteriosum. Only 10%–20% of patients survive the acute episode, but a small number may develop a chronic aneurysm at the site of the tear. The commonest acute radiographic signs of traumatic aortic injury (Fig. 39.26) are widening of the superior mediastinum, and obscuration of the aortic knuckle. Other radiographic signs include deviation of the left main bronchus anteriorly, inferiorly and to the right, and rightward displacement of the trachea, a nasogastric tube or the right parasternal line. A left apical extrapleural cap or a left haemothorax may be visible.

CARDIAC INJURY[13]

This is rare but may result from penetrating or blunt trauma. Penetrating injuries are usually rapidly fatal but may cause tamponade, ventricular aneurysm or

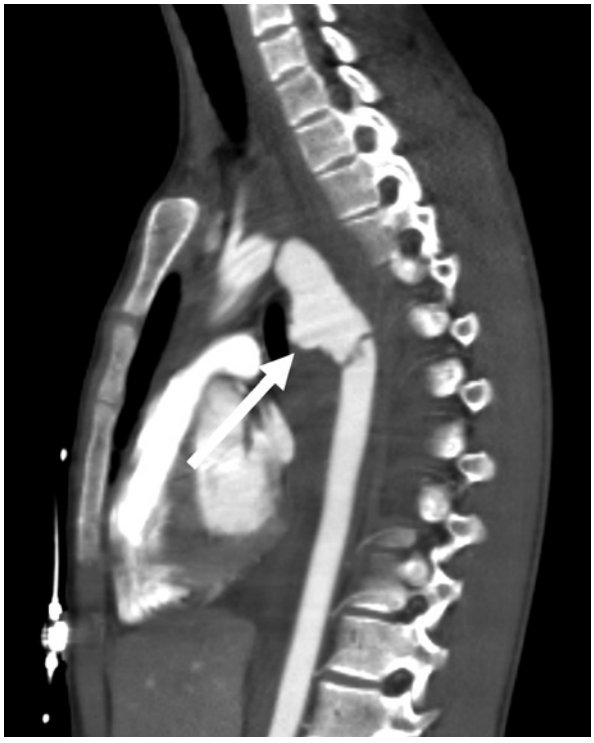

Figure 39.25 Traumatic aortic injury on computed tomography thoracic angiogram. Usually best seen on sagittal reformats, there is an intimal tear leading to abnormal contour, causing pseudoaneurysm formation *(arrow)*. There is surrounding haematoma.

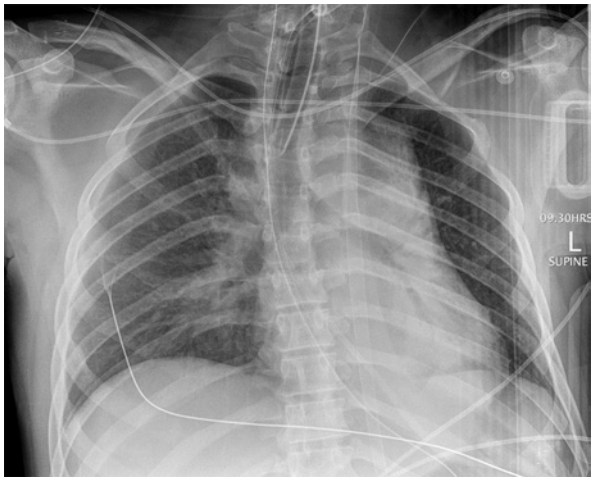

Figure 39.26 Traumatic aortic injury on chest X-ray. There is enlargement and obscuration of the aortic knuckle, causing superior mediastinal widening. The haematoma causes deviation of the left main bronchus downward and the nasogastric tube rightward. There is a small left apical extrapleural cap.

septal defects. Blunt trauma may cause myocardial contusion and infarction and may be associated with transient or more permanent rhythm disturbance.

OESOPHAGEAL RUPTURE[14]

This is usually the result of instrumentation or surgery, but occasionally occurs in penetrating trauma, and is rarely spontaneous and due to sudden increase of intraoesophageal pressure (Boerhaave syndrome). Clinically there is acute mediastinitis; radiographically there are signs of pneumomediastinum, with or without a pneumothorax or hydropneumothorax, which is usually left-sided. The diagnosis should be confirmed by a CT swallow (Fig. 39.27). This should initially be with water-soluble contrast medium in order to avoid the small risk of granuloma formation in the mediastinum that has been described following barium leakage. Chylothorax due to damage to the thoracic duct may become apparent hours or days after trauma. Thoracic surgery is the commonest cause.

THE POSTOPERATIVE CHEST

THORACIC COMPLICATIONS OF GENERAL SURGERY

ATELECTASIS

Atelectasis is the commonest pulmonary complication of thoracic or abdominal surgery. The chest X-ray usually shows elevation of the diaphragm due to a poor inspiration. Linear opacities are present in the lower zones, and represent a combination of subsegmental volume loss and consolidation. The shadows usually appear about 24 hours postoperatively and resolve within 2–3 days.

PLEURAL EFFUSIONS

Pleural effusions are common immediately following abdominal surgery and usually resolve within 2 weeks. They may be associated with pulmonary infarction. Effusions due to subphrenic infection usually occur later.

PNEUMOTHORAX

Pneumothorax, when it complicates extrathoracic surgery, is usually a complication of positive-pressure ventilation or central venous line insertion. It may complicate nephrectomy.

ASPIRATION PNEUMONITIS

Aspiration pneumonitis is common during anaesthesia, but fortunately is usually insignificant. When significant, patchy consolidation appears within a few hours, usually basally or around the hila. Clearing occurs within a few days, unless there is superinfection.

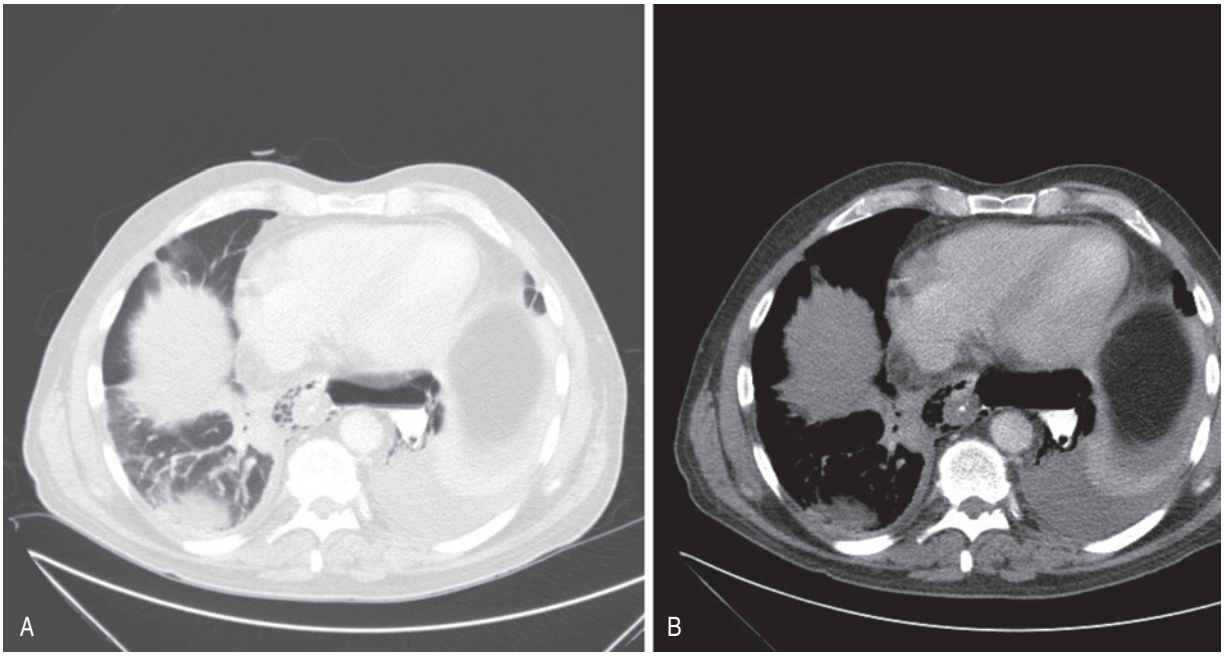

Figure 39.27 Oesophageal rupture. The patient swallowed oral contrast just prior to the computed tomography scan. The contrast has leaked into the posterior mediastinum, to the left of the lower oesophagus adjacent to the gastro-oesophageal junction. There is a pre-existing pneumomediastinum due to oesophageal rupture.

PULMONARY OEDEMA

In the postoperative period, oedema may be cardiogenic or non-cardiogenic.

PNEUMONIA

Postoperative atelectasis and aspiration pneumonitis may be complicated by pneumonia. Postoperative pneumonias, therefore, tend to be associated with bilateral basal shadowing.

SUBPHRENIC ABSCESS

Subphrenic abscess usually produces elevation of the hemidiaphragm, pleural effusion and basal atelectasis. Loculated gas may be seen below the diaphragm, and fluoroscopy may show splinting of the diaphragm. Subphrenic abscess can be demonstrated by CT or ultrasound.

PULMONARY EMBOLISM

Pulmonary embolism may produce pulmonary shadowing, pleural effusion or elevation of the diaphragm, but is not excluded by a normal radiograph. In the ICU setting the radiological investigation of choice is CTPA.

THORACIC COMPLICATIONS OF CARDIAC SURGERY

Most cardiac operations are performed through a sternotomy incision, and wire sternal sutures are often seen on the postoperative films. Mitral valvotomy is now rarely performed via a thoracotomy incision, but this route is still used for surgery of coarctation of the aorta, patent ductus arteriosus, Blalock–Taussig shunts and pulmonary artery banding.

Widening of the cardiovascular silhouette is usual, and represents bleeding and oedema. Marked or progressive widening of the mediastinum suggests significant haemorrhage (Fig. 39.28). Some air commonly remains in the pericardium following cardiac surgery, so that the signs of pneumopericardium may be present.

Left basal shadowing is almost invariable, representing atelectasis. This shadowing usually resolves over a week or two. Small pleural effusions are also common in the immediate postoperative period.

Pneumoperitoneum is sometimes seen due to involvement of the peritoneum by the sternotomy incision. It is of no pathological significance (see Fig. 39.2).

Violation of left or right pleural space may lead to a pneumothorax. Damage to a major lymphatic vessel may lead to a chylothorax or a more localised chyloma. Phrenic nerve damage may cause paresis or paralysis of a hemidiaphragm.

Surgical clips or other metallic markers have sometimes been used to mark the ends of coronary artery bypass grafts. Prosthetic heart valves are usually visible radiographically, but they may be difficult to see on an underpenetrated film.

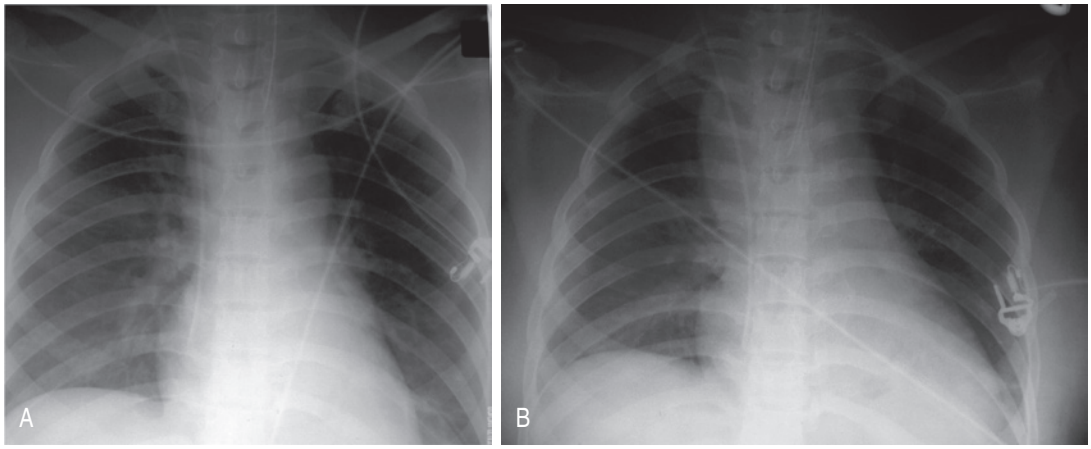

Figure 39.28 Following cardiac surgery (a) the postoperative chest radiograph appears satisfactory. A few hours later (b) the mediastinum has widened considerably due to mediastinal haemorrhage.

Sternal dehiscence may be apparent radiographically by a linear lucency appearing in the sternum and alteration in position of the sternal sutures on consecutive films. The diagnosis is usually made clinically and may be associated with osteomyelitis. A first or second rib may be fractured when the sternum is spread apart. The importance of this observation is that it may explain chest pain in the postoperative period.

Acute mediastinitis may complicate mediastinal surgery, although it is more commonly associated with oesophageal perforation or surgery. Radiographically there may be mediastinal widening or pneumomediastinum, and these features are best assessed by CT scan.

POST-PNEUMONECTOMY

The initial postoperative film will show an air-filled pneumonectomy space with volume loss. Thereafter, the pneumonectomy space fills with fluid, at approximately 2 ribs per day for a standing film. The residual air bubble in the pneumonectomy cavity should shrink over time. If, however, the air bubble increases in size, this is indicative of a bronchopleural fistula, and a CT is indicated. If the pleural effusion rapidly increases in size, this may indicate a haemothorax, which could be life threatening and best evaluated by CT.

Ultrasound in the intensive care unit

Ubbo F Wiersema

Point-of-care ultrasound has become established as an integral part of intensive care practice. An increasing number of clinical applications have been developed that facilitate time-critical therapeutic decision making and invasive diagnostic procedures.[1] This chapter will describe ultrasound techniques that have an established role in intensive care, and are readily acquired with a short period of training. Acquisition of ultrasound proficiency is best achieved with a combination of theoretical learning (basic physics of ultrasound, relevant anatomy, image interpretation), direct supervision of image acquisition and practice.[2,3]

EQUIPMENT

The ideal ultrasound machine for intensive care applications is compact, easily transportable and robust. The console should be waterproof and able to withstand repeated disinfection procedures. To avoid transmission of nosocomial skin flora between patients the transducer, console and electrocardiograph leads (if used) should be disinfected (e.g. with alcohol-based wipes) after each examination.[4,5] Single-use coupling gel should be used instead of multi-use bottles.

Different transducers (probes) are designed for different applications:

- A low-frequency (3–5 MHz) phased array transducer (transthoracic echocardiography transducer) is suitable for chest and abdominal ultrasound.
- A mid-frequency (5–8 MHz) microconvex curved array transducer is also suitable for chest ultrasound and is sometimes useful for subclavian (SC) vein ultrasound.
- A high-frequency (6–13 MHz) linear array transducer is necessary for vascular access and ocular ultrasound.
- A low-frequency (2–5 MHz), large-footprint, curved array transducer provides optimal abdominal ultrasound imaging, but is not essential.

CHEST ULTRASOUND

Ultrasound waves are unable to penetrate aerated lung tissue. Historically, this has limited ultrasound of the chest largely to the evaluation of pleural effusions. In recent years, the recognition that analysis of ultrasound artefacts arising from the pleura can provide valuable information about underlying lung pathology has led to wider application of lung ultrasound, including the diagnosis of pneumothorax and parenchymal lung disease.[1,4] Compared with chest radiography and computed tomography (CT), ultrasound is rapid, inexpensive and safe from ionising radiation. Acute lung parenchymal pathology invariably abuts the pleura and can thus be detected by ultrasound. Diagnostic accuracy of ultrasound compares favourably with CT, and significantly exceeds clinical examination and plain radiography.[6]

EQUIPMENT

Several transducers can be used for chest ultrasound. The standard transthoracic echocardiography, phased array, low-frequency (3–5 MHz) transducer provides good depth penetration and sufficient resolution for most chest ultrasound applications. This transducer is ideally suited for evaluating pulmonary oedema and pleural effusions[7,8] and can therefore be used to complement echocardiographic assessment of cardiac function. A microconvex 5–8 MHz curved array transducer provides better artefact visualisation than lower-frequency transducers, but depth penetration may be insufficient for large patients. The microconvex design facilitates placement of the transducer between the ribs of thin patients.[4] A high-frequency linear array transducer (6–13 MHz) allows detailed pleural line analysis, and is optimal for pneumothorax detection (e.g. after venous cannulation) but has limited other applicability.

Imaging in 2D is adequate for most examinations. M-mode is useful for lung sliding analysis. Doppler imaging is not required.[4]

EXAMINATION TECHNIQUE

Mechanically ventilated patients can usually be satisfactorily examined in the supine or semi-recumbent position. Imaging of the posterior lungs is achieved by scanning along the posterior axillary line with the arm lifted out of the way over the anterior chest. A thorough examination of the lungs involves scanning

ABSTRACT

Point-of-care ultrasound provides a fast, simple and safe imaging modality for a range of diagnostic and procedural applications. Lung ultrasound may be used in the diagnosis of pneumothorax, pleural effusion, consolidation, alveolar-interstitial syndrome, and diaphragmatic dysfunction. Interpretation of lung ultrasound images is based in large part on the recognition of distinct artefacts generated at the pleural line. Abdominal ultrasound provides rapid assessment for free intraperitoneal fluid and abdominal aortic aneurysm. An integrated approach with lung, abdominal and deep vein ultrasound, plus echocardiography, may be used for diagnosis in undifferentiated respiratory or circulatory failure. Ultrasound should routinely be used to guide pleural or ascitic aspiration and central venous cannulation; it may also be used to guide arterial or peripheral venous cannulation.

bilaterally over four quadrants of the anterior chest wall (upper and lower zones laterally and medially), the upper and lower lateral chest wall (bounded by the anterior and posterior axillary lines), and upper, middle and lower zones of the posterior chest wall.[4,9] For a complete study, each intercostal space, along multiple vertical lines, should be imaged.[7,8,10] The findings for each space can then be documented in tabulated form. Only the dorsal lung segments behind the scapulae cannot be examined by ultrasound.

Fluid-filled chest pathology (e.g. pleural effusions, atelectasis) is gravity dependent and thus lies inferiorly. In contrast, aerated pathology (i.e. pneumothorax) is non-dependent, and lies superiorly. Detection of specific pathology should thus be directed accordingly, noting that in the supine patient the least dependent region is the basal anterior chest, which is where a small pneumothorax will collect.[9]

The examination sequence should commence with scanning of the lower lateral chest. Here identification of the diaphragm provides a useful landmark for further imaging. Subdiaphragmatic structures (liver, spleen and kidneys) may be identified to confirm the location of the diaphragm. Right-sided subdiaphragmatic structures are usually easier to visualise than left-sided structures. Diaphragmatic movement with tidal ventilation should be identified. The scanning depth should initially be set to 15–20 cm to evaluate basal lung pathology. The scanning depth can then be reduced to 10 cm (and use of a higher-frequency transducer considered) to facilitate artefact analysis and complete the examination over the whole chest wall.

For each region of interest, the transducer should be placed between the rib spaces and aligned with the longitudinal axis of the patient. The orientation marker on the transducer should face cephalad. By convention, the orientation marker is displayed on the upper left of the screen with abdominal ultrasound and displayed on the upper right of the screen with echocardiography. Choice of transducer and type of examination selected from the display menu will determine the default marker location on the screen.

IMAGE INTERPRETATION

For every region examined, image interpretation involves each of the following steps:

- identification of the pleural line between the ribs
- artefact analysis
- lung sliding analysis
- evaluation for pathology that can be directly visualised (e.g. pleural effusion, consolidation).

EXTRAPLEURAL LANDMARKS

In 2D mode, with the transducer aligned with the longitudinal axis of the patient, the ribs above and below the pleural space cast a dark shadow that extends down to the full depth of the image on the screen. Between the ribs, the pleural line can be identified as a bright (hyperechoic) horizontal line located 0.5 cm deep to the outer surface of the ribs (Fig. 40.1). The pleural line is the reference line for artefact analysis and lung sliding analysis.

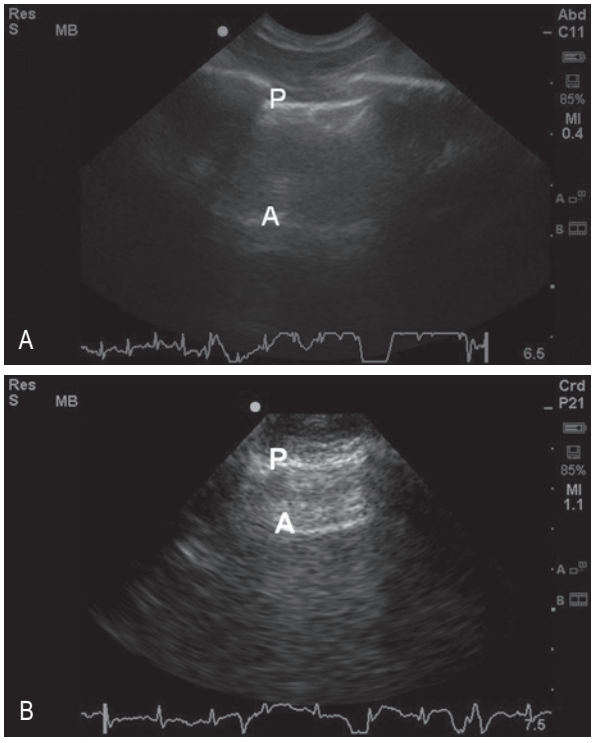

Figure 40.1 A lines demonstrated with a 5–8 MHz microconvex curved array transducer (A) and 1–5 MHz phased array transducer (B). Note the horizontal bright (hyperechoic) pleural line *(P)* and A line *(A)* flanked on each side by dark rib shadows.

ARTEFACT ANALYSIS

Ultrasound waves cannot be transmitted through aerated tissue. Normal lung parenchyma is thus not visible beyond the visceral pleura. The pleural line is formed by the reflection of ultrasound waves at the interface between the pleura and lung parenchyma (see Fig. 40.1). All artefacts used for analysis of lung pathology (except E lines) arise from the pleural line.

- *A-line artefacts* (see Fig. 40.1): these are bright horizontal repetitions of the pleural line due to reverberation artefacts, and are a normal finding.[4,11] The vertical distance between two adjacent A lines is the same as the distance between the skin and the pleural line. Usually only one or two A lines are visible, depending on image gain and depth settings. A lines are so-called because they are reminiscent of the cross bar of the capital letter A framed by the diagonal shadows cast by the ribs.

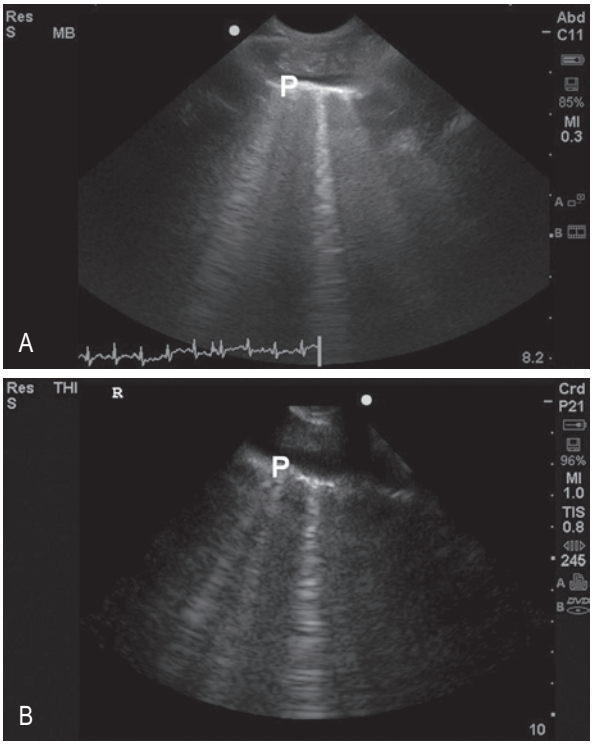

Figure 40.2 B lines demonstrated with 5–8 MHz microconvex curved array transducer (A) and 1–5 MHz phased array transducer (B). Note vertical bright (hyperechoic) lines originating at the pleural line *(P)* and extending to the bottom of the screen.

- *B-line artefacts* (Fig. 40.2): these were previously known as *comet-tail artefacts*[11] or *ultrasound lung comets*,[7] and are defined as discrete vertical bright lines originating at the pleural line and fanning out to the bottom of the screen without fading.[12] B lines arise from reverberation artefacts generated at the interface of fluid-filled or fibrosed interlobular septa abutting the visceral pleura.[11,13] The presence of multiple B lines, termed '*B pattern*', erases the A-line artefact. With greater loss of aeration, the B lines become more closely spaced, or confluent (*white-out*) (Fig. 40.3). B lines are equivalent to Kerley B lines seen on the chest radiograph, although they may be present before radiographic changes are visible. Isolated B lines or short, ill-defined vertical artefacts are of uncertain significance.
- *E-line artefacts* (Fig. 40.4): these have a very similar appearance to B lines, but arise superficial to the pleural line.[4,9] They occur with subcutaneous emphysema where pockets of air create an air–tissue interface that generates reverberation artefacts. It is important to distinguish B lines from E lines by clearly identifying the origin of vertical artefacts in relation to the pleural line, although subcutaneous emphysema is usually easy to detect clinically.

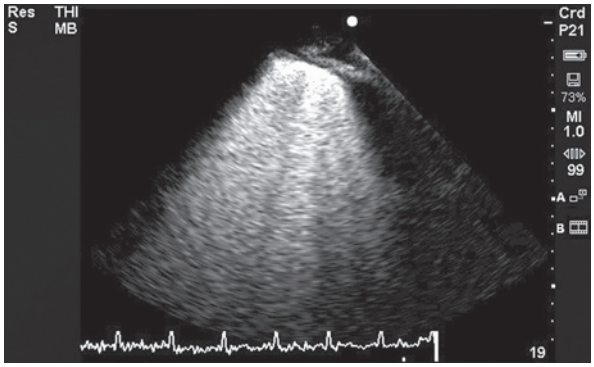

Figure 40.3 Confluent B lines creating a 'white out' appearance, demonstrated with a 1–5 MHz phased array transducer.

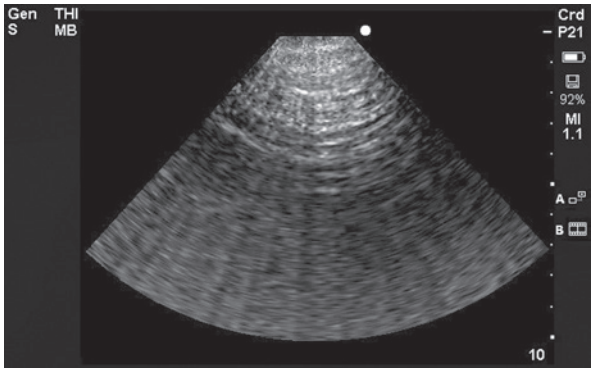

Figure 40.4 E lines demonstrated with a 1–5 MHz phased array transducer. Note the vertical bright (hyperechoic) lines originated above the pleural line, which is poorly defined.

LUNG SLIDING ANALYSIS

With tidal inflation of the normal lung, the visceral pleura slides against the parietal pleura. On ultrasound this is seen as movement below the pleural line. The movement is best appreciated using M-mode imaging, which shows an image reminiscent of the seashore: above the pleural line there are a series of horizontal lines created by extrapleural tissue static in time (the sea), and below the pleural line there is a grainy appearance due to reflection from moving visceral pleura (the beach) (Fig. 40.5).[4,9] The transducer must be held completely still on the chest wall. Diagnostic accuracy is improved if a higher-frequency transducer is used. Lung sliding is absent if the visceral pleura cannot be visualised because of air in the pleural space (pneumothorax) (Fig. 40.6), or if lung movement is abolished (e.g. pleural fibrosis, dense consolidation, atelectasis or apnoea). Lung sliding may appear absent in patients with chronic obstructive pulmonary disease, or at the apices with small volume tidal ventilation. The *lung pulse sign* (see section on Atelectasis) can be present only when lung sliding is absent (Fig. 40.7).[14]

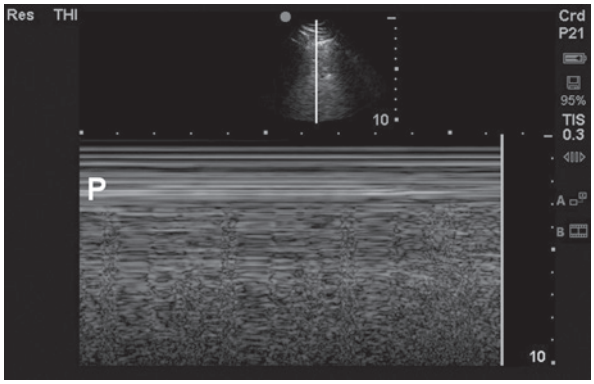

Figure 40.5 Lung sliding (seashore sign) demonstrated with a 1–5 MHz phased array transducer in M-mode. Note the smooth horizontal lines above the pleural line *(P)* (extrapleural tissues static over time), and the 'sandy' appearance below the pleural line (due to artefact from visceral pleural sliding with tidal ventilation).

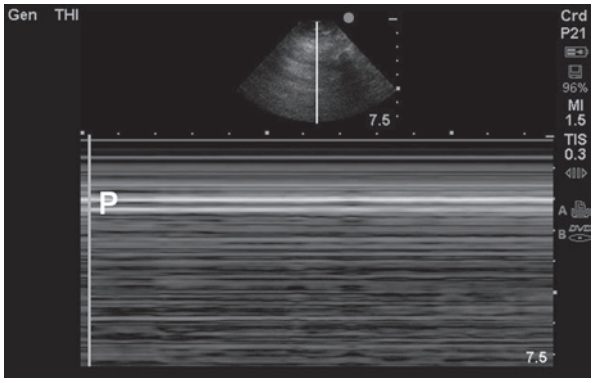

Figure 40.6 Absent lung sliding demonstrated with a 1–5 MHz phased array transducer in M-mode. Note the smooth horizontal lines above and below the bright (hyperechoic) pleural line *(P)*.

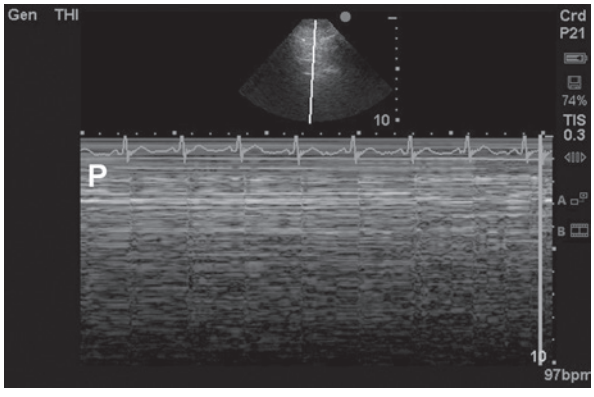

Figure 40.7 Lung pulse sign demonstrated with a 1–5 MHz phased array transducer in M-mode. Note the vertical lines below the pleural line *(P)* due to transmitted cardiac pulsations.

DIRECTLY VISUALISED PATHOLOGY

Ultrasound waves are able to penetrate non-aerated tissues. Thus pleural fluid, and non-aerated lung pathology (such as consolidation or complete atelectasis), can be readily visualised.

SPECIFIC PATHOLOGIES

The diagnostic accuracy of ultrasound is comparable to CT and superior to plain radiography for all the pathologies discussed in this section. Ultrasound is also sensitive to rapid changes in severity of disease and can thus be used to monitor disease progression and make timely clinical decisions.[15–17]

The ultrasound appearance of normal lung is characterised by the presence of A lines and lung sliding. About a quarter of normal individuals have one or two B lines at the lung bases, but other artefacts should be absent.[5,7,11]

Pleural effusion

Ultrasound enables the detection of small pleural effusions (<50 mL) not visible on chest radiography. Ultrasound also provides information about the nature of an effusion; septated pleural collections are better characterised with ultrasound than with CT.

Examination for pleural effusion commences with identification of the diaphragm on scanning over the lower lateral chest. The diaphragm appears as a smooth bright (hyperechoic) line overlying the abdominal contents (usually liver or spleen, with the kidneys deep and caudal to these). Pleural fluid manifests as a relatively homogeneous dark (hypoechoic) area between the diaphragm and parietal pleura (Fig. 40.8). As pleural fluid acts as an acoustic window, the

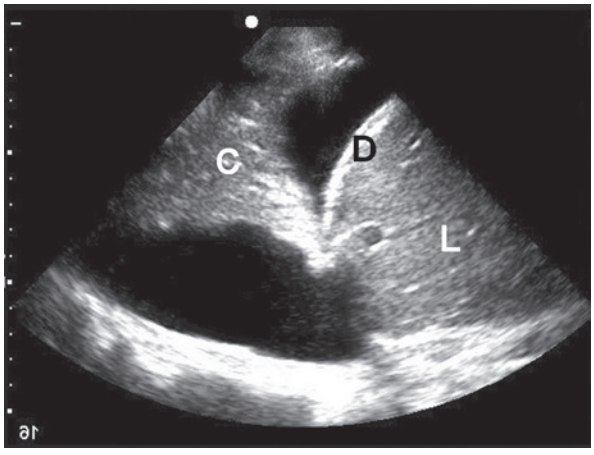

Figure 40.8 Liver *(L)*, diaphragm *(D)*, pleural effusion and collapsed/consolidated lung *(C)* demonstrated with a 1–5 MHz phased array transducer aligned with the longitudinal axis of the patient in the basal right mid-axillary line.

lung surface (visceral pleura) can be seen as a regular deep border to the effusion. Aerated lung will show a bright pleural line, often with B lines adjacent to the effusion. Normal lung will tend to float above an effusion, whereas collapsed or consolidated lung will float within a moderate or large effusion (see Fig. 40.8). A small pleural effusion confined to the costophrenic angle may be difficult to detect. However, its presence can be inferred if the dome of the diaphragm, which is normally obscured by aerated lung, can be seen. Large effusions allow direct visualisation of mediastinal structures (e.g. aorta and great vessels) if sufficient depth is imaged.

Pleural effusion quantification Various techniques have been described to estimate the volume of pleural fluid.

Measurements are made scanning in the basal intercostal spaces of the posterior axillary line with the transducer aligned in a transverse plane. In supine mechanically ventilated patients, a posterior pleural separation greater than 5 cm strongly predicts a drainage volume of greater than 500 mL.[18] In semi-recumbent (15 degrees) mechanically ventilated patients, the maximum pleural separation (in mm) multiplied by 20 gives an estimate of drainage volume (in mL).[19] Measurements can be made at either end-expiration or end-inspiration, but are not very reliable at estimating volumes of small or very large effusions. A multiplane method, obtained by multiplying the longitudinal extent of the effusion by the cross-sectional area at mid length, increases measurement accuracy.[20] However, a precise volume measurement is rarely necessary for clinical decision making.

Nature of pleural effusion Ultrasound characteristics may indirectly suggest the nature of an effusion and can be used to guide the decision whether to perform thoracocentesis. On ultrasound the appearance of an effusion can be categorised as simple, with a uniformly anechoic (black) appearance; or complex, with echogenic material (bright dots), or septa visible within the effusion. Complex effusions can be classified as complex non-septated with echogenic foci, complex septated or homogeneously echogenic.[21]

Transudates typically appear anechoic (see Fig. 40.8). In addition, the low viscosity of a transudate allows substantial movement of lung tissue with tidal ventilation. This is best appreciated as a sinusoidal pattern of the lung surface line with M-mode during tidal ventilation.[4] The pleural line is usually smooth.

Exudates are usually but not always complex. On M-mode imaging there is minimal sinusoidal movement with tidal ventilation if the exudate is very viscous. The pleural line may appear thickened and irregular from pleural inflammation. A homogeneously echogenic pattern may be almost tissue-like in appearance and should not be mistaken for an area of consolidation. In patients who clinically appear infected, a complex, relatively hyperechoic, septated, or homogeneously echogenic pattern suggests empyema. An anechoic or minimally hyperechoic pattern is unlikely to represent empyema.[19] Haemothoraces appear complex with septa and areas of differing echogenicity, depending on the age of the blood.

Thoracocentesis Ultrasound guidance of thoracocentesis decreases complications and improves fluid collection rates.[5] It allows identification of the optimal site for drainage, and measurement of the depth of the pleural space. Potential hazards such as the diaphragm or pleural adherences can be avoided, and the risk of intrafissural or intraparenchymal tube placement reduced. The decision to perform thoracocentesis is based on size, suspected nature of the effusion and clinical circumstances.

Alveolar consolidation

Consolidated lung (except bronchi) is not aerated and can therefore be directly visualised where it abuts the pleura, or where there is a pleural effusion between the chest wall and consolidated lung (Fig. 40.9).[14,22] Artefacts that arise from the pleural line are absent, although B lines may be seen at the edges of consolidated areas. Consolidation is rarely confined just to deeper lung tissue, almost always extending to involve peripheral lung tissue adjacent to pleura. The full extent of consolidation can thus usually be defined. In mechanically ventilated patients, consolidation preferentially affects the basal posterior lung segments. By contrast, with community-acquired pneumonia, consolidation may affect any lung region.

The echo-texture of consolidation resembles that of liver (hepatisation), although usually coarser in appearance (see Fig. 40.9). When examining the right basal chest, care should be taken to distinguish between consolidated lung and liver parenchyma by clearly

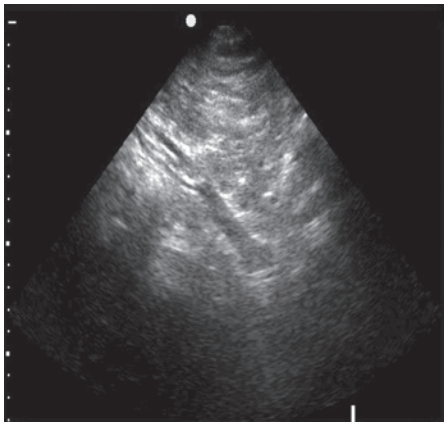

Figure 40.9 Consolidated lung demonstrated with a 1–5 MHz phased array transducer aligned with the longitudinal axis of the patient in the mid-left mid-axillary line. Note the dark (hypoechoic) diagonal region representing the oblique fissure, and the bright (hyperechoic) punctiform air bronchograms.

identifying the diaphragm (see Fig. 40.8). The borders of the consolidated area may be irregular at the junction with normal lung tissue, but will be regular if the full thickness of lung is affected.

Within consolidated lung, air bronchograms appear as bright (hyperechoic) punctiform or linear artefacts (see Fig. 40.9). The air bronchogram artefact moves with respiration (dynamic air bronchogram), outwards (towards the transducer) with inspiration and inwards (away from the transducer) with expiration.[23] The dynamic air bronchogram distinguishes consolidation from resorptive atelectasis.[23]

Atelectasis

Resorptive atelectasis commonly affects the dependent lung regions of mechanically ventilated patients. On ultrasound the affected lung appears consolidated, but air bronchograms are static with respiration.[23]

Complete lobar collapse may occur with bronchial intubation or mucus plugging. This can be detected immediately on ultrasound by absence of lung sliding and the lung pulse sign.[14] These signs are best appreciated using M-mode imaging with a high-frequency transducer. The lung pulse sign consists of vibrations in the M-mode trace (below the pleural line) due to transmitted cardiac pulsations (see Fig. 40.7). Over time, progressive absorption of gas leads to the development of consolidated lung (resorptive atelectasis).

Alveolar–interstitial syndrome

Alveolar–interstitial syndrome encompasses disease processes with which there is predominant interstitial involvement, and partial loss of lung aeration. In the acute setting this is most often due to hydrostatic or capillary leak pulmonary oedema. Less common causes include interstitial fibrosis (interstitial pneumonia) and opportunistic infection (in immunocompromised patients). Ultrasound has a high diagnostic accuracy for alveolar–interstitial syndrome.[11]

On ultrasound the hallmark of alveolar–interstitial syndrome is the presence of multiple (at least three) B lines largely independent of patient positioning.[7,11] The ultrasound pattern of B lines corresponds to the degree of lung aeration.[16] In mild disease, where thickening is confined to interlobular septa, the B lines are characteristically 7 mm apart (measured at the pleural line) (see Fig. 40.2). With progressive pulmonary oedema and increasing alveolar flooding, or with fine fibrosis, B lines are more closely spaced (approximately 3 mm apart). In severe cases B lines become confluent, creating a 'white-out' pattern (see Fig. 40.3); this pattern is equivalent to ground-glass opacification on CT.[5,11,24] Complete alveolar flooding is indistinguishable from primary alveolar consolidation.[16,24] With respiration, the B lines move to-and-fro across the screen with lung sliding.

In acute alveolar–interstitial syndrome, a number of ultrasound findings can be used to distinguish acute respiratory distress syndrome (ARDS) from cardiogenic pulmonary oedema.[24] ARDS is characterised by a non-uniform distribution of B lines, with areas of normal lung and areas of confluent B lines or white-out. Areas of consolidation are often present, particularly in the posterobasal regions. Lung sliding is reduced, or absent, in densely affected regions and the pleural line appears irregular, thickened and coarse when examined with a high-frequency transducer. In contrast, cardiogenic pulmonary oedema shows a homogeneous distribution of B lines. Consolidation is infrequent and pleural line abnormalities are absent. Pleural effusions are common.

With cardiogenic pulmonary oedema, a *lung comet score* can be used to provide a semiquantitative measure of extravascular lung water. The score is obtained by adding together the number of B lines seen from each intercostal space examined over the anterior and lateral chest.[7,8,10] The number of B lines has been shown to correlate with functional class, and severity of systolic and diastolic left ventricular dysfunction on cardiac echocardiography.[8] Reduction in lung comet score occurs with resolution of interstitial oedema.[17] An absence of B lines is consistent with a low pulmonary artery occlusion pressure.[25,26] During fluid resuscitation, the new appearance of B lines heralds the development of interstitial oedema before radiographic changes are visible.

In acute lung injury/ARDS, a lung ultrasound *reaeration score* based on the severity of interstitial changes (Table 40.1) provides a semiquantitative measure of positive end-expiratory pressure induced lung recruitment.[16] The lung ultrasound reaeration score has also been used to evaluate resolution of ventilator-associated pneumonia with antibiotics.[15]

Pneumothorax

The diagnosis of pneumothorax by ultrasound requires more expertise than other aspects of chest ultrasound[5] due to the reliance on artefact analysis and low incidence of pneumothorax. However, in experienced hands the diagnostic accuracy of ultrasound for occult

Table 40.1 Lung ultrasound reaeration score

LUNG PATHOLOGY	DEGREE OF AERATION	ULTRASOUND FINDINGS
Normal lung	More aeration	A lines
Interstitial infiltrate	↕	B lines
Alveolar-interstitial infiltrate	↕	White out (confluent B lines)
Alveolar consolidation	Less aeration	Consolidation

Loss of aeration may be due to oedema, inflammation or fibrosis.
See references 15, 16.

pneumothorax, defined as pneumothorax visible on CT but not plain radiograph, matches that of CT.[1,6,9]

As free pneumothorax is non-dependent, signs of pneumothorax should be sought anteroapically in the semi-recumbent patient or anterobasally in the supine patient. Where there is a pneumothorax, the parietal and visceral pleura are separated by air through which ultrasound waves cannot penetrate. Thus any lung pathology, or artefacts abutting or arising at the visceral pleura, cannot be visualised; lung sliding, B lines and the lung pulse sign must be absent. However, the A-line sign is present, generated at the tissue/air interface of the parietal pleura. The combination of A lines, absent B lines, absent lung sliding and absent lung pulse sign is 100% sensitive, but not specific for pneumothorax. Detection of the edge of the pneumothorax, termed the *lung point sign*, confirms the diagnosis of pneumothorax and allows a rough assessment of its size.[9] With the transducer held perfectly still, using 2D mode, the lung is seen to slide in and out of view with tidal ventilation. This can also be appreciated using M-mode imaging, which shows alternating lung sliding and absent lung sliding. The lung point sign will be visualised anteriorly with an occult or small pneumothorax and more laterally with a moderate-sized pneumothorax.[9] The lung point sign will be absent with a large pneumothorax, where lung sliding is absent over the entire chest.[9] In mechanically ventilated patients, care should be taken to avoid mistaking a temporary cessation of lung sliding, due to a pause in ventilation, for true lung sliding; the lung pulse sign should be present with pauses in ventilation.

A false-positive diagnosis of pneumothorax is more likely in patients with chronic obstructive pulmonary disease. If clinical uncertainty remains, then chest CT may be indicated. During cardiopulmonary resuscitation, the exclusion of pneumothorax may be particularly difficult because lung sliding will be absent unless there is effective ventilation, and the lung pulse sign will be absent during apnoeic periods because of the lack of cardiac contractility.

Subcutaneous emphysema is characterised by an air–liquid interface superficial to the pleural line. This creates E-line artefacts, which are similar in appearance to B lines but arise superficially to the pleural line (see Fig. 40.4). The presence of subcutaneous emphysema is suggestive of pneumothorax. Unfortunately, the presence of E lines precludes further ultrasound analysis for signs of pneumothorax or other lung pathology. In these circumstances, other imaging techniques may be required depending on the clinical circumstances.

DIAPHRAGMATIC DYSFUNCTION

Ultrasound provides a fast, simple and safe alternative to fluoroscopy or phrenic nerve conduction studies for the assessment of diaphragmatic dysfunction.[27] Ultrasound techniques are based on the measurement of either the extent of diaphragmatic excursion with respiration, or changes in diaphragm thickness with respiration.[27]

Diaphragmatic excursion is measured with a 3–5 MHz phased array probe placed below the right or left costal margin in the mid clavicular or anterior axillary line, directed to best visualise the posterior hemidiaphragm perpendicular to the ultrasound beam. Normal diaphragm movement with inspiration is caudal, towards the ultrasound probe in this view, and rostral (away from the probe) during expiration (Fig. 40.10). Measurements are made in M-mode. Normal values for diaphragmatic excursion during quiet spontaneous breathing are 1.8 ± 0.3 cm for males and 1.6 ± 0.3 cm for females.[28] Inaccuracies can arise from non-perpendicular alignment of the ultrasound beam with the hemidiaphragm.

Thickness of the hemidiaphragm is measured with a linear high frequency (7–11 MHz) probe placed over the zone of apposition of the hemidiaphragm to the rib cage, between the 8th and 10th intercostal space in the mid axillary line (Fig. 40.11). Measurements are made

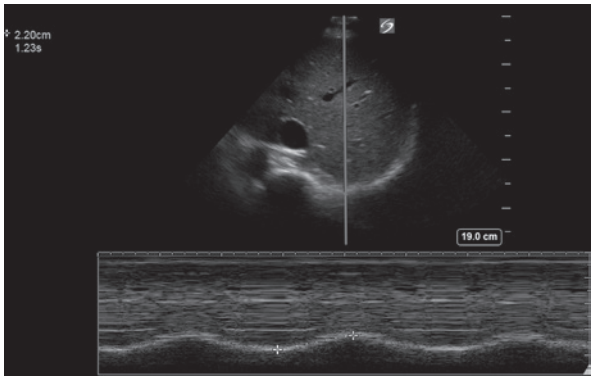

Figure 40.10 Diaphragmatic excursion demonstrated with a 1–5 MHz phased array transducer placed over the liver in the anterior axillary line, using M-mode.

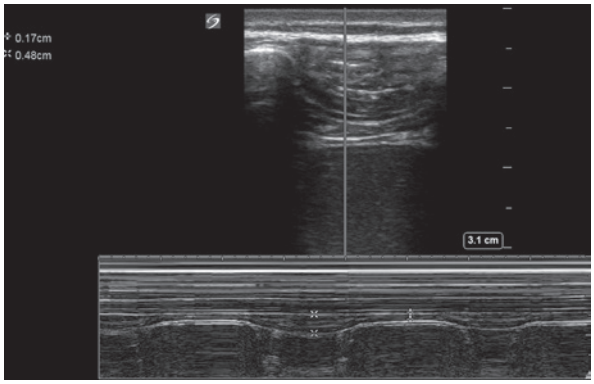

Figure 40.11 Diaphragmatic thickening demonstrated with a 6–13 MHz linear array transducer in the mid-axillary line, using M-mode.

in M-mode. Normal diaphragm thickness is 1.8–3 mm at end-expiration, with greater than 30% increase during active inspiration.

Assessment of diaphragmatic excursion and thickening during unsupported respiration provides a measure of work of breathing[29]; reduced excursion and reduced thickening predict failure to wean from mechanical ventilation.[27,30] Diaphragmatic atrophy (thinning and reduced excursion) can develop within a few days of controlled mechanical ventilation.[31] Diaphragmatic paralysis manifests as absent, or paradoxical diaphragmatic excursion during unsupported respiration. Patient ventilator synchrony may be assessed during supported mechanical ventilation by timing of diaphragmatic excursion in relation to the timing of the airway pressure waveform.[27]

DIAGNOSTIC ALGORITHMS

A number of algorithms exist that incorporate chest ultrasound in the diagnostic assessment of patients with undifferentiated respiratory failure, shock, trauma (E-FAST) or cardiac arrest.

The bedside lung ultrasound in emergency (BLUE) protocol combines lung ultrasound with deep-vein ultrasound to facilitate a diagnosis in patients with acute respiratory failure.[6,32] The A line, B line and lung sliding profile on lung ultrasound are used to differentiate pulmonary oedema, pneumonia and pneumothorax.[6,32] In patients with lung sliding and A lines throughout the chest (normal lung ultrasound), the presence of venous thrombosis on deep vein ultrasound makes pulmonary embolism the likely cause of acute respiratory failure,[6] averting the requirement for a diagnostic CT pulmonary angiography. Unnecessary CT pulmonary angiography may also be avoided if lung ultrasound or echocardiography clearly demonstrates an alternative diagnosis.[33]

Direct diagnosis of pulmonary embolism with lung ultrasound is unreliable.[34]

The fluid administration limited by lung sonography (FALLS) protocol combines lung ultrasound with echocardiography to aid the diagnosis of the cause of acute circulatory failure.[6] Firstly, obstructive shock is excluded by ultrasound examination for tension pneumothorax, pericardial tamponade and pulmonary embolism (right ventricular dilatation). Secondly, cardiogenic shock is excluded by examination for signs of left heart disease and B lines. Finally, patients with hypovolaemic or distributive shock will have A lines, indicating that fluid resuscitation can safely be administered, titrated until B lines appear. In this way fluid administration is limited by the development of pulmonary oedema, which coincides with loss of fluid responsiveness.[6,35] For undifferentiated hypovolaemic shock, abdominal ultrasound is added to detect free peritoneal fluid and abdominal aortic aneurysm.[36]

ABDOMINAL ULTRASOUND

A complete ultrasound examination of the abdomen requires radiological expertise. However, detection of haemoperitoneum (and haemopericardium) with focused assessment with sonography in trauma (FAST) is well established in emergency medicine,[37-39] and the same examination sequence can be readily applied to the intensive care patient to detect intraperitoneal fluid of any cause. Examples include detection of haemoperitoneum after abdominal surgery, or ascites in patients with chronic liver disease and portal hypertension. Once detected, if the ascites requires paracentesis, the optimal location for needle puncture can be determined by scanning more widely over the abdomen.

Low-frequency curved or phased array transducers are suitable for the FAST examination. The examination sequence consists of four standard views[37,38]:

- *Right upper quadrant:* with the transducer in the anterior or mid axillary line, at the level of the xiphisternum, aligned with the longitudinal axis of the patient (orientation marker cephalad). Three potential spaces where fluid may collect are examined in turn by moving the transducer cephalad and caudad: the subdiaphragmatic space, hepatorenal recess (Morison's pouch) and around the inferior pole of the kidney (Fig. 40.12). In the supine patient, the hepatorenal recess is the most dependent and sensitive site for detection of peritoneal fluid accumulation.
- *Left upper quadrant:* with the transducer aligned longitudinally along the posterior axillary line. The subdiaphragmatic, splenorenal and inferior renal

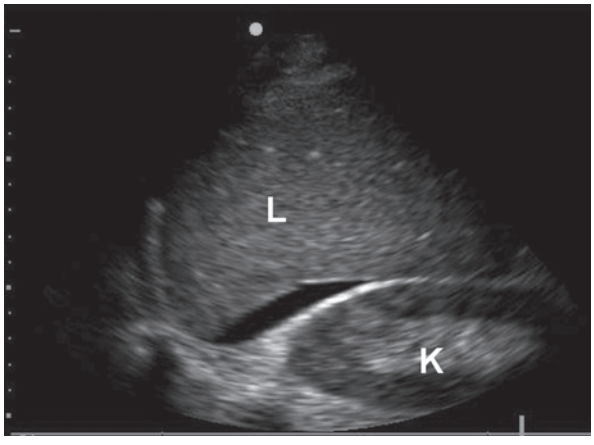

Figure 40.12 Right upper quadrant FAST scan (1–5 MHz phased array transducer) demonstrating free intraperitoneal fluid in the hepatorenal recess (Morison's pouch). Liver *(L)*, kidney *(K)*.

pole regions are examined. Fluid is more likely to be detected subdiaphragmatically than in the splenorenal recess because the phrenicocolic ligament closely apposes the spleen and kidney.[36]

- *Pelvis:* with the transducer just cephalad to the symphysis pubis and directed caudally. Images should be obtained in both longitudinal and transverse planes. The pelvis view is difficult to obtain if the bladder is decompressed (urinary catheter in situ) because the filled bladder is used as an 'acoustic window' to the pelvic peritoneal spaces.
- *Subcostal cardiac view:* to detect pericardial effusion.

The Extended-FAST (E-FAST) examination adds focused lung ultrasound for the detection of traumatic haemothorax and pneumothorax.[38] The basal anterior chest is examined bilaterally (supine patient) for signs of pneumothorax, and the basal posterolateral chest is examined for pleural fluid (haemothorax).

The abdominal aorta is imaged with the transducer placed over the epigastrium perpendicular to the abdominal wall. By convention the probe marker is pointed towards the patient's right side for the transverse view, and towards the patient's head for the longitudinal view. In the transverse view, the aorta lies to the left of the inferior vena cava and anterior to the vertebrae. The aorta appears round in cross section, thick walled and pulsatile. In the longitudinal view, the aorta can be distinguished from the inferior vena cava by its anatomical relation to the heart. The normal aortic diameter is less than 3 cm, measured from outer wall to outer wall. The entire length of the abdominal aorta should be imaged to look for aneurysmal dilatation by sliding the probe from the epigastrium to the umbilicus. The combination of abdominal aortic aneurysm and haemorrhagic shock should prompt consideration of ruptured abdominal aortic aneurysm, but retroperitoneal haemorrhage may be difficult to identify on ultrasound.

ULTRASOUND-GUIDED VASCULAR CANNULATION

Central venous cannulation is an essential component of intensive care practice. With the traditional 'landmark technique', location of the vein for cannulation is based on identification of skin surface anatomical landmarks and palpation, and is reliant on normal anatomy and venous patency. Complications include failure to cannulate the vein, pneumothorax, arterial puncture, haematoma, haemothorax and nerve injury. Risk of complication depends on operator experience, urgency and patient co-morbidities, with reported rates of 5%–20%.[40] Inclusion of ultrasound with the procedure improves first-pass success, leads to lower complication rates and is advocated by patient safety practice recommendations.[40–44] Ultrasound can also be used to aid arterial cannulation.[1,45]

ULTRASOUND TECHNIQUE

For the ultrasound novice, learning the necessary skills to image the central veins requires only a short period of supervised training, although developing good hand–eye coordination for real-time imaging during cannulation may take longer.

A high-frequency (7–11 MHz) linear transducer provides optimal image resolution suitable for vascular structures close to the skin surface. The vertical imaging depth should be set to ensure complete visualisation of the vein to be cannulated and significant structures (e.g. artery) deep to the vein. To avoid left–right confusion, the orientation marker on the screen should match the orientation of the transducer on the patient.

Ultrasound can be used in an indirect or direct way to assist cannulation. With the indirect (static) approach, imaging is used only prior to skin preparation to confirm location and patency of the vein. This avoids the need for a sterile transducer cover, but doesn't account for distortion of anatomy during needle puncture and may increase the risk of needle damage to the posterior vessel wall.[44] This technique is best suited to cannulation of large superficially located veins. The direct (dynamic) approach involves real-time ultrasound guidance of needle insertion. The vein can be imaged in a transverse or longitudinal plane. Transverse imaging gives a better view of the anatomical relationships of the vein to surrounding structures (Fig. 40.13). However, the full depth of the needle may be difficult to visualise (Fig. 40.14).[42–47] Longitudinal imaging provides optimal visualisation of the entire length of the needle and its depth of insertion,[47,48] but is technically more difficult than cannulation with transverse imaging.[42,44] The direct approach requires sterile gel and transducer cover.

VESSEL IDENTIFICATION

The anatomical position of the artery and vein may vary from the usual pattern, particularly in the neck. Certain characteristics are used to distinguish vein from artery and determine venous patency.[44] Veins are thin-walled, elliptical in cross-section and compressible with light external pressure (see Fig. 40.13). Arteries are thick-walled, circular in cross-section, and more pulsatile (during normal haemodynamic conditions). Veins are usually larger than the adjacent artery; however, the internal jugular vein may appear smaller due to anatomical variation or hypovolaemia, and will appear slit-like in the hypovolaemic patient who is not in the Trendelenburg position. Colour flow Doppler demonstrates pulsatile arterial blood flow during systole. Venous blood flow is visible on colour flow Doppler during both systole and diastole if a low-velocity (Nyquist) scale is used.

Thrombus appears as an irregular filling defect that is often quite mobile. Thrombus downstream from the site where the vein is being scanned may not be

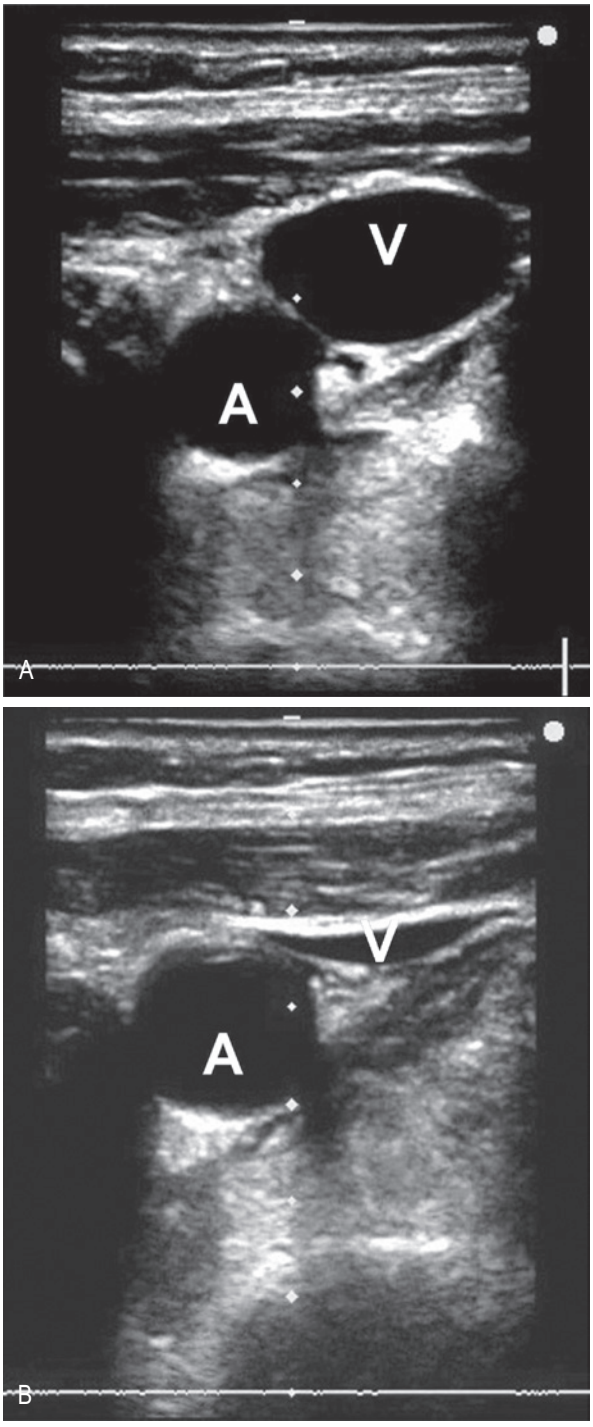

Figure 40.13 Right internal jugular vein *(V)* and carotid artery *(A)* imaged in a transverse (short-axis) plane with a 6–13 MHz linear array transducer. The vein has an oval contour without external compression (A), but appears slit-like when light external compression is applied (B). The depth markers down the centre of the image are at half-centimetre intervals.

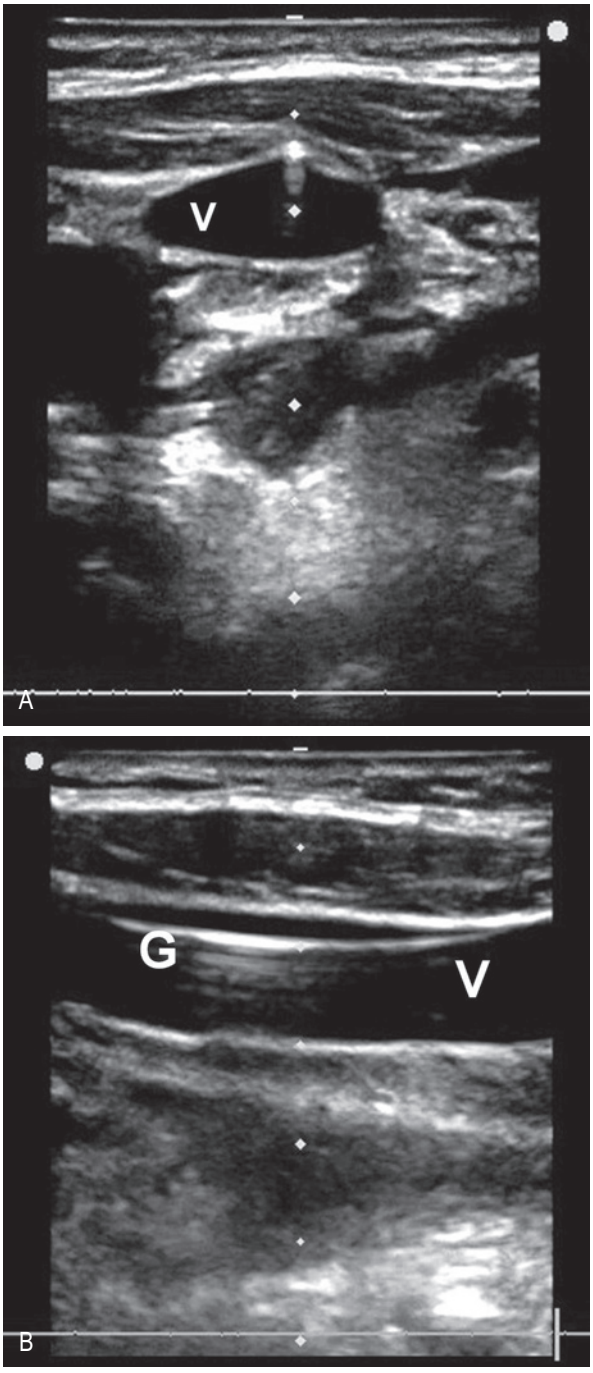

Figure 40.14 Right internal jugular vein cannulation demonstrated with a 6–13 MHz linear array transducer. In the transverse (short-axis) image (A), the needle is visualised in cross-section as a bright (hyperechoic) dot seen at the top of the vein *(V)*. Note that in this still image it is not possible to determine which part of the needle shaft is being visualised and thus at what depth the needle tip is. The longitudinal (long-axis) image (B) shows the guidewire *(G)* within the vein *(V)*.

visible, but its presence can be suspected if the vein is incompressible with light pressure. Absence of colour flow Doppler across part of the venous lumen may help to identify thrombus.

INTERNAL JUGULAR VEIN CANNULATION

Cannulation of the internal jugular (IJ) vein is ideally suited to ultrasound guidance because of the ease with which good images can be obtained, and the significant incidence of anatomical variants. The IJ vein is classically described as being located lateral to the carotid artery as it courses behind the sternocleidomastoid muscle between the anterior and posterior triangles of the neck. However, in a small proportion of patients the IJ vein runs medial to the carotid artery and in the majority of patients the vein overlies the artery to some extent.[42,44] The degree of overlap is increased by excessive head rotation away from the neutral position, and is more likely to occur with older age and obesity. In two-thirds of patients, the right IJ is larger than the left IJ.[49] A quarter of patients have one IJ vein less than 0.4 cm^2 in cross-sectional area.[49] As anatomical variation is not predictable a priori from skin surface features, ultrasound should be used for IJ vein cannulation (Box 40.1).[40,42,44]

SUBCLAVIAN VEIN CANNULATION

More consistent surface landmarks and less anatomical variation make the landmark technique for SC vein cannulation very reliable. However, if unsuccessful after two attempts, the risk of complications (pneumothorax, SC artery puncture) increases significantly with further attempts.[44] Ultrasound may be used to guide SC-vein cannulation, but the clavicle often obscures a clear image of the vein. A microconvex transducer (which is easier to place under the clavicle than a linear transducer) sometimes improves visualisation of the vein. Alternatively, cannulation can be attempted from a more lateral, axillary vein, approach, where the clavicle does not obscure imaging of the vein. This latter technique requires a steeper angle of needle entry with potential risk of pneumothorax, and should be attempted only under direct ultrasound guidance.[44] The axillary vein approach has been reported to be superior to the standard landmark technique with both novice and experienced operators.[51,52] Routine use of ultrasound for SC cannulation is not supported by current literature, but is recommended in high-risk patients to identify SC vein location and patency, or to guide an axillary vein approach.[44] Following the procedure, ultrasound can also be used to examine the lung for evidence of pneumothorax.

FEMORAL VEIN CANNULATION

The femoral vein can be reliably identified from surface landmarks and palpation of the femoral artery. The femoral vein is usually medial to the femoral artery, but significant vessel overlap may occur, particularly in children.[53] Ultrasound is recommended to identify vessel overlap and patency.[1,44] Evaluation for compressibility of the femoral and popliteal veins is a reliable method of diagnosing proximal deep vein thrombosis.[1]

Box 40.1 A suggested approach to direct ultrasound guidance of internal jugular vein cannulation using the Seldinger method

1. Obtain informed consent for procedure
2. Place patient in Trendelenburg position with head slightly rotated away from the side to be cannulated
3. Image IJ vein to determine suitability for cannulation; presence of unsuitable anatomy or thrombus should prompt cannulation of an alternative site
4. Ensure appropriate ultrasound depth, marker position and gain settings
5. Prepare and drape sterile field
6. With the help of an assistant, apply sterile sheath over transducer with coupling gel inside sheath and separate sterile coupling gel outside sheath
7. Scan along the vein to determine the optimal site for venous puncture: easy to access with the needle, large cross-sectional area and minimum overlap with the carotid artery. The degree of head rotation may need to be adjusted to minimise vessel overlap
8. For right-handed cannulation, hold the transducer with the left hand
9. If imaging in a transverse (short-axis) plane, advance the needle incrementally and then adjust the transducer position each time to ensure visualisation of the needle tip (see Fig. 40.14). With longitudinal (long-axis) imaging, puncture the skin with the needle directly underneath one end of the transducer; adjust the needle direction (not the transducer position) to ensure that it remains visible on the screen as the needle advances. With either method, needle damage to the posterior wall of the vein may be less with a bevel-downward rather than bevel-upward approach[50]
10. Once venous blood is aspirated, place the transducer on the drapes and hold the needle with the left hand whilst removing the syringe from the needle with the right hand
11. Insert the guidewire into the needle with the right hand
12. Remove the needle over the guidewire and then scan over the vein to confirm satisfactory guidewire placement (see Fig. 40.14)
13. Dilate and cannulate the vein over the guidewire to complete the procedure

OPTIC NERVE ULTRASOUND

Simple 2D ultrasound measurement of the diameter of the nerve sheath surrounding the optic nerve

provides a rapid, non-invasive method of detecting elevated intracranial pressure (ICP). In patients presenting to hospital with suspected traumatic brain injury, ultrasound-measured optic nerve sheath diameter (ONSD) identifies patients with elevated ICP who warrant further neuroimaging.[54,55] Furthermore, with traumatic brain injury changes in ONSD correlate with changes in invasively measured ICP.[56,57] However, invasive monitoring remains the gold standard for ICP measurement where this is not contraindicated by a risk of infection or haemorrhage. Validation of ultrasound ONSD in other clinical settings is limited.

A high-frequency (10–15 MHz) linear transducer is used with the image depth set to 3–4 cm. A thick layer of acoustic gel is applied over the closed upper eyelids, with the patient lying supine or 20 degrees head up. The transducer is then lightly placed over the upper, lateral eyelid, with the examiner's hand resting on the patient's forehead and the transducer held like a pencil. Care must be taken to ensure that no pressure is applied to the globe with the transducer. To reduce the risk of harmful effects (cavitation) of ultrasound acoustic output, the mechanical index (MI) should be set to less than 0.23. The possibility of thermal damage is limited by scanning for less than 5 minutes.

The optic nerve is seen as a hypoechogenic column beyond the globe and optic disk, surrounded bilaterally by the hyperechogenic optic nerve sheath (Fig. 40.15). With the optic nerve aligned directly opposite the transducer, the ONSD is measured perpendicular to the vertical axis of the imaging plane, at a depth of 3 mm from the optic disk (see Fig. 40.15). At this depth, detection of significant swelling is maximised, and distortion of ONSD measurement by artefactual shadowing is minimised. Normal values for ONSD are less than 5 mm. Values greater than 5.7–6.0 mm predict an elevated ICP (>20 cmH_2O).[55] Inaccuracies can arise if the transducer is orientated in a strictly axial imaging plane, with the optic nerve scanned along the visual axis.[58]

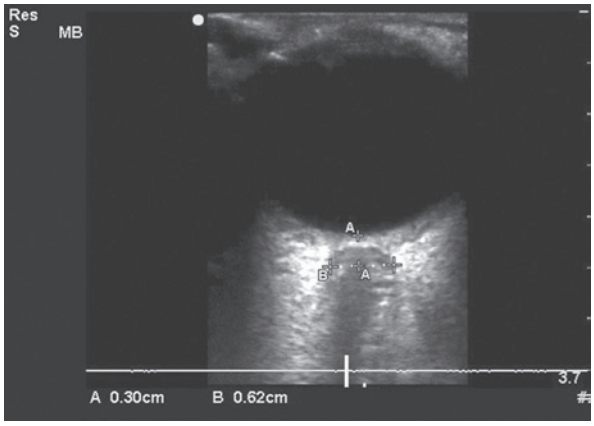

Figure 40.15 Globe and optic nerve demonstrated with a 6–13 MHz linear array transducer. Measurement of the optic nerve sheath diameter (vertical calliper) is demonstrated 3 mm deep (horizontal calliper) to the optic nerve head.

Extracorporeal membrane oxygenation

Vincent Pellegrino, Alexander (Sacha) Richardson

EXTRACORPOREAL MEMBRANE OXYGENATION FOR RESPIRATORY FAILURE

The management of severe lung injury remains a significant problem in critically ill patients. Despite the use of protective mechanical lung ventilation, the mortality of patients with severe acute respiratory distress syndrome (ARDS) remains high and increases with the severity of lung injury.[1,2] Protective lung ventilation in patients with severe ARDS may be limited by progressive hypoxaemia and hypercapnia, despite recourse to adjunctive therapies that improve oxygenation, such as inhaled nitric oxide (NO) or prone positioning.

Veno-venous extracorporeal membrane oxygenation (VV-ECMO) is an alternative form of lung support that provides non-pulmonary oxygen delivery and carbon dioxide removal, facilitates lung protective ventilation and provides time for lung recovery. Although previously predominantly used as a neonatal and paediatric support, it is now increasingly being used in adults.[3]

Current ECMO systems are mobile, can facilitate interhospital patient transport even over long distances, can be instituted quickly and provide support over days to months.

DEFINITIONS

EXTRACORPOREAL MEMBRANE OXYGENATION

This is a form of extracorporeal support comprising specialised *access cannula* to drain venous blood, an external circuit (*tubing*), a gas exchange device (*oxygenator*) where blood becomes enriched with oxygen (O_2) and has carbon dioxide (CO_2) removed, and a *return cannula* through which circuit blood returns to the patient. A pump drives the circuit blood flow and heat exchange is possible. A *fresh gas flow (FGF)* is delivered to the oxygenator. ECMO can provide adequate oxygenation and CO_2 clearance in patients with minimal or absent native lung function. ECMO may achieve circuit blood flows up to approximately 7 L of blood per minute.

MODE

The vessels from which ECMO circuit blood is obtained and returned define the *mode of ECMO*. VV-ECMO is the ECMO mode used for respiratory support. Blood is removed from the great veins and returned to the right atrium and the patient's native circulation is powered entirely by the heart. Veno-arterial extracorporeal membrane oxygenation (VA ECMO) should not be used to support isolated respiratory failure.

CONFIGURATION

The *configuration of VV-ECMO* refers to the manner in which the cannulae interact with the native circulation and is defined by the cannulae insertion sites, the type of cannula used and the tip positions (Table 41.1). *Access cannulae* drain blood from the venous system under negative pressure and may be either single stage or multistage. Single-stage cannulae drain blood from a short region near the tip only. Multistage cannulae drain blood through side holes over a long length of the cannula, in addition to the tip, and allow a greater negative pressure in the circuit. For this reason they can provide higher circuit blood flow. *Return cannulae* deliver blood back to the patient under positive pressure from the ECMO circuit and expel blood only near the cannula tip (single stage). A double-lumen cannula is available for adult VV-ECMO support (Avalon Elite) that contains both access and return lumens within a single cannula.[4]

EXTRACORPOREAL CO_2 REMOVAL

Extracorporeal CO_2 removal ($ECCO_2R$) systems differ from ECMO. They use smaller cannulae, low-blood-flow extracorporeal circuits and oxygenators, and predominantly remove CO_2.[5] Circuit blood flow is limited to less than 3 L/min and such systems cannot support patients with minimal lung function or severe hypoxaemia, but can eliminate virtually all the CO_2 produced. By controlling CO_2, they facilitate protective lung ventilation.[6] Recently, several new $ECCO_2R$ systems have become available. Current $ECCO_2R$ systems may be pump-driven veno-venous systems with a membrane oxygenator PALP (Maquet, Germany) or Hemolung RAS (ALung Technology)[7] or be 'pumpless' and use

ABSTRACT

Extracorporeal membrane oxygenation (ECMO), a form of extracorporeal life support, can provide mechanical pulmonary and circulatory support for patients with life-threatening respiratory failure or cardiogenic shock. The anatomical configuration of the access and return cannulas within the patient determine the mode of ECMO (veno-venous or veno-arterial), which correspond to isolated respiratory support (VV-ECMO) or cardio-respiratory support (VA ECMO). Current generation blood pumps, membrane oxygenators and circuit coatings have markedly improved the safety and reliability of ECMO, resulting in the expansion of its use worldwide.

Table 41.1 Configurations of veno-venous extracorporeal membrane oxygenation

CONFIGURATION	INSERTION SITE	CANNULA TIP POSITION	CANNULA TYPE AND SIZE	ADVANTAGES/ DISADVANTAGES
Femoro-femoral (fem-fem)	*Access:* Right or left femoral veins *Return:* Right or left femoral veins	*Access:* Hepatic IVC *Return:* Right atrium	*Access:* Multi- or single-stage (21–25F) *Return:* Single-stage (21–23F)	*Advantages:* Rapid to establish, safe, easy to secure and transport *Disadvantages:* Frequent problems with access insufficiency
Femoro/jugular–femoral (high-flow)	*Access:* Femoral vein and right jugular vein *Return:* Femoral vein	*Access:* Hepatic IVC and SVC *Return:* Right atrium	*Access:* Multi- or single-stage (21–25F) and short single-stage cannula (17–19F) *Return:* Single-stage (19–23F)	*Advantages:* Can fully support severe respiratory failure even in large patients *Disadvantages:* Multiple cannulations required
Femoro-jugular (fem-jug)	*Access:* Femoral vein *Return:* Right jugular vein	*Access:* Hepatic IVC *Return:* SVC/ right atrium	*Access:* Multistage (21–25F) *Return:* Short single-stage (19–21F)	*Advantages:* Full support and infrequent access insufficiency *Disadvantages:* Longer to insert, difficult to secure and maintain dressing, decannulation risk
Dual-lumen/two-stage (Avalon)	Right jugular vein	*Access:* Hepatic IVC and SVC *Return:* Right atrium	31F	*Advantages:* Single cannulation, allows ambulation *Disadvantages:* Difficult to secure and maintain dressings, high circuit pressures

In all cases, ECMO blood flow travels from the vena cavae to the atria (cavo-atrial flow) to minimise recirculation.
IVC, Inferior vena cava; *SVC*, superior vena cava.

an arterio-venous mode (iLA Membrane Ventilator Novalung)[8] or utilise a dialysis membrane in addition to the gas exchange membrane (Prismalung, Gambro-Baxter, DECAPsmart, Hemodec).[9]

GAS EXCHANGE PRINCIPLES IN VENO-VENOUS EXTRACORPOREAL MEMBRANE OXYGENATION

OXYGEN DELIVERY

Delivery of oxygen to the circuit blood by the oxygenator is governed by the oxygen-carrying capacity of the blood. Current adult membrane oxygenators can oxygenate up to 7 L of deoxygenated blood flow per minute. The quantity of oxygen that can be delivered to the patient on VV-ECMO depends on the quantity of blood arriving at the oxygenator (circuit blood flow), the pre-oxygenator O_2 saturation and the haemoglobin. Additional FGF to the oxygenator cannot increase the oxygen delivery to the circuit blood. *In the presence of a large pulmonary shunt, the patient's arterial oxygen saturation will depend predominantly on the proportion of deoxygenated venous return that can be captured by the VV-ECMO circuit.* Capturing additional deoxygenated venous blood with VV-ECMO will improve the arterial oxygen saturation. The oxygen consumption and haemoglobin will also affect the patient's arterial oxygen saturation in the presence of a large lung shunt.

CARBON DIOXIDE REMOVAL

Removal of CO_2 *by the membrane oxygenator is largely determined by the ratio of fresh gas flow to circuit blood flow in the oxygenator*. For a given circuit blood flow, increasing the FGF to the oxygenator will increase CO_2 removal. The FGF rate to the membrane oxygenator is titrated to achieve a desired partial pressure of CO_2 in the arterial blood. Normally, the ratio of FGF (L/min) to the circuit blood flow (L/min) at commencement of ECMO is approximately 1:1. With lung recovery, FGF can be gradually reduced while maintaining circuit blood flow. When the lung is capable of safely removing all CO_2 production, FGF is ceased to the oxygenator and extracorporeal respiration ceases.

RECIRCULATION

Optimal configuration of VV-ECMO must ensure adequate separation between the access and return cannulae within the venous system in order to minimise *recirculation* of ECMO circuit blood flow.[10] Blood

entering the oxygenator with high oxygen content can accept little additional oxygen owing to the nature of the oxygen content curve. This will greatly reduce the quantity of oxygen delivery the patient can receive from the ECMO circuit and may be a cause of arterial hypoxaemia. Some degree of recirculation is inevitable, particularly at higher pump blood flow rates. Clinically significant recirculation results in a reduced colour difference between pre- and post-oxygenator blood (both appear bright red) or an O_2 saturation of over 80% in the pre-oxygenator blood. In contrast, recirculation does not reduce CO_2 clearance.

HIGH OXYGEN CONSUMPTION

High cardiac output in conjunction with high oxygen consumption due to illness, patient size and fever may result in hypoxaemia, despite optimal VV-ECMO configuration and maximal circuit blood flow ≥7 L/min. This is associated with low pre-oxygenator oxygen saturation (<60%).

EQUIPMENT

Current generation blood pumps, membrane oxygenators and circuit coatings have improved the safety and reliability of ECMO.[11] This has allowed less-specialised bedside staffing and allowed ECMO care to be integrated into the scope of practice of ICU medical and nursing staff.[11] Major features are given below.

ROTARY PUMPS

Rotary pumps have largely superseded roller pumps and offer many advantages when used in circuits with low resistance to flow. These magnetically coupled pumps generate a rotational force, which drives blood radially within the pump head. A negative pressure is generated in the centre of the pump (inlet) and a positive pressure at the periphery (outlet). The pressure gradient within the pump head drives circuit blood flow, which is proportional to the rotational speed controlled by the operator. The pressure load across the circuit and the circuit resistance determine the actual circuit flow rate. The pressure load across a VV-ECMO circuit is negligible, as both access and return cannulae are sited in the venous system. Pump head thrombosis, which can cause rapid and very severe haemolysis, is rare with current rotary pump heads.

MEMBRANE OXYGENATORS

Membrane oxygenators made from polymethylpentene have markedly improved the safety and reliability of ECMO.[12] Plasma leak across the membrane seen in previous microporous membrane oxygenators has been eliminated. They allow high gas transfer with low resistance to blood flow and can be coated to minimise activation of coagulation. Acute oxygenator failure is now extremely rare.

SURFACE COATINGS

Surface coatings to reduce blood–surface interaction and activation of coagulation and inflammatory systems are present on all current ECMO components. The patient-centred benefits of one coating compared with another have not been established in ECMO.[13,14]

INDICATIONS AND PATIENT SELECTION

VV-ECMO is indicated for life-threatening forms of acute respiratory failure where the risks of less-invasive support are considered greater than the risks of ECMO (Fig. 41.1). It is predominantly used to provide support and allow time for recovery of the underlying condition where there is a reasonable expectation of long-term survival without severe

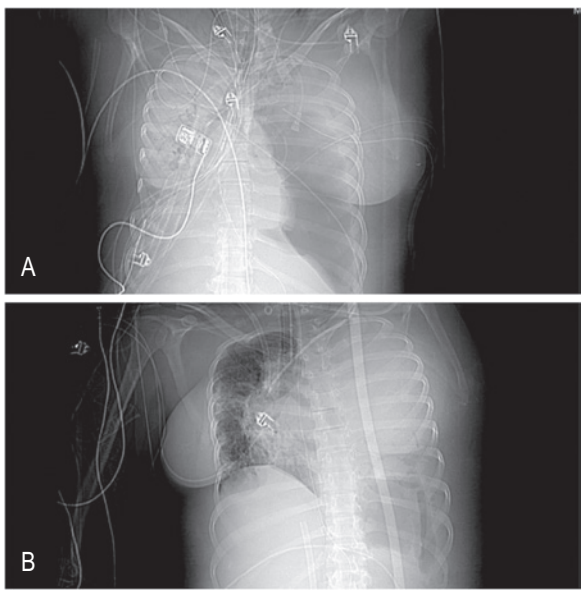

Figure 41.1 Veno-venous extracorporeal membrane oxygenation (VV-ECMO) for severe respiratory failure secondary to influenza. The patient was commenced on VV-ECMO urgently following the development of a tension pneumothorax during mechanical ventilation, which resulted in a cardiac arrest. (A) An extensive left-sided pneumothorax despite two intercostal catheters on day 1 of VV-ECMO support with extensive right-sided consolidation. By day 8 (B) the pneumonitis had resolved and the patient could be weaned from extracorporeal gas exchange despite the development of extensive left-sided haemothorax during ECMO support, which resulted in lung necrosis (noted at thoracotomy) and ultimately death.

disability. Cardiac function must be adequate, as VV-ECMO provides no direct cardiac support. Adult ECMO outcomes for respiratory support from case series from specialised centres suggest that outcomes are improving.[15,16] Increasing clinical experience with ECMO support has helped define conditions that are more likely to be associated with successful outcome.[17]

Conditions where the use of VV-ECMO is commonly associated with recovery and favourable outcomes (age <70) despite severe respiratory failure are:

- ARDS with primary lung injury from infection,[18] aspiration or direct trauma
- primary graft dysfunction following lung transplantation[18,19]
- pulmonary vasculitis (Goodpasture's, ANCA-associated, autoimmune)
- bronchopulmonary fistula with severe air leak.

Conditions where recovery is unlikely with the use of VV-ECMO as a rescue therapy in the event of severe respiratory failure are:

- respiratory failure associated with long-term immunosuppression (heart, renal, bone marrow transplant recipients, HIV, graft-versus-host disease)
- respiratory failure associated with malignancy[20]
- chronic lung transplant rejection[21]
- severe septic shock where multiple advanced organ failure and purpura are present prior to the initiation of ECMO.

ECMO is also used as a bridge to lung transplantation in selected patients with advanced forms of irreversible respiratory failure.[22] ECMO should be used for known cases of irreversible end-stage respiratory failure (cystic fibrosis, interstitial lung disease, chronic obstructive airways disease) only after careful case selection by lung transplant centres.

The decision to institute ECMO for severe respiratory failure is often complex and clinical triggers and logistic factors must be considered when determining the need for and the timing of ECMO. These include:

- severity of lung injury
- adequate trial of less invasive interventions
- rate of lung injury progression
- need for interhospital transport
- risk of bleeding.

Clinical triggers for VV-ECMO initiation in suitable patients[23] include:

- ratio of Pa_{O_2} mm Hg to Fi_{O_2} <75 (Sa_{O_2} <90%)
- hypercapnia with pH <7.15 with safe mechanical ventilation settings (plateau pressure ≤30 mm Hg (3.99 kPa) and tidal volume ≤6 mL/kg predicted body weight)
- extensive (3–4 quadrant) lung infiltrate consistent with acute lung injury

despite:

- optimising circulatory support (cardiac assessment with echocardiography) using inotropes or volume state therapy (where appropriate)
- trial of high positive end-expiratory pressure (PEEP) (18–22 cm H_2O) and recruitment manoeuvre (if not contraindicated)
- 2- to 12-hour trial of iNO or alternative pulmonary vasodilator (if available).

Rapidly progressive (6–12 hours) lung infiltrates and increasing ventilator requirements particularly in the early stages of hospital admission are often associated with a fulminant illness that reduces the time window when ECMO may be of benefit and generally favours the earlier use of ECMO.

Survival prediction models have been built using worldwide datasets of VV-ECMO patients, such as the RESP,[24] PRESERVE[25] and ECMOnet scores,[26] to aid in risk adjusting survival from differing institutions and provide a guide to expected outcomes.

ECMO is a mobile support that can be used across all patient transport modalities (road, fixed wing and helicopter) with very low rates of complications reported.[27-29] Unstable patients with severe respiratory failure requiring interhospital transport should be considered for ECMO prior to transfer.

CANNULATION FOR VENO-VENOUS EXTRACORPOREAL MEMBRANE OXYGENATION

ECMO cannulae can be safely inserted using a percutaneous dilation technique or by a surgical cut-down approach. Percutaneous dilation, which avoids skin cutting, can achieve a tight seal between skin, vessels and cannulae. This avoids bleeding associated with surgical dissection. It can also be performed quickly in a variety of settings without the need for surgical equipment or staffing.

Risks associated with 'blind' percutaneous cannulation for VV-ECMO can be greatly reduced with the use of real-time vascular ultrasound and echocardiography guidance prior to and during percutaneous dilation and cannulae advancement. Ultrasound guidance and echocardiography are increasingly being adopted in numerous hospital departments and equipment is widely available. Image intensifiers can also help prevent complications associated with VV-ECMO cannulation; however, they introduce additional patient transfers, require additional staffing, and may not be available in smaller centres (Table 41.2).

Utility of real-time vascular and cardiac ultrasound in VV-ECMO[30] includes:

- cardiac assessment
  - cardiac function
  - detection of proximal pulmonary artery emboli
  - detection of pericardial collections and extrinsic cardiac compression

Table 41.2 Potential major complications of cannulation for veno-venous extracorporeal membrane oxygenation

COMPLICATION	CAUSE	PREVENTION
Haemorrhage	Perforation of venous system	• Real-time guidewire localisation • Ensuring guidewire continually has free movement through dilators during dilator insertion • Use 'soft' tapered dilators • Enter femoral vessel below inguinal ligament
	Cannula site bleeding	• Maintain tight skin/tissue seal with cannula • Avoid arterial puncture • Avoid transfixing the inguinal ligament • Avoid surgical dissection
Cardiac injury	Femoral dilator/cannula advanced into interatrial septum	• Image intensifier or echocardiography guidance
	Jugular dual-lumen dilator/cannula advanced into right ventricle	• Image intensifier or echocardiography guidance
Cannula malposition	Femoral access cannula in lower IVC	• Image intensifier or echocardiography guidance
	Jugular dual-lumen cannula tip in hepatic vein or right ventricle	• Image intensifier or echocardiography guidance • Adequate cannula securing

IVC, Inferior vena cava.

- identification of proximal vein thrombosis prior to cannulation (unilateral occlusive jugular vein thrombosis is a contraindication to contralateral jugular vein cannulation owing to the risk of cerebral oedema)
- anatomical assessment of the target vessel and branches
  - reduces carotid or femoral artery puncture
  - prevents inadvertent sapheno–femoral junction cannulation
  - identifies abnormal anatomy
- maintenance of guidewire J-loop position in the right atrium
  - detects inadvertent guidewire entrapment ('kinking') during serial dilation
  - prevents excessive guidewire introduction and cardiac effects during cannula insertion
- guides optimal cannula tip placement
  - ensures femoral access cannulae are sited within the hepatic inferior vena cava (IVC)
  - ensures return cannula sited in the right atrium without encroachment on the interatrial septum
  - ensures optimal positioning of dual-lumen VV cannula (Avalon Elite) return port[31]
  - prevents dual-lumen VV cannula (Avalon Elite) tip being sited in the hepatic vein.[31]

EXTRACORPOREAL MEMBRANE OXYGENATION-SPECIFIC PATIENT CARE

MANAGEMENT OF CIRCUIT BLOOD FLOW SETTINGS

Rotary (constrained vortex) blood pumps generate circuit blood flow proportional to their pump speed and are afterload sensitive. In VV-ECMO, afterload across the pump is low and stable provided there are no circuit obstructions. Generally, the pump operates in a pump-speed-controlled mode where pump speed is the set variable and resulting pump flow is measured. Pump speed settings are chosen to deliver sufficient circuit blood flow to achieve required oxygen delivery. Depending on patient size, oxygen consumption and lung shunt, circuit blood flow between 4 and 7 L/min will be required to achieve safe arterial oxygen saturations of over 85%, while maintaining safe lung ventilation.

MONITORING OF CIRCUIT PRESSURE

The pressure in the extracorporeal circuit becomes progressively more negative from drainage cannula tip to the inflow to the pump head. The maximal positive circuit pressure occurs at the outlet of the pump head and falls progressively to the return cannula. The oxygenator is located distal to the pump head and receives blood under positive pressure. The pressure change across the oxygenator can be measured safely and easily without introducing circuit connectors and gives an indication of clot burden within the oxygenator. One current-generation ECMO pump (Cardiohelp-HLS, Maquet) has integrated pressure monitoring of pre- and post-oxygenator pressure in addition to negative-pressure monitoring at the pump head inlet.

ACCESS INSUFFICIENCY

As pump speed is increased, the negative pressure at the access cannula inlet also becomes more negative. If venous return to the access (draining) ECMO

cannula is inadequate for the degree of pump suction, venous 'suck-down' will occur and circuit blood flow will fall and become variable, usually with audible and visible effects on the inflow of the circuit. *Restricted and variable circuit flow with or without visible chaotic movement of the access tubing is termed access insufficiency.* This situation must be identified and rectified quickly (reducing pump speed) to prevent haemolysis and potential vascular injury.[32] Access insufficiency may prevent adequate circuit blood flow and oxygen delivery. Multistage access cannulae distribute the negative circuit pressure over a longer length of a vessel and deliver higher maximal blood flow than similar single-stage access cannulae.

Factors that increase the occurrence of access insufficiency include:

- femoral access cannula tip sited too low
- dual-lumen cannula not optimally sited
  - distal tip sited in the hepatic vein (instead of IVC)
  - catheter withdrawn and superior vena cava (SVC) access sited too high within the right brachiocephalic vein
- reduced venous return
  - blood or volume loss
  - vasodilation
  - raised intrathoracic or intra-abdominal pressure (coughing, dysynchronous breathing, constipation, abdominal distension)
- reduced venous capacitance
  - extrinsic right heart compression.

TITRATION OF FRESH GAS FLOW TO THE OXYGENATOR

FGF to the oxygenator maintains the diffusion gradients for O_2 delivery to, and CO_2 removal from, the circuit blood. FGF can be composed of dry air–oxygen mix or pure O_2. The partial pressure of O_2 in the FGF determines the post-oxygenator blood partial pressure O_2. The FGF rate determines the partial pressure of CO_2 in the post-oxygenator and its rate is chosen to achieve a desired partial pressure of CO_2 in the patient's arterial blood.

LUNG VENTILATION

Non-injurious lung ventilation is a primary goal of ECMO support in respiratory failure. Non-pulmonary gas exchange facilitates low pressure and volume strategies and several lung ventilation modes have been advocated during the different phases of ECMO support. PEEP levels are chosen to maintain lung aeration. Peak lung pressures can easily be maintained below 30 cm H_2O with ECMO support. A low driving pressure (plateau pressure – PEEP) may be beneficial[33]; as such, tidal volumes may be negligible and remain much less than the anatomical dead space of the lung during ECMO support. Improving lung compliance and the return of physiological tidal volume herald lung recovery from acute lung injury.

WEANING

As lung recovery occurs, it is standard to wean ECMO gas flow until it is off, at which point the patient is no longer receiving extracorporeal support. Cannulae are generally removed after a period of time off gas flow (usually 2–24 hours). There is no need to wean circuit blood flow below 3 L/min during weaning, which reduces the need for additional anticoagulation. Percutaneously inserted venous cannulae can be removed at the bedside (off anticoagulation) and skin sites compressed for 20 minutes.

In general, ECMO weaning and decannulation are performed in advance of airway extubation. Where ECMO is used in chronic respiratory failure conditions, it can be advantageous to extubate patients during ECMO support to maintain wakefulness and avoid the complications of sedation. Ambulant ECMO is highly desirable for cystic fibrosis patients being bridged to transplantation to maintain secretion clearance.[34] Whether ambulant ECMO provides additional benefit for patients with acute respiratory failure is currently uncertain.

ANTICOAGULATION

Anticoagulation for ECMO is given to reduce the rate of clot formation within the circuit, and reduce clot formation associated with cannulae.[35] Clotting is often seen in low-flow regions of the oxygenator but is not an indication for circuit change. It is generally accepted that systemic anticoagulation with heparin should be provided for all patients on ECMO *provided there is no bleeding and there is no anticipated or recent surgery.* Anticoagulation practices are based on patient bleeding risk profiles and VV-ECMO can be successfully run for days without anticoagulation in order to arrest bleeding. Essential surgery can also be performed during ECMO support.[36]

EXTRACORPOREAL MEMBRANE OXYGENATION-SPECIFIC PATIENT COMPLICATIONS

Prevention of complications is fundamental to successful ECMO care. Patients are at increased risk of bleeding, particularly from the injured lung, and have an increased risk of haemolysis. VV-ECMO can provide great stability to the patient with severe respiratory failure, but may also induce dangerous complications if the circuit is breached (accidental decannulation, circuit rupture) or the blood pump fails. Staff training and bedside resources to standardise decision making are important components of successful ECMO programmes. Avoiding excessive sedation, provision

of timely pressure care and physical therapy during VV-ECMO support are becoming routine.

BLEEDING

Bleeding remains the main complication of ECMO; however, many sources of bleeding can be prevented. Cannulation site bleeding should be uncommon in VV-ECMO if optimal percutaneous cannulation techniques are used and surgical dissection is avoided. Pulmonary bleeding is a frequent cause of death during VV-ECMO support for respiratory failure.[37] Insertion of intercostal catheters during ECMO is an extremely high-risk intervention and should not be performed unless no other alternative remains. In particular, intercostal catheters should not be inserted for pneumothoraces or pleural fluid drainage unless they are massive or cause haemodynamic compromise.[38] During VV-ECMO, pneumothoraces may be managed by increasing ECMO support and reducing (or ceasing) pulmonary ventilation, without the need for tube insertion. Fibrinolysis and secondary consumptive coagulopathy can occur during ECMO, particularly with older circuits and induce generalised bleeding. Monitoring of fibrinogen and D-dimer levels and elective ECMO circuit changes are required to control this process.

Therapies for managing severe bleeding during ECMO support are given in the section *ECMO for cardiac failure*.

HAEMOLYSIS

Haemolysis (repeated plasma free Hb >0.1 g/dL) is extremely uncommon with current-generation circuits; however, regular monitoring of plasma free Hb is still routine in many centres. Severe haemolysis (plasma free Hb >1.0 g/L or with hyperkalaemia or red urine) suggests pump head thrombosis and must be treated with an urgent circuit change.[39]

AIR EMBOLISM

Air will rapidly enter the circuit during pump operation if there is any breach in the negative pressure region of the circuit. Taps and other potential breaches on the negative (pre-pump) side of the circuit should be avoided. Air that enters the circuit will de-prime the pump head (reducing circuit flow), accumulate in the oxygenator and may reach the return line and cause patient air embolism. Staff education and circuit design are essential preventative measures. De-airing the circuit following air embolism is technically challenging.

CLINICAL TRIALS

ECMO has been used since 1966 as a rescue therapy for severe acute respiratory failure that is refractory to mechanical ventilation.[40] The process of establishing the clinical efficacy for this practice has a long and fascinating history owing to the unique ethical[41] and logistical challenges inherent in this form of support and the patient populations with this disease. In the 1970s and 1980s, uncontrolled observational reports suggested clinical benefits with the use of extracorporeal support, but these were not realised in subsequent randomised controlled trials (RCTs).[42,43]

In 2001 the CESAR trial,[44] a prospective randomised adult ECMO trial conducted in the United Kingdom, commenced enrolment. The results were published in 2009, and the intention-to-treat analysis showed that significantly more patients allocated to consideration for treatment including ECMO survived to 6 months without disability compared with those allocated to conventional management. This result represented a relatively large treatment effect, albeit with borderline precision and with a sample size that was less than initially planned. Reasonable concerns with regard to the basis of the efficacy, the quality of respiratory care in the control arm and the generalisability of the findings outside the United Kingdom have been raised.[45]

In 2011 Noah et al.[46] compared the outcomes of patients in the H1N1 flu pandemic referred to an ECMO centre to matched controls of H1N1 flu patients from the same pandemic who were not referred. Survival was 74% in the ECMO centre patients and 49% in the database matched pairs.

Currently, a French multinational adult ECMO trial for severe respiratory failure (EOLIA) has completed patient recruitment and is expected to report outcomes early in 2018. Mechanical ventilation strategies for both arms demand protective lung ventilation (ClinicalTrials.gov Identifier: NCT01470703).

EXTRACORPOREAL MEMBRANE OXYGENATION FOR CARDIAC FAILURE

Mortality from cardiogenic shock and refractory cardiac arrest is very high and frequently cannot be adequately managed with medical therapy. Veno-arterial extracorporeal membrane oxygenation (VA ECMO) is a rapidly deployable, short-term system for complete or partial support of the circulatory system. It can allow time for reversible forms of cardiac failure to recover and can prevent end-organ damage from under perfusion. It can provide organ support before, during or after therapeutic cardiovascular procedures. In patients with advanced chronic heart failure and secondary acute end-organ injury, it can provide a bridging support to longer-term devices and allow time for thorough case selection.

Traditionally, VA ECMO has been employed by surgical staff in the operative setting, but progressively it is being applied in non-operative settings by a number of trained specialists. Although previously

predominantly used as a neonatal and paediatric support, it is increasingly being used in adults.

Additional explanations of ECMO are given in the section on ECMO for respiratory support.

DEFINITIONS

MODE

VA ECMO is the ECMO *mode* used for cardiac support. Blood is removed from the right atrium and adjacent veins and then returned to the aorta, bypassing the native heart and lungs. VA ECMO comprises a specialised *access cannula* to drain venous blood, an external circuit (*tubing*), a gas exchange device (*oxygenator*) where blood becomes enriched with oxygen and has CO_2 removed, and a *return cannula* through which circuit blood returns to the arterial system. A pump drives the circuit blood flow and heat exchange is possible. A *FGF* is delivered to the oxygenator. ECMO circuit flows are adequate to provide complete systemic perfusion (5–7 L of blood per minute); however, it may not provide specific left ventricular 'unloading'.[47] Percutaneous cardiopulmonary bypass and temporary cardiopulmonary bypass are other terms for VA ECMO.

In veno-pulmonary artery (VPA) ECMO, venous blood is accessed from a large central vein and returned to the pulmonary arterial system via a specialised surgical conduit after it has passed through the oxygenator. It provides short-term right ventricular (and respiratory) support in the intraoperative setting following left ventricular assist device (VAD) insertion.[48]

CONFIGURATION

The *configuration of VA ECMO* determines the manner in which the ECMO circuit interacts with the native circulation. Cannulae insertion sites and the tip positions define configuration. Broadly, there are three adult VA ECMO configurations (Table 41.3):

- femoro-femoral
- jugulo-subclavian[49]
- central (including VPA ECMO).

Table 41.3 Configurations of veno-arterial extracorporeal membrane oxygenation

CONFIGURATION	INSERTION SITE	CANNULA TIP POSITION	CANNULA TYPE AND SIZE	ADVANTAGES/DISADVANTAGES
Femoro-femoral ECMO (fem-fem)	*Access:* Femoral vein *Return:* Common femoral artery (with distal perfusion cannula)	*Access:* Right atrium *Return:* Iliac artery or distal aorta	*Access:* Multistage (19–25F) *Return:* Single-stage (15–21F)	*Advantages:* Quick to deploy Surgery not required *Disadvantages:* High rate of limb ischaemia if distal perfusion cannula not used Unable to ambulate Allows cephalic differential hypoxaemia
Jugulo-subclavian ECMO[3]	*Access:* Right jugular vein *Return:* Right subclavian artery (tunnelled)	*Access:* Right atrium *Return:* Right subclavian artery (T-graft)	*Access:* Short single-stage (19–23F) *Return:* Specialised graftable	*Advantages:* Allows ambulation and unrestricted sitting Reduces cephalic differential hypoxia *Disadvantages:* Right arm swelling or axillary plexus injury
Central ECMO (atrio-aortic)	*Access:* Sternotomy or tunnelled subcostally *Return:* Sternotomy or tunnelled subcostally	*Access:* Right atrium via atrial appendage *Return:* Proximal ascending aorta	Standard by-pass cannulae (access and return) inserted via sternotomy (36–46F) *or* Specialised long-term surgical (graftable) arterial cannula and malleable atrial cannula (tunnelled with closed sternum) (36–46F)	*Advantages:* Accessible during cardiac surgery Large cannula and lower circuit resistance *Disadvantages:* Surgical site bleeding Restricted patient movement and pressure area care Respiratory effects of sternotomy
Femoro-pulmonary artery ECMO (VPA ECMO)[2]	*Access:* Femoral vein *Return:* Tunnelled via chest wall	*Access:* Right atrium *Return:* Main pulmonary trunk	*Access:* Multistage (19–25F) *Return:* Specialised surgical graft and short single-stage 19F cannula	*Advantages:* Maintains full LVAD flows Provides respiratory and right heart support Removal without surgery *Disadvantages:* Pulmonary artery vascular graft remains in situ

ECMO, Extracorporeal membrane oxygenation; *LVAD*, left ventricular assist device; *VPA*, veno-pulmonary artery.

DISTINCT FROM EXTRACORPOREAL MEMBRANE OXYGENATION

Short-term *VAD* may employ similar cannulae, circuit tubing and pumps to ECMO, but does not include an oxygenator and is configured to provide single ventricular mechanical support only. Left VAD (LVAD) is configured using a left heart access cannula with an aortic return cannula. Right VAD (RVAD) is configured using right heart access with a pulmonary artery return. Biventricular VAD support configurations (BiVAD) are distinct from VA ECMO.

BLOOD FLOW PRINCIPLES

VA ECMO blood flow bypasses the native heart and lungs. Two arterial circulations may be identifiable during VA ECMO support. In contrast to VV-ECMO, recirculation is not seen during VA ECMO support.

NATIVE CARDIAC OUTPUT

Native cardiac output produces pulsatile pulmonary and aortic blood flow during VA ECMO support. Cardiac function can vary from absent to near-complete during different phases of VA ECMO support. Oxygen and CO_2 gas tensions of the native cardiac output will reflect the pulmonary gas exchange and predominantly be delivered to the coronary and cephalic circulations. Because CO_2 is only delivered to the lung by the native cardiac output through the pulmonary circulation, airway end-tidal CO_2 excretion is also indicative of native cardiac output.

CIRCUIT BLOOD FLOW

The distribution of the returning VA ECMO circuit blood within the arterial tree is dependent on the particular VA ECMO configuration, ECMO circuit blood flow and the native cardiac output. The gas tensions in the ECMO circuit blood flow reflect gas exchange across the oxygenator. During complete VA support, ECMO circuit blood flow provides all systemic perfusion and arterial gas tensions will be similar to post-oxygenator readings. In this state, the arterial waveform is non-pulsatile. As cardiac function returns, pulsatility will be seen and arterial gas tensions will reflect the proportion of native and circuit blood flow reaching the sampling site.

DIFFERENTIAL OXYGENATION DURING VENO-ARTERIAL EXTRACORPOREAL MEMBRANE OXYGENATION

A significant lung shunt in association with an improving native cardiac output can result in large degrees of differential oxygenation in patients supported with peripheral VA ECMO. With femoral arterial VA ECMO return, highly oxygenated blood is preferentially distributed to the caudal regions as native cardiac output improves while deoxygenated blood leaving the left ventricle predominantly perfuses the coronary and cephalic circulations. For this reason, patients on peripheral VA ECMO should have arterial oxygenation monitored via the right arm.

CIRCUIT PRESSURE

The pressure gradient across a VA ECMO circuit is greater than in VV-ECMO owing to the physiological systemic arteriovenous pressure. Consequently, in VA ECMO, it is normal to require higher pump speeds to achieve full support, and pressure monitoring in the circuit (see VV-ECMO) will record higher pressures at the membrane and in the return line. Such high ECMO circuit pressure may limit the ability for the provision of continuous renal replacement via the ECMO circuit.

INDICATIONS AND PATIENT SELECTION

VA ECMO is indicated for life-threatening forms of cardiac failure where the risks of less invasive support are considered greater than the risks of ECMO and there is a reasonable expectation of long-term survival without severe disability. Currently, ECMO is generally considered in patients up to the age of 70 without other chronic organ failures or terminal illnesses.

Common indications for VA ECMO support with a reasonable chance (>50%) of subsequent recovery and favourable outcomes include:

- acute fulminant myocarditis[50-52]
- cardiomyopathy (bridge to VAD)[53]
- acute myocardial infarction (AMI)-cardiogenic shock prior to multiple organ failure[54]
- drug overdose with profound cardiac depression or arrhythmia[55,56]
- pulmonary embolism with cardiogenic shock[57]
- primary graft failure: post heart[58,59]/heart–lung transplant.

The use of ECMO for refractory 'in-hospital' cardiac arrest (with ECMO commenced within 60 minutes)[60,61] is associated with recovery rates of approximately 30% (alive to discharge), which may be superior to standard treatment.[62]

Conditions where recovery is rare (<25%) despite the use of VA ECMO as a rescue therapy include:

- adult cardiogenic shock with established multiorgan failure
- adult septic shock with severe myocardial depression and multiorgan failure
- heart transplant with chronic rejection
- 'out of hospital' and prolonged cardiac arrest, although there is some evidence for improved outcomes compared to conventional cardiopulmonary resuscitation (CPR) in selected cases.[61-64]

Cardiac and vascular lesions that prevent the successful application of VA ECMO are:

- aortic dissection
- severe aortic regurgitation[65]
- severe mitral regurgitation.

ECMO is also used as a bridge to VAD and heart transplantation (the 'double bridge' strategy) in selected patients with advanced forms of irreversible cardiac failure.[66] Decisions regarding the choice of mechanical support modalities in this population should involve specialised transplant services.

CLINICAL TRIGGERS FOR VENO-ARTERIAL EXTRACORPOREAL MEMBRANE OXYGENATION INITIATION IN SUITABLE PATIENTS WITH CARDIOGENIC SHOCK

Due to the rapid onset of end-organ damage with cardiogenic shock and refractory arrest, the timing of VA ECMO initiation is critical in patient outcome. A guide to the clinical triggers and logistic factors to be considered when determining the timing of ECMO for a deteriorating patient with cardiogenic shock is given below:

- pharmacological support of cardiac index and blood pressure is likely to exacerbate the underlying primary cardiac illness (e.g. AMI-cardiogenic shock or recurrent ventricular fibrillation [VF])
- cardiac index and blood pressure inadequate despite pharmacological support:
  - moderate- or high-dose inotropes (epinephrine [adrenaline] >0.3 µg/kg/min equivalent) in combination with an intra-aortic balloon pump (IABP), vasopressors and positive-pressure ventilation for predominately left ventricular failure
  - moderate- or high-dose inotropes (epinephrine [adrenaline] >0.3 µg/kg/min equivalent) in combination with pulmonary artery vasodilator and/or systemic vasopressors for predominantly right ventricular failure
- onset of secondary hepatic, renal or skin ischaemia despite pharmacological support
- lactate greater than 5 mmol/L and rising despite pharmacological support.

VA ECMO is a mobile support that can be used across all patient transport modalities (road, fixed wing and helicopter) with very low rates of complications reported.[67,68] Time delays incurred with ECMO retrieval must be considered during assessment.

EXTRACORPOREAL MEMBRANE OXYGENATION-CARDIOPULMONARY RESUSCITATION

Cardiac arrest refractory to conventional CPR and Advanced Cardiac Life Support (ACLS) therapies may be salvaged with ECMO. Favourable neurological outcome following cardiac arrest diminishes rapidly following prolonged conventional CPR without return of spontaneous circulation (ROSC) due to cerebral hypoperfusion. VA ECMO rapidly restores a perfusing circulation in the absence of native cardiac function, allowing more time for reversible causes of the arrest to be diagnosed and treated. There is observational data to suggest improved outcomes in selected patients undergoing ECMO-CPR (ECPR) who do not attain ROSC with conventional CPR for both in-hospital and out-of-hospital cardiac arrest[63,64,69,70]; however, the logistics required to appropriately deploy the therapy in a timely fashion for cardiac arrest are considerable and patient selection is key.[71]

CANNULATION FOR VENO-ARTERIAL EXTRACORPOREAL MEMBRANE OXYGENATION

ECMO cannulae can be safely inserted using a percutaneous dilation technique or by a surgical cut-down approach. Percutaneous dilation, which avoids skin cutting, can achieve a tight seal between skin and cannulae. This avoids bleeding associated with surgical dissection. It can also be performed quickly in a variety of settings without the need for surgical equipment or staffing.[72]

Risks associated with 'blind' percutaneous cannulation for VA ECMO can be greatly reduced with the use of real-time vascular ultrasound and echocardiography guidance prior to and during percutaneous dilation and cannulae advancement. Ultrasound guidance and echocardiography are increasingly being adopted in numerous hospital departments and equipment is widely available. Image intensifiers can also help prevent complications associated with VV-ECMO cannulation; however, this introduces additional patient transfers, requires additional staffing and may not be available in smaller centres.

UTILITY OF REAL-TIME VASCULAR AND CARDIAC ULTRASOUND IN VENO-ARTERIAL EXTRACORPOREAL MEMBRANE OXYGENATION

- Cardiac assessment[30]
  - Cardiac and valvular function
  - Detection of proximal pulmonary artery emboli
  - Detection of pericardial collections and extrinsic cardiac compression
  - Presence of aortic disease
  - Detection of intracardiac thrombosis
- Anatomical assessment of the target vessel and branches
  - Prevents inadvertent sapheno-femoral junction venous cannulation
  - Prevents inadvertent profunda femoris artery injury (arterial cannulation)
  - Identifies abnormal anatomy

- Immediate confirmation of needle entry in vein and confirmation of arterial cannulation prior to dilation (required during pulseless resuscitation)
- Maintenance of guidewire J-loop position during dilation
  - Detects inadvertent guidewire entrapment ('kinking') during serial dilation
  - Prevents excessive guidewire introduction and cardiac effects during cannula insertion
- Guides optimal cannula tip placement
- Weaning study from V ECMO[73,74]
  - LVOT (left ventricular outflow tract) blood flow assessment.

EXTRACORPOREAL MEMBRANE OXYGENATION-SPECIFIC PATIENT CARE

ASSESSMENT OF NATIVE CARDIAC OUTPUT

This is approximately assessed at the bedside using the pulsatility of the arterial blood pressure and end-tidal CO_2 trace (Fig. 41.2). It can be measured from velocity–time integration of blood flow through the LVOT with echocardiography, but not by thermodilution due to partial loss of indicator into the ECMO circuit. Native cardiac output must be assessed regularly during VA ECMO support to titrate lung ventilation in order to avoid gross abnormalities in lung V/Q ratios. It is also important in assessing the adequacy of overall systemic perfusion.

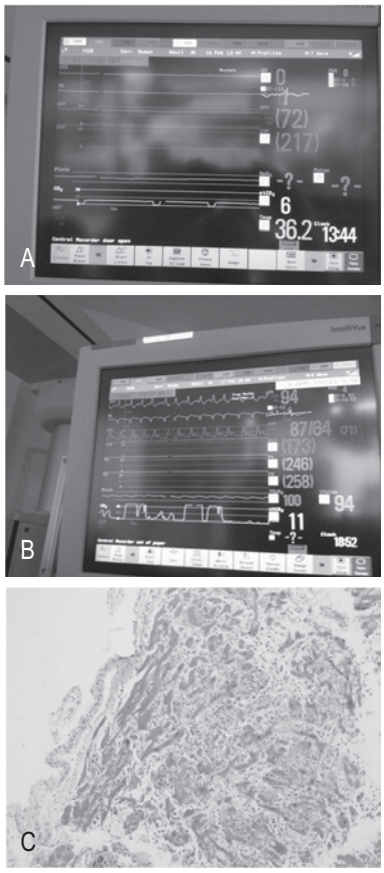

Figure 41.2 The stages of cardiac support with veno-arterial extracorporeal membrane oxygenation (VA ECMO) for a case of severe lymphocytic myocarditis. Arterial pulsatility was lost on day 1 following ECMO initiation for cardiogenic shock. On day 2 (A) after ECMO support the asystole and ventricular standstill were frequently seen for hours. By day 3 (B), pulsatility and end-tidal CO_2 signals returned with cardiac recovery following immunosuppressive therapy. The patient was decannulated by day 7 and extubated by day 9 and made a full recovery. (C) Cardiac biopsy on day 1 showing heavy lymphocytic infiltration.

MANAGEMENT OF CIRCUIT BLOOD FLOW SETTINGS

VA ECMO circuit blood flow settings are primarily chosen to achieve adequate overall systemic perfusion. ECMO circuit flow, which is continually measured, in combination with the native cardiac output equate to the total body blood flow. Adequate mechanical systemic perfusion allows inotropic support to be weaned or ceased and lowers myocardial work. Adequate mechanical circulatory support can allow safe performance of high-risk percutaneous cardiac procedures.

ACCESS INSUFFICIENCY

Access insufficiency can occur in all modes of ECMO and is described in the section on ECMO for respiratory failure.

TITRATION OF FRESH GAS FLOW TO THE OXYGENATOR

FGF to the oxygenator maintains the diffusion gradients for O_2 delivery to, and CO_2 removal from, the circuit blood (see ECMO for respiratory failure). Where VA ECMO provides partial circulatory support, significant CO_2 clearance will occur via the lungs and low rates of FGF to the oxygenator will be required to prevent respiratory alkalosis. Inadequate FGF during VA ECMO will prevent oxygenation of venous blood within the ECMO circuit and impose an extrapulmonary right-to-left shunt.

LUNG VENTILATION

Many patients on peripheral VA ECMO support do not require mechanical ventilation or sedation, in contrast to patients configured with central VA ECMO support. Positive-pressure ventilation is beneficial in the management of pulmonary oedema, which may develop

during VA ECMO support where left ventricular failure is more severe than right ventricular failure. Mechanical lung ventilation may also form part of the management of a lung shunt, which becomes evident during VA ECMO as native cardiac function returns (see below).

PREVENTION OF DISTAL LIMB ISCHAEMIA

All patients with a peripheral ECMO arterial return catheter should have a *distal perfusion cannula* inserted to prevent limb ischaemia occurring as a result of the occlusive and compressive effects of the return cannula.[75] The presence of normal lower limb perfusion should not prevent the insertion, as limb ischaemia may progress quickly. Distal perfusion cannulae are not required for specialised surgical cannulation using a 'T' graft.

DIFFERENTIAL HYPOXIA

Differential hypoxia occurs when hypoxaemic blood from the pulmonary circulation is ejected from the left heart while fully oxygenated blood enters the arterial circulation from the ECMO circuit. It develops during peripheral VA ECMO support as cardiac function returns when a large intrapulmonary shunt is present, and its development indicates cardiac recovery. It is not seen in central VA ECMO as the ECMO circuit blood enters the arterial tree at the proximal aorta. Its development can be anticipated in known cases of combined severe respiratory and cardiac failure, or it may only become apparent following successful resuscitation. Right subclavian artery return configuration will reduce the cerebral effects in peripheral ECMO, compared with femoral return.

Management includes weaning off any inotropic agents, treating the lung shunt with positive-pressure ventilation, PEEP, bronchoscopy, and inhaled NO if appropriate. Increasing the ECMO circuit blood flow should reduce the proportion of venous return able to reach the lungs. If severe hypoxaemia persists ($Sa_{O_2} < 85\%$) despite other measures, consideration of changing the mode of ECMO support from VA to VV should be considered.

LOSS OF PULSATILITY

The ability of the heart to open the aortic and pulmonary valves and contribute to cardiac output may be temporarily lost in severe forms of cardiac failure. The progressive loss of pulsatility during VA ECMO support may indicate extrinsic cardiac compression or progressive cardiac failure, and urgent echocardiography is required to establish the cause. Extrinsic cardiac compression from bleeding is more common in the postoperative cardiac setting and must be managed surgically.

Severe myocardial failure with loss of pulsatility is associated with increased risk of intracardiac thrombosis with arterial embolisation. Management is aimed at preservation of some intracardiac blood flow and higher anticoagulation targets. Increased inotropic support, reduction in arterial pressure and reduced ECMO circuit blood flow may improve cardiac blood flow.

MANAGEMENT OF LEFT VENTRICULAR FAILURE

Pathology that results in a predominance of left ventricular heart failure (LVF), compared with right ventricular failure (e.g. massive left ventricular AMI), the presence of aortic or mitral valve regurgitation or high mean arterial pressure can result in progressive distension of the left ventricle, and congestion of the pulmonary circulation and lungs during VA ECMO support. Non-surgical options for control of LVF during VA ECMO support include positive-pressure ventilation and high PEEP, reduction in mean arterial pressure and decreasing inotropic support (inotropes may increase RV function more than LV function in diseases of the LV). Surgical options include the addition of a left heart drainage cannula to the circuit, conversion from ECMO to a LVAD, or the use of minimally invasive transaortic valve axial pumps.[76-78]

PREVENTION AND MANAGEMENT OF BLEEDING

Prevention of bleeding remains the greatest challenge for ECMO patient care and preventative strategies are given in the section *ECMO for respiratory failure*. Surgical site bleeding is the most common cause of severe bleeding in VA ECMO. The management of severe bleeding during ECMO commonly involves the following responses and involvement of surgeons and specialist haematology support:

INITIAL RESPONSE TO BLEEDING

- Heparin should be ceased and not be recommenced until all bleeding has stopped for 12–24 hours.
- Aggressively replace all clotting element deficiencies:
  - cryoprecipitate until fibrinogen >1.5 g/dL
  - platelets until count is >80,000 and normal maximal amplitude (MA) on a thromboelastogram (TEG)
  - fresh frozen plasma (FFP) or human prothrombin complex (Prothrombinex) until international normalised ratio (INR) is <1.3 and there is normal reaction (R) time on TEG.

ADDITIONAL TREATMENTS IF THERE IS SEVERE OR REFRACTORY BLEEDING

- Fibrinolytic treatment[79,80]
- Factor VIIa treatment[81,82]
- Radiological or surgical intervention.

Protamine is not given to bleeding patients with heparin-bonded circuits owing to the risk of acute circuit thrombosis.

ANTICOAGULATION

Anticoagulation for ECMO in the setting of severe cardiac failure reduces the risk of clot formation within the heart, extracorporeal circuit and cannulae. Heparin is the first-line therapy despite both its limitations and the spectrum of heparin-induced thrombocytopenia and thrombosis (HITTs). Most centres target anticoagulation values below those for management of thromboembolic disease. Definitive recommendations for the titration of heparin therapy are lacking. Activated clotting time (ACT), activated partial thromboplastin time (APTT) and TEG are all used in different centres, but there remains poor correlation between tests and no relevant outcome data on which to base recommendations.[83]

HITT is a rare, but potentially devastating, complication of heparin therapy during ECMO support. Case reports of successful management with the use of intravenous direct thrombin inhibitors (heparin ceased) exist.[84]

WEANING AND DECANNULATION

VA ECMO for cardiac failure generally runs for 3–12 days, which allows time for assessment of cardiac recovery or planning for alternative support if indicated. Cardiac recovery is suggested by improving pulsatility with low or no inotropic support. A formal echocardiographic weaning study is required to assess suitability for decannulation.[85] During a weaning study, haemodynamics, ventricular function and native cardiac output are monitored and measured at progressively lower ECMO circuit blood flow rates (to 1 L/min in adults). Adequate recruitment in the native cardiac output during weaning and haemodynamic stability support the decision to schedule decannulation. Central and peripheral configurations of VA ECMO require surgical repair of the artery after decannulation.

EXPECTED PATIENT OUTCOMES

The clinical effectiveness of VA ECMO for cardiogenic shock and refractory cardiac arrest has not been evaluated in prospective clinical trials. A number of larger case series and cohort studies allow some assessment of the expected outcomes in the more common patient groups that received VA ECMO support. Successful patient outcomes from a complex intervention are likely to occur in centres with clinical leadership, training and competency programmes, adequate protocols and resources and governance programmes. The application of ECMO before end-organ damage and use in selected patients with either reversible conditions or suitable for longer-term treatment options will also probably be associated with improved outcomes.

In addition, the Extracorporeal Life Support Organization (ELSO), which was established in 1989, maintains a registry of ECMO use in registered ECMO centres around the world. The ELSO registry provides annual outcome data for members (see www.elsonet.org) in addition to educational programmes and resources.

Acute gastrointestinal bleeding

Constantinos Simillis, Shahnawaz Rasheed

INTRODUCTION

Acute gastrointestinal bleeding (or haemorrhage) is a common major medical emergency and a common reason for admission to the intensive care unit (ICU).[1] It may result in significant morbidity and mortality, with mortality rates ranging from 4% to 10%.[1–4] The majority of cases die of causes not directly related to bleeding, but due to significant co-morbidities such as cardiopulmonary or multiorgan failure.[2,5,6] This observation emphasises the benefit of good supportive care in the ICU for patients presenting with gastrointestinal bleeding.

Upper gastrointestinal bleeding is that originating proximal to the ligament of Treitz, and this includes the oesophagus, stomach and duodenum. Lower gastrointestinal bleeding is that originating from the small bowel and colon. Peptic ulcer disease accounts for 75% of upper gastrointestinal bleeding. Bleeding from varices, oesophagitis, duodenitis and Mallory–Weiss syndrome each account for between 5% and 15% of cases.[2–4] About 20% of gastrointestinal bleeding arises from the lower gastrointestinal tract, commonly due to diverticular disease.[2–4] Common aetiological causes for gastrointestinal bleeding are listed in Box 42.1.

RESUSCITATION

Patients with acute gastrointestinal bleeding should have immediate and continual assessment with appropriate management of airway, breathing and circulation. Airway compromise should be managed with immediate basic airway manoeuvres or, if needed, advanced airway manoeuvres. The goals of managing a patient with acute gastrointestinal bleeding are, first, to resuscitate, second, to control active bleeding and, third, to prevent recurrence of haemorrhage. Either colloid or crystalloid solutions may be given through large-bore intravenous cannulae to achieve volume restoration prior to administering blood products. The local major haemorrhage protocol may be activated and patient is transfused with blood, platelets, and clotting factors. Anticoagulation medication, such as aspirin, clopidogrel, warfarin, new oral anticoagulants, non-steroidal anti-inflammatory drugs (NSAIDs), should be stopped in the acute setting. Patients on warfarin should be offered prothrombin complex concentrate. A multidisciplinary approach involving haematology, cardiology/neurology, and gastroenterology is necessary when managing patients on anticoagulant medications. Vital signs should be closely monitored. Significant gastrointestinal bleeding is indicated by syncope, haematemesis, systolic blood pressure below 100 mm Hg (13.3 kPa), postural hypotension and a blood transfusion requirement of more than four units of blood in 12 hours to maintain blood pressure. In patients with hypovolaemic shock, central venous pressure and hourly urine output should be observed.

UPPER GASTROINTESTINAL BLEEDING

CLINICAL PRESENTATION

Haematemesis and melaena are the most common presentations of acute upper gastrointestinal bleeding. Bright red haematemesis usually implies active haemorrhage from the oesophagus, stomach or duodenum. There may be epigastric pain, but bleeding ulcers can be painless, especially in elderly patients and users of NSAIDs. A history of vomiting and retching preceding haematemesis suggests Mallory–Weiss syndrome. Coffee-ground vomitus refers to the vomiting of black material which is assumed to be blood. Melaena is the passage of black tarry stools usually due to acute upper gastrointestinal bleeding. Haematochezia is the passage of bright red or maroon blood from the rectum, in the form of pure blood or blood mixed with stool, and usually represents a lower intestinal source of bleeding, although it may be a feature of massive upper gastrointestinal bleeding. In cases of massive gastrointestinal bleeding leading to hypovolaemic shock, the patient may exhibit symptoms and signs of tachycardia, tachypnoea, hypotension, anxiety or confusion, pallor, sweating and oliguria.

RISK ASSESSMENT

Risk factors associated with poor outcome in patients presenting with acute upper gastrointestinal bleeding include being an inpatient, older age (>60 years),

ABSTRACT

Acute gastrointestinal bleeding is a common major medical emergency which is associated with significant morbidity and mortality. The goals of managing acute gastrointestinal bleeding are, first, to resuscitate, second, to control active bleeding and, third, to prevent recurrence of haemorrhage. Patients with non-variceal upper gastrointestinal bleeding are assessed using formal risk assessment scoring systems to predict their risk of mortality and need for intervention. These patients should receive early diagnostic and therapeutic endoscopy and be given antacids. Patients with variceal upper gastrointestinal haemorrhage should be managed with a combination of terlipressin, somatostatin, antibiotics and endoscopic therapy. If this fails, further treatment may be given in the form of balloon tamponade or transjugular intrahepatic portosystemic shunt. Lower gastrointestinal bleed tends to resolve spontaneously and the main aim is to identify the source of bleeding. It may be managed with colonoscopy/sigmoidoscopy, angiogram with the option of angioembolisation, and rarely proceed with surgery.

KEYWORDS

Gastrointestinal bleeding
gastrointestinal haemorrhage
variceal bleeding
non-variceal bleeding
ulcer
diverticular disease
rectal bleeding
endoscopy

significant co-morbidity (especially cardiac failure or malignancy), liver disease/cirrhosis, known varices, haemodynamic disturbance (hypotension with systolic blood pressure <100 mm Hg, tachycardia with pulse ≥100 beats/min), and witnessed haematemesis or haematochezia (suspected continued bleeding after admission).[2,4,7–9]

To assess the risk of serious adverse events, or need for intervention, formal risk assessment scoring systems may be used such as the Rockall scoring system and the Blatchford scoring system.[5,10] The Rockall scoring system, which is used to predict rebleeding and mortality risk, is based on a combination of clinical and endoscopic findings.[5] The initial (pre-endoscopic) Rockall score is derived from age (0–2 points), shock (0–2 points) and co-morbidity (0–3 points). If the pre-endoscopic score is above 0, there is a significant risk of mortality (score 1: predicted mortality 2.4%; score 2: predicted mortality 5.6%) requiring hospital admission and endoscopy, whereas those patients scoring 0 can be safely discharged with outpatient follow-up.[5] The final post-endoscopy score has additional points for endoscopic diagnosis (0–2 points) and endoscopic stigmata of recent haemorrhage (0–2 points), giving a maximum score of 11 points (see Table 42.1). Patients with a post-endoscopic Rockall score less than 3 have a low risk of rebleeding or mortality and should be considered for early discharge and outpatient follow up. Increasing post-endoscopic Rockall score leads to higher risk of rebleeding and death, and should be used in association with other clinical factors in assigning patients to different levels of care.

The Blatchford risk score was derived to predict death and the need for treatment (transfusion, endoscopic treatment, surgery) (see Table 42.2).[10] The total Blatchford score can range from 0 to 23, where a score of 0 is the clinical cut-off above which patients are considered to be at risk of needing an intervention.[5,10] The full score was validated internally on 197 patients and performed better than the Rockall score in predicting the need for treatment.[10]

Box 42.1 Common causes of acute gastrointestinal bleeding

Upper gastrointestinal bleeding
Peptic ulcers (duodenal ulcer:gastric ulcer, 3:1)
Varices (oesophageal varices:gastric varices, 9:1)
Portal hypertensive gastropathy
Mallory–Weiss syndrome
Gastritis, duodenitis and oesophagitis

Lower gastrointestinal bleeding
Diverticular bleeding
Angiodysplasia and arteriovenous malformation
Colonic polyps or tumours
Meckel diverticulum
Inflammatory bowel diseases
Haemorrhoids, anal fissure

Table 42.1 The Rockall numerical risk scoring system

	SCORE*			
	0	*1*	*2*	*3*
Age†	<60	60–79	≥80	
Shock†	No shock (systolic blood pressure ≥100, pulse <100)	Tachycardia (systolic blood pressure ≥100, pulse ≥100)	Hypotension (systolic blood pressure <100)	
Co-morbidity†	No major co-morbidity		Cardiac failure, ischaemic heart disease, any major co-morbidity	Renal failure, liver failure, disseminated malignancy
Diagnosis‡	Mallory–Weiss tear, no lesion identified, and no stigmata of recent haemorrhage	All other diagnoses	Malignancy of upper gastrointestinal tract	
Major stigmata of recent haemorrhage‡	None or dark spot only		Blood in upper gastrointestinal tract, adherent clot, visible or spurting vessel	

*The total score can range from 0 to 11, with a score of 2 representing the clinical cut-off, above which patients are considered to be at high risk of death or rebleeding.

†Scores are calculated on admission.

‡Scores are added after endoscopy.

Table 42.2 The Blatchford numerical risk scoring system

RISK MARKER AT ADMISSION	SCORE
BLOOD UREA (mmol/L)	
≥6.5<8.0	2
≥8.0<10.0	3
≥10.0<25	4
≥25	6
HAEMOGLOBIN (g/L) FOR MEN	
≥120<130	1
≥100<120	3
<100	6
HAEMOGLOBIN (g/L) FOR WOMAN	
≥100<120	1
<100	6
SYSTOLIC BLOOD PRESSURE (mm Hg)	
100–109	1
90–99	2
<90	3
OTHER MARKERS	
Pulse ≥100 (beats/min)	1
Presentation with melaena	1
Presentation with syncope	2
Hepatic diseases	2
Cardiac failure	2

A total score can range from 0 to 23. A score of 0 is the clinical cut-off, above which patients are considered to be at risk of needing an intervention.

Blatchford O, Murray WR, Blatchford M. A risk score to predict need for treatment for upper-gastrointestinal haemorrhage. *Lancet*. 2000;356(9238):1318–1321.

PHARMACOLOGICAL TREATMENT

Acid-suppressing drugs such as proton pump inhibitors (PPIs) and H_2-receptor antagonists are very effective drugs to promote ulcer healing. An acidic environment impairs platelet function and haemostasis; therefore, reducing the secretion of gastric acid optimises platelet aggregation and clot formation.[11] Pharmacological control without endoscopic haemostasis is inadequate and there is a lack of evidence to support pre-endoscopic treatment with PPIs, with no evidence of benefit in terms of mortality, rebleeding or need for surgery.[12,13] Patients with non-variceal upper gastrointestinal bleeding and stigmata of recent haemorrhage shown at endoscopy should be offered PPIs.[12–14] There is evidence that potent acid suppression using intravenous PPIs post-endoscopy results in reduced rebleeding, reduced need for surgery, and reduced need for repeated endoscopic treatment.[13,14] PPIs should be recommended in high-risk peptic ulcer bleeding patients as an adjuvant to endoscopic therapy and a combination of endoscopic and pharmacological therapy offers the best therapy for ulcer-bleeding patients.

Table 42.3 Stigmata of haemorrhage and risk of recurrent bleeding in peptic ulcers

STIGMATA OF HAEMORRHAGE	% RECURRENT BLEEDING
Spurter or oozer	85–90
Protuberant vessel	35–55
Adherent clot	30–40
Flat spot	5–10
None	5

ENDOSCOPY

Endoscopy is the investigation of choice, with potential therapeutic benefit, and should be offered within 24 hours of presentation to hospital to provide optimal clinical outcome.[15] Early endoscopy and endoscopic therapy (<24 hours from admission) is associated with a reduced transfusion need, a reduction in rebleeding, a lower need for surgery, and a reduction in length of stay compared to patients receiving later endoscopy.[15–17] Endoscopy allows identification of the site and nature of bleeding and treatment can be provided endoscopically. Endoscopy may induce serious hypoxia in patients with cardiorespiratory disease, and careful supervision with continuous monitoring of blood pressure, pulse and oxygen saturation with a pulse oximeter is mandatory.

HIGH-RISK LESIONS

Most patients with acute upper gastrointestinal haemorrhage stop bleeding spontaneously and have an uneventful recovery. No specific intervention is required in these patients. Endoscopic haemostasis should be used in patients with a high risk of persistent or recurrent bleeding. Stigmata of haemorrhage found during endoscopy are integral to the Rockall scoring system[5] and are important predictors of recurrent bleeding. These stigmata include localised active bleeding (i.e. pulsatile, arterial spurting or simple oozing), an adherent blood clot, a protuberant vessel, or a flat, pigmented spot on the ulcer base (Table 42.3).[16,18,19] Only high-risk lesions (active arterial bleeding, non-bleeding visible vessels or an adherent blood clot) should be treated endoscopically since only these are at risk of further bleeding.[16,18,19] The proximal postero-inferior wall of the duodenal bulb and the high lesser curve

of the stomach are common sites for severe recurrent bleeding, probably owing to their respective large arteries (gastroduodenal and left gastric arteries).

Adrenaline (epinephrine) injection

Endoscopic injection of adrenaline (1:10,000 dilution) into and around the ulcer bleeding point is an effective, cheap, portable and easy-to-learn method of haemostasis.[20] Injection into ulcers with adherent blood clot significantly reduces rebleeding from approximately 35%–10%.[18,21] Debate exists as to whether the haemostatic effect is a result of local tamponade by the volume injected or vasoconstriction by adrenaline, or a combination of both. When different volumes of adrenaline solution 1:10,000 are compared, there were no significant differences in the rate of initial haemostasis between three groups with 20, 30 and 40 mL of endoscopic injections, but the rate of peptic ulcer perforation was significantly higher in the group receiving 40 mL adrenaline, and the rate of recurrent bleeding was significantly higher in the 20 mL adrenaline group (20.3%) than in the 30 mL (5.3%) and 40 mL (2.8%) adrenaline groups.[22] Absorption of adrenaline into the systemic circulation has been documented, but without any significant effect on the haemodynamic status of the patient.[23]

Thermal

This method uses direct pressure and heat energy (heater probe) or electrocoagulation (bipolar coagulation probe [BICAP]) to control ulcer bleeding. The depth of tissue injury induced by these devices is minimal, as the bleeding vessel is tamponaded prior to coagulation. The overall efficacy of the heater probe and BICAP probe methods are comparable to the adrenaline injection,[24] and any complications, including mucosal perforation, are rare.[24,25]

Mechanical

The advantage of haemoclips over thermocoagulation is that there is no tissue injury induced and hence the risk of perforation is reduced. Studies comparing haemoclips with injection and thermocoagulation have shown favourable results for endoscopic clipping, including higher definitive haemostasis and reduced rebleeding compared to injection, and comparable efficacy to thermocoagulation.[26–28] However, the application of haemoclips in certain sites, for example lesser curve, gastric fundus and posterior wall of the duodenum, is technically difficult.

Combination

Combinations of endoscopic treatments, comprising an injection of adrenaline coupled with either a thermal or mechanical therapy, are superior to the use of a single modality treatment resulting in decreased rebleeding and emergency surgery rate, without increased risk of complications.[28,29]

Repeat endoscopy

Repeat endoscopy should be performed within 24 hours when initial endoscopic treatment was considered suboptimal due to difficult access, poor visualisation or technical difficulties. In addition, repeat endoscopy reduces the risk of rebleeding[28,30] and should be considered for patients in whom rebleeding is likely to be life threatening. For patients who rebleed after endoscopic therapy, they should be considered for repeat endoscopic treatment, selective arterial embolisation or surgery. In a study investigating the best salvage treatment for patients with recurrent bleeding after endoscopic therapy, repeat endoscopic therapy was found to be comparable to surgery in securing haemostasis, with similar 30-day mortality and transfusion requirements; however, morbidity was significantly higher after surgery compared to repeat endoscopy.[31]

ANGIOGRAPHY

Angiography and angioembolisation is a diagnostic and therapeutic option for gastrointestinal haemorrhage. Angiography alone can be helpful as a diagnostic tool to locate the site of bleeding for subsequent radiological or surgical intervention. In cases of the bleeding being very brisk and obscuring the endoscopic view, angiography may help to identify the source of bleeding. Once the bleeding point is identified, angiography may be also used to embolise the bleeding point with simultaneous superselective coil transcatheter embolisation. Agents can be delivered radiologically to occlude the vascular supply, such as coils or particles, with the aim of reducing blood flow to the bleeding vessel and thereby reduce perfusion pressure and enable clot formation at the bleeding site.[32] Studies reporting on the use of angiography and embolisation have demonstrated high rates of technical success, low rebleeding rate, and low complication rates.[33–36] An important complication of embolisation is the risk of ischaemia that can be caused by reducing the blood flow to the organ supplied by the target blood vessel (e.g. hepatic/splenic infarction and duodenal ischaemia) and also the risk of embolisation of an inappropriate vessel.[33–36] Angiography may be preferred to surgery in patients with multiple comorbidities where there is a high risk of postoperative morbidity and mortality, and its use is well established in managing haemorrhage secondary to peptic ulcer disease in patients that are high risk for surgery.[37,38]

SURGERY

Surgery remains the definitive method of stopping haemorrhage, but there is little agreement on the exact indications and best timing for surgical intervention. These issues are even less clear now that endoscopic treatment and angioembolisation are so effective. Accordingly, good cooperation among intensivists, gastroenterologists, radiologists and surgeons is essential. Indications for surgery can be:

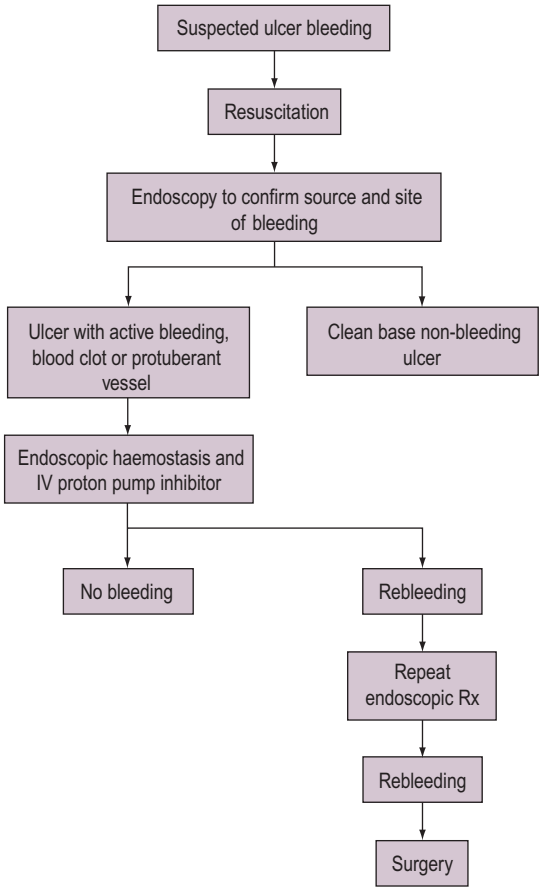

Figure 42.1 Management of peptic ulcer bleeding. *IV*, Intravenous; *Rx*, treatment.

- arterial bleeding that cannot be controlled by endoscopic haemostasis or angioembolisation
- massive transfusion (i.e. total of 6–8 units of blood) required to maintain blood pressure
- recurrent clinical bleeding after initial success in endoscopic haemostasis
- evidence suggestive of gastrointestinal perforation.

Surgical procedures include underrunning of the ulcer, underrunning plus vagotomy and drainage, and various types of gastrectomy. The overall mortality of emergency surgery for gastrointestinal bleeding is about 15%–20%. Early surgery should be considered in patients with hypovolaemic shock and/or large peptic ulcer with protuberant vessels. A protocol to manage bleeding peptic ulcer is shown in Fig. 42.1.[39]

PREVENTION OF REBLEEDING

ACID SUPPRESSION

Acid suppression therapy should be given to patients at high risk of rebleeding and to patients undergoing endoscopic therapy to achieve haemostasis, in order to maintain intragastric pH above 6 to stabilise clots and prevent rebleeding.[11] A meta-analysis concluded that in ulcer bleeding, PPIs reduce the risk of rebleeding and the need for surgery or repeat endoscopy, and decrease mortality among high-risk patients.[14]

TRANEXAMIC ACID

There is insufficient evidence to make recommendations regarding the use of antifibrinolytic agents such as tranexamic acid. Meta-analyses demonstrated that tranexamic acid did not significantly reduce the rate of rebleeding or need for surgery but significantly reduced mortality.[40,41]

NON-STEROIDAL ANTI-INFLAMMATORY DRUGS

NSAID use and *Helicobacter pylori* (*H. pylori*) infection increase the risk of upper gastrointestinal bleeding, with this risk increasing further when both factors are present.[42] The elderly and patients with a history of peptic ulcer could benefit the most from a reduction in NSAID gastrotoxicity. Clinical factors reported to increase the risk of developing NSAID-associated upper gastrointestinal complications include a history of ulcer or gastrointestinal bleeding, increasing age, concomitant anticoagulation or corticosteroid therapy and high-dose NSAID use.[43]

HELICOBACTER PYLORI

Eradication of *H. pylori* results in reduced recurrence of uncomplicated peptic ulcer disease[44] and prevents recurrent bleeding.[45] Treatment of *H. pylori* infection is more effective than antisecretory non-eradicating therapy in preventing recurrent bleeding from peptic ulcer.[45] The rapid urease test for *H. Pylori* is quick, easy to perform and inexpensive, but PPI therapy is associated with false negative rapid urease results. Therefore, when negative for this test, additional biopsies should be examined histologically, and mucosal biopsies should be obtained from the antrum and body of the stomach at the initial endoscopy prior to commencing PPI therapy.[46] For those patients who test positive for *H. pylori*, a 1-week course of eradication therapy should be prescribed with a further 3 weeks ulcer healing treatment.

ACUTE STRESS ULCERATION

Acute stress ulceration is associated with shock, sepsis, burns, multiple trauma, head injuries, spinal injuries and respiratory, renal and hepatic failure. Bleeding may be occult or overt, from 'coffee-ground' aspirates to frank haemorrhage. Lesions are most commonly seen in the gastric fundus, and range from mild erosions to acute ulcerations. The exact mechanism leading to acute mucosal erosion/ulceration in critically ill patients is still unclear. Hypoxia and hypoperfusion of the gastroduodenal mucosa are probably the most important factors, but haemodynamic instability,

respiratory failure and coagulopathy are also strong independent factors in critically ill patients. The reported incidence of stress-related mucosal bleeding in ICU patients ranges from 8% to 45%.[47] It has been declining in the last decade as a result of highly effective management of hypotension and hypoxaemia in the ICU.

Prophylactic treatment for acute stress ulceration, given in the oral form of the drug if possible, aims for gastric alkalinisation (gastric pH > 3.5), with the rationale that gastric acidity is the main cause of stress ulceration.[47] The incidence of stress ulceration appears to be lower with prophylactic gastric alkalinisation than with placebos, although an improvement in survival has not been shown.[48,49] Concerns have included gastric bacterial overgrowth and associated nosocomial pneumonia, but these have not been substantiated by existing data. On balance, prophylactic treatment should probably be reserved only for at-risk patients. Drugs given include the following:

- Antacids – Antacids can maintain gastric alkalinisation and contain magnesium, aluminium, calcium or sodium. Complications may arise from excessive intake of these minerals, and bowel stasis and diarrhoea can also be problems.
- Sucralfate – Sucralfate is effective in increasing mucus secretion, mucosal blood flow, and local prostaglandin production. It promotes ulcer healing and mucosal resistance against acid and pepsin (i.e. it is cytoprotective). As it does not alter gastric pH, Gram-negative bacterial colonisation of gastric juice is less likely. The incidence of nosocomial pneumonia may be less with sucralfate than with antacids or H_2-receptor antagonists, but this is debatable and is offset by the potential risk of aspiration.[49]
- H_2-receptor antagonists – These drugs suppress acid secretion by competing for the histamine receptor on the parietal cell.
- PPIs – These drugs block the final common pathway of acid secretion by the parietal cell, namely the proton pump. They were shown to protect critically ill patients requiring ventilation from the development of stress-related mucosal bleeding from the upper gastrointestinal tract.[50] All PPIs can be given as oral medications. Omeprazole and pantoprazole are also available in intravenous form for those who cannot be fed orally.

VARICEAL BLEEDING

Varices are abnormal, dilated veins at the junction between the portal and systemic venous systems, usually in the oesophagus (oesophageal varices, 90%) and less frequently in the stomach (gastric varices, 8%) or other sites (ectopic varices, 2%). Acute variceal bleeding is a serious complication of portal hypertension related to liver disease, with a high mortality. The degree of liver failure, using the Child–Pugh classification, is the most important prognostic factor for early rebleeding and survival.[51] The size of the varices and their propensity to bleed is directly related to the portal pressure, which, in most cases, is directly related to the severity of the underlying liver disease.

RESUSCITATION

Immediate resuscitation with whole blood and fluid is mandatory. Overtransfusion may cause a rebound increase in portal pressure (with a consequent increased risk of rebleeding) and must be avoided. Fresh frozen plasma and platelet transfusion may be indicated. A nasogastric cannula is often inserted for the removal of blood (and also for drug administration). Lactulose (15–30 mL every 4–6 hours) can be given to prevent or correct hepatic encephalopathy. When the patient is haemodynamically stable, upper gastrointestinal endoscopy should be performed to identify the source of bleeding. A protocol to manage variceal bleeding is shown in Fig. 42.2.

PHARMACOLOGICAL TREATMENT

Vasopressin

Vasopressin used to be the most widely used agent to reduce portal blood pressure and control variceal bleeding. Adverse effects of vasopressin such as cardiac ischaemia (in about 10% of patients) and worsening coagulopathy (by release of plasminogen activator) have discouraged the use of this drug in recent years. Terlipressin, a triglycyl synthetic analogue of vasopressin, has a longer half-life and fewer cardiac side-effects and appears more effective and safe when used in combination with glyceryl trinitrate.[52] Terlipressin used in the treatment of acute variceal haemorrhage results in a significant decrease in mortality.[53] When terlipressin was used specifically before endoscopy, it resulted in better bleeding control and decreased mortality, suggesting that terlipressin may be given prior to endoscopic diagnosis to patients suspected of variceal haemorrhage.[52] Terlipressin given after endoscopic diagnosis of acute variceal haemorrhage resulted in improved haemostasis.[54,55]

Somatostatin

Infusion of somatostatin and its analogues (octreotide, vapreotide) reduces portal blood pressure and azygos blood flow. They are safe and effective vasoactive agents to be used in acute variceal bleeding.[56] Although they do not reduce mortality, they result in a decrease in the amount of blood transfusion required and in the number of patients failing initial haemostasis.[57] When somatostatin was used before endoscopy, it resulted in improved haemostasis, but no reduction in rebleeding or mortality.[58] Somatostatin given after endoscopic confirmation of variceal haemorrhage made no difference in rebleeding or mortality.[59] The

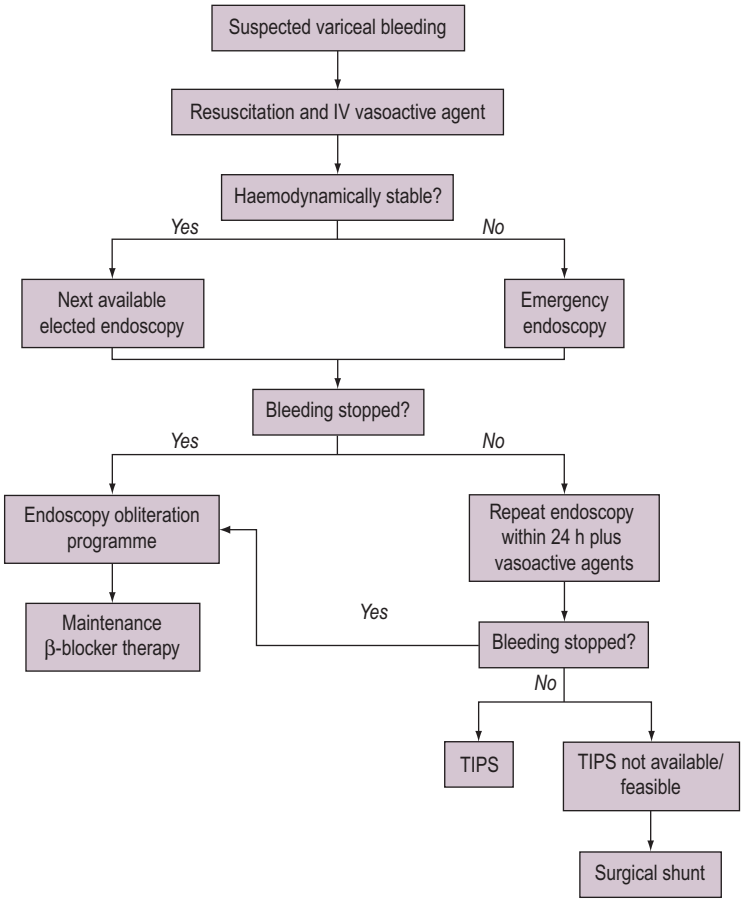

Figure 42.2 Management of variceal haemorrhage. *TIPS*, Transjugular intrahepatic portosystemic shunt. *IV*, Intravenous.

combination of somatostatin, octreotide or vapreotide, with endoscopic therapy was superior to endoscopic therapy alone, with improved haemostasis and decreased rebleeding, although there was no survival benefit.[60]

Antibiotics

Prophylactic antibiotic use in patients with cirrhosis and upper gastrointestinal bleeding was found to result in significantly reduced bacterial infections, all-cause mortality, bacterial infection mortality, rebleeding events and hospitalisation length.[61]

Propranolol

Propranolol monotherapy used for secondary prevention of variceal haemorrhage results in decreased risk of mortality and rebleeding.[62] The combination of beta blocker and nitrate is superior to beta blocker therapy alone and of equal efficacy to variceal band ligation.[63,64] Variceal band ligation combined with a beta blocker is recommended as secondary prevention for oesophageal variceal haemorrhage. In patients unsuitable for variceal band ligation, combination of non-selective beta blocker and nitrate would be the alternative.

ENDOSCOPIC VARICEAL LIGATION

Endoscopic variceal ligation is performed with rubber bands mounted on the banding device at the tip of the endoscope, which are released to strangulate the bleeding varices. Studies comparing endoscopic variceal ligation with endoscopic sclerotherapy showed that the technique is as effective as injection sclerotherapy in acute bleeding with fewer procedure-related complications, possibly because there is no tissue chemical irritation. A meta-analysis demonstrated that variceal band ligation therapy was superior to sclerotherapy in terms of rebleeding, all-cause mortality, and death due to bleeding in patients with bleeding oesophageal varices.[65] A further randomised controlled trial (RCT) demonstrated better control of oesophageal variceal bleeding with ligation than sclerotherapy, and complications were found to be greater in the sclerotherapy group, particularly in regard to sepsis and oesophageal ulceration.[66] Based on the current evidence,

patients with confirmed oesophageal variceal haemorrhage should undergo endoscopic variceal band ligation rather than injection sclerotherapy.

ENDOSCOPIC SCLEROTHERAPY

During endoscopy, sclerosants can be injected directly into the variceal columns (intravariceal injection) or into the mucosa adjacent to the varices (paravariceal injection) to cause venous thrombosis and inflammation, and tissue fibrosis. A commonly used sclerosant is cyanoacrylate. Possible complications include ulcer formation, fever, chest pain and mediastinitis. RCTs comparing the efficacy and complications of cyanoacrylate injection versus banding ligation for the management of bleeding gastric varices demonstrated better haemostasis, decreased rebleeding, and lower amount of blood transfusions required with injection treatment compared to banding.[67,68] Therefore, patients with confirmed gastric variceal haemorrhage should have endoscopic injection.

BALLOON TAMPONADE

Balloon tamponade is a temporary measure that can control massive variceal bleeding which does not respond to endoscopic therapy. Variceal bleeding can be controlled by exerting pressure directly on the bleeding point using a balloon. The Sengstaken–Blakemore tube has been replaced by the four-lumen Minnesota tube, which allows aspiration of gastric and oesophageal contents. Inflation of the gastric balloon (by 250–350 mL of water) is often sufficient to stop the bleeding by occluding the feeding veins to the oesophageal varices. If bleeding continues, the oesophageal balloon can be inflated by air and kept at a pressure of 50–60 mm Hg (6.7–8.0 kPa). Rates of haemostasis associated with balloon tamponade are reported to be 80%–95% in patients with either oesophageal or gastric varices.[69] Duration of using balloon tamponade should be limited to 24 hours to avoid tissue pressure necrosis. Other complications of balloon tamponade include pneumonia, oesophageal tears and discomfort. Because of available effective pharmacological and endoscopic therapies with lower complication rates, balloon tamponade should be used only in the exceptional cases when these therapies fail to control of bleeding.[70,71]

TRANSJUGULAR INTRAHEPATIC PORTOSYSTEMIC SHUNT

Transjugular intrahepatic portosystemic shunt (TIPS) can be administered once the patient has been stabilised and is the definitive treatment of choice for uncontrolled variceal haemorrhage. Using a transjugular approach, a catheter is inserted into the hepatic vein, and advanced under fluoroscopic guidance into a branch of the portal vein.[72] By means of a guidewire and dilators, a self-expandable metal stent is introduced to create an intrahepatic portosystemic shunt. This procedure significantly reduces portal blood pressure and thus bleeding from varices. Major complications include intra-abdominal haemorrhage and stent occlusion. Hepatic encephalopathy has been reported in 25%–60% of patients. Nevertheless, this is an effective salvage treatment for uncontrolled variceal bleeding. Meta-analysis comparing TIPS with endoscopic therapy showed that the former has improved haemostasis but at the cost of increasing risk of hepatic encephalopathy.[73] TIPS should be reserved for the subset of patients who continue to bleed or develop recurrent bleeding after endoscopic therapy. Unlike shunt surgery, TIPS will not reduce the chance of future liver transplantation. A meta-analysis comparing portosystemic shunts (TIPS and surgical shunts) versus endoscopic therapy demonstrated a reduction in the rate of rebleeding with shunt therapy, but this was at the cost of an increased incidence of chronic hepatic encephalopathy with no difference in mortality.[74]

SURGERY

Surgical treatments for variceal bleeding include direct devascularisation of the lower oesophagus plus the proximal stomach and a variety of surgical shunts. The role of surgery has diminished since the advent of endoscopic treatment and TIPS.[75] Surgery is now used as a second-line treatment, when bleeding continues or recurs after two sessions of injection sclerotherapy or banding ligation. Both staple transection of the oesophagus and portocaval shunt surgery are highly effective emergency measures. Despite successful control of bleeding, long-term survival is not significantly improved.

Hepatic encephalopathy is one of the major complications of shunting operations.[74] Higher shunt dysfunction and reintervention was observed in TIPS patients compared to those receiving a distal splenorenal surgical shunt operation.[74] Expectations that the Warren distal splenorenal shunt will preserve antegrade portal flow and avoid accelerated deterioration of liver function have not been realised. The Warren shunt is technically more difficult, especially if performed as an emergency. Choice of surgery should be carefully made in those who are potential transplant candidates, as it may complicate subsequent surgery.

LOWER GASTROINTESTINAL BLEEDING

CLINICAL PRESENTATION

Common causes of lower gastrointestinal bleeding include diverticular disease, vascular malformations (angiodysplasia), ischaemic colitis, haemorrhoids, inflammatory bowel disease (e.g. ulcerative colitis, Crohn disease), post-polypectomy bleeding, colonic polyps, carcinoma, and radiation enteropathy. Haematochezia (bright-red blood) is the most common presentation of lower gastrointestinal bleeding. However, bleeding from small intestine and caecum/right colon

may also present as melaena (black, tarry stools). Abdominal pain preceding a massive bleeding episode suggests either ischaemia or inflammatory bowel disease. Painless massive bleeding is common in diverticulosis, angiodysplasia or from a Meckel diverticulum. In a patient with portal hypertension, haemorrhoids may present with massive haematochezia.

Risk factors associated with poor outcome in patients presenting with acute lower gastrointestinal bleeding include being an inpatient, older age (>60 years), evidence of acute haemodynamic instability at presentation (tachycardia, hypotension and syncope), ongoing bleeding, evidence of gross rectal bleeding, significant co-morbidity, specific drugs such as aspirin or NSAIDs, an elevated creatinine, and anaemia (initial hematocrit ≤35%).[76–80] Diverticular disease is the commonest cause of lower gastrointestinal bleeding, accounting for 23%–48% of cases, and with a 9% chance of recurrence at 1 year and 25% at 4 years.[81]

INVESTIGATIONS

Localisation of the site and determination of the cause of bleeding in acute colonic haemorrhage allows treatment to be appropriately focused. Haemorrhoids and rectal tumour can be identified by proctosigmoidoscopy, which should always be performed. Haematochezia associated with haemodynamic instability may be indicative of an upper gastrointestinal bleeding source and thus warrants an upper endoscopy. When both proctosigmoidoscopy and gastroscopy are negative, the lower gastrointestinal tract should be examined by colonoscopy, angiography or radionuclide scan.

COLONOSCOPY

Colonoscopy should be the initial diagnostic procedure for patients presenting with acute lower gastrointestinal bleeding.[82] The endoscopist should intubate the terminal ileum to rule out proximal blood suggestive of a small bowel lesion. The colonic mucosa should be carefully inspected during colonoscopy with aggressive attempts made to wash residual stool and blood in order to identify the bleeding site.[83] Visualisation is often unsatisfactory due to the dark discoloration of blood, and colonoscopy may yield better results after adequate colon preparation once bleeding has stopped. In studies of urgent colonoscopy without oral or rectal preparation, caecal intubation rates are low (55%–70%).[84,85] In addition, colonoscopy should be deferred until patients are haemodynamically stable and upper gastrointestinal bleeding has been excluded by upper endoscopy.[86] Urgent colonoscopy does not seem to be necessary as there is little difference in outcome when compared with elective colonoscopy, although studies support that urgent colonoscopy (defined variably as colonoscopy within 12–24 hours) improves diagnostic and therapeutic yield.[82,86,87]

COMPUTED TOMOGRAPHY ANGIOGRAPHY/ANGIOGRAPHY

Computed tomographic angiography and angiography should be considered in high-risk patients with ongoing bleeding who do not respond adequately to resuscitation and who are unlikely to tolerate bowel preparation and colonoscopy. It is also helpful when the view of endoscopy is completely obscured by active haemorrhage or when endoscopy could not identify the bleeding point. Furthermore, it is helpful in defining abnormal vasculatures including angiodysplasia, arteriovenous malformation and various inherited vascular anomalies (e.g. Rendu–Osler–Weber syndrome, pseudoxanthoma elasticum and Ehlers–Danlos syndrome). Angiography localises a lower gastrointestinal bleeding source in 25%–70% of exams,[88,89] although it relies on active brisk bleeding (more than 0.5 mL/min) to identify the bleeding point. Computed tomographic angiography is widely available, easy to perform, and accurate at localising the bleeding site, and is an acceptable first-line screening test if needed before angiography or emergent surgery.

RADIONUCLIDE SCAN

A red cell scan (99mTc labelled red blood cells) can localise a bleeding source in 65%–80% of exams, and may increase the diagnostic yield of angiography by enabling targeted contrast injection.[90,91] One advantage of the red cell scan is the ability to perform repeated scans after the initial injection of tagged cells, making red cell scans most suitable for the evaluation of intermittent, obscure-overt gastrointestinal bleeding.[90,92]

MANAGEMENT

CONSERVATIVE

A significant proportion of lower gastrointestinal bleeding (80%–85%) will stop bleeding spontaneously without any specific treatment.[81,93] The patient should be resuscitated, the coagulation corrected, and any anticoagulation medication withheld. Diverticular disease which is the most common cause of lower gastrointestinal bleed resolves spontaneously in 75% of cases.[81] NSAIDs should be avoided in patients with a history of acute lower gastrointestinal bleeding, particularly if secondary to diverticulosis or angioectasia. Patients with established cardiovascular disease who require aspirin (secondary prophylaxis) should generally resume aspirin as soon as possible after bleeding ceases, but aspirin for primary prevention of cardiovascular events should be avoided.[94,95] Dual antiplatelet therapy should not be discontinued in patients with an acute coronary syndrome within the past 90 days or coronary stenting within the past 30 days.[94,96] As with all patients with gastrointestinal bleed on anticoagulants, a multidisciplinary approach involving haematology, cardiology/neurology, and gastroenterology should be sought.

ENDOSCOPY

Endoscopic haemostasis therapy should be provided to patients with high-risk endoscopic stigmata of bleeding including active bleeding (spurting and oozing), non-bleeding visible vessel, or adherent clot.[97] The endoscopic haemostasis modality used is most often guided by the aetiology of bleeding, access to the bleeding site, and the endoscopist's experience with the various haemostatic modalities. Adrenaline injection therapy can be used to gain initial control of an active bleeding lesion and improve visualisation but should be used in combination with a second haemostatic modality, including mechanical or contact thermal therapy, to achieve definitive haemostasis.[82,87,97] Bleeding from colonic diverticula can be controlled with endoscopic clips, as clips may be safer in the colon than contact thermal therapy and are generally easier to perform than band ligation, particularly for right-sided colon lesions.[98] Bleeding from vascular anomalies or post-polypectomy can be treated by mechanical (clip) or contact thermal therapy, with or without the combined use of dilute adrenaline injection.[99,100] Bleeding colonic polyps can be removed by polypectomy or coagulated by thermocoagulation.

ANGIOGRAPHY AND ANGIOEMBOLISATION

Angiography alone can be helpful as a diagnostic tool to locate the site of bleeding for subsequent radiological or surgical intervention. Once the bleeding point is identified, angiography may be used to embolise the bleeding point with simultaneous superselective coil transcatheter angioembolisation. Studies have shown that angioembolisation is safe and effective in achieving immediate haemostasis, with high technical and clinical success rates, although it has a low risk of bowel ischaemia and late rebleeding.[88,101,102]

SURGERY

Surgery for acute lower gastrointestinal haemorrhage should be considered after all other therapeutic options have failed and should take into consideration the extent and success of prior bleeding control measures,

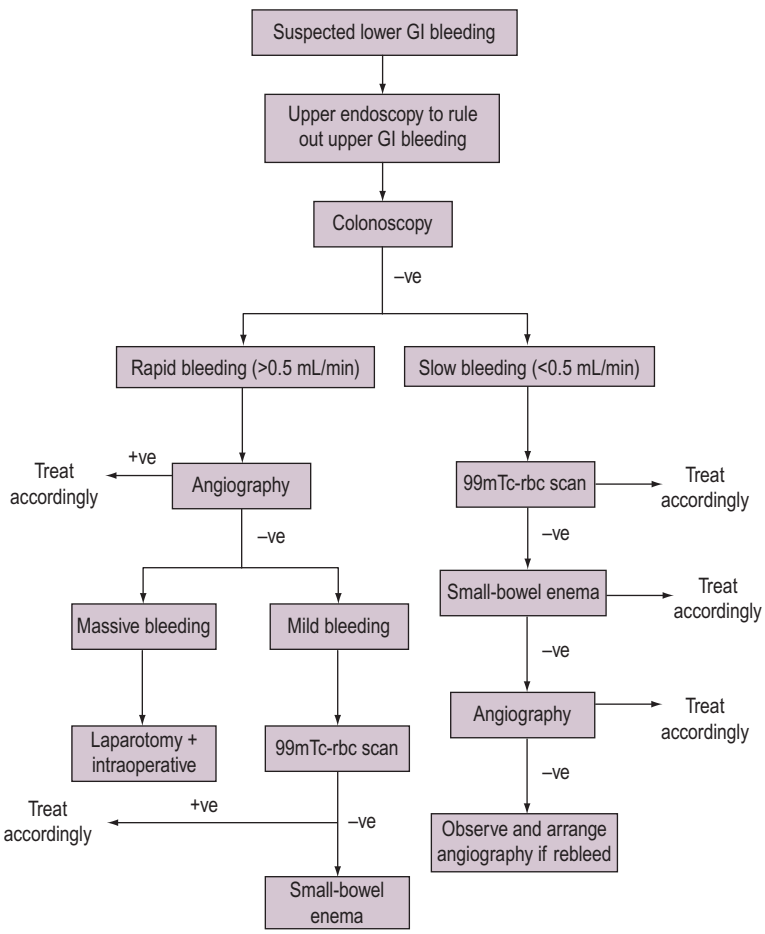

Figure 42.3 Management of lower gastrointestinal bleeding. *GI*, Gastrointestinal.

severity and source of bleeding, and the level of comorbid disease. Before surgery it is important to make all attempts to localise the source of bleeding to avoid continued or recurrent bleeding from an unresected culprit lesion or to avoid unnecessary extensive colonic resection. Localised segmental resection of the colon, with its associated risks of morbidity and mortality, is warranted after localisation of the bleeding site. When an obvious and refractory massive lower gastrointestinal bleeding is not identified by endoscopic or angiographic examinations, immediate laparotomy with possible subtotal colectomy should be offered.[103] A protocol to manage lower gastrointestinal bleeding is shown in Fig. 42.3.

Acute pancreatitis

Aimée L Brame, Duncan LA Wyncoll

Acute inflammation of the pancreas produces a spectrum of symptoms, which may be mild and self-limiting, or reflect severe disease that rapidly leads to acute respiratory distress syndrome (ARDS), multiple-organ failure and death. In a majority of patients, a treatable underlying cause is identified. Although mild, interstitial, oedematous pancreatitis is more common, it is the more severe form – acute necrotising pancreatitis (ANP) – which accounts for the associated mortality, 17%–21% even in specialist centres.[1,2]

Management of patients with severe ANP is time consuming, labour and resource intensive. Long-term follow-up suggests that, although some survivors suffer permanent exocrine and endocrine insufficiency, most maintain a good quality of life.[3]

In the last 20 years there has been a gradual move towards aggressive supportive therapy for ANP. Numerous putative therapeutic interventions have been tried, but few have provided any objective evidence of clinical benefit.

AETIOLOGY

Biliary disease (35%–40%)[1] and alcohol (35%)[4] remain the two commonest causes of acute pancreatitis worldwide. Although no discernible cause is found in many of the remaining cases, there are well-established associations with a number of infections, certain drugs, hyperlipidaemias and trauma. See Box 43.1 for a more exhaustive list.

RANSON CRITERIA

Although the overall mortality rate for acute pancreatitis is approximately 5%–10%, the vast majority of deaths occur in those with the severe form of the disease. Since 1974 the standard means of documenting the severity of disease and risk of mortality has been by Ranson criteria (Box 43.2).[5] These factors were determined following the analysis of just 100 patients with predominantly alcohol-induced pancreatitis using clinical and laboratory data obtained at admission and after 48 hours, and the number of positive criteria should predict outcome. A decade later these criteria were re-evaluated and the first eight were found to be most predictive – this is now known as the Glasgow criteria, or Imrie score. This applies to both alcohol and non-alcohol induced pathology.[6]

SCORING

The Atlanta Symposium developed the first universally applicable classification system for acute pancreatitis in 1992.[7] This divided the disease into two broad categories, interstitial oedematous (without recognisable tissue necrosis) and acute necrotising (with parenchymal and peripancreatic necrosis).[7] The classification has since been revised (2012) and now includes clinical assessment of severity and organ failure (Modified Marshall Score) and defines terms for describing the local complications of acute pancreatitis (Box 43.3).[8]

The Modified Marshall score uses Pa_{O_2}/Fi_{O_2} ratio, serum creatinine and systolic blood pressure to define the presence of organ dysfunction and, hence, severity at 48 hours.[9] The Acute Physiology and Chronic Health Evaluation (APACHE) II scoring system has also been used in predicting the severity of pancreatitis, and can be used daily throughout the patient's hospital admission rather than solely within the first 48 hours, thus potentially documenting progress or deterioration. However, such scoring systems are complex to perform and have been evaluated only prospectively 24–48 hours after the onset of pancreatitis, which means that the criteria may not be valid for patients subsequently admitted to the intensive care unit (ICU). Those factors with most predictive value for mortality include advanced age, presence of renal or respiratory insufficiency and presence of shock.

The scoring of patients with acute pancreatitis is important for a number of reasons. Firstly, the clinician can be alerted early to the presence of potentially severe disease. Secondly, comparisons of severity can be made both within and between patient series; and thirdly, rational selection of patients can be made for inclusion in trials of potential new treatments or interventions.

ABSTRACT

Acute pancreatitis is an acute inflammatory disorder of the pancreas and is one of the commonest gastrointestinal disorders requiring admission to hospital and critical care. The mortality rate is high and the treatment essentially supportive. There are multiple published guidelines and reviews; however, there are few high-quality randomised controlled trials as a result of the acuity of presentation and variability of disease aetiology and progression.

The aim of this review is to summarise the current evidence and best practice guidelines with regard to severity assessment, fluid management, imaging, pharmacological therapy, surgery and endoscopic intervention and nutrition.

KEYWORDS

Acute pancreatitis
necrotising pancreatitis

Toxins
Scorpion venom, organophosphates, methyl alcohol

Box 43.2 Adverse prognostic factors in acute pancreatitis ranson score

On admission
Age >55 years
White cell count >16,000/mm^3
Glucose 11 mmol/L
Lactate dehydrogenase 400 IU/L
Aspartate transaminase >250 IU/L
Within 48 hours of hospitalisation
Decrease in haematocrit >10%
Increase in blood urea >1.8 mmol/L
Calcium <2 mmol/L
PaO_2 <8 kPa
Base deficit >4 mmol/L
Fluid deficit >6 L

Risk factors	Mortality rate
0–2	<1%
3–4	≅15%
5–6	≅40%
>6	≅100%

Blamey et al.[6] found that only eight variables (not lactate dehydrogenase, base deficit and fluid deficit) were predictive and are often referred to as the Glasgow criteria or Imrie score.

Box 43.3 Severity grading for acute pancreatitis – revised atlanta classification 2012

Grades of severity
- Mild acute pancreatitis
  - No organ failure
  - No local or systemic complications
- Moderately severe acute pancreatitis
  - Transient organ failure (resolves <48 hours) ±
  - Local or systemic complications without persistent organ failure
- Severe acute pancreatitis
  - Persistent single or multiorgan failure (>48 hours)

Modified from Banks PA, Bollen TL, Dervenis C, et al. Classification of acute pancreatitis – 2012: Revision of the Atlanta classification and definitions by international consensus. *Gut*. 2013;62:102–111.

THE MANAGEMENT OF SEVERE PANCREATITIS

IMAGING

Dynamic contrast-enhanced computed tomography (CT) provides the best means of accurately visualising the pancreas and diagnosing pancreatitis and its local complications. It may also be used for guiding percutaneous catheter drainage. Local complications are defined as peripancreatic fluid collections, necrosis (sterile or infected), pseudocysts and walled-off necrosis.[8]

In severe acute pancreatitis, there is lack of normal enhancement to contrast of all or part of the gland. This is consistent with pancreatic necrosis, defined as diffuse or focal areas of non-viable parenchyma. Microscopically, there is evidence of damage to the parenchymal network, acinar cells and pancreatic ductal system and necrosis of perilobular fat. Areas of necrosis are often multifocal, rarely involving the whole gland, and may be confined to the periphery with preservation of the core. Necrosis develops early in the course of the disease and is usually established 96 hours after the onset of symptoms. The extent of pancreatic necrosis and the degree of peripancreatic inflammation have been used to determine outcome. A grading system combining the two CT prognostic indicators (the extent of necrosis and the grade of peripancreatic inflammation) gives the 'CT severity index'.[10]

A strong correlation has been established between the CT depiction of necrosis and the development of complications and death.[11] In patients with necrosis in

the pancreatic head, the outcome is as severe as when the entire pancreas is affected. By contrast, for patients with necrosis in only the distal portion of the gland, the outcome is usually good, with few complications. The mechanism may be that necrosis in the pancreatic head causes obstruction of the pancreatic duct, and produces a rise in pressure in the acinar cells leading to damage and leakage of activated destructive proteases.

Following the initial CT scan, repeated scanning is indicated if the patient's clinical condition deteriorates, usually through the development of pancreatic necrosis, abscess or pancreatic pseudocyst, haemorrhage, or colonic ischaemia or perforation.

Ultrasonography in acute pancreatitis is less useful since visualisation of the gland may be obscured by 'gas-filled' bowel. Moreover, the degree of necrosis, which determines prognosis, cannot be assessed. However, there may be a role for this mode of imaging in demonstrating gallstones or duct dilatation, or in the subsequent management when ultrasound-guided fine-needle aspiration of the pancreas or surrounding tissue may help to establish the presence of infection.

FLUID THERAPY

Early aggressive intravenous fluid therapy is of paramount importance when treating patients with acute pancreatitis. Hypovolaemia arises from vomiting (± diarrhoea), poor oral intake, third spacing of fluid, oedema and diaphoresis. This results in hypotension, worsening tissue perfusion, exacerbating pancreatic tissue necrosis and precipitates dysfunction in other organ systems. Aggressive hydration (5–10 mL/kg/h)[12] with isotonic crystalloid solution should occur in all patients without contraindication and fluid status should be reassessed at frequent intervals in the first 24 hours.[12] Higher fluid administration rates may be required; however, one randomised controlled trial (RCT) demonstrated fluid volumes of 10–15 mL/kg/h were associated with increased need for mechanical ventilation (94% vs 65%), intra-abdominal compartment syndrome, sepsis and mortality (30.6% vs 10%) compared with 5–10 mL/kg/h strategy.[13]

SURGERY IN SEVERE PANCREATITIS

During the 1980s, most patients with acute pancreatitis of even moderate severity underwent operative intervention; this was particularly true for those patients thought to have infected pancreatic necrosis. The results were poor, with mortality rates in excess of 50%, although this was sometimes without ICU support. In the 1990s the concept of a conservative, non-surgical approach to severe ANP was developed. The aim now is often to postpone surgery for as long as possible and early referral to a specialist centre for supportive management is considered paramount.

Asymptomatic pseudocysts and pancreatic necrosis do not warrant surgical intervention, regardless of size and location, unless gastric outflow or bile duct patency is compromised.[12] In stable patients with infected necrosis, drainage should be delayed for a period of at least 4 weeks to allow formation of a fibrous wall and liquefaction of the necrotic tissue. Many patients improve such that intervention is unnecessary at this point.

Unstable patients with infected necrosis should receive a course of antibiotics to allow the inflammation to become organised prior to targeted, minimally invasive surgical intervention.[12,14]

Many centres report that a conservative approach and avoiding open necrosectomy result in lower mortality. Open surgery is reserved for concomitant intra-abdominal complications, such as perforation, bleeding or ischaemia.[15]

If severe acute pancreatitis is an unsuspected 'chance' finding at laparotomy, a T-tube should be inserted into the common bile duct, particularly if it has been explored and the opportunity taken for placement of a feeding jejunostomy tube. Some surgeons oppose this approach, as opening a hollow viscus risks peritonitis.

For those patients with mild gallstone pancreatitis, the risk of recurrence is high (18% at 90 days),[12] early cholecystectomy is advocated to prevent recurrent and potentially more serious disease. In more severe biliary acute pancreatitis (AP), cholecystectomy should be delayed until the inflammatory response and clinical picture have resolved.[16]

PANCREATIC ABSCESSES

Pancreatic abscesses are circumscribed collections of pus containing little or no pancreatic necrosis, which arise as a later consequence of severe acute pancreatitis or pancreatic trauma. They commonly occur about 3–4 weeks after the onset of severe pancreatitis, and a CT scan most accurately makes the diagnosis. If the appropriate expertise is available, percutaneous catheter drainage may be very successful. Some series report effective drainage of intra-abdominal collections with a single treatment in 70% of patients, increasing to 82% with a second attempt, although proceeding to open surgical drainage is more frequently required in pancreatic abscess, especially if complicated by yeast infection.[17]

ENDOSCOPIC RETROGRADE CHOLANGIOPANCREATOGRAPHY

Endoscopic retrograde cholangiopancreatography (ERCP) represents an alternative approach, particularly for patients with severe biliary pancreatitis or those who are too frail for surgery. In mild gallstone pancreatitis, early ERCP decreases morbidity and mortality in patients with acute pancreatitis and biliary sepsis/obstruction, whereas in mild pancreatitis

without cholangitis, the risks of intervention probably outweigh the benefits.[18]

This observation is confirmed by both a systematic review of the five ERCP trials[19] and by the recommendations of the 2013 International Association of Pancreatology on the management of severe acute pancreatitis in the critically ill.[14]

TREATMENT WITH PHARMACOLOGICAL AGENTS

Theories regarding the pathogenesis of acute pancreatitis have promoted the concept that autodigestion of the gland and peripancreatic tissue by activated pancreatic enzymes is a central component. This has led to the suggestion that the reduction of pancreatic exocrine secretion, thereby 'resting the pancreas', might improve outcome. The problem is that the secretory status of the pancreas in severe ANP is not known. Consequently, it is not clear whether inhibition of secretion actually occurs or whether this is beneficial. Therapies designed to inhibit pancreatic secretion, such as H_2-blockers, atropine, calcitonin, glucagon and fluorouracil, do not alter the course of the disease.

Other therapies are more controversial.

SOMATOSTATIN AND OCTREOTIDE

Somatostatin and its long-acting analogue octreotide are potent inhibitors of pancreatic secretion. They also stimulate activity of the reticuloendothelial system and play a regulatory role, mostly inhibitory, in the modulation of the immune response via autocrine and neuroendocrine pathways. Both are cytoprotective with respect to the pancreas.[20] Other effects include:

- Somatostatin also blocks the release of tumour necrosis factor and interferon-γ by peripheral mononuclear cells.
- Octreotide increases the phagocytotic activity of monocytes.

These actions may be important in the modulation of the pathogenesis of ARDS and septic shock, both of which can complicate severe ANP. Both agents are effective in experimental pancreatitis, and in the prevention of complications in patients undergoing surgery for chronic pancreatitis, but there are potential difficulties:

- Pre-emptive administration is not possible in the acute situation.
- Both agents are powerful splanchnic vasoconstrictors.
- The development of pancreatic necrosis has been linked to hypoperfusion of the gland and vasoconstrictors worsen the histological severity of experimental pancreatitis.[21]

Consequently, these agents have both beneficial and detrimental effects. Systematic evaluation suggests that there is insufficient evidence to support the use of octreotide or somatostatin in the treatment of patients with moderate to severe acute pancreatitis.[22,23] Octreotide may have a role in prophylaxis prior to ERCP[24] but the ideal delivery method and dosage are not clear.

Protease inhibitors

A further pathogenic mechanism involved in acute pancreatitis is autodigestion of the pancreas by the activation of proteases. More accurately, there is an imbalance between proteases and antiproteases. Aprotinin and gabexate mesilate are proteolytic enzyme inhibitors that act on serine proteases such as trypsin, phospholipase A_2, kallikrein, plasmin, thrombin and C1r and C1s esterases.

In a meta-analysis of 17 trials, protease inhibitors did not achieve a significant risk reduction in mortality, length of stay or need for surgery, even in severe disease.[25–27] The majority of published data is observational and to date there are no placebo-controlled randomised studies evaluating protease inhibitors in ANP.

The reason why these agents, in clinical practice, do not have the expected beneficial effect on outcome may be the lag time between the onset of pancreatitis and administration. Additionally, derangement to the microvascular control of the pancreas combined with increased vascular permeability may contribute. Continuous regional arterial infusion or intraperitoneal administration may be more advantageous in prophylaxis prior to ERCP,[28] but so far trials using these modes of administration have only involved small numbers of patients. At present, there is insufficient evidence to recommend protease inhibitors in ANP and their use is not supported in the majority of published guidelines.[29,30]

ANTI-INFLAMMATORY THERAPY

Patients with ANP exhibit a generalised uncontrolled inflammatory response. Potentially there is a therapeutic window between the onset of symptoms and the development of organ failure during which anti-inflammatory therapy might be successful. Potential targets include tumour necrosis factor-α, interleukin (IL)-1β, IL-6, IL-8, IL-10, platelet-activating factor and intracellular adhesion molecules.[31] Although many have been studied in animals, there are limited human data.

Changes in hypopituitary–adrenal axis hormone levels strongly suggest that the existence of relative adrenocortical insufficiency in patients with ANP is very comparable to that of severe sepsis and multiple-organ failure[32]; however, there are currently no positive published trials of corticosteroid therapy in patients with ANP, and no evidence for use as either therapy or prophylaxis.

NSAIDs have been evaluated in several studies and may provide a beneficial effect in prophylaxis post-ERCP and are also useful adjunctive analgesics.[33]

Recombinant IL-10, anti-TNF-α and platelet activating factor (Lexipafant) have all been investigated in animal models, but there is insufficient human data and the use of these agents is not recommended.[34]

PROPHYLACTIC ANTIBIOTICS

Bacterial infection of necrotic pancreatic tissue occurs in approximately 50% of patients with ANP, and infection is the major cause of morbidity and mortality. Early studies investigating the role of prophylactic antibiotics in acute pancreatitis showed no benefit, but most included patients with mild disease and employed agents (e.g. ampicillin) with inefficient penetration of pancreatic tissue. Subsequent studies have still not clarified their role, and prophylactic use remains widespread but controversial.

Carbapenems have exceptional penetration into pancreatic tissues and broad activity against most of the common pathogens encountered in this disease. In the 1990s there was hope that this new class of antibiotic would prove more useful, and some of the early trials did suggest a modest benefit with imipenem.[35] The incidence of septic complications was significantly reduced in the treated group (12.2% vs 30.3%), although there was only a trend towards decreased mortality (7% vs 12%). However, the most recent systematic review, which included 14 trials (but still only 841 patients), suggested antibiotic prophylaxis was not associated with a statistically significant reduction in mortality (relative risk [RR], 0.74 [95% confidence interval (CI), 0.50–1.07]), in the incidence of infected pancreatic necrosis (RR, 0.78 [95% CI, 0.60–1.02]) or in the incidence of non-pancreatic infections (RR, 0.70 [95% CI, 0.46–1.06]).[36] Of note, though, in the majority of these trials, patients with severe ANP and overt shock *were excluded*, leaving open the possibility that prophylactic antibiotics may still have a role in the very sickest patients.

Whilst antibiotic prophylaxis is not recommended, intravenous antibiotics should be given in cases of suspected infection of necrotising pancreatitis after aspiration or cultures have been performed.[12,14]

Patients with mild pancreatitis definitely do not benefit from antibiotics.

PROPHYLACTIC ANTIFUNGAL THERAPY

The incidence of fungal infection correlates with the extent of pancreatic necrosis, as well as the severity of disease on admission. Antibiotic administration has been claimed to promote fungal infection; however, up to 25% of patients with ANP who do not receive antibiotics also develop fungal infection with an associated mortality rate of up to 84%.[37] Advocates of prophylactic antifungal therapy argue that it may delay the need for surgery, which is associated with a better outcome. Routine administration of antifungal agents is not recommended.[12]

SELECTIVE DECONTAMINATION OF THE GUT

The original selective digestive decontamination (SDD) strategy contained three components: oropharyngeal and gastric decontamination with polymyxin E, tobramycin, and amphotericin B and intravenous cefotaxime for 4 days.[38] There is ongoing debate as to the effectiveness of this strategy and results are conflicting regarding any reduction in mortality, particularly when applied to a general critically ill population. However, more promising results have been seen in specific patient populations.

Severe acute pancreatitis may be a clinical situation which supports the hypothesis that gut hypoperfusion promotes bacterial translocation, leading to infection of the inflamed pancreas and peripancreatic tissue.[39,40] The only controlled trial of SDD in pancreatitis was performed in 102 patients[41] who were randomised to receive SDD: oral colistin, amphotericin and norfloxacin with addition of a daily dose of the three drugs given as a rectal enema and systemic cefotaxime until Gram-negative bacteria were successfully eliminated from the oral cavity and rectum. Surveillance samples were taken regularly to assess whether any subsequent infection was of exogenous or endogenous origin. There were 18 deaths (35%) in the control group, compared with 11 (22%) in the SDD group ($P < 0.05$). This difference was caused by a fall in late mortality due to significant reduction in the incidence of Gram-negative pancreatic infection. There was also a reduction in the mean number of laparotomies in the SDD patients. Since the SDD regimen used in this study incorporated intravenous cefotaxime, it could be argued that the improvement in outcome was not due to the colistin, amphotericin or norfloxacin components, but merely due to a systemic antibiotic effect.

Meta-analyses and even large randomised controlled trials of this intervention continue to suggest clear trends towards a reduction in mortality in critically ill patients.[42] However, the perhaps unfounded fear of the emergence of resistant Gram-positive cocci prevents widespread adoption of this strategy.

Probiotics have been investigated in three prospective randomised controlled double-blinded studies. The studies were relatively small and results contradictory. A non-significant reduction in mortality was seen in two of the studies.[43,44] The third study observed an increase in gut ischaemia (5.9% vs 0, $P = .004$) and mortality in the probiotic arm compared with the placebo (16% vs 6%, RR, 2.53; 95% CI, 1.22–5.25).[45] Probiotics are not recommended.

Nutritional support in acute necrotising pancreatitis

The provision of nutritional support for the patient with ANP is an essential component of supportive therapy, especially since many patients with pancreatitis are nutritionally depleted prior to their illness and face increased metabolic demands throughout the

course of their disorder. Failure to reverse or prevent malnutrition, and a prolonged negative nitrogen balance, increases mortality rates.

TOTAL PARENTERAL NUTRITION

Severe pancreatitis is still sometimes stated as an absolute contraindication to enteral nutrition (EN), and some physicians consider total parenteral nutrition (TPN) as 'standard' therapy. This is largely because it is regarded as a way of 'resting the pancreas', based on the assumption that the necrotic pancreas is still a secretor of activated enzymes. In fact, the secretory state of the pancreas has never been prospectively studied in severe necrosis. Several retrospective and prospective evaluations of TPN in acute pancreatitis have failed to demonstrate conclusively an effect on survival, or on the incidence and severity of organ failure.

ENTERAL NUTRITION

An increasing number of reports on the use of EN in severe ANP confirm that it is safe and feasible for all but the minority of patients. Enteral feeding maintains the gut mucosal barrier and helps prevent bacterial translocation and secondary infection of necrotic pancreatic tissue. Feeding should therefore commence early.

Enteral feeding can be oral, nasogastric or nasojejunal.[46] Nasogastric (NG) placement is easier than nasojejunal (NJ) and may therefore be preferential route; however, NG feeding is not tolerated by a number of patients. Intragastric delivery of nutrients may result in an increased volume of pancreatic protein and bicarbonate secretion, which, in combination with delayed gastric emptying, can precipitate vomiting and pain. It may therefore be preferable to place a nasojejunal tube with the tip distal to the third part of the duodenum, under radiological, endoscopic or magnetic guidance. The upper part of the duodenum contains cholecystokinin (CCK) secreting cells, stimulation of which causes gallbladder contraction and increased pancreatic exocrine secretion and may worsen the course of the disease. NJ feeding bypasses this area and conforms to the concept of 'pancreatic rest'.

EN is associated with reduced infectious complications, organ failure and mortality compared with parenteral nutrition (PN).[47] A number of comparisons of EN with PN have been made in mild and severe acute pancreatitis, all suggesting that EN is well tolerated without adverse effects on the course of the disease.[48]

In ANP, where there is often an ileus and slow bowel transit time, some patients do not tolerate EN and in some, additional nutritional support is required even after NJ insertion; in this situation TPN with normoglycaemic control should be used.

An international task force has recently made some recommendations,[49] which can be summarised as follows:

1. Most patients with mild or moderate uncomplicated pancreatitis do not benefit from nutritional support.
2. In moderate to severe pancreatitis, let hyperacute inflammation settle, then start a trial of EN.
3. In patients who require surgery for diagnosis or treatment, a jejunal tube should be placed, either pulled down from the stomach, or a separate jejunostomy.
4. TPN is indicated only if a 5- to 7-day trial of EN is not tolerated.
5. In all patients, whether fed enterally or parenterally, a protocol ensuring good glycaemic control is recommended.

CONCLUSION

The main determinant of outcome in severe acute pancreatitis is the extent of pancreatic necrosis and the subsequent risk for the development of infected necrosis. A thorough assessment using appropriate scoring systems and the early use of dynamic contrast-enhanced CT will highlight those patients likely to benefit from early critical care. Despite numerous suggested specific therapies, there is still no incontrovertible evidence that any one confers a significant mortality benefit. However, general supportive measures should include vigorous replacement of fluid losses to correct circulating volume, correction of electrolyte and glucose abnormalities, and respiratory, cardiovascular and renal support as necessary. Patients with sterile necrosis should receive a broad-spectrum prophylactic antibiotic that adequately penetrates pancreatic tissue if they develop shock. Due attention should also be paid to nutritional support, for which EN is recommended prior to initiation of TPN.

Liver failure

Chris Willars, Hafiz Hamad Ashraf, Anand Damodaran, Julia Wendon

44.1 ACUTE HEPATIC FAILURE

DEFINITIONS

The manner in which acute deteriorations in hepatic function are described is not uniform. In this chapter, we use the term *acute hepatic failure* to describe both *acute liver failure* (ALF) and *acute-on-chronic liver failure* (ACLF) – which are distinct clinical entities that require very different management strategies.

ACUTE LIVER FAILURE

ALF is a rare condition, with about 400 cases per year in the United Kingdom. ALF arises in the context of massive parenchymal injury and results in a multisystem disorder that is phenotypically similar to severe septic shock. Liver damage is manifest by coagulopathy and encephalopathy, which occurs within days or weeks of the liver injury. There is diversity in terms of aetiology and clinical progression.

Patients with ALF may initially appear relatively well, but progression to multiorgan failure is rapid. The key to a successful outcome lies in prompt recognition, resuscitation and referral to a specialist centre. Only 40% of patients with ALF recover spontaneously, leaving many in need of a liver transplantation, and even those who do eventually recover are often gravely ill.[1]

CLASSIFICATION

The clinical classification described by O'Grady et al.[2] (Table 44.1.1) uses the time from jaundice to encephalopathy to differentiate between hyperacute, acute and subacute liver failure. It is particularly useful because it informs us of likely aetiology and clinical course.

Hyperacute liver failure progresses rapidly (the onset of encephalopathy is within 7 days of the development of jaundice) and is generally associated with profound coagulopathy, high-grade encephalopathy, severe organ dysfunction and a higher incidence of intracranial hypertension, but confers higher rates of spontaneous survival. The onset of encephalopathy often precedes clinical jaundice.

ALF has an intermediate course. Common aetiologies include the viral hepatitides and idiosyncratic drug reactions.

Subacute liver failure is associated with a later onset of encephalopathy, but with the worst outcomes in the absence of transplantation. Aetiology is frequently seronegative (idiopathic – the history suggests a viral or immune-mediated aetiology, but all serological tests are negative) or drug related. Jaundice is inevitable but the transaminitis is often less pronounced than in acute and hyperacute presentations. Patients frequently present with established ascites and so may be clinically difficult to distinguish from those with chronic liver disease (CLD).

AETIOLOGY

Determination of the aetiology of ALF (Box 44.1.1) is important for prognostication and because specific therapy may be available. There is a wide geographical variation in the aetiology of ALF. Acetaminophen (paracetamol) toxicity is responsible for the majority of cases of ALF seen in the United Kingdom and the United States, whereas viral hepatitis is the most common cause of ALF worldwide (Table 44.1.2).

A good history and review of the results of blood tests over the preceding weeks are essential to making a diagnosis. Any new drug ingestion (prescribed, recreational or over the counter) should be considered a potential culprit and discontinued if possible. In addition, any treatments that may be detrimental to liver recovery should be avoided.

DIAGNOSIS

A standardised investigative pathway ensures clinical consistency. *Laboratory tests* that may be useful in establishing a diagnosis are listed in Table 44.1.3. It is paramount that diagnosis proceeds in tandem with resuscitative measures.

ABSTRACT

Acute liver failure (ALF) is a life-threatening illness carrying high mortality. Progression to multiorgan failure can be rapid. Determination of the time from jaundice to encephalopathy allows the clinician to predict the likely aetiology and clinical progression.

Common aetiologies include drugs (especially acetaminophen), viruses, toxins and vascular events.

Diagnosis is established by the exploration of history, the identification of clinical features and the interpretation of serological and radiological investigations.

Patients are best managed in a specialist intensive care unit. Specific treatments are available where the cause is known. Proactive management of intracranial hypertension, prompt resuscitation of the cardiovascular system and the management of metabolic disarray is of paramount importance. Transplantation remains a cornerstone of treatment. Identification of patients who will not survive without urgent liver transplantation is not straightforward and good outcomes rely on the efforts of a multidisciplinary team.

KEYWORDS

Acute liver failure
liver transplant
fulminant liver failure
paracetamol
acetaminophen
critical care
hepatitis
cerebral oedema
intracranial hypertension

Table 44.1.1 Classification of acute liver failure

DEFINITION	TIME (DAYS)	COMMONEST AETIOLOGIES
Hyperacute	<7 days	Acetaminophen overdose, hepatitis A and B
Acute	8–28 days	Hepatitis A, B, E, idiosyncratic drug reactions
Subacute	29 days–8 weeks	Idiosyncratic drug reaction, seronegative hepatitis

Table 44.1.2 Geographical distribution of aetiology in acute liver failure

	U.K.	U.S.	FRANCE	INDIA	JAPAN
Paracetamol	54	40	2	–	–
Drug induced	7	12	15	5	–
Seronegative	17	17	18	24	45
Hepatitis A/B	14	12	49	33	55
Hepatitis E	–	–	–	38	–
Other	8	19	16	–	–

Box 44.1.1 Aetiology of acute liver failure

Viral hepatitis
Hepatitis A, B, D, E, seronegative hepatitis
Herpes simplex, cytomegalovirus, chickenpox – usually limited to immunocompromised hosts

Drug related
Acetaminophen
Antituberculous drugs
Recreational drugs (ecstasy, cocaine)
Idiosyncratic reactions (anticonvulsants, antibiotics, non-steroidal anti-inflammatory drugs [NSAIDs])
Aspirin in children may lead to Reye syndrome
Kava kava

Toxins
Carbon tetrachloride, phosphorous, *Amanita phalloides*, alcohol

Vascular events
Ischaemia, veno-occlusive disease, Budd–Chiari syndrome (hepatic vein thrombosis)
Hyperthermic liver injury

Pregnancy
Acute fatty liver of pregnancy, HELLP syndrome, liver rupture

Other
Wilson disease, autoimmune, lymphoma, carcinoma, haemophagocytic syndrome, trauma

HELLP, **H**aemolysis (microangiopathic haemolytic anaemia), **e**levated **l**iver enzymes and **l**ow **p**latelets.

Figure 44.1.1 A collapsed liver in the case of a 42-year-old man with acute liver failure.

Doppler ultrasound is very useful in determining patency of the hepatic artery, vein and portal vein. Budd–Chiari syndrome, ischaemic hepatitis, portal vein thrombosis and even tricuspid regurgitation may be apparent. *Ultrasound examination* of the liver parenchyma may reveal heterogeneity, fatty infiltration (reflectivity) and tumour. Splenomegaly and ascites are evident, if present.

Axial computed tomography (CT) imaging provides additional information about other abdominal anatomy, lymphadenopathy and liver perfusion. Serial imaging in ALF may demonstrate a collapsing liver (Fig. 44.1.1). Nodularity of the liver should not be assumed to represent cirrhosis and CLD. The imaging pattern of subacute liver failure, with focal areas of collapse and regeneration, may be difficult to distinguish from cirrhosis.

Liver biopsy is rarely undertaken in the acute setting because of the high risk of bleeding. The contribution of histology to the assessment of ALF is controversial. Features suggestive of specific diagnoses, such as Wilson disease (cirrhosis), and autoimmune features may be evident and histology may be particularly useful if infiltration with tumour is suspected and a tissue diagnosis is required prior to consideration of systemic chemotherapy. However, in ALF, non-specific confluent necrosis is the commonest histological finding. Its severity has been used to assess prognosis: >50% necrosis is associated with poor prognosis. However, nodules of regeneration may occur randomly, particularly in subacute liver failure, and sampling error may thus make this a less than ideal tool for predicting outcome. The transjugular route is considered safest, although there is a risk of sampling error.

Echocardiography should be performed to exclude low cardiac output states as a cause of hypoxic hepatitis, and where transplantation is considered.

Table 44.1.3 Aetiology of acute liver failure and initial investigations

Hepatitis A virus (HAV)	Immunoglobulin M (IgM) anti-HAV
Hepatitis B + D viruses (HBV, HDV)	HBsAg, IgM anti-core, HBeAg, HBeAb, HBV DNA, delta antibody
Hepatitis E virus (HEV)	IgM antibody
Seronegative hepatitis	All tests negative: diagnosis of exclusion
Paracetamol	Drug levels in blood and clinical pattern of disease – may be negative on third or subsequent days after overdose; markedly elevated aspartate and alanine serum transaminase (often >10,000)
Idiosyncratic drug reactions	Eosinophil count may be elevated, although most diagnoses are based on temporal relationship
Ecstasy	Blood, urine, hair analysis and history
Autoimmune	Autoantibodies, immunoglobulin profile
PREGNANCY-RELATED SYNDROMES	
Fatty liver	Uric acid elevated, neutrophilia, often first pregnancy, history, CT scan for rupture and assessment of vessels
HELLP syndrome	Platelet count, disseminated intravascular coagulation a prominent feature; CT scan as above
Liver rupture	May be seen in association with pre-eclampsia, fatty liver and HELLP
Wilson disease	Urinary copper, ceruloplasmin (although low in many causes of acute liver failure), present up to second decade of life, Kayser–Fleischer rings, low alkaline phosphate levels
Amanita phalloides	History of ingestion of mushrooms, diarrhoea
Budd–Chiari syndrome	Ultrasound of vessels (HV signal lost, reverse flow in portal vein), CT angiography, ascites, prominent caudate lobe on imaging, haematological assessment
Malignancy	Imaging and histology; increased alkaline phosphate and LDH; often imaging may be interpreted as normal
Ischaemic hepatitis	Clinical context, marked elevation of transaminases (often >5000); may demonstrate dilated hepatic veins on ultrasound, echocardiogram
Heatstroke	Myoglobinuria and rhabdomyolysis are often prominent features

CT, Computed tomography; *HELLP,* **h**aemolysis (microangiopathic haemolytic anaemia), **e**levated **l**iver enzymes and **l**ow **p**latelets; *HbsAg,* hepatitis B surface antigen; *HIV,* human immunodeficiency virus; *HV*, high velocity; *LDH,* lactate dehydrogenase.

PARACETAMOL (ACETAMINOPHEN) TOXICITY

Paracetamol, taken intentionally or inadvertently, remains one of the commonest forms of acute hepatotoxicity. This incidence of paracetamol overdose has risen since the 1970s, and in 1998 the Medicines Control Agency (United Kingdom) introduced legislation to limit its availability, and paracetamol is now sold as 16 × 500 mg tablets; a maximum of 8 g per packet.

Cytochrome P450 enzymes convert ~5% of acetaminophen to *N*-acetyl *p*-benzoquinone imine (NAPQI), a metabolite that is normally detoxified by conjugation with hepatic glutathione. Hepatocellular glutathione becomes rapidly depleted in overdose, and NAPQI persists, causing damage to cell membranes leading to hepatocyte death unless NAC (N-acetylcysteine) or methionine is administrated in a timely fashion.

Following massive paracetamol ingestion, relatively small doses are absorbed and when NAC is administered early less than 1% of cases result in significant hepatotoxicity.

The recommended dosage schedule is 150 mg/kg in 5% dextrose over 15–60 minutes, followed by 50 mg/kg in 5% dextrose over 4 hours, and followed by 100 mg/kg in 5% dextrose over 16 hours. Ongoing administration at doses of 150 mg/kg over a 24-hour period may be indicated.

Even late administration of *N*-acetylcysteine (up to 36 hours after ingestion) may improve outcome. The risk factors listed in Table 44.1.4[3] confer a predisposition to paracetamol-induced hepatotoxicity:

The Prescott nomogram (Fig. 44.1.2) is used in the United Kingdom and Europe to determine the risk of acetaminophen toxicity. It can be applied only to a single acute overdose presenting within 16–24 hours.

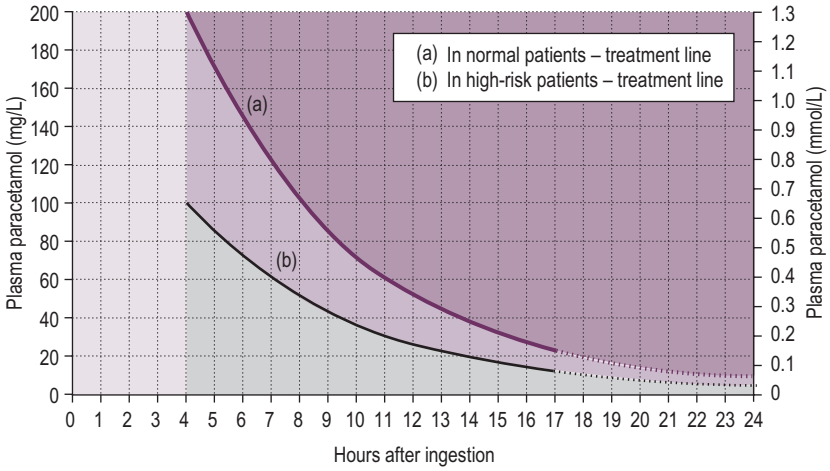

Figure 44.1.2 The Prescott nomogram.

Table 44.1.4 Risk factors for paracetamol hepatotoxicity

DECREASED HEPATIC GLUTATHIONE STORES	INDUCTION OF CYTOCHROME P450
Anorexia nervosa	Phenytoin
Bulimia	Carbamazepine
HIV	Rifampicin
Cystic fibrosis	Phenobarbital
Malnourishment	Long-term ethanol ingestion

HIV, Human immunodeficiency virus.

From Greene SL, Dargan PI, Jones AL. Acute poisoning: understanding 90% of cases in a nutshell. *Postgrad Med J.* 2005;81(954):204–216 (published by BMJ group).

If in doubt, commence treatment. NAC administration can be lifesaving, and adverse reactions and unpleasant side effects are rare.

It should be noted that negative paracetamol levels 16–24 hours after ingestion do not exclude the potential for hepatotoxicity. A staggered overdose is said to have occurred where there have been multiple ingestions over a period of time. Overdoses may be intentional or unintentional. Combined analgesics confer a risk of inadvertent overdose when they are abused for their narcotic content. A clear and detailed history is extremely important.

Patients with features of moderate or severe overdose should be managed in a critical care environment; the importance of early appropriate fluid resuscitation should not be underestimated. Contact should be made with a tertiary centre, and cases discussed with decision to transfer made in a timely fashion.

Early signs of nausea and vomiting after overdose are followed by signs of liver failure (see later) 48–72 hours after ingestion.

ACUTE VIRAL HEPATITIS

Acute viral hepatitis accounts for 40%–70% of patients with ALF worldwide.

Acute hepatitis A virus (HAV) infection rarely leads to ALF (0.35% of infections), but continues to account for up to 10% of cases; morbidity increases with the age of infection. It is hoped that the prevalence will decrease with improving hygiene standards generally and the uptake of vaccination.

Acute hepatitis B virus (HBV) causes 25%–75% of viral hepatitis-induced ALF. The liver injury is immunologically mediated with active destruction of infected hepatocytes. Diagnosis is by the presence of the immunoglobulin (Ig)M antibody to hepatitis B core antigen. Hepatitis B surface antigen (HbsAg) is frequently negative by the time of presentation. Hepatitis B DNA should also be assayed. ALF may also be seen with hepatitis D as either a co-infection or supra-infection.

Re-activation of hepatitis B is an increasing cause of ALF and should always be considered in a patient who has received steroids or chemotherapy. High-risk patients should be screened for sAg and HBV DNA and treated with antiviral agents if they are positive. This is not only a recognised problem in oncology and haematology but also it is a potential risk to patients in intensive care where steroids may be administered.

Hepatitis C virus (HCV) infection is commonly associated with CLD but *not* with ALF. It is detected by the presence of antibodies to HCV in serum. HCV-related cirrhosis will be discussed in detail in the subsequent chapter.

Hepatitis E virus (HEV), like hepatitis A, is transmitted via the faecal–oral route. It is particularly prevalent in the Indian subcontinent and Asia generally and is responsible for sporadic instances of ALF in the Western world. A particular genotype of hepatitis E can be transmitted via blood. HEV can be diagnosed

by the detection of antibodies to HEV in serum. Mortality can be as high as 25% in pregnant women.

Other viruses, such as herpes simplex 1 and 2, varicella zoster virus, cytomegalovirus, Epstein–Barr virus and measles virus, may all rarely cause ALF, but may be seen especially in the immunocompromised patient. Diagnosis is by serological and polymerase chain reaction (PCR) testing. Rift Valley fever, dengue fever, yellow fever, Lassa fever and the haemorrhagic fevers should be considered in those who are at risk.

SERONEGATIVE HEPATITIS

A cause for ALF can be established in approximately 60%–80% of patients.[4] Seronegative hepatitis (so-called) is seen in patients in whom there are no identifiable viral causes or obvious candidate drugs. Such patients may present with a prodromal illness and with acute or subacute manifestations of the disease. Prognosis is poorer than those with an identifiable virus, and once they have poor prognostic criteria the chances of survival without liver transplant are exceptionally small. A subgroup may represent an acute autoimmune form of ALF, although many will not have any positive immune markers such as elevated IgG or positive smooth-muscle or liver kidney antibodies. The pattern of markers shows an increased incidence of autoantibody positivity in seronegative cases and viral cases with elevated IgM in viral causes.[5,6]

DRUG-INDUCED LIVER INJURY (DILI)

Drug-induced hepatitis is responsible for approximately 15%–25% of cases of ALF. In some patients there appears to be a true hypersensitivity reaction, and symptoms develop after a sensitisation period of 1–5 weeks, recur promptly with re-administration of the drug and may be accompanied by fever, rash and eosinophilia. In others the clinical pattern is less acute and liver failure can manifest up to 6 months after exposure. Some herbal remedies are implicated as putative hepatotoxins, but their role is made more difficult to assess by the variable nature of the constituent parts. Halothane hepatitis is now almost unheard of.

RECREATIONAL DRUGS AND LIVER FAILURE

Ecstasy (methylenedioxymethamphetamine) may cause ALF, although, given the prevalence of exposure to the drug, the incidence is presumably low. Proposed mechanisms of injury include immune-mediated mechanisms and/or heatstroke. Cocaine use may result in ischaemic hepatitis. Yellow phosphorus, carbon tetrachloride, chloroform, trichloroethylene and xylene (glue sniffing) are very rare causes of ALF.

AMANITA PHALLOIDES

Mushroom poisoning can be seen even when only very small amounts have been ingested (e.g. *Amanita phalloides*). The initial presentation is often with diarrhoea. Patients subsequently develop signs of hepatic necrosis at 2–3 days after ingestion. The liver injury is caused by amatoxins. Forced diuresis may be helpful as large amounts of toxin are excreted in urine, but inadvertent dehydration may result in renal failure. Thioctic acid, silibinin (silybin) and penicillin have been advocated as therapy, but have not been subjected to controlled trials.

FULMINANT WILSON DISEASE

The characteristic features are those of cirrhosis, seen on imaging, with concomitant problems, such as thrombocytopenia, which may be long-standing, Kayser–Fleischer rings on examination and frequently non-immune-mediated haemolysis.

ACUTE BUDD–CHIARI SYNDROME (HEPATIC VENOUS OBSTRUCTION)

Hepatic venous obstruction (Budd–Chiari syndrome) may cause ALF. There are symptoms and signs of liver of necrosis, often with capsular pain from congestion and ascites. In Asia this may be associated with anatomical anomalies of the inferior vena cava, whereas in Europe and the United States the experience is normally of thrombosis of the hepatic veins, often with an underlying procoagulant condition (Fig. 44.1.3).

ISCHAEMIC HEPATITIS

Heat shock injury is now relatively rarely seen but ischaemic hepatitis remains relatively common. They are normally associated with a congested liver that is subjected to a secondary insult – hypoxia or decreased-flow arterial inflow. This is seen with hypoxaemic respiratory failure, cardiac arrhythmias and hypotension.

PREGNANCY-RELATED ACUTE LIVER FAILURE

Pregnancy-related liver failure includes HELLP (**h**aemolysis [microangiopathic haemolytic anaemia], **e**levated **l**iver enzymes and **l**ow **p**latelets), acute fatty liver of pregnancy and liver rupture, often in association with pre-eclampsia. The prognosis of pregnancy-related ALF is usually good, although some develop severe liver injury with small-vessel disease, liver ruptures may require packing and occasionally transplantation is required (Fig. 44.1.4).

MALIGNANCY

Malignancy may also present with ALF, albeit rarely. The clinical pattern normally is that of elevated biliary enzymes in addition to the transaminases. This pattern of disease may be seen in those with hepatic lymphoma, often with an elevated lactate

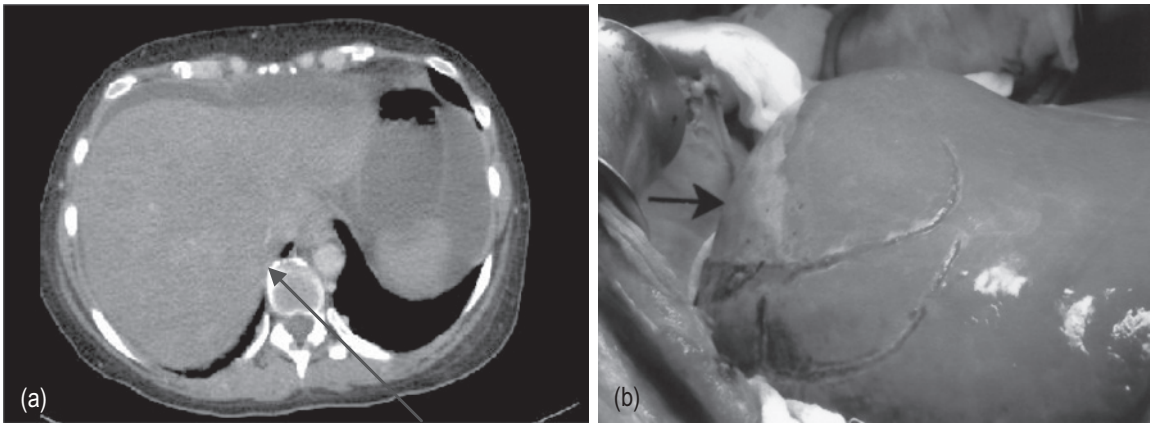

Figure 44.1.3 (a) Acute Budd–Chiari syndrome: The intrahepatic inferior vena cava (*arrow*) is grossly attenuated. (b) Budd–Chiari liver: The *arrow* shows liver necrosis; ischaemic/infarcted liver.

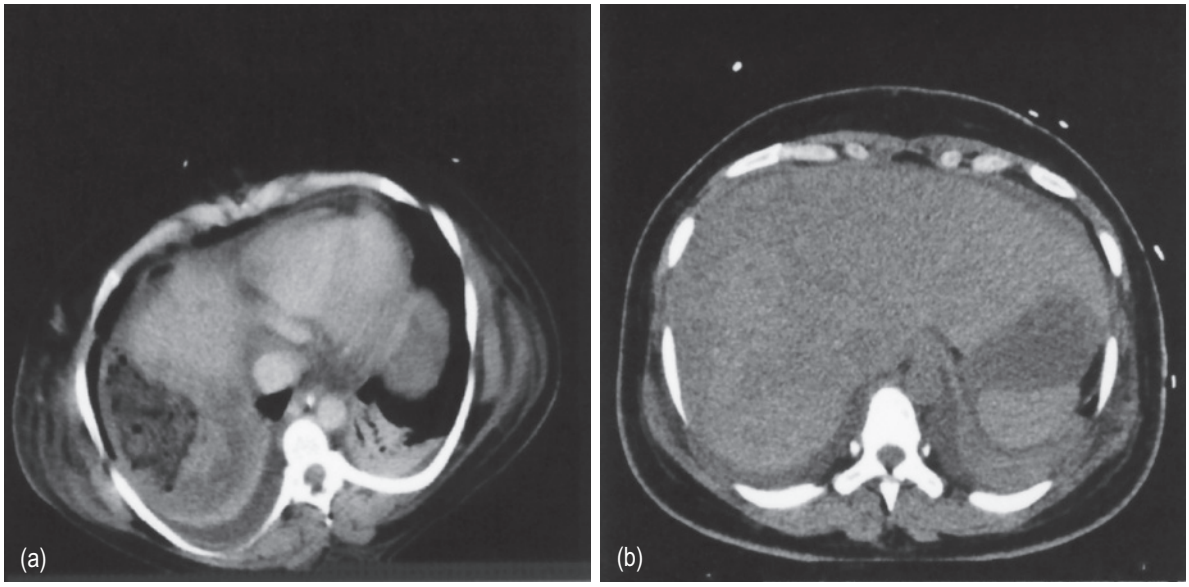

Figure 44.1.4 Liver computed tomography in pregnancy-related liver disease demonstrating abnormal perfusion (a and b) with rupture, packing (a) and associated areas of infarction. Major bleeding into the liver.

dehydrogenase or indeed with diffuse infiltration with other malignancies.

CLINICAL FEATURES

JAUNDICE

The above classification uses the time from jaundice to encephalopathy to describe ALF as either hyperacute, acute or subacute. In hyperacute liver failure (paracetamol toxicity, *Amanita* poisoning, acute viral hepatitis), encephalopathy may precede the onset of clinical jaundice.

ALF is frequently accompanied by a rapidly progressive syndrome of multiorgan failure requiring high levels of organ support.

HEPATIC ENCEPHALOPATHY

Hepatic encephalopathy is described by the modified Parsons–Smith scale (Table 44.1.5), which is based on functional impairment, changes in consciousness,

Table 44.1.5 Modified Parsons–Smith scale of hepatic encephalopathy

GRADE	CLINICAL FEATURES	NEUROLOGICAL SIGNS	GLASGOW COMA SCORE
0/subclinical	Normal	Seen only on neuropsychometric testing	15
1	Trivial lack of awareness, shortened attention span	Tremor, apraxia, incoordination	15
2	Lethargy, disorientation, personality change	Asterixis, ataxia, dysarthria	11–15
3	Confusion, somnolence to semi-stupor, responsive to stimuli	Asterixis, ataxia	8–11
4	Coma	±Decerebration	<8

cognitive function and behaviour. The presence of encephalopathy is essential for a diagnosis of ALF.

INTRACRANIAL HYPERTENSION

Hepatic encephalopathy is frequently complicated by cerebral oedema and intracranial hypertension with diminished cerebral perfusion and a risk of transtentorial herniation. The onset is rapid and allows little time for adaptive mechanisms (in contrast to patients with CLD where there is time for adaptation and control of cellular osmolarity). This has a significant implication in terms of the transfer of patients with ALF between hospitals. Intubation and ventilation with adequate sedation and implementation of neuroprotective strategies (see below) should be considered prior to transfer in any patient with progressive encephalopathy.

Patients with high-grade encephalopathy (coma) are at greatest risk of developing cerebral oedema. Elevated arterial ammonia levels, a higher MELD (model for end-stage liver disease) score, younger age, and requirement for vasopressor and renal replacement therapy (RRT) are independent risk factors for hepatic encephalopathy and arterial ammonia levels greater than 200 μmol/L are associated with cerebral herniation.[7,8]

Ammonia is produced by bacteria in the bowel and is taken up by cerebral astrocytes for deamination to glutamine. Water then moves into the intracellular compartment down its osmotic gradient. There are also induced changes in neurotransmitter synthesis and release, mitochondrial function and neuronal oxidative stress. The net result is astrocyte swelling and cerebral oedema.[9,10]

The association between the development of encephalopathy and markers of inflammation is well demonstrated, both in regard to systemic inflammatory response syndrome (SIRS) markers and inflammatory mediators such as tumour necrosis factor (TNF).[11,12] Curiously, a similar relationship between inflammation and encephalopathy is seen in patients with CLD.[13] What is not yet clear is whether treatments that modulate the inflammatory response will be of benefit. This and other avenues proposed from basic animal research may well result in several novel approaches to the treatment of cerebral oedema and possibly encephalopathy over the forthcoming years.

Blood–brain barrier injury, increased cerebral blood flow and hyperaemia accompanying astrocyte swelling can potentiate cerebral oedema independently of astrocyte glutamine concentration. Thus, cerebral oedema may be vasogenic with inflammatory disruption of the blood–brain barrier or cytotoxic with osmotic dysregulation.

Blood flow is intimately coupled to cerebral metabolic rate, arterial oxygen and carbon dioxide tensions and acid-base status. The 'toxic liver hypothesis' describes the situation whereby there is a massive release of pro-inflammatory cytokines in association with the profound systemic inflammatory response and accumulation of toxic metabolites that accompanies ALF. Altered cerebral blood flow and loss of autoregulation occurs in the face of this inflammatory milieu.

The Munro–Kellie hypothesis states that the intracranial cavity is essentially an incompressible box and that any increase in the volume of one of the intracranial components (blood, brain, cerebrospinal fluid) must be accompanied by a decrease in the volume of another. CT studies have demonstrated that effacement and ventricular attenuation are frequent radiological findings.

Diencephalic transtentorial herniation causes posterior cerebral artery insufficiency with temporal, thalamic, and occipital infarction; obstructive hydrocephalus; and brainstem ischaemia, compression and death.

The normal range for intracranial pressure (ICP) is between 7 and 15 mm Hg (0.93–2 kPa) in the supine adult. Many definitions of intracranial hypertension have been volunteered, but a pressure of greater than 20 mm Hg (2.66 kPa) for a period of 20 minutes should be considered worthy of treatment. The US Acute Liver Failure Study Group (USALFG) recommends osmotic therapy for patients with an ICP greater than 25 mm Hg (3.33 kPa).[14]

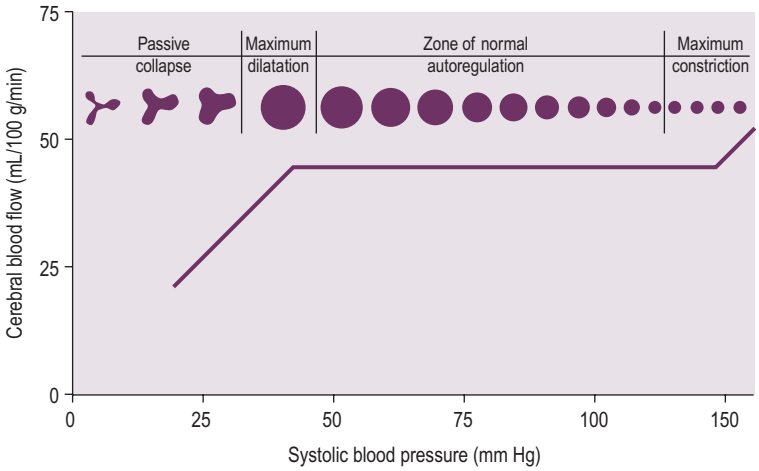

Figure 44.1.5 The relationship between systolic blood pressure and cerebral blood flow. Autoregulation may be lost, however, with flow pathologically dependent on pressure.

The clinical management of the cerebral complications of ALF has been developed pragmatically and by the extrapolation of data from the neurosurgical literature. The use of ICP monitoring is controversial. Advocates would point out that clonus, brisk reflexes and hypertonicity can be detected clinically, but pupillary changes, systemic hypertension and reflex bradycardia are not apparent until intracranial hypertension is established, and that radiographic changes are nonspecific. Sceptics would point out that there is no randomised controlled trial (RCT) evidence supporting an outcome benefit associated with ICP monitoring in ALF and that insertion confers a risk of intracranial haemorrhage. The USALFG found bleeding complications in up to 10% of patients, although many institutions use parenchymal monitors, which may be more accurate but confer a higher bleeding risk. At the authors' institution, standard practice is to use an epidural bolt, which may be slightly less accurate but confers a bleed rate of less than 1%. Bleeding associated with monitor insertion may be minimised by appropriate coagulation support at the time of placement. Some centres support coagulation at the time of insertion with plasma products and platelets, whereas others use recombinant factor VII. Non-invasive methods including transcranial Doppler ultrasonography, tympanometry and optic nerve ultrasound have been used but lack sensitivity and specificity.

Standard practice in the authors' institution is that patients whose conscious level deteriorates to grade 3/4 coma are electively intubated, sedated and ventilated with the head end elevated at 30 degrees. Stimulation is avoided. A combination of opiate (e.g. fentanyl) and propofol is commonly used. The decision to move to ICP monitoring is highly individual and is supported by a hyperacute presentation, younger age and higher arterial ammonia levels (>150 mmol/L). Decision making is frequently supported by reverse jugular venous oximetry and Doppler estimation of middle cerebral arterial flow.

A cerebral perfusion pressure of greater than 50 mm Hg (6.66 kPa) has been suggested as optimal. It is of note that patients with ALF often do not autoregulate to pressure and consequently increases in blood pressure may be associated with increased cerebral blood flow and potentially increased ICP, particularly if they are at a critical point on their pressure–volume curve. Sustained cerebral perfusion pressures less than 40 mm Hg (5.33 kPa) have been associated with very poor outcomes in some studies,[15] whereas others report good outcome despite periods of cerebral hypoperfusion (Fig. 44.1.5).

Invasive cardiovascular monitoring is mandatory (the authors advocate flow monitoring to guide fluid resuscitation). Norepinephrine (noradrenaline) and vasopressin are commonly used pressor agents. The use of terlipressin was associated with a rise in ICP in one study.[13]

In most patients, maintenance of P_{CO_2} 4.5–5.0 kPa is considered ideal. Cerebral blood flow is intimately coupled to arterial carbon dioxide tension and minute ventilation must therefore be carefully controlled. Lung injury/acute respiratory distress syndrome (ARDS) is relatively common and so protective ventilation strategies should be utilised.

Hyponatraemia and hyperammonaemia have been shown to be detrimental, whereas an RCT showed benefit to the patients whose serum Na was maintained between 145 and 155 mmol/L.[4] The use of hypertonic saline has been associated with a significant reduction in ICP, although the same study was not powered to detect a difference in outcome.

First-line treatment of a sustained rise in ICP remains mannitol 0.5 g/kg given as a bolus with an appropriate subsequent diuresis. It is essential that serum osmolarity is maintained at less than 320 mOsm

to avoid damage to the blood–brain barrier and worsening of vasogenic oedema. Hypertonic saline is increasingly used in this setting.

Hypothermia has been shown to reduce cerebral blood flow, ICP and cerebral ammonia uptake.[16,17] The role of hypothermia as an early preventive intervention in grade III/IV coma is contentious and the results of controlled studies are awaited. Fever should be avoided.

Other treatment options that have been shown to be potentially beneficial are thiopental and intravenous indomethacin (0.5 mg/kg).[18] Potential monitoring and treatment algorithms, as used by this unit, are detailed in Fig. 44.1.6.

SEPSIS

Sepsis is common in ALF and both culture-positive and negative SIRS are seen. Patients are functionally immunosuppressed in terms of impaired cell-mediated immunity, complement levels and phagocytosis.[17] Functional immunoparesis can only be observed and depression of human leucocyte antigen (HLA) DR expression correlates with the prognosis and severity of liver injury.[20,21] As such, scrupulous attention with regard to hand washing and line care needs to be applied to decrease the risk of nosocomial infection. Regular culture screens are required and antimicrobials are indicated in patients with any clinical suggestion of sepsis. Prophylactic intravenous antifungals should be considered, especially in those listed for transplantation. The choice of antimicrobial agent should be driven by local resistance patterns. Antimicrobial therapy should be reviewed in the light of culture results on a daily basis.

COAGULOPATHY

Coagulopathy is the hallmark of ALF, with prolongation predominantly of the prothrombin time and to lesser degrees the activated partial thromboplastin ratio (APTR). In a small percentage of patients the coagulopathy will respond, at least partially, to vitamin K. Intravenous vitamin K 10 mg is normally administered. Thrombocytopenia is common and frequently consumptive in nature. Bleeding is rare, although it may be seen in those with severe prolongation of APTR, low fibrinogen and severe thrombocytopenia. Coagulation or repletion of coagulation factors is necessary for clinical bleeding and prophylactically before major invasive procedures. Coagulation support is normally not given routinely so that the international normalised ratio (INR) can be monitored with regard to prognosis.

CARDIOVASCULAR CONSIDERATIONS

Patients with ALF develop a hyperdynamic circulation with peripheral vasodilation and central volume depletion. Hypotension is common and may initially respond to volume repletion. Assessment of volume responsiveness in the clinical setting may be difficult and pressure measurements are a poor indicator of volume status. Hypotension that does not respond to volume will normally require some form of invasive haemodynamic monitoring and frequently the institution of vasopressor agents. Increasingly it is recognised that volume responsiveness, as in general intensive care unit (ICU) patients, is best determined by dynamic rather than static variables.

The requirement for pressor agents should raise the possibility of adrenal dysfunction. Patients with ALF have been demonstrated to have impaired responses to adrenocorticotropic hormone (ACTH).[22,23] The response at 30 and 60 minutes in terms of cortisol should be examined following 250 µg ACTH in all patients with ALF who are requiring pressor agents. A subnormal response should result in consideration of hydrocortisone replacement therapy, normally given for a period of 10 days. Interestingly, adrenal dysfunction has similarly been reported in acute-on-chronic liver failure, and steroid replacement may result in improved outcome.[23,24]

Elevated troponin levels can be observed in patients with liver failure, especially those with cardiovascular failure.[25]

RESPIRATORY CONSIDERATIONS

Ventilatory support is frequently required in patients with ALF, usually because of a decreased conscious level rather than hypoxia, at least in the initial stages of disease.

Common respiratory complications are pleural effusions, atelectasis and intrapulmonary shunts. ARDS and acute lung injury may be seen and can be precipitated by extrapulmonary sepsis or inflammation.

Ventilatory strategies are influenced by both the respiratory and the multiorgan involvement that is characteristic of ALF. Thus patients with deep levels of coma and who are at risk of cerebral oedema will require close attention to CO_2 levels and tailored sedation regimens. Hypercapnia may have to be tolerated in patients progressing to ARDS. This requires balancing against the cerebral needs of these patients as hypercarbia and increased cerebral blood flow will tend to increase ICP. Pleural effusions may require drainage if they are impeding ventilation. Weaning may be facilitated by undertaking tracheostomy during the recovery period of ALF.

RENAL CONSIDERATIONS

Renal failure is common, with an incidence as high as 50%. Incidence is even higher up to 75% with paracetamol-induced liver failure, where the drug may also exert a directly toxic effect on the renal

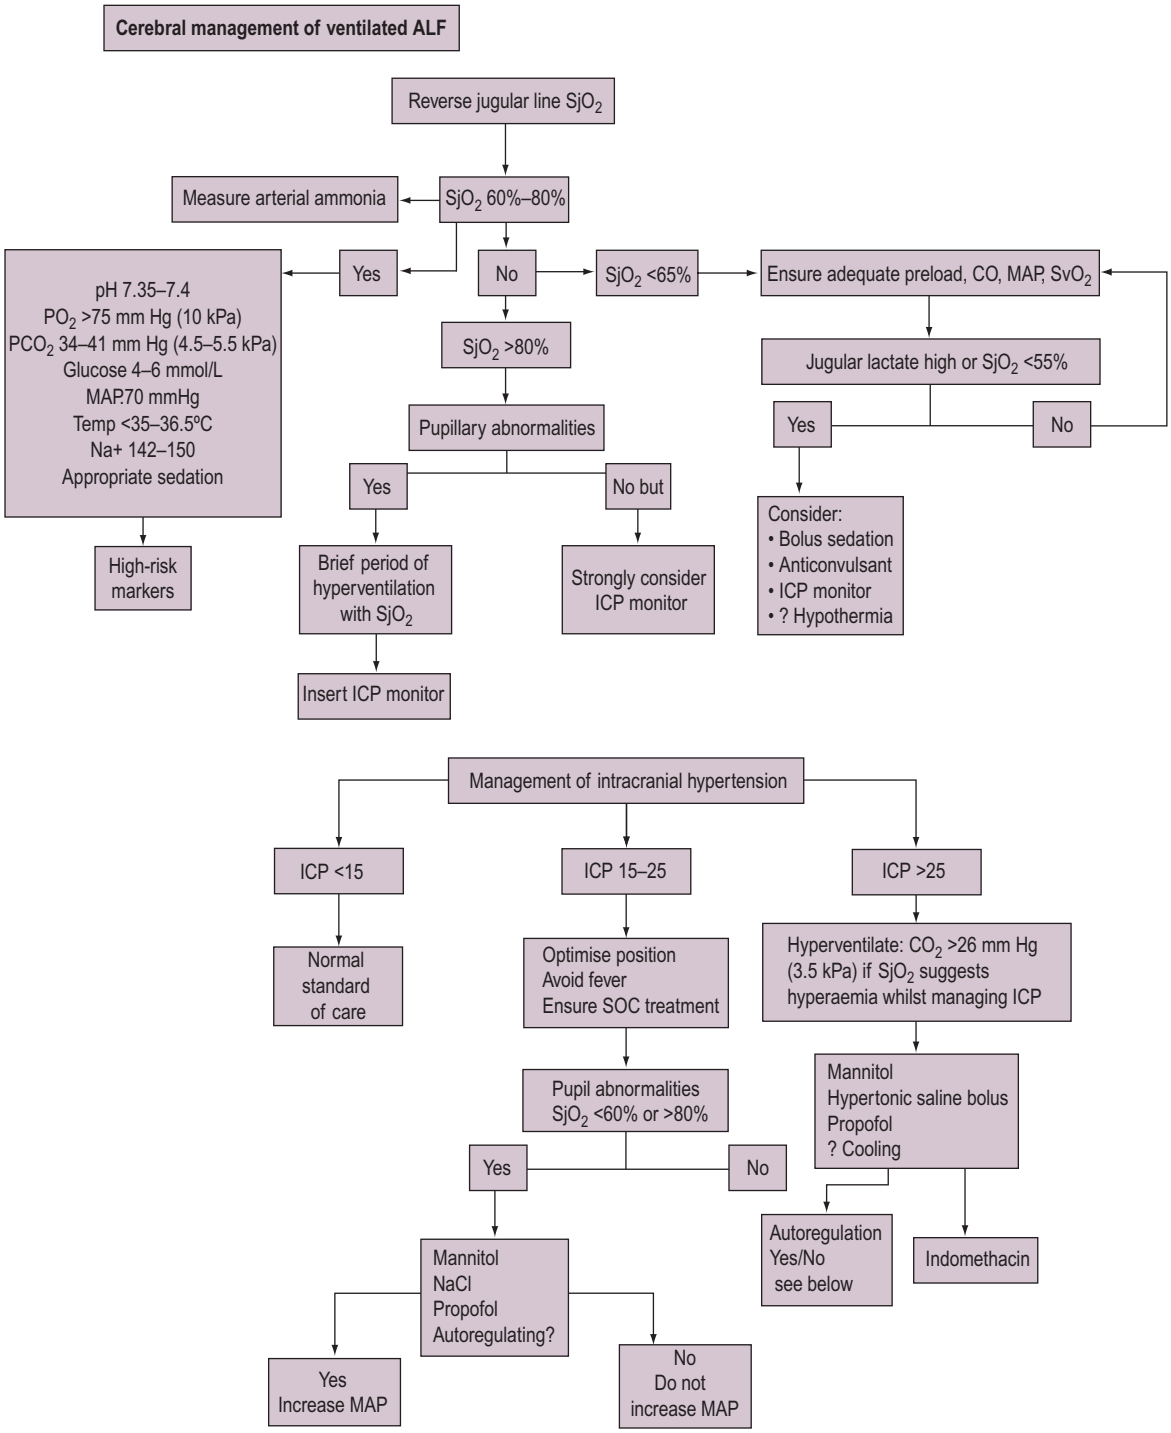

Figure 44.1.6 Treatment of raised intracranial pressure. *ALF*, Acute liver failure; *CO*, cardiac output; *ICP*, intracranial pressure; *MAP*, membrane-associated protein; *SjO_2*, jugular venous oxygen saturation; *SOC*, Standard of Care; *SvO_2*, venous oxygen saturation.

tubule.[26] The aetiology of acute renal dysfunction is frequently multifactorial, with hepatorenal failure being a rare occurrence. Acute tubular necrosis (ATN) and pre-renal renal failure are common. As such, volume therapy and maintenance of intrathoracic blood volume are essential in the management of such patients, as is the avoidance of nephrotoxins. Intra-abdominal hypertension is frequent and may reduce renal perfusion pressure and contribute to renal dysfunction; the measurement of intra-abdominal pressure may be a valuable component of monitoring.

Established renal failure requires the institution of RRT. In patients with ALF early consideration should be given to RRT to control fluid balance and acid-base disturbances and to avoid rapid changes in osmolarity. It may limit or control elevations of arterial ammonia and retard the development of cerebral complications. The haemodynamic instability and associated cerebral complications of this patient group have resulted in the application of continuous modes of RRT rather than intermittent haemodialysis. The inability of the liver to metabolise and utilise lactate or acetate buffer solutions results in the use of bicarbonate buffers.

A balance needs to be achieved between the risk of bleeding and platelet protection across an extracorporeal filter. A prostaglandin, such as epoprostenol, may be advantageous in terms of decreasing bleeding and prolonging filter life. Alternatively, circuits may be run without anticoagulation, with regional heparin or citrate or low-dose systemic heparin. In patients with thrombocytopenia, consideration should be given to the diagnosis of heparin-induced thrombocytopenia and, if confirmed, heparin should be withdrawn and circuits primed with an alternative agent (e.g. danaparoid).

METABOLISM AND FEEDING

Enteral nutrition should commence as soon as feasible after admission if there are no contraindications. In patients with large aspirates (>200 mL/4 h) a prokinetic agent should be commenced: erythromycin (250 mg intravenously 6-hourly) appears to be more effective than metoclopramide. Endoscopic placement of a post-pyloric feeding tube should be considered in refractory cases, although this may need to be delayed in patients with or at risk of cerebral oedema. In patients with profound coagulopathy, placement of a nasogastric tube may be associated with nasal/pharyngeal bleeding and oral tube placement may be preferred in ventilated patients. The optimal nature of the enteral feed used has not been investigated, but metabolic data on these patients show increased calorific requirements.[27,28] Patients with ALF demonstrate both peripheral and hepatological insulin resistance.[26] Tight glycaemic control would seem reasonable in this population. Hypokalaemia is common and may contribute to increased renal ammonia production.

Metabolic acidosis is a relatively frequent occurrence that may relate to lactic acidosis, hyperchloraemic acidosis or renal failure.

Hyperlactataemia may be secondary to volume depletion and hence will resolve with appropriate fluid loading or may reflect the inability of the liver to metabolise the lactate produced. A failure of blood lactate to normalise following volume loading is associated with a poor prognosis.[29,30] Metabolic acidosis may be a secondary effect of other drugs ingested as part of an episode of self-harm. Falls in serum phosphate levels are seen in ALF associated with liver regeneration and are associated with a good prognosis in paracetamol-induced ALF.[31] Pancreatitis is a common complication of ALF and should be actively sought.

SPECIFIC TREATMENTS

The management of ALF is largely supportive, providing an optimal environment for either regeneration or stability until a suitable liver becomes available. Once patients develop poor prognostic criteria the chances of effective liver regeneration and thus of spontaneous recovery are low; the prognosis is very poor without liver transplantation. The role of extracorporeal liver support systems remains a hope for the future, but at present no system has been shown to have a definitive survival benefit in a controlled trial.

- *N*-acetylcysteine is administered for paracetamol-induced ALF, as mentioned above. Its role in non–paracetamol-induced ALF remains undefined, although a US study[32] suggests that it may be of benefit in patients with ALF and grade 1–2 encephalopathy (presumably because transplantation is required to impact on the outcome when higher grades of encephalopathy are achieved).
- Chelating agents are not of benefit in patients with established ALF secondary to Wilson disease, but they play an important role in chronic presentations. The withdrawal of such treatments, or indeed non-compliance – especially in teenagers – may precipitate ALF.
- Antiviral therapy has a predominant role in preventing re-activation of hepatitis B in patients exposed to chemotherapy and steroids.
- Thrombolytic therapies may be of benefit in patients with early acute Budd–Chiari syndrome, although increasingly the treatment option would be to undertake a transhepatic portosystemic shunt (TIPS), decompressing the liver with a stent passed either through the hepatic vein (if the clot is soft enough) or via the inferior vena cava and through to the portal vein. Such procedures should be undertaken in units with the facilities to transplant as there is a risk of precipitating ALF. Chemotherapy may be offered

to those with lymphoma involving the liver and in these instances tissue is paramount, either of liver or from another diagnostic site.
- Steroid therapy is beneficial in acute autoimmune hepatitis but its role in autoimmune ALF has been less clear. A recent publication from the Paris group suggests that steroids for those with established ALF are potentially detrimental.[33]

PROGNOSIS

Prognostication is important in the management of ALF. Overall, survival rates in patients treated for ALF are greater than 60%.[34,35] It is essential not only to identify those patients who will not survive without liver transplant, but also to identify those who will succumb even if offered such a procedure.[36] Approximately 55% of patients will survive without needing a liver transplantation.[35]

Several risk stratification systems are presented in Box 44.1.2. The most commonly used are those of O'Grady and Clichy. The MELD has also been examined with regard to prognosis in ALF and may be particularly useful in non-paracetamol cases.[37] The Sequential Organ Failure Assessment (SOFA score) and the Acute Liver Failure Study Group (ALFSG) index are also used. It is essential that such systems are rigorously applied and in the context of paracetamol are only utilised at least 24 hours post-ingestion and following appropriate volume resuscitation.

44.2 CIRRHOSIS AND ACUTE-ON-CHRONIC LIVER DISEASE

CLD is said to be evident when liver dysfunction has been present for a period greater than 6 months. It presents far more commonly to the ICU than does ALF. Acute on chronic liver failure (ACLF) is a specific syndrome characterized by acute decompensation (AD), organ failure (OF) and high short-term mortality. AD refers to development of ascites, encephalopathy, gastrointestinal hemorrhage and/or intercurrent bacterial infections. OFs (liver, kidney, brain, coagulation, respiration, circulation) are defined by the CLIF-SOFA score (CLIF stands for chronic liver failure) (Box 44.2.1). High short-term mortality means a 28-day mortality rate ≥15%.[38] Acute decompensations in hepatic and extrahepatic organ function in the previously stable cirrhotic are frequently precipitated by infection and bleeding (often variceal), but may also reflect a trajectory of decline in liver function in a patient with end-stage disease. Acute decompensations are termed ACLF.

Box 44.1.2 Prognostic criteria for acute liver failure

O'Grady criteria
Paracetamol related
Acidosis (pH <7.3), *or*
Prothrombin time of >100 s (INR >6.5), creatinine > 300 mol/L and grade III/IV encephalopathy – all occurring within a 24-h timeframe
Non–paracetamol-related
Any three of the following in association with encephalopathy:
- Age <10 or >40 years
- Bilirubin >300 mol/L
- Time from jaundice to encephalopathy >7 days
- Aetiology: either non-A, non-B (seronegative hepatitis) *or* drug-induced
- Prothrombin time >50 s, *or*
- Prothrombin time >100 s/INR >6.5

French criteria (Clichy criteria)
The criteria are the presence of encephalopathy (coma or confusion), *and*
Age <20 years with factor V level <20%, *or*
Factor V levels <30% if >30 years of age 59

INR, International normalised ratio.

Box 44.2.1 CLIF Consortium Organ Failure score: simplified version of the CLIF-SOFA score

Organ/system	Variable	Score = 1	Score = 2	Score = 3
Liver	Bilirubin (mg/dl)	<6	6 to ≤12	>12
Kidney	Creatinine (mg/dl)	<2	2 to <3.5	≥3.5 or RRT
Brain	Encephalopathy grade (West Haven)	0	1–2	3–4
Coagulation	INR	<2	2 to <2.5	≥2.5
Circulation	MAP (mm Hg)	≥70	<70	Vasopressors
Respiratory	PaO_2/FiO_2	>300	≤300 and >200	≤200

CLIF, Chronic liver failure; *FiO_2*, fraction of inspired oxygen; *INR*, international normalised ratio; *MAP*, mean arterial pressure; *PaO_2*, partial pressure of arterial oxygen; *RRT*, renal replacement therapy; *SOFA*, sequential organ failure assessment.
Reproduced from Hernaez R, Solà E, Moreau R, Ginès P. Acute-on-chronic liver failure: an update. *Gut* 2017;66:541–553. doi:10.1136/gutjnl-2016-312670.

Box 44.2.2 Common aetiologies of chronic liver disease

- Chronic infection with hepatitis B and C viruses
- Alcohol
- Primary biliary cirrhosis
- Autoimmune chronic active hepatitis
- Primary sclerosing cholangitis
- Budd–Chiari syndrome
- Veno-occlusive disease
- Amyloidosis
- α_1-antitrypsin deficiency
- Wilson disease

AETIOLOGY OF CHRONIC LIVER DISEASE

There are myriad causes of CLD. Those most frequently encountered are listed in Box 44.2.2. It is beyond the scope of this chapter to discuss these in any depth, but we will focus on the management of decompensations, complications and extrahepatic organ failure.

The ICU physician is seldom involved in the management of stable CLD. Acute on chronic presentations are relatively common, however, and patients with previously unrecognised cirrhosis may decompensate following unrelated medical interventions. Wherever possible, planned interventions in patients with documented cirrhosis should be undertaken in specialist centres with appropriated peri-procedural supervision.

DECOMPENSATED CHRONIC LIVER DISEASE

ACLF commonly presents with one of the following:

- encephalopathy
- sepsis
- renal failure
- variceal bleeding
- cardiorespiratory failure.

The cause of decompensation should be sought in all cases when it is not clinically apparent. In addition to sepsis and bleeding, alcohol, dehydration, drug therapies (e.g. opiates and sedatives), hepatocellular carcinoma (HCC) and portal vein thrombosis should be considered. Ultrasound should be undertaken in all patients, examining the hepatic veins and portal veins for patency. In patients with ascites a diagnostic tap should always be undertaken for microbiological culture and cell count (a polymorphonuclear [PMN] count >250 mm^3 is indicative of bacterial peritonitis).

Signs of HCC should be sought on ultrasound, alpha-fetoprotein and axial imaging techniques. The therapies available for HCC have improved dramatically in recent years and prognosis can be good, especially with the option of cure with liver transplantation.

ENCEPHALOPATHY IN CHRONIC LIVER DISEASE

Hepatic encephalopathy is a brain dysfunction caused by liver insufficiency and/or portosystemic shunting; it manifests as a wide spectrum of neurological or psychiatric abnormalities ranging from subclinical alterations to coma.[39] Overt hepatic encephalopathy (OHE) will occur in 30%–40% of those with cirrhosis at some time during their clinical course and in the survivors in most cases repeatedly.[40] It may manifest as inattention, retardation in psychomotor speed and visuospatial ability progressing through personality changes and disturbance of the sleep–wake cycle to acute confusion with agitation, somnolence and coma. The International Society for Hepatic Encephalopathy and Nitrogen Metabolism (ISHEN) consensus uses the onset of disorientation or asterixis as the onset of OHE. Hepatic encephalopathy is frequently seen in patients with cirrhosis and a systemic inflammatory response (and so sepsis should be actively sought and treated). Encephalopathy in CLD has pathophysiological and clinical features that are different from those seen in ALF. Importantly, the cirrhotic cohort does not normally develop intracranial hypertension and, as such, the management centres on the prevention of encephalopathy, the treatment of worsening encephalopathy, the control of the airway and the prevention of aspiration in those who are deeply encephalopathic.

Ammonia levels are frequently (but not always) elevated in encephalopathy and thus therapy includes bowel cleansing with agents such as lactulose and non-absorbable antibiotics such as rifaximin. There is little evidence-based research to support any particular avenue of treatment. Increased blood ammonia alone does not add any diagnostic, staging, or prognostic value for HE in patients with CLD. A normal value calls for diagnostic reevaluation.[39]

A systematic review by Tsipotis et al. showed that extracorporeal liver support using albumin dialysis resulted in a net decrease in serum bilirubin level but not in serum ammonia or bile acids and although it achieved an improvement in hepatic encephalopathy relative to standard medical therapy, it did not result in increased survival.[41]

The role of inflammation seems to be of importance in the development of encephalopathy.[42,43] As many as 70% of patients with bacteraemia demonstrate a 'septic encephalopathy', which manifests as lethargy, confusion, agitation or even coma. The inflammatory response develops when inducers of inflammation are recognized by sensors that engage effectors of the response.[44] Microbial inducers trigger inflammation by using pathogen-associated molecular patterns (PAMPs) and virulence factors. PAMPs are unique molecular signatures that are recognized by pattern-recognition receptors (PRRs) which include toll-like receptors (TLRs). Virulence factors are detected

through the effects of their activity (functional feature recognition). Endogenous inducers called danger-associated molecular patterns (DAMPs) released by necrotic cells are recognized by host receptors inducing sterile inflammation.[45] The immune system then mounts a systemic response to fight the invading microbe. The final pathway is to induce responses to eliminate the invading microbe. This early systemic response can be excessive and lead to organ damage and multiorgan failure through a process called immunopathology.[45] There is some evidence that pro-inflammatory mediators mobilised during SIRS/sepsis modulate the action of ammonia on the brain. In 2004 Shawcross et al.[43] demonstrated that neuropsychological test scores deteriorate when hyperammonaemia is induced in cirrhotics with infection, during the inflammatory state, but not following its resolution. This synergism may be attributed to a number of possible mechanisms[46]:

- Systemic inflammation and ammonia induce neutrophil degranulation and release reactive oxygen species into peripheral circulation which may then cross the blood brain barrier.[47]
- Circulating endotoxin arising from the gut (bacterial translocation), superimposed sepsis and hyperammonemia upregulate the expression of microbial pattern recognition receptors such as Toll-like receptors (TLRs).[47]
- Dysregulation of cerebral blood flow, which occurs in cirrhosis, may be exaggerated in sepsis.

The prognosis in cirrhotic patients with sepsis is considerably worse following the onset of encephalopathy.

The role of feeding in the development of encephalopathy has always caused controversy. Recent guidance suggests that protein restriction is not appropriate and a study examining early versus slow introduction of protein into enteral nutrition showed no increase in encephalopathy and indeed appeared beneficial in respect of the nitrogen balance.[48,49]

SEPSIS IN CHRONIC LIVER DISEASE

A classical definition of sepsis is SIRS in response to a proven or suspected microbial event. This definition may not be universally applicable, however. The compensated and decompensated cirrhotic may demonstrate components of SIRS under resting conditions. For example, cirrhotics often have an elevated resting heart rate with a hyperdynamic circulation, hyperventilation due to the evolution of hepatic encephalopathy and reduced baseline PMN count owing to hypersplenism. Indeed, the response of the cirrhotic patient to infection may be characterised only by an exacerbation of circulatory changes already present at baseline, or may be distinctly uncharacteristic with, for example, blunting of the elevation in body temperature, which is usually seen in sepsis.

The mortality of cirrhotic patients who fulfil SIRS criteria is significantly higher than in those who do not,[50] and a majority of those with SIRS have intercurrent infection. It is often unclear whether SIRS acts as a predisposition to, or is a consequence of, infection in this cohort. In one retrospective analysis of non-transplanted patients with ACLF, bacteraemia was associated with increased illness severity, requirements for organ support, and mortality.[51] The same group found that severity of hepatic encephalopathy and SIRS score greater than 1 were predictive of bacteraemia.[52]

Bacterial infections are more common in cirrhosis than in the general population, and are higher still during episodes of decompensation. Cirrhotic individuals are significantly more likely to die while hospitalised (adjusted risk ratio [RR] 2.7), to have hospitalisations associated with sepsis (adjusted RR 2.6) and to die from sepsis (adjusted RR 2.0).[53]

The increased incidence of sepsis in those with underlying liver disease is multifactorial. Patients are frequently physically debilitated, deconditioned, malnourished and cachectic. Bactericidal and opsonic activity is reduced. Monocyte function is altered and there is depression of the phagocytic activity of the reticuloendothelial system owing to the presence of intra- and extrahepatic shunts through sinusoids without Kupffer cells, and reduced Kupffer cell numbers and function.[54] Serum complement levels are low. Ascites and peripheral oedema are often present, and iatrogenic factors may be contributory. There may be an associated genetic susceptibility to severe infection and sepsis.

The acquisition of a sepsis syndrome is frequently accompanied by encephalopathy, renal failure and worsening coagulopathy. The in-hospital mortality of septic cirrhotics is, accordingly, much higher and has been recently estimated at 70%,[55] and infection is responsible for 30%–50% of deaths in patients with cirrhosis.[56]

The main sites of infection in cirrhosis are ascites, urinary tract, lungs and blood. The commonest organisms are *Escherichia coli*, followed by *Staphylococcus aureus*, *Enterococcus faecalis, Streptococcus pneumoniae, Pseudomonas aeruginosa,* and *Staphylococcus epidermidis*. However, resistant Gram-positive organisms and extended spectrum beta lactamase (ESBL)-producing enterobacteria are becoming increasingly common (particularly in nosocomial infection). Cephalosporins therefore fail in a substantial proportion of infections acquired during hospitalisation.

The epidemiology of sepsis in cirrhosis is in a state of flux. Resistant organisms are increasing in prevalence both in nosocomial infection and in patients who require long-term antibacterial prophylaxis. Liver transplantation programmes have given chronic

cirrhotics a chance of salvation, and encourage physicians to treat episodes of sepsis more aggressively than ever before. Surveillance and early diagnosis of infection, coupled with adequate and appropriate antibiosis have led to improved outcomes in cirrhotic patients with spontaneous bacterial peritonitis (SBP) and other severe infections.

An enhanced inflammatory response can cause an exaggerated and damaging inflammatory response that may provoke single or multiple organ failures. Organ failure is an important determinant of outcome in patients with cirrhosis, with mortality increasing with the number of organ systems failing. Single-organ failure confers a mortality of 33%, double-organ failures a mortality of 73% and three-organ failure a mortality of 97%.[57,58]

Tissue hypoperfusion occurs secondary to systemic hypotension, microvascular dysfunction, shunting, microthrombi formation, vasoplegia, and reduced red blood cell deformity and tissue oedema. NO synthesis may be responsible for defective mitochondrial respiration. Direct tissue damage is caused by cellular infiltrates, particularly neutrophils releasing lysosomal enzymes and superoxide-derived free radicals.[59]

PATHOPHYSIOLOGY OF SEPSIS IN CIRRHOSIS

ENDOTOXIN SIGNALLING

The interaction between PAMPs (e.g. lipopolysaccharide on the outer membrane of Gram-negative bacteria) and PRRs leads to immune cell activation, initiation of pathogen clearance and secretion of proinflammatory cytokines culminating in T cell activation (Fig. 44.2.1).[60] Macrophages of the M1 phenotype release inflammatory mediators like TNF, IL-1B, IL-6 and IL-8 resulting in upregulation of adhesion molecules by endothelial cells, neutrophil recruitment and containment of the infection. The M2 phenotype is activated in the presence of IL-4 and IL-13. Disorganisation of the macrophage phenotypes in the presence of a programmed cell death protein receptor (PD-1R) intensifies the inflammatory response and suppresses macrophage function. This leads to an immunocompromised state.[60]

The Gram-negative flora of the intestine provides a reservoir of LPS. LPS is absorbed and transported in the portal vein where it is rapidly cleared by Kupffer cells. Under normal circumstances the liver does not show signs of excessive inflammation. In addition to its ability to clear LPS, the liver also responds to LPS

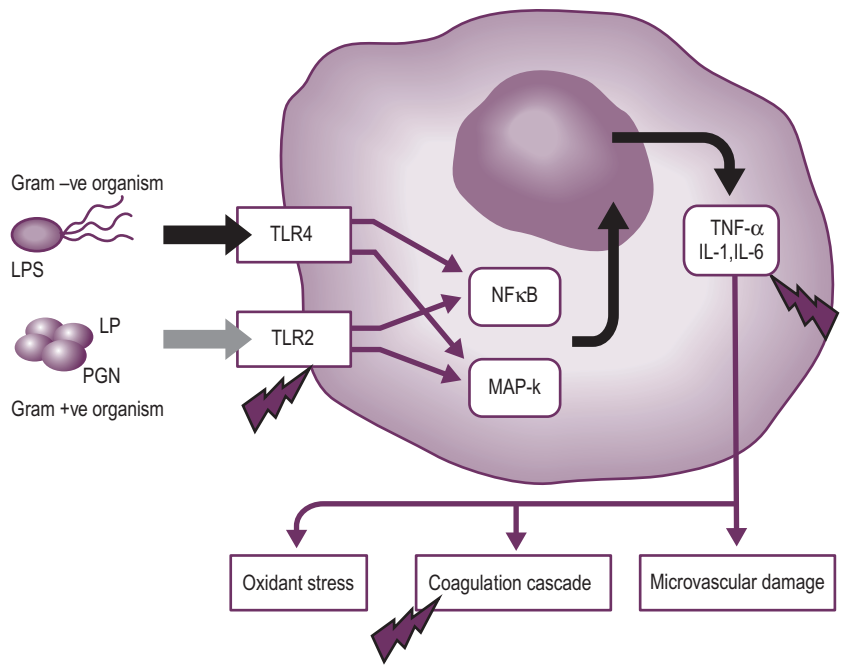

Figure 44.2.1 Endotoxin signalling pathway. The flashpoints represent changes in cirrhosis that make patients more susceptible to infection. *IL*, Interleukin; *LP*, lipopeptide; *LPS*, Lipopolysaccharide; *MAP*, membrane-associated protein; *NFκB*, nuclear factor-κB; *PGN*, peptidoglycan; *TLR*, Toll-like receptor; *TNF*, tumour necrosis factor. *Reproduced with permission from Wong F, Bernardi M, Balk R, et al. Sepsis in cirrhosis: report on the 7th meeting of the International Ascites Club.* Gut. *2005;54:718–725.*

with the production of cytokines and reactive oxygen intermediates, primarily by Kupffer cells.

In many types of CLD, levels of endotoxin[61] are elevated and tend to increase progressively as liver function deteriorates. Mortality is higher in patients with significant endotoxaemia than in those without.[62]

Cytokines, such as TNFα, IL-6 and IL-1 are essential components of the immune defence mechanism, but may propagate overwhelming septic shock. These may be over-produced and/or up-regulated in CLD, although the absolute levels of inflammatory cytokines are extremely variable in cirrhotic cohorts with septic complications. NO production is enhanced in cirrhosis, and is further increased in sepsis, with the induction of NO synthase by LPS exacerbating tissue hypoperfusion.

BACTERIAL TRANSLOCATION

Bacterial translocation is the migration of bacteria or bacterial products from the intestinal lumen to mesenteric lymph nodes or other extraintestinal organs and sites.[63] As mentioned above, elevated levels of endotoxin are a frequent finding in CLD, and levels tend to increase with disease severity (Child classification). Chromogenic assay in patients undergoing angiographic intervention demonstrates a gradient in terms of endotoxin level between portal and systemic circulations,[64] suggesting that the bowel is the source of the endotoxaemia. Moreover, only a single layer of intestinal epithelial cells form a barrier between the sterile host and trillions of live bacteria.[65]

Small bowel hypomotility, alterations in intestinal flora and disruption of mucosal barrier function promote bacterial translocation in the cirrhotic population. It is proposed that bacterial translocation is one of the main causes of spontaneous infection in this cohort and may perpetuate the persistent hyperdynamic state. Portal hypertension, ascites and increased severity of liver dysfunction are risk factors for bacterial translocation in this cohort. The epithelium demonstrates structural changes in cirrhosis, with widening of the intercellular spaces, and there is increased intestinal permeability.[66] Intestinal permeability is increased with portal hypertension (NO may be implicated in disruption of the intestinal epithelium).[67] Permeability is increased further if there is concomitant alcohol intake.

Organisms are usually removed from intestinal tissue by phagocytes. The intestinal immune system is centred on the gut-associated lymphoid tissue (GALT), which is comprised of Peyer's patches, lamina propria lymphocytes, intraepithelial lymphocytes and mesenteric lymph nodes. The innate immune response is centred on the stimulation of TLRs, a cytokine response and bacterial killing by monocytes and lamina propria lymphocytes. Under normal circumstances, any organism breaching the intestinal mucosal barrier is killed. Thus, in order for translocation to become clinically significant, there needs to be an overall failure of local and systemic immune defence.

The currently available therapies are directed towards reducing translocation by promoting gut motility, decreasing bacterial overgrowth or changing the composition of the gut flora. Selective digestive decontamination has been shown to be effective in preventing infection in patients with gastrointestinal haemorrhage,[68] and in prophylaxis in patients with ascites.

IMMUNE PARESIS

As stated above, there is up-regulation of TLRs, increased levels of circulating cytokines and activation of monocytes in cirrhotics. This does not, however, correspond to increased bacterial killing. Rather, the innate immune system is impaired with decreased phagocytosis and opsonisation.[63] This has been described as a 'sepsis-like immune paralysis'.[69]

GENETIC SUSCEPTIBILITY

It is recognised that a genetic variables may confer a predisposition towards the acquisition of infection in cirrhotic patients.

The management of sepsis in patients with liver failure should proceed along the same lines as in the cohort without liver failure. However, consideration should be given to some of the issues outlined below, which are peculiar to this population.

MANAGEMENT OF SEPSIS IN CIRRHOSIS

The principles of early goal-directed therapy in the treatment of sepsis are valid; that is, the early restoration of the circulating volume and maintenance of an adequate cardiac output, but the manner by which adequacy is assessed is complex. The circulation is frequently hyperdynamic in patients with acute or chronic liver failure – with or without infection. The oxygen extraction ratio is not uniform and shunting may occur. As a consequence, central venous oxygen saturations may be artificially high and not representative of an inadequately resuscitated patient. Early goal-directed therapy titrated to central venous oxygen saturation as outlined by Rivers et al.[70] may therefore not be applicable to this cohort. Furthermore, the use of the central venous pressure has been demonstrated to be unreliable[71] as a marker for preload-responsiveness. The authors would therefore advocate the early use of a cardiac output monitor, several of which are in widespread use. These provide markers of preload and preload responsiveness. Stroke volume response to fluid challenge or passive leg raising may be used in the mechanically ventilated or the spontaneously breathing patient.

Lactate levels have been used as markers of the adequacy of fluid resuscitation in sepsis.[72] In sepsis, lactate levels are elevated due to a higher metabolic rate and the inhibition of pyruvate dehydrogenase, and reflect

uptake by the liver. In liver disease, this uptake is markedly diminished and elevated lactate levels may not therefore imply anaerobic metabolism. Lactate levels are thus inadequate markers in this cohort, although elevated levels still unquestionably identify the sicker patients.

In terms of fluid resuscitation, albumin does not confer a mortality benefit over crystalloid in the critically unwell cohort. It does have a specific role in the treatment of patients undergoing large-volume paracentesis and has been demonstrated to preserve haemodynamics and attenuate a tendency towards hepatorenal syndrome (HRS).[73,74] A small, non-blinded, RCT suggested that 20% albumin was more effective in terms of improving systemic haemodynamics than a 6% hydroxyethyl starch (HES) solution in SBP.[75]

Vasopressor therapy is often required for the maintenance of adequate mean arterial pressure. Norepinephrine (noradrenaline) is the most frequently used pressor agent in the author's unit, with α-agonism attenuating a vasodilated, hyperdynamic systemic circulation and β-agonism augmenting ventricular function (which is frequently impaired in this cohort). Dopamine has no benefit over norepinephrine in the critically unwell and may be associated with a greater number of adverse events.[76] It is also not preferred in the liver failure cohort as it may cause dilatation of the superior mesenteric artery, leading to increased portal pressures. Vasopressin is used in refractory shock and to mitigate very high norepinephrine requirements.

In general terms, ventilatory management should proceed as per management in the general intensive care cohort, with attention paid to protective ventilatory strategies if ARDS is clinically apparent (limiting tidal volumes to ~6 mL/kg and plateau pressure to <30 cmH_2O). Endotracheal intubation is performed for airway protection in advanced (grade III/IV) encephalopathy and for the treatment of respiratory failure. It is worth noting that raised ICP is not normally a feature of CLD.

Both ALF and chronic cirrhosis are hypermetabolic states with marked catabolism and a net negative nitrogen balance. Assessment of the degree of malnutrition and muscle wasting in the chronic cirrhotic is often difficult owing to the presence of ascites and oedema. Dysphagia and gastroparesis are common in patients with cirrhosis and portal hypertension,[77] and the development of encephalopathy of any grade may be associated with a risk of aspiration. In both sepsis and liver failure the potential for both cholestasis and steatosis is significant. In the event of variceal bleeding, it is usual practice at the authors' institution to wait for 48 hours before placement of a nasogastric feeding tube owing to the risk of precipitating further bleeding. Immunonutrition has not been studied in critically unwell patients with liver failure.

The protein load associated with enteral feeding may predispose to hyperammonaemia, which is common in the (decompensated) cirrhotic. Lactulose, L-ornithine L-aspartate and non-absorbable antibiotics – such as neomycin, rifaximin, metronidazole, oral vancomycin and oral quinolones – have been administered in an effort to decrease the colonic concentration of ammoniagenic bacteria. Branched chain amino acid-enriched formulae may provide protein supplementation in the patient with troublesome hepatic encephalopathy.

Hyperglycaemia is common in sepsis and may be pro-coagulant, induce apoptosis and inhibit neutrophil function. Landmark clinical trials have suggested that the strict maintenance of glycaemic control is beneficial in critically unwell surgical patients.[78] The same group failed to demonstrate a mortality benefit in a medical cohort.[79] Meier et al.[80] compared the consequences of intensive glycaemic control (3.5–6.5 mmol/L) with loose glycaemic control (5.0–8.0 mmol/L). The incidences of hypoglycaemia and of bacteraemia were higher in the tight control group, with a trend towards worsened survival at 21 days. There are no RCTs examining the efficacy of tight glycaemic control in the cirrhotic population, and there is a high prevalence of hypoglycaemic events in this cohort.

The efficacy of high-volume continuous venovenous hemofiltration (CVVH) in severe sepsis and septic shock has generated a great deal of interest in the critical care community in recent years. It is proposed that the removal of mediators of the inflammatory cascade such as IL-2, IL-6, IL-8, IL-10, TNFα, C3a and C5a may attenuate the inflammatory response, improve haemodynamics and thereby end-organ perfusion and function. Animal studies were initially encouraging. A series of observational, interventional, randomised (but small scale and uncontrolled) studies showed beneficial cardiovascular effects and an improvement in predicted hospital and 28-day mortality.[81] However, a recent large randomised study demonstrated that intensive renal support in critically ill patients with acute kidney injury did not decrease mortality, improve recovery of kidney function, or reduce the rate of non-renal organ failure compared with less-intensive therapy.[82] There is consequently a lack of consensus on the optimal timing for the commencement of RRT, the appropriate dose or the type of membrane (pore size, surface area) for critically ill patients. Data for the septic/cirrhotic cohort are lacking.

SPONTANEOUS BACTERIAL PERITONITIS

SBP is infection of cirrhosis-related ascites. It may cause a florid sepsis syndrome with shock and renal failure, or have an onset that is insidious and detected only at paracentesis. The incidence and severity of infection in cirrhosis is greater than in the population without cirrhosis. Infection with multiresistant organisms is common, end organ damage is greater in cirrhotics with delays in diagnosis and treatment initiation

leading to higher mortality particularly in hypotensive patients with cirrhosis.[83] Pyrexia, changes in mental state and abdominal tenderness are common. Routine paracentesis demonstrates an incidence of SBP of up to 27% at the time of hospital admission.[84] Mortality rates for patients surviving their first hospital admission are 70% at 1 year, and 80% at 2 years. Prolonged bacteraemia, immune paresis and intrahepatic shunting probably play a role in the aetiology of SBP.

The bacterial concentration in ascitic fluid tends to be comparatively low and so 10–20 mL of ascitic fluid are introduced into blood culture bottles at the bedside to increase the diagnostic yield. Clinical factors associated with an increased risk of infection are poor liver function, variceal bleeding, low ascitic fluid protein levels, prior SBP and hospitalization.[83]

It is extremely important, in terms of management, to differentiate SBP from secondary peritonitis. The mortality rate of SBP approaches 100% if appropriate surgical intervention is omitted. However, the mortality rate is about 80% if a patient with SBP receives an unnecessary exploratory laparotomy.[85] Culture in SBP tends to reveal a single responsible pathogen.

There has been an emergence of enterobacteria strains harbouring ESBLs or beta lactamases, which are able to hydrolyse cephalosporins and broad-spectrum penicillins and other resistant bacteria, such as *P. aeruginosa*, methicillin-resistant *S. aureus* (MRSA), vancomycin-resistant enterococci (VRE) and *E. faecium*. Predispositions for the acquisition of multi-resistant organisms include hospitalisation, antibiotic exposure and norfloxacin prophylaxis. Authors have suggested that quinolones should be avoided in the treatment of SBP or any other infection in patients on long-term norfloxacin prophylaxis.[86] Pathological bacterial translocation may be considered an end result of intestinal barrier dysfunction, genetic predisposition to infection and immune dysfunction resulting in an excessive proinflammatory response and tissue damage ('immunopathology'), organ failure (kidney injury, cerebral oedema, disseminated intravascular coagulation, variceal bleed, adrenal insufficiency and shock).[83]

The choice of empirical antimicrobials is made based upon the type and severity of infection and on local antibiotic resistance patterns. A response to antimicrobials must be assessed by a second paracentesis 48 hours after commencement of treatment. A failure of reduction in neutrophil count by more than 25% may be considered treatment failure and antibiotics must then be changed.[83] Through as yet unclear mechanisms, the intravenous administration of 20% albumin has been shown to reduce the incidence of renal failure and decrease mortality rates from 29% to 10%.[87]

The use of prophylactic antibiotics must be restricted to patients at high risk of infections (upper GI bleed, previous SBP, advanced cirrhosis and low total protein content in ascitic fluid). Oral quinolones (norfloxacin or ciprofloxacin) are effective in the prevention of SBP recurrence. Rifaximin, a non-absorbable broad spectrum antimicrobial that reaches high faecal concentrations, causes minimal alterations to gut microflora and reduces expression of bacterial virulence factors, has been shown to have significant benefit in prophylaxis of SBP in patients with encephalopathy.[88]

RENAL FAILURE IN CHRONIC LIVER DISEASE

Acute kidney injury and hypervolaemic hyponatraemia are the major determinants of poor prognosis in advanced cirrhosis.[89] Renal failure occurs in 27% of septic cirrhotics in the absence of SBP and in 33% with SBP.[90] HRS is a prerenal failure that does not respond to fluid therapy. The diagnostic criteria are listed in Box 44.2.3.[91]

There is an association with renal/splanchnic insufficiency. Infections, bleeding and large-volume paracentesis without adequate volume replacement are common precipitating factors. Type 1 HRS progresses rapidly, and often occurs in the setting of haemodynamic compromise. Type 2 HRS is said to be characterised by a slowly progressive deterioration in renal indices and is frequently associated with ascites. HRS is associated with a diminished survival probability (Fig. 44.2.2). Liver transplantation is the final treatment of HRS types 1 and 2 and must be considered in all patients.

Ischaemic ATN is common in patients with acute or chronic liver failure who develop SIRS/sepsis. The administration of 20% albumin was associated with a reduction in the incidence of renal failure and of mortality.[92] Terlipressin may also have a role in the treatment of HRS.[93,94] More recent data suggest that norepinephrine may be equally applied.[95-98]

Ascitic drainage should be undertaken with appropriate albumin loading if large-volume drainage is undertaken, or in patients at risk of central volume depletion.[99]

Box 44.2.3 Diagnostic criteria for hepatorenal syndrome

- Cirrhosis with ascites
- Creatinine >1.5 mg/dL
- No improvement in serum creatinine (>1.5) after 2 days of diuretic withdrawal and volume expansion with albumin (1 g/kg/day up to 100 g/day)
- Absence of shock
- No nephrotoxins
- Absence of parenchymal kidney disease (proteinuria >500 mg/day, microhaematuria >50 red blood cells per high-power field) and/or abnormal renal ultrasound

VARICEAL BLEEDING IN CHRONIC LIVER DISEASE

The development of infection in cirrhosis is associated with a failure to control variceal bleeding and with early variceal rebleeding. The incidence of sepsis is also higher in patients with uncontrolled bleeding (Fig. 44.2.3).

Propranolol, which is used to lower portal pressures following variceal haemorrhage, was shown to lower the incidence of infection from 42% to 15% in a cohort of 73 cirrhotics.[100] It is not clear whether this effect is attributable to increased gut motility, and thus reduced bacterial translocation. Variceal band ligation is offered if there are contraindications to a non-cardioselective beta blocker. Proton pump inhibitors, isosorbide mononitrate monotherapy, sclerotherapy and TIPS are not recommended as primary prophylaxis.[101]

Infection may predispose to variceal bleeding because of an elevation in sinusoidal pressure – and hence portal pressure – and a worsening of coagulopathy. NO synthesis (the circulating form is *S*-Nitrosothiol) attenuates platelet aggregation, and heparinoid synthesis by endothelial cells increases.

It is recommended that patients with bleeding complications be treated with antibiotics.[102] The management of variceal haemorrhage remains that of basic resuscitation and care of the airway. Coagulation factors require appropriate supplementation along with other blood products. Cultures should be taken and all patients with variceal haemorrhage should be given antibiotics, which has been shown to decrease the risk of rebleeding.[103,104] Splanchnic vasoconstrictors, such as terlipressin, are beneficial in controlling oesophageal haemorrhage, but their role in gastric variceal haemorrhage per se has not been examined.[95,105] Octreotide is an alternative if terlipressin is unavailable.[101] Banding ligation therapy remains the treatment of choice for oesophageal haemorrhage, with tissue adhesives being utilised in gastric varices.

Failure to control variceal bleeding after two endoscopic sessions should result in consideration of TIPS insertion.[106,107] In patients in whom TIPS (Fig. 44.2.4) might be considered to be of benefit in controlling variceal bleeding, consideration needs to be given to the severity of the underlying liver disease that may in its own right make TIPS ill-advised.[108]

CARDIORESPIRATORY FAILURE

Cirrhotics display altered haemodynamics at baseline, with a hyperkinetic, vasodilated circulation. Patients tend to be tachycardic and hypotensive, with high cardiac output and low peripheral vascular resistance. Despite this, cirrhotic patients may have markedly abnormal tissue oxygenation, with arteriovenous O_2 content difference and O_2 uptake.[109] These changes become more profound with the onset of the septic state. Fluid resuscitation is complex, and probably best guided by the use of a cardiac output monitor. Patients may not respond to vasopressors as vigorously as the non-cirrhotic septic cohort. Left ventricular dilatation and dysfunction may be apparent on echocardiography.

Respiratory failure is common in the cirrhotic cohort. Intubation is often required for airway protection in encephalopathy. Ventilator-associated pneumonia is common. Alveolar macrophage activity may be diminished.

Tense ascites inhibits diaphragmatic descent and predisposes to basal atelectasis/collapse. There may

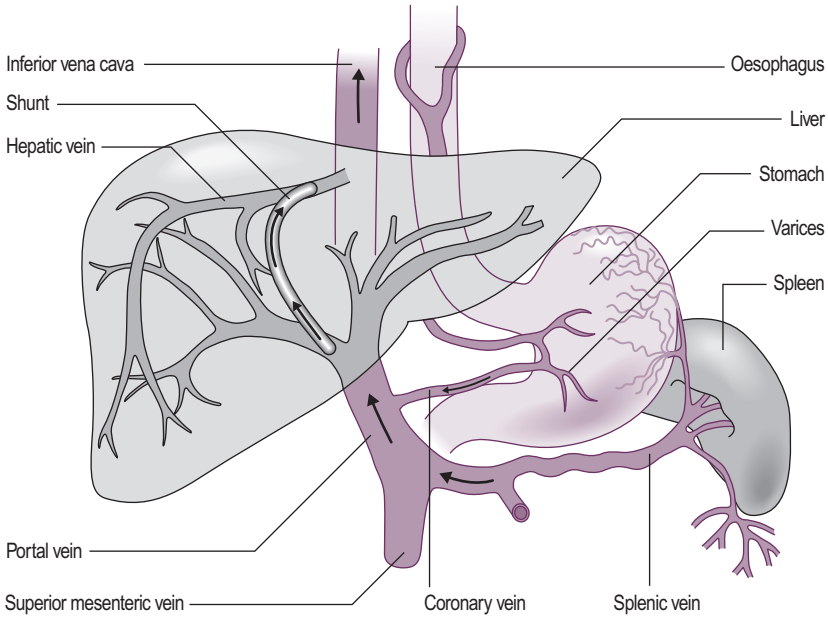

Figure 44.2.4 Transjugular intrahepatic portal systemic shunt.

be an accumulation of fluid owing to increased capillary membrane permeability, which may be exacerbated by attempts to resuscitate a relatively vasoplegic circulation.

There is a relatively high incidence of ARDS in cirrhosis. Mortality rates in ventilated cirrhotics are high.

DECOMPENSATIONS IN LIVER FUNCTION DURING THE SEPTIC EPISODE

Sepsis has the potential to worsen liver function, particularly in chronic cirrhotics. ACLF has been defined as 'a syndrome characterised by the acute deterioration of liver function in a patient with compensated or decompensated, but hitherto stable cirrhosis. It is commonly precipitated by an acute event/precipitating factor and associated with failure in the function of extra-hepatic organs' (European Association for the Study of Liver failure, EASL). The mechanisms underlying decrements in liver function are likely to be multifactorial.

As outlined above, levels of pro-inflammatory cytokines are increased in many forms of CLD. It is now believed that Kupffer cell induction by bacterial cell wall products may mediate hepatic inflammation. Hepatic stellate cells (HSCs), the main fibrogenic cells in the liver, are also mediators of inflammation, regulating leucocyte trafficking and activation.[110] Activation of HSCs by LPS has been proposed as a potential direct link between inflammation and hepatic fibrosis. Activation of the stellate cell to a myofibroblast-like phenotype allows the production of fibrillar collagens and other matrix proteins that characterise the fibrotic response.[111]

There is a large body of evidence to support the role of endotoxin and LPS derived from Gram-negative bacteria in the development of hepatic inflammation. Alcohol exposure (acute and chronic) increases gut permeability to LPS, resulting in increased LPS serum levels.[110] Injury to the liver may be attenuated by selective digestive decontamination and by colectomy, whereas the addition of LPS may augment liver injury caused by alcohol.[112]

What is, perhaps, unclear are the relative roles that Gram-negative and Gram-positive bacteria play in the pathogenesis of sepsis-related liver injury. There may be synergy between the TLR-2- and TLR-4-mediated pathways.[111]

COAGULOPATHY

The liver is responsible for the synthesis of the zymogens of both pro- and anticoagulant factors. Cirrhosis is associated with a relative deficiency of the procoagulant factors II, V, VII and X, and the anticoagulant factors protein C, protein S and antithrombin. Cirrhotic patients with severe sepsis have relatively lower levels of zymogen forms of clotting factors when compared with cirrhotic patients with infection (but not severe sepsis) and uninfected cirrhotics. Decreased zymogen levels are independently correlated with an elevated Child–Pugh score (Box 44.2.4) and are associated with significant increases in the relative RRs of in-hospital death.[113] Thrombocytopenia is secondary to hypersplenism and becomes more profound in sepsis.

Box 44.2.4 The Child–Pugh classification is a means of assessing the severity of liver cirrhosis

Score	Bilirubin (micromol/L)	Albumin (g/L)	Prolonged prothrombin time (s)	Encephalopathy	Ascites
1	<34	>35	<4	None	None
2	34–50	28–35	4–6	Mild	Mild
3	>50	<28	>6	Marked	Marked

If there is primary biliary cirrhosis or sclerosing cholangitis then bilirubin is classified as <68 = 1; 68–170 = 2; >170 = 3.
The individual scores are summed and then grouped as:

- <7 = A
- 7–9 = B
- >9 = C

The haemostatic profile of patients with liver disease is different to that of healthy individuals. Even though laboratory tests often show a natural bleeding tendency, this assumption is false; the patient with liver disease is in a state of 'rebalanced haemostasis' which can easily be tipped towards both bleeding and thrombosis. Thromboprophylaxis must also not be withheld in patients with cirrhosis or acute liver failure.[114]

ACUTE ALCOHOLIC HEPATITIS

Alcoholic hepatitis refers to a clinical syndrome of recent onset of jaundice and/or ascites in a patient with ongoing alcohol misuse. Alcohol steatohepatitis (ASH) is the predominant cause of this syndrome and is defined by the coexistence of steatosis, hepatocyte ballooning and a neutrophil inflammatory infiltrate. Alcoholic hepatitis is a frequent cause of decompensation and requires aggressive treatment. The severity can be assessed using the Glasgow score, MELD score or Maddrey score, and in high-risk patients steroid therapy may be considered.[115,116] Severe forms of ASH are defined as a Maddrey discriminant function ≥32. Response to steroids over the first 7 days is associated with improved outcome.[117] The role of antioxidants has been examined but no benefit was seen.[118,119] Another approach has been to look at the value of enteral feeding, which was comparable with steroid treatment over a 4-week period, albeit in a small study.[120] The use of pentoxifylline has been reported in a single-centre study to decrease the risk of developing hepatorenal failure and hence impacts the outcome.[121] Pentoxifylline has antioxidant and anti-TNF properties and patients with severe alcoholic hepatitis treated with the drug exhibited a higher 6-month survival. Other drugs that have been tried include anti-TNF agents (infliximab) and *N*-acetylcysteine. The latter may have synergistic effects with corticosteroids.

Abdominal surgical catastrophes

Stephen J Streat

Intra-abdominal surgical catastrophes are common in intensive care units (ICUs) and typically occur in older, co-morbid patients. They may be initiated by a traumatic, vascular or inflammatory event but often become complicated by sepsis (primarily or secondarily), multiple organ failure, multiple surgical procedures and a long intensive care stay.[1] Mortality remains comparatively high[2,3] both during and after the ICU period; hospitalisation is often very long and both reduced functional status[4,5] and life-expectancy may follow.

Treating clinicians must carefully and repeatedly assess the costs, including iatrogenic suffering,[6] and benefits[7] of treatment during an illness that can seem to have the character of a tragic saga[8] or the game of Snakes and Ladders (*"… implicit in the game is unchanging twoness of things, the duality of up against down, good against evil; the solid rationality of ladders balances the occult sinuosities of the serpent; in the opposition of staircase and cobra we can see, metaphorically, all conceivable oppositions."*).[9]

The clinical issues are themselves challenging and complex. Few randomised controlled trials are available to inform strategic, rather than tactical, decision making. Many patients have idiotypic features which make generalising from literature to the individual patient a risky endeavour. New treatments and treatment strategies continue to be introduced or to be subject to 'indication creep', often without robust evidence. All this is occurring in association with a 'shifting baseline' of slow continuous improvements in clinical outcomes in sepsis[10] and other critical illnesses, confounding inferences which some are tempted to draw between specific treatments and outcomes.

Herein lies considerable potential for conflict to arise between intensivists and other involved clinicians, particularly surgeons, whose relationship with the patient may reflect a different 'moral economy'[11] and who may have different views of what constitutes realistic goals and reasonable strategies[12] for patients who are often near the end of life.[13] Families may hold different views about 'what is reasonable to expect and to strive for' or about 'what the patient might want for themselves'. Most patients are not able to participate in strategic discussions while in the midst of such an illness, but any opportunities to ascertain the values, preferences and goals of the at-risk patients themselves should be recognised and taken (e.g. before anaesthesia for elective or emergency surgery).[13] Intensivists treating these patients must maintain expertise in: 'realistically seeing the big picture' while refraining from prematurely deciding that the situation is irrecoverable, maintaining appropriate patience, equipoise and commitment of the entire treating team, facilitating communication and cooperation and negotiating and maintaining consensus between all members of the treating team and the family, as well as in ensuring that the clinical care provided is holistic and meticulous in its detail.[6,13]

Vascular catastrophes, intra-abdominal sepsis and some serious abdominal complications are discussed in this chapter; trauma, gastrointestinal bleeding and pancreatitis are covered elsewhere (Chapters 76–81, 42 and 43, respectively).

VASCULAR CATASTROPHES

ABDOMINAL AORTIC ANEURYSM

Abdominal aortic aneurysm (AAA) is a disease of the elderly, and remains up to six times more common in men than women.[14] The prevalence of AAA, defined as infrarenal aortic diameter of 30 mm or more detected by ultrasound screening, was ~2% in Swedish 65-year-old men in 2009,[15] around half of what had been found in UK studies a decade earlier. Population-based screening of asymptomatic men (but not women) aged 65 years and older has been widely adopted and, with early elective repair, has reduced AAA rupture and associated mortality.[16,17]

Aortic diameter is the strongest predictor of the risk of rupture, which is below 1% per year with aortic diameter less than 5 cm and about 17% per year with aortic diameter of 6 cm or more. The risk of rupture is higher in women (who have faster aneurysm growth rates than men)[18] and is increased by current smoking and hypertension. Aortic aneurysm expansion is around 0.3 cm per year for aneurysms smaller than 5 cm and around 0.5 cm per year for those larger than 5 cm.

Elective endovascular aortic repair (EVAR) of unruptured aneurysms was rapidly adopted[19] because

ABSTRACT

Intra-abdominal surgical catastrophes are common in intensive care units (ICUs), typically occurring in older, co-morbid patients. They may be initiated by a traumatic, vascular, infective or inflammatory event but often become complicated by sepsis, multiple organ failure, multiple surgical procedures and prolonged intensive care stay. Mortality remains comparatively high; hospitalisation is prolonged and full recovery may not occur. Intensivists must see the big picture while refraining from prematurely deciding that the situation is irrecoverable, should maintain their own patience and stamina and support the entire treating team, facilitate communication and consensus with the family, and ensure that the clinical care provided is comprehensive and meticulous. This chapter discusses vascular catastrophes and intra-abdominal sepsis together with some serious abdominal complications including abdominal compartment syndrome, the open abdomen, enterocutaneous fistulas and colonic pseudo-obstruction which may later develop as a result and contribute to the syndrome of 'abdominal surgical catastrophe'.

KEY WORDS

enterocutaneous fistula

of lower perioperative mortality than open repair. Perioperative mortality has fallen for both treatments, but is probably now plateauing at ~1% for EVAR and 2%–3% for open repair.[14]

RUPTURE OF AN ABDOMINAL AORTIC ANEURYSM

Rupture of an AAA remains highly lethal – a French national epidemiological study in 2013 identified 1117 patients with ruptured aortic aneurysm from death records and hospital databases. Only 43% survived rupture, with 22% dying before hospital admission, and a further 35% in hospital.[20]

The clinical features of rupture of an abdominal aortic (or iliac artery) aneurysm include the sudden onset of shock and back pain or abdominal pain or tenderness in an elderly patient. The diagnosis may be missed initially,[21] as a pulsatile abdominal mass is commonly not detectable[22] and some patients may not have shock when first seen.

Immediate bedside ultrasound may sometimes confirm the clinical diagnosis but risks delaying vascular surgical referral and repair without diagnostic benefit.[23] It is sometimes appropriate to not proceed to repair[24] (severe co-morbidity or functional impairment) and this decision should be very carefully considered.[6,8,25]

Computed Tomography (CT) angiography is usually performed[24] unless the patient has frank shock and this is now increasingly followed by EVAR rather than open repair, although robust evidence of the overall superiority of EVAR is not yet available. Despite a large number of non-randomised studies showing increasing EVAR use and often lower mortality in EVAR-treated patients, the most recent Cochrane review[26] based on data from 868 patients in only four randomised controlled trials (RCTs) found no early mortality advantage (Odds Ratio [OR], 0.88; 95% Confidence Interval [CI], 0.66–1.16), but a suggestion of reduced bowel ischaemia with EVAR (OR, 0.37; 95% CI, 0.14–0.94).

A very small number (~0.6%) of patients with aortic aneurysm have infection of the aneurysm[27] and usually present acutely with pain and commonly with rupture. Infection of the aneurysm should be suspected in patients with impaired immunity and when there are signs of systemic inflammation at presentation. A wide variety of organisms can occur, most commonly with streptococci, staphylococcus aureus or salmonella.

A period of intensive care after aneurysm repair is appropriate for most patients. During this time, common physiological abnormalities (e.g. hypothermia, dilutional coagulopathy, minor bleeding, circulatory shock, renal tubular dysfunction) can be corrected and serious complications can be sought and if possible treated (e.g. major bleeding, abdominal compartment syndrome, renal failure, myocardial infarction, acute lung injury, peripheral ischaemia, stroke, pulmonary embolism, persistent ileus, mesenteric ischaemia, pancreatitis and acalculous cholecystitis).

Abdominal compartment syndrome (ACS) occurs in ~15% of patients with ruptured aortic aneurysm undergoing either open repair or EVAR.[28] It is more likely in patients with blood loss greater than 5 L. Around 10% of patients undergoing open repair have the abdomen left open postoperatively and a further 5% have a later decompressive laparotomy for ACS. Around 7% of patients having EVAR develop ACS and most undergo later decompressive laparotomy. ACS is associated with much higher 30-day mortality (42% vs. 24%) and greatly increases the risk of major complications including myocardial infarction, acute kidney injury, multiple organ failure, intestinal ischaemia and resection and prolonged ICU stay.[28]

Rapid ventilator weaning and extubation is recommended in patients without major complications, perhaps with thoracic epidural anaesthesia[29] if coagulation allows. In others, an assessment of overall progress should be made after 24–48 hours. Severe or progressive multiple organ failure[30] or major cerebral, visceral or limb infarction should lead to a reappraisal of the appropriateness of continued intensive therapies.

ACUTE AORTIC OCCLUSION

This is a rare syndrome presenting with painful lower limb paraparesis or paraplegia and absent distal circulation and is usually due to thrombotic occlusion of a stenotic or aneurysmal aorta and less often to saddle embolism. Minimising delay to revascularisation is of the essence, but hospital mortality (~30%) remains high.[31]

MESENTERIC ISCHAEMIA

Mesenteric ischaemia is an uncommon condition which presents with two distinct syndromes[32] – occlusive ischaemia and non-occlusive mesenteric ischaemia (NOMI).

Occlusive ischaemia may occur after atherosclerotic arterial thrombosis or arterial embolism and less often after venous occlusion. Patients present with abdominal severe pain, and often nausea, vomiting and diarrhoea, followed later by distension, rigidity and shock. Although outcomes have improved[33] with a multidisciplinary approach including endovascular revascularisation, surgery (often gut resection) and intensive care, mortality remains very high.[34]

In a single-centre French study,[35] NOMI was confirmed (by endoscopy or laparotomy) in ~0.8% of around 12,500 predominantly 'medical' ICU admissions and had a mortality of 76%. The syndrome develops usually a few days after ICU admission in the setting of severe circulatory failure (due to bleeding, sepsis or cardiac failure), and should be suspected when there are signs of severe gastrointestinal disturbance, tissue ischaemia, often in association with acute

kidney injury or ischaemic hepatitis. CT scan findings include gas in the portal veins, intestinal pneumatosis or dilatation, and absence of bowel contrast enhancement. Endoscopy can confirm ischaemia and at laparotomy segmental intestinal necrosis may allow for resection or may be so extensive as to preclude this option. Measures should be taken to improve intestinal blood flow (including reduction in splanchnic vasoconstrictors and perhaps abdominal decompression).[36]

AORTIC DISSECTION AND INTRAMURAL HAEMATOMA

Aortic dissection has a commonly reported incidence of 5–30 per million per year,[37] but the true incidence is probably several times that if cases outside specialist surgical centres and those who die before hospital are also included.[38] The typical patient is an elderly hypertensive[39] and presents with pain in a distribution corresponding to the site of dissection. Cases have been reported in young people and in circumstances suggesting acute situational hypertension. Pericardial tamponade, haemothorax, myocardial infarction, stroke, paraplegia due to spinal cord ischaemia, anuria or an acute abdomen may be present. Most aortic dissections originate in the ascending thoracic aorta. Some dissections extend to involve the abdominal aorta, but spontaneous dissection of the abdominal aorta alone is rare. Acute intramural aortic haematoma has similar clinical features to aortic dissection and accounts for ~10% of cases of what is now termed 'acute aortic syndrome'.[40] Diagnosis is best established by CT aortography. In all cases, pain, blood pressure and heart rate should all be controlled after which Type A dissections (involving the thoracic aorta, sometimes including the descending aorta) are probably best treated surgically whereas type B dissections (involving the descending aorta alone) may be more suitable for endovascular repair.[40,41] An abdominal catastrophe may subsequently develop due to mesenteric ischaemia, often associated with acute kidney injury. Mortality remains high (somewhat lower for intramural haematoma)[40] but is falling in association with earlier diagnosis and treatment.[37]

SPONTANEOUS RETROPERITONEAL HAEMORRHAGE

Spontaneous retroperitoneal haemorrhage (excluding aortic aneurysm rupture) is uncommon and usually associated with anticoagulant therapy, including warfarin, unfractionated heparin, low-molecular-weight heparin and antiplatelet agents,[42] or with vascular or malignant disease of the kidney or adrenal gland and less commonly with spontaneous rupture of the retroperitoneal veins. The presentation is most often with acute abdominal pain, shock and a palpable abdominal or groin mass, and CT will confirm the diagnosis.[43,44] Transfusion, correction of coagulopathy and interventional radiological embolisation[44] may control some situations, but surgery may be required in others, either to stop bleeding or to relieve intra-abdominal hypertension. Mortality remains high.

INTRA-ABDOMINAL SEPSIS

Intra-abdominal sepsis is very common in the ICU; indeed, in many countries the abdomen is the most common cause of sepsis in ICU admissions. The issue of sepsis is covered in Chapter 70.

The general principles of the treatment of severe sepsis[45] are to support oxygen transport with ventilator support, fluid therapy and inotropic support, to identify and if possible remove the septic source[45,46] and to give appropriate antimicrobial therapy.[45,47] A clear role for other therapies is not yet established.[45] Sepsis is a time-critical condition wherein delay in the execution of these principles is likely to worsen outcome.[45]

In the critically ill patient with intra-abdominal sepsis, effective source control usually involves surgery, although occasionally interventional procedures may suffice. Laparotomy is recommended (without delay or further investigation) for most patients presenting acutely with shock and clinical evidence of peritonitis.[48] Diagnostic peritoneal aspiration or lavage, ultrasonography, CT scanning or laparoscopy may have limited applicability in some circumstances.

Common syndromes[49] include:

- Faecal peritonitis
  - Primarily – usually due to diverticular disease or colonic malignancy
  - Secondarily – after prior anterior resection
- Perforated upper abdominal viscus (usually of a gastric or duodenal ulcer)
- Biliary obstruction (sometimes with perforation)
- Intestinal infarction without perforation (usually adhesive, less commonly ischaemic)
- Appendicitis (often perforated in older patients).

Less common syndromes include localised intra-abdominal abscess, acalculous cholecystitis, toxic megacolon, perforation of a fallopian tube abscess, spontaneous bacterial peritonitis (SBP) (in end-stage liver disease or nephrotic syndrome) and chronic ambulatory peritoneal dialysis (CAPD)-associated peritonitis (some of which is surgical).

SURGICAL SOURCE CONTROL

Surgical source control should remove the septic focus at the first ('damage control') operation, but definitive surgery may not be feasible or desirable at this time. The abdomen may be left open (with a temporary fascial closure) if required for intra-abdominal hypertension or to facilitate repeat laparotomy.

Initial surgery[46] involves:

- Removal of all peritoneal contamination (both macroscopically and by generous lavage)

- Drainage of abscesses
- Resection of devitalised tissue
- Defunctioning of the gut (diverting the enteric stream) to prevent ongoing contamination.

Failure of the sepsis syndrome to settle ('failure to thrive') after apparently definitive surgical source control should suggest (early) ongoing contamination or ischaemia or (after some days) the development of abscess. Repeat laparotomy on clinical grounds is recommended when early postoperative progress is unsatisfactory,[50] whereas CT scanning followed by directed laparotomy or interventional radiological drainage is recommended when late abscess is suspected.

INTESTINAL-SOURCE PERITONITIS

Peritonitis secondary to contamination by intestinal contents usually results in mixed aerobic (most often due to Gram-negative and some Gram-positive organisms – usually enterococci) and anaerobic infection, although yeasts are commonly cultured from abdominal fluid samples.[51] Recommended antibiotic regimens[52] are based on a paucity of randomised controlled trial evidence and usually involve either monotherapy with a carbapenem (or piperacillin–tazobactam) or combination therapy with a third- or fourth-generation cephalosporin and metronidazole. Similar antibiotic regimens are appropriate in sepsis following intestinal infarction without perforation.

BILIARY SEPSIS

Biliary ultrasound, followed by endoscopic sphincterotomy and stone removal without delay, is recommended for critically ill patients with cholangitis.[53] Antibiotic regimens should cover aerobic Gram-negative bacilli and enterococci.

ACALCULOUS CHOLECYSTITIS

Acalculous cholecystitis is a rare but serious condition in intensive care units. A small number of patients with the syndrome of acute cholecystitis will have acalculous cholecystitis, but these patients have low mortality and do not present to intensive care units. Of greater concern are the perhaps half of all cases of acalculous cholecystitis which develop insidiously in intensive care patients already critically ill for another reason (e.g. recent trauma or surgery) and can therefore go unrecognised until gangrene, perforation or abscess develop. The gallbladder histology in such patients usually includes prominent ischaemia and arteriosclerosis and low cardiac output may predispose to the condition. There should be a high index of suspicion in an intensive care patient who develops new abdominal pain or clinical signs of sepsis. Although scintigraphy, CT scanning, ultrasound and laparoscopy[54] have all been used to help establish the diagnosis, none perform reliably.[55] Percutaneous cholecystostomy[46,56] may be preferable to open cholecystectomy in critically ill patients.

TOXIC MEGACOLON

Toxic megacolon[57] is a rare indication for intensive care admission. It is characterised by systemic toxicity accompanying a dilated, inflamed colon and is usually due to inflammatory bowel disease, although other causes including infection by Clostridium difficile, cytomegalovirus (in patients with HIV disease or immunosuppression) or rarely other organisms may be becoming more common. The diagnosis should be considered in patients with diarrhoea and abdominal distension. Limited sigmoidoscopy (despite the risk of perforation) and biopsy may both yield important microbiological information and help in the decision to operate. Supportive therapy in the ICU is usually recommended and includes both antibiotics as for colonic perforation and, in inflammatory bowel disease, steroids (equivalent of ~400 mg/day of hydrocortisone). Other immunosuppression (with calcineurin inhibitors or anti-tumour necrosis factor monoclonal antibody) has support from randomised controlled trials in severe ulcerative colitis, but is not recommended in the setting of toxic megacolon where there is a high risk of perforation and sepsis.[57] Frequent surgical reassessment and abdominal X-rays are used to monitor progress. Intravenous nutrition may help to reduce the activity of Crohn's disease but does not reduce hospital stay or the need for surgery in ulcerative colitis. A period of several days of careful observation may be reasonable to assess the response to medical treatment but urgent surgery (subtotal colectomy with end-ileostomy) is indicated for increasing colonic dilatation, perforation, bleeding or progressive systemic toxicity. Parenteral metronidazole may be effective in severe pseudomembranous colitis without megacolon (but early surgery is often recommended if megacolon develops).

RUPTURE OF A TUBO-OVARIAN ABSCESS

Rupture of a tubo-ovarian abscess is a rare cause of peritonitis presenting to intensive care units and is best treated with surgical extirpation. Antibiotic therapy should include activity against anaerobic organisms.

SPONTANEOUS BACTERIAL PERITONITIS

SBP is usually a monomicrobial infection, but both aerobic Gram-negative bacilli and a variety of Gram-positive organisms (especially enterococci) are equally commonly isolated.[58] The development of SBP in patients with end-stage liver disease is often followed by hepatic decompensation and multiple organ failure.

Those who recover are at high risk of death without liver transplantation. Early albumin supplementation has been shown to reduce both renal failure and mortality in SBP associated with end-stage liver disease.[59]

Treatment with a broad-spectrum beta-lactam antibiotic is usual[60] but may not be appropriate in view of the incidence and lethality of infection with enterococci.[58] Recovery should be followed by secondary oral antibiotic prophylaxis.

CAPD-ASSOCIATED PERITONITIS

CAPD-associated peritonitis rarely necessitates intensive care admission and such patients should be assessed for an unrecognised gastrointestinal septic source,[61] abscess formation or the presence of unusual organisms including fungi.

TERTIARY PERITONITIS

Tertiary peritonitis ('peritonitis in the critically ill patient that persists or recurs at least 48 hours after the apparently adequate management of primary or secondary peritonitis')[62] occurs occasionally in ICU patients with prior laparotomy. It is commonly due to *Pseudomonas aeruginosa*, *Staphylococcus epidermidis*, *Enterococcus* spp., *Enterobacter* spp., resistant *Bacteroides* or *Candida* spp.[62,63] and antimicrobial treatment should reflect these organisms until guided by cultures. When infection is due to *Candida* spp., other antimicrobial agents should be discontinued and any foreign bodies removed if possible, and treatment with echinocandins is increasingly recommended.[64]

COMPLICATIONS

THE ABDOMINAL COMPARTMENT SYNDROME

Intra-abdominal hypertension can occur in critically ill patients, particularly after laparotomy for trauma or sepsis and in association with obesity[65] and excessive fluid administration. Intra-abdominal hypertension has been defined as intra-abdominal pressure (IAP) greater than 12 mm Hg (1.6 kPa) and abdominal compartment syndrome as IAP greater than 20 mm Hg (2.66 kPa) with associated organ dysfunction.[66] IAP can be measured via intravesical pressure,[66] is normally 5–7 mm Hg (0.66–0.93 kPa) in critically ill adults and is increased in patients with increased body mass index. Physiological impairment (including cardiorespiratory, renal, splanchnic and neurological) can occur with acute increases in IAP to levels above 12 mm Hg. However, in the absence of evidence from randomised controlled trials, expert opinion[67] continues to suggest that the development of the abdominal compartment syndrome (IAP >20 mm Hg with associated organ dysfunction) should prompt a search for decompressive measures. Traditionally this involved urgent decompressive laparotomy and temporary fascial closure; however, other measures with potentially less risk should also be sought including sedation and analgesia, neuromuscular blockade, avoidance of the prone position, gastric and colonic decompression, neostigmine or other prokinetic agents, diuresis or ultrafiltration, or percutaneous drainage of intraperitoneal fluid or gas.[67]

THE OPEN ABDOMEN AND ABDOMINAL REPAIR

In 2009 and with the objectives of describing the clinical course, standardising clinical guidelines and facilitating research design, a classification of the open abdomen was produced and more recently was amended[68] with these resultant grades:

- Grade 1, without adherence between bowel and abdominal wall or fixity of the abdominal wall (lateralisation), subdivided into: 1A, clean; 1B, contaminated; and 1C, with enteric leak. (An enteric leak controlled by closure, exteriorisation into a stoma, or a permanent enterocutaneous fistula is considered clean.)
- Grade 2, developing fixation, subdivided into: 2A, clean; 2B, contaminated; and 2C, with enteric leak.
- Grade 3, frozen abdomen, subdivided into: 3A clean and 3B contaminated.
- Grade 4, an established enteroatmospheric fistula, is defined as a permanent enteric leak into the open abdomen, associated with granulation tissue.

The use of a negative-pressure wound technique over porous materials is increasingly recommended[69,70] and has facilitated the care of the patient with an open abdomen including providing decompression and allowing repeat laparotomy, removal of ascitic fluid, prevention of evisceration and encouraging abdominal repair as soon as possible.[71] The management of grade 4 open abdomen remains problematic as proximal defunctioning is often impossible and control of wound contamination may be difficult to achieve, even with the use of a negative-pressure wound care system.

ENTEROCUTANEOUS FISTULAS – INTESTINAL, BILIARY AND PANCREATIC

These are rare complications in intensive care patients but they usually present formidable problems because of their common associations with serious gastrointestinal co-morbidity (e.g. inflammatory bowel disease, intestinal malignancy, pancreatitis) and concurrent severe sepsis. In addition, fistulation through an open abdomen, complex fistulation with multiple collections, inability to proximally defunction or distal intestinal obstruction are commonly present. A standard approach to fistula management should apply[72]

including attention to drainage of sepsis, control of the fistula by drainage or if necessary by proximal defunctioning, protection of the skin from the deleterious effects of the fistula fluid, nutritional support and replacement of fluid and electrolyte losses. Somatostatin analogues reduce enterocutaneous fistula output, shorten time to closure and increase the likelihood of spontaneous closure[72] but may increase the risk of biliary stasis, cholelithiasis, liver dysfunction, and both hypoglycaemia and hyperglycemia. Parenteral nutrition is usually recommended for high output or more proximal enterocutaneous fistulas but more distal intestinal, biliary or pancreatic fistulas can probably be safely treated (after patient stability and good skin protection) with a trial of enteral nutrition.[72] Persistent high-output fistula should lead to investigation of possible causes including complete disruption of the gut lumen, distal obstruction or persistent intra-abdominal sepsis. Definitive operative treatment for fistulas that do not close should await clinical recovery and if possible nutritional repletion.

COLONIC PSEUDO-OBSTRUCTION

Colonic pseudo-obstruction (Ogilvie's syndrome, a severe form of colonic ileus) is not uncommonly encountered in critically ill patients.[73] The syndrome may contribute to ventilatory difficulty, intra-abdominal hypertension and failure of enteral feeding and carries a small risk of spontaneous perforation with high resultant mortality. Conventional conservative treatment includes nasogastric drainage, intravenous fluid replacement and avoidance of opioids and anticholinergic agents. Treatment with neostigmine has been found to be highly effective[74] but may cause symptomatic bradycardia and even cardiac arrest.[75] Colonoscopy or surgery may be required if these measures fail.[73]

Implications of solid tumours for intensive care

Timothy Wigmore, Pascale Gruber

The term solid tumour refers to masses of tissue not containing cysts or liquid. There are over 200 types and they are classified according to the tissue of origin. The majority arise from epithelial tissues and are termed carcinomas. They are further differentiated into squamous cell (which include tumours of skin, oropharynx, oesophagus, cervix and lung) and adeno (which include those originating in lung, colon, breast, pancreas and stomach). Rarer tumours originate from connective tissue (sarcomas), the neuroectoderm (gliomas, glioblastomas, neuroblastomas, medulloblastomas) or germ cells (teratomas, seminomas and choriocarcinomas).

There were 12.7 million new cancer cases worldwide in 2008 and this number is expected to reach 26 million by 2030.[1] This increase is attributable to an ageing population and lifestyle changes, with diet, lack of physical activity and obesity all playing a role. The most common cancers worldwide are lung (12.7% of the total), breast (10.9%) and colorectal cancers (9.7%) whilst the commonest causes of cancer deaths are lung (18.2% of the total), stomach (9.7%) and liver cancer (9.2%).

This case load presents a substantial challenge to intensive care physicians. In the SOAP (Sepsis Occurrence in Acutely Ill Patients) study,[2] cancer patients accounted for 15% of all intensive care unit (ICU) admissions, 85% of which were solid tumours. The Intensive Care National Audit and Research Centre case-mix review of 128 adult general ICUs in the United Kingdom demonstrated that bowel and oesophageal tumours accounted for the fourth and eighth most common reason for ICU admission, respectively.[3]

Patients with solid cancers present to ICU either postoperatively, with complications of cancer treatment, as a result of the underlying cancer itself or with other co-morbidities unrelated to the cancer.

CANCER TREATMENTS

Cancer treatments fall broadly into the three main categories: chemotherapy, radiotherapy and surgery. Many patients have a combination of all three, and it is increasingly common for patients to receive neoadjuvant chemotherapy prior to surgery to facilitate surgical resection. Chemotherapeutic agents affect DNA synthesis, structure or repair and are usually unselective in that they affect all rapidly dividing cells. They may therefore also affect cells in the gut (with resulting mucositis and diarrhoea), bone marrow (leading to thrombocytopenia, anaemia and immunosuppression) and hair (causing alopecia). Additionally, many chemotherapeutic drugs have agent-specific side effects which may have implications for the ICU (Table 46.1). For example, anthracycline or trastuzumab-related cardiomyopathy, bleomycin-related lung injury or ifosfamide-induced encephalopathy.

Agents commonly used in combinations are represented by acronyms. Confusingly, the same agent may be represented by different letters depending on whether the generic or brand name has been used, and equally multiple agents may be represented by the same letter (Table 46.2).

SPECIFIC CHEMOTHERAPY-INDUCED TOXICITIES

BLEOMYCIN-RELATED LUNG INJURY

Bleomycin is an antibiotic derived from Streptomyces spp. which causes DNA scission through the generation of oxygen superoxide radicals. It is used for the treatment of head and neck squamous cell carcinomas, cancers of the cervix and germ cell tumours. It causes a pneumonitis in up to 40% of patients, with subsequent mortality in up to 2%.[4] Toxicity is caused by the generation of oxygen free radicals with subsequent alveolitis and fibrosis. This is exacerbated by high oxygen concentrations.

IFOSFAMIDE NEUROTOXICITY

Ifosfamide is an alkylating agent used in the treatment of head and neck, cervical, ovarian, breast and lung cancers. It causes encephalopathy in between 10% and 30% of patients, with a severity ranging from mild confusion to coma. The diagnosis is essentially

ABSTRACT

The number of patients affected by cancer continues to increase, as does the range of treatments on offer and survival. As a consequence, many more patients are now presenting to the critical care unit with treatment-related organ dysfunction, complications of their cancer or intercurrent illnesses. Treatment complexity has also increased, and a knowledge of common regimes and their associated toxicities is a necessity, as is a knowledge of the common cancer-related emergencies. In this chapter we consider both and also detail management, prognostication and emerging trends in outcome.

KEYWORDS

Cancer
solid tumour
chemotherapy
immunotherapy
radiotherapy
SVC obstruction
superior mediastinal syndrome
spinal cord compression

Table 46.1 Characteristic toxicities of commonly used chemotherapeutic agents

DRUG NAME OR GROUP	SOLID TUMOURS FOR WHICH TYPICALLY USED	MODE OF ACTION	CHARACTERISTIC TOXICITIES
Anthracyclines – doxorubicin, idarubicin	Breast, bladder, stomach, lung, ovary, thyroid	Intercalates DNA	Cardiotoxicity, 'hand-foot syndrome'
Alkylating agents – cyclophosphamide, ifosfamide	Many	Inhibits DNA replication	Immunosuppression, haemorrhagic cystitis, LV dysfunction, hyponatraemia
• Ifosfamide	Ovarian, breast, lung, testicular		Neurotoxicity
• Melphalan	Multiple myeloma, ovarian		Myelosuppression, interstitial pneumonitis
Bleomycin	Squamous cell, testicular	Induces DNA strand breaks	Pulmonary fibrosis
Cyproterone	Prostate	Inhibit tumour 'flare'	Hepatotoxicity
Fluouracil	Colorectal, pancreatic	Thymidylate synthase inhibitor	Cardiotoxicity, neurodegeneration
Ipilimumab	Metastatic melanoma	Anti-CTLA4 antibody	Diarrhoea, colitis, fatigue, transaminitis, hypophysitis
Methotrexate	Choriocarcinoma	Inhibits folic acid metabolism	Mucositis, pulmonary fibrosis, hepatitis, immunosuppression
Nivolumab	Metastatic melanoma, renal	Anti-PD-1 antibody	Colitis, dermatitis, pneumonitis, hepatitis, lymphopenia, nephritis
Platinum analogues, e.g. carboplatin, cisplatin, oxaliplatin	Lymphoma, sarcoma, ovarian, small cell lung	Selective inhibition of tumour DNA synthesis	Myelosuppression, nephro/oto/neurotoxicity, hypomagnesaemia with cisplatin
Procarbazine	Glioblastoma multiforme	Causes free radical formation	Myelosuppression, hypersensitivity rash
Monoclonal antibodies			
• Bevacizumab (Avastin)	Colon, non–small-cell lung	Inhibits VEGF, inhibiting cell growth	Mucocutaneous bleeding, GI perforation
• Cetuximab	Colorectal, squamous cell, head and neck	Binds to EGFR, inhibits cell division	Severe hypersensitivity reactions
• Trastuzumab (Herceptin)	Breast	Binds HER2 receptor, inhibits cell division	Cardiotoxicity, hypersensitivity
Tamoxifen	Breast	Oestrogen receptor antagonist	Thrombosis, endometrial Ca, strokes
Taxanes, e.g. docetaxel, paclitaxel	Breast, prostate, non–small-cell lung	Impair mitosis	Cardiac conduction defects, peripheral neuropathy, hypersensitivity
Topoisomerase inhibitors, e.g. irinotecan, topotecan	Colon	Inhibits DNA replication	Acute cholinergic syndrome
Vinca alkaloids – vincristine, vinblastine	Nephroblastoma	Inhibits assembly of microtubules arresting mitosis	Neuropathic ileus, peripheral neuropathy, hyponatraemia

EGFR, Epidermal growth factor receptor; *GI*, gastrointestinal; *HER2*, human epidermal growth factor 2; *LV*, left ventricular; *PD-1*, programmed death receptor-1; *VEGF*, vascular endothelial growth factor.

Table 46.2 Examples of commonly used chemotherapy regimes

AC	Breast cancer	Adriamycin, cyclophosphamide
BEP	Germ cell tumours	Bleomycin, etoposide, cisplatin
CAV	Lung cancer	Cyclophosphamide, adriamycin, vincristine
CEF	Breast cancer	Cyclophosphamide, epirubicin, fluorouracil
FOLFOX	Colorectal tumours	Fluorouracil, leucovorin (folinic acid), oxaliplatin
FOLFIRI	Colorectal tumours	Fluorouracil, leucovorin (folinic acid), irinotecan
PCV	Brain tumours	Procarbazine, CCNU (lomustine), vincristine
VIP	Germ cell tumours	Ifosfamide, cisplatin, etoposide

one of exclusion with normal brain imaging and an electroencephalography (EEG) demonstrating metabolic encephalopathy. The aetiology is thought to be related to direct toxicity from metabolites of ifosfamide, notably chloroacetaldehyde or dicarboxylic acid. The incidence is greater in those with pre-existing low albumin, raised creatinine or with cisplatin pretreatment.[5] The natural history of the encephalopathy is to regress over a period of days to weeks after cessation of ifosfamide. Methylene blue (50 mg 4-hourly intravenously) has been shown to ameliorate or even terminate symptoms.[6]

ANTHRACYCLINE CARDIOMYOPATHY

Anthracylines, such as daunorubicin, doxorubicin and epirubicin, are widely used anti-cancer agents. Anthracyclines can cause both acute and chronic cardiac dysfunction. Acutely, 5% of patients suffer from arrhythmias or acute cardiac failure that resolves with standard treatment. Chronically, anthracyclines cause a dose-dependent cardiomyopathy which becomes apparent anywhere between 3 months and several years after treatment and can result in severe myocardial dysfunction. Initial treatment is with ACE inhibition, but the full range of medical therapies for heart failure may be required, including cardiac resynchronization.[7]

TRASTUZUMAB (HERCEPTIN) CARDIOTOXICITY

Trastuzumab may cause a non–dose-related, reversible myocardial dysfunction. This appears to involve an element of myocardial stunning rather than myocyte destruction. It is often asymptomatic but can cause symptoms of cardiac failure in approximately 12% of patients after 5 years of treatment.[8] Trastuzumab is commonly combined with anthracyclines, which increases the incidence of heart failure at 5 years to 20%. Its occurrence does not preclude future dosing providing cardiac function has recovered prior to further use.[9]

IMMUNOTHERAPY

Immunotherapy is being increasingly utilised in the treatment of solid tumours, with impressive results being obtained in tumours such as metastatic melanoma that would have previously carried an almost universal poor prognosis. Check point inhibitors that augment the ability of the immune system to target tumour cells through the targeting of receptors (check points) such as cytotoxic T-lymphocyte antigen 4 (CTLA-4) and programmed death receptor-1 (PD-1) that inhibit the proliferation and function of T cells is one such group of drugs. Examples include ipilimumab (a CTLA-4 inhibitor) and nivolumab (a PD-1 inhibitor). Side effects are related to immune dysfunction, with colitis, dermatitis, hepatitis, pneumonitis, uveitis and encephalopathy all being commonly encountered, with an incidence of over 60% in patients receiving ipilimumab. Some 10%–15% of these patients will have grade 3–4 toxicity (life threatening) which may require admission to the ICU. Patients may also manifest with endocrine dysfunction, with thyroiditis, diabetes and hypophysitis observed.

Management is supportive plus treatment with immunosuppressants (steroids, infliximab which is a TNF-alpha inhibitor, tacrolimus and mycophenolate). The majority of patients recover spontaneously, but approximately 25% of patients will have long-term sequelae.[10]

RADIOTHERAPY

Radiotherapy causes damage to cells through the production of oxygen free radicals by the ionisation of water molecules. These in turn cause damage to cellular DNA. Damage to healthy surrounding tissue is minimised by targeting the radiation beam through multiple planes that intersect within the tumour. Despite this, radiation commonly causes acute inflammation and subsequent fibrosis in the tissues through which it passes. Common examples are pericarditis, pericardial, myocardial and lung fibrosis. This can cause organ dysfunction, particularly when combined with a chemotherapeutic agent known to have toxicities associated with that same organ.

DISEASE-RELATED ADMISSIONS

A number of oncological emergencies can occur that require admission to the ICU.

TUMOUR LYSIS SYNDROME

Tumour lysis occasionally follows treatment for bulky solid tumours, particularly small cell lung tumours, neuroblastomas and breast carcinomas.[11,12] The syndrome results from the rapid death of large numbers of tumour cells. This may occur spontaneously but usually follows chemotherapy, radiotherapy and occasionally surgery, with a consequent release of high concentration of intracellular contents. This results in a constellation of metabolic abnormalities, specifically hyperuricaemia (and subsequent nephropathy due to deposition of uric acid crystals in the distal tubules), hyperkalaemia, hyperphosphataemia and hypocalcaemia (due to the precipitation of calcium phosphate). The priority with tumour lysis syndrome is prevention, and patients with high- or intermediate-risk tumours should receive intravenous hydration and rasburicase (recombinant urate oxidase) as prophylaxis.[13] Rasburicase has generally replaced allopurinol as the agent of choice. Rasburicase catalyses the formation of water-soluble allantoin from uric acid, resulting in a rapid reduction in uric acid levels. In contrast, allopurinol prevents uric acid formation through the inhibition of xanthine oxidase which results in a slower decrease in uric acid concentration and increases the concentrations of xanthine which can result in xanthinuria, in itself a cause of renal failure.[14] Urinary alkinisation reduces the risk of uric acid precipitation by rendering it more water-soluble but simultaneously increases the risk of calcium phosphate precipitation in the kidneys and other organs. Hyperkalaemia and hyperphosphataemia sometimes require renal replacement therapy.

SPINAL CORD COMPRESSION

Breast, prostate, lung and kidney cancers have a predilection for bony metastasis. High spinal cord compression may require semi-urgent invasive mechanical ventilation. Treatment usually takes the form of steroids followed either by surgery or by radiotherapy.

CARDIAC TAMPONADE

Pericardial effusions due to epicardial metastasis or mediastinal lymph drainage obstruction are relatively common with advanced lung and breast cancers.[15] Cardiac tamponade is less frequent and may develop with pericardial effusions as small as 200 mL if accumulated rapidly. On echocardiography, cardiac tamponade classically demonstrates right atrial or ventricular diastolic collapse, increase in right ventricular size or failure of inferior vena cava collapse on inspiration. The management of cardiac tamponade in the acute setting is pericardiocentesis with subsequent pericardial window formation. For some tumours, treatment of the underlying cancer with chemotherapy and/or radiotherapy will result in longer-term resolution.

ELECTROLYTE DISORDERS

Rapid and life-threatening changes in electrolyte concentrations may result from paraneoplastic disorders, losses from treatment-induced diarrhoea or renal dysfunction. Paraneoplastic disorders result from the secretion of hormones or hormone-like substances from tumours. Syndrome of inappropriate antidiuretic hormone secretion (SIADH) typically occurs in the setting of small cell lung carcinomas which account for 80% of the total incidences of SIADH. SIADH also occurs with pancreatic, colonic, prostate, duodenal and head and neck tumours. It can be seen with cisplatin, ifosfamide, vincristine, vinblastine and cyclophosphamide use. Hyponatraemia is particularly marked when secondary to cyclophosphamide due to concurrent fluid loading to reduce the risk of haemorrhagic cystitis.[16] Chronic mild hyponatraemia (Na+> 125 mmol/L) rarely requires intervention while severe hyponatraemia (Na+<125 mmol/L) should be cautiously corrected to avoid osmotic demyelination.

Hypercalcaemia represents the most common metabolic consequence of solid tumours and occurs in 10%–20% of patients.[17] The release of parathyroid hormone-related peptides from lung, head and neck, kidney and pancreatic cancers, together with osteolytic calcium release from tumours with bony metastases (e.g. breast and prostate) can result in life-threatening hypercalcaemia. Treatment of hypercalcaemia is with a combination of saline rehydration, calcitonin, and bisphosphonates (e.g. pamidronate). Saline corrects hypercalcaemic-induced dehydration, calcitonin reduces resorption from bone by blocking osteoclast maturation and increasing renal calcium excretion, and bisphosphonates cause osteoclasts to apoptose.[18] The response to furosemide is variable and often requires the use of high doses resulting in electrolyte abnormalities, and is therefore not recommended.[19] The effect of bisphosphonates may be poor in those with parathyroid hormone related protein (PTHrP) induced hypercalcaemia, although zoledronic acid may be useful.[20,21]

Hypokalaemia requiring admission to the ICU is often the result of diarrhoea due to chemotherapy or radiotherapy. Hypokalaemia may also be caused by adrenocorticotropic hormone (ACTH)-producing lung tumours or from tumours that produce insulin.

Electrolyte disorders may be of sufficient severity to be life threatening requiring immediate correction with intravenous replacement. They are also often accompanied by a normal anion gap hyperchloraemic metabolic acidosis caused by concomitant bicarbonate loss. This can result in marked acidaemia with consequent respiratory compensation that can lead to exhaustion in an already debilitated patient. It is best managed

with bicarbonate replacement, although care needs to be taken to avoid worsening hypokalaemia.

SUPERIOR MEDIASTINAL SYNDROME

Patients with anterior mediastinal compression typically present to the ICU either postoperatively or as an emergency with airway obstruction, cardiac compression or superior vena cava (SVC) obstruction. The aetiology in adults is most commonly a thymoma, although lymphomas, germ cell tumours and sarcomas can also be responsible.[22] Airway obstruction may occur due to compression of the trachea or bronchi. In an emergency there is often little time for formal assessment. Imaging may be available in the form of computed tomography (CT) or magnetic resonance imaging (MRI) demonstrating the level and degree of compression. A decrease in cross-sectional area of 50% is predictive of airway complications.[23,24] If supine imaging is unavailable, and symptoms permit, a CT scan can be conducted with the patient at 20–30 degrees of head up, or in lateral or prone position to minimise airway compromise. Flow volume loops can demonstrate intrathoracic or extrathoracic airway obstruction, although correlation with subsequent airway obstruction is variable.

Induction of anaesthesia may result in catastrophic airway obstruction due to a reduction in intrathoracic volume, increased size of (often very vascular) tumours with increased central blood volume, and increased compressibility of airways with reduction in smooth muscle tone. Equally, cardiovascular collapse may occur due to compression of the pulmonary arteries or SVC. Should it be necessary to intubate the patient with superior mediastinal syndrome, there are a number of key points that need to be considered.[25,26]

1. Establish venous access in the lower half of the body in case of superior vena caval obstruction which would result in significantly slowed transit of administered drugs and fluids.
2. Have intravenous fluid administration established to minimise the cardiovascular effects of vascular obstruction during induction.
3. In high-risk cases, establishment of femoral venovenous bypass under local anaesthesia prior to induction offers a route out in the event of complete airway obstruction. Having bypass on 'standby' is unlikely to be adequate due to the time required to establish it in the event of emergency.
4. Gaseous induction with preservation of spontaneous respiration or, if circumstances permit, an awake fibreoptic intubation to assess the degree of airway obstruction is advisable.
5. Neuromuscular blockade is best avoided. Subsequent positive-pressure ventilation (in concert with smooth muscle relaxation) may cause worsened bronchiolar obstruction leading to atelectasis and ventilation/perfusion mismatch. It will also increase the pressure of the mass on mediastinal structures such as the SVC, heart and pulmonary arteries with consequent potential cardiovascular collapse. If blockade is absolutely necessary, a trial of short-acting paralysis (e.g. with suxamethonium) should be undertaken first.
6. Should airway obstruction or cardiovascular collapse occur following intubation, repositioning the patient either sitting up, laterally or prone may be effective by reducing the mass effect. If this is ineffective and venovenous bypass is not possible, then emergency thoracotomy with manual displacement of the mass can be considered.

SUPERIOR VENA CAVA COMPRESSION

SVC compression may be part of superior mediastinal syndrome but often occurs in isolation. When caused by tumour, the aetiology is normally lung cancer, lymphoma or a germ cell tumour.[27] The clinical presentation depends on the time period during which the compression has evolved as collaterals involving the azygos, internal mammary or oesophageal vessels develop over time and relieve the pressure. Patients typically present with facial and arm swelling, dyspnoea, cough and dysphagia. Those presenting to the ICU are likely to have more immediately life-threatening features either of airway obstruction or cerebral oedema, in which case they may have stridor and a headache or a decreased level of consciousness.[28] In the absence of these features, SVC obstruction does not represent a true emergency and management should await histological diagnosis if one has yet to be made.[29] Endovascular stenting results in rapid resolution of symptoms in the vast majority of cases[30] and can be undertaken even in cases of complete obstruction. Radiotherapy is also effective in reducing tumour burden and achieving disease control in those cancers that are radiosensitive, (which includes the majority responsible for SVC obstruction), but takes up to 4 weeks to take effect and can make subsequent histological diagnosis impossible. Steroids such as dexamethasone have a role in cases where the tumour is known to be steroid sensitive (for example, with lymphomas or thymomas) but are otherwise not indicated.[31]

NEUTROPENIA

Neutropenia is a common occurrence following the administration of chemotherapy and obviously predisposes the patient to infection. Care of the neutropenic patient in the intensive care setting is detailed in the chapter 'Haematological malignancies and critical care'.

USE OF CHEMOTHERAPY IN THE INTENSIVE CARE UNIT SETTING

There is little published data on the administration of chemotherapy for solid tumours in the ICU.

Chemotherapy in the ICU should be considered if its administration results in amelioration of life-threatening symptoms or a significant chance of improved patient outcome.[32] Prognostic indicators following chemotherapy administration appear to be similar to those for the general critically ill patient with cancer.[33]

THE EFFECT OF CRITICAL CARE ON CANCER

There has been little work looking into the effect of an ICU stay on tumour progression but much of what happens to a patient during this period (be it disease or treatment mediated) has an impact on the function of the immune system and a potential consequent effect on tumour growth and metastases. The systemic inflammatory response syndrome associated with critical illness has been shown to decrease 5-year survival in patients with lung cancer.[34] Studies conducted in animals have shown that surgery in itself promotes metastasis. This is likely due to a combination of production of pro-inflammatory stimulators of tumour growth, the release of tumour cells directly into the circulation and the stress response. The stress response is mediated through the effect of catecholamines. Adrenaline acts via beta-2 receptors to decrease the number and activity of cytotoxic T and natural killer (NK) cells, both of which are known to destroy cancer cells. Noradrenaline has a similar effect, and has been found to induce the production of metastases in a rat model.[35,36] Interestingly, this effect was abolished by the administration of beta-blockers. Tumours such as breast, colon and prostate seem to express beta-receptors which up-regulate growth when stimulated.

Hypoxia is tumour stimulating. Hypoxia leads to the production of cellular proliferative and angiogenic growth factors (notably vascular endothelial growth factor) via the generation of hypoxia-inducible factors 1-alpha and and 2-alpha. Invasive mechanical ventilation, a common response to hypoxia, may similarly have a role to play; it results in the generation of immunomodulatory cytokines that add to the complex interplay of pro- and anti-inflammatory pathways.[37]

Blood transfusion can also increase the risk of tumour progression, particularly in the case of colorectal tumours. This is again thought to be related to immunosuppression. However, leucodepletion appears to make no difference to the impact on cancer recurrence after transfusion, and animal studies have suggested that transfusion of older blood may be implicated.[38]

Sedatives, induction agents and analgesics are also known to impact on cancer progression. Thiopentone, ketamine and propofol all decrease NK activity and numbers, with propofol having the least effect.[39] Morphine and fentanyl both decrease NK activity. Morphine has also been reported to promote angiogenesis and increase breast tumour cell growth in mice.

In summary, admission to the ICU for a patient with cancer carries a significant potential risk of promoting tumour growth and metastasis.

OUTCOMES FOR PATIENTS ADMITTED TO THE INTENSIVE CARE UNIT WITH SOLID TUMOURS

The traditional view of the outcome for the critically ill cancer patient has been almost universally poor. However, for those with solid tumours, recent evidence has challenged and indeed overturned this view. Survival figures for those admitted to the ICU have steadily improved over the past 15 years and approach those of patients admitted with non-oncological diagnoses in the most recent publications.[40–42] The aetiology of the improvement relates to improvements in general critical care, less cytotoxicity in chemotherapeutic regimes, novel antibacterials and antifungals and, crucially, a recognition that the admission of a patient with cancer to the ICU does not carry a universally poor outcome.

That said, the concept of considering all patients with solid tumours as a homogenous group is flawed. A substantial proportion of the patients that present to the ICU with an underlying diagnosis of solid tumour will be there for postoperative management. They have a similar mortality to patients admitted following any other major operative procedure. Critically ill patients with cancer and a medical diagnosis have a higher mortality than their compatriots without cancer. In the largest study to date (of 12,290 patients across 80 units in the Netherlands), such patients had higher acuity, ICU and hospital mortality (30.4% vs. 16.2% in the ICU, and 44.6% vs. 23.7% in hospital), with a greater need for organ support. Significant differences in outcomes according to cancer diagnosis were also present; respiratory tract cancers were associated with an odds ratio (OR) of 2.15 and upper gastrointestinal (GI) cancers 1.42 for death in the ICU.[43]

In addition to pre-morbid characteristics, the degree of physiological impairment at the point of presentation is a strong predictor of short-term mortality. Vasopressor use and the need for mechanical ventilation is commonly predictive and, in Puxty's systematic review, the need for the latter increased ICU mortality by nearly six times.[41] Additional organ support, in particular the requirement for renal replacement therapy, is also associated with poorer outcome.[44] Continued progression of organ dysfunction over the succeeding 72 hours after ICU admission has also been shown to be indicative of poor outcome[45] and in these patients differ little from patients admitted to the ICU with a non-oncological diagnoses.

RETURN TO INTENDED ONCOLOGICAL THERAPY

Given that the intention in most cases of an admission of critically ill cancer patients to the ICU is to enable

return to intended oncological therapy, there is a surprising dearth of data. In two studies with a total of 171 patients with advanced lung cancer admitted to the ICU, only 15 received further cancer treatment.[46,47]

QUALITY OF LIFE AND LONG-TERM OUTCOMES

There are also few studies reporting either quality of life measures or long-term outcomes (1 year or more). In the two largest studies, quality of life (as measured by SF-36 and EurQoL-5D) was poor in survivors at 3 months but recovered somewhat at a year,[48] whilst the probability of quality-adjusted survival in medical patients at 18 months was just 19.1%.[49]

Acute kidney injury

Rinaldo Bellomo

INTRODUCTION

Acute Kidney Injury (AKI), formerly referred to as acute renal failure, is the new international consensus term for a condition that remains a major complication of critical illness and a therapeutic challenge for the intensivist. The term AKI has been introduced to emphasise a gradation of dysfunction and abnormality that begins long before 'failure' occurs.[1] In the intensive care units (ICUs), AKI describes a syndrome characterised by a rapid (hours to days) decrease in the kidney's ability to eliminate a variety of small and middle molecular weight solutes, including nitrogen waste products such as urea and creatinine, which are measured to estimate the extent of such functional loss. Other typical clinical manifestations include decreased urine output, metabolic acidosis, and hyperkalaemia. More recently, an additional manifestation that has been clearly identified is the release of biomarkers of injury into the urine.[2,3]

AKI can now be defined and classified using changes in serum creatinine and urine output using the so-called Kidney Disease: Improving Global Outcomes (KDIGO) criteria.[4] This classification divides AKI into the stages of severity. Using this or similar classifications, it is clear that AKI is a major ICU syndrome with an incidence of some degree of renal dysfunction being reported in greater than 50% in large studies of critically ill patients[5] and in more than one third of patients on day 1 in Australia and New Zealand ICUs.[6]

ASSESSMENT OF RENAL FUNCTION

Renal function is complex but, in the clinical context, monitoring of renal function is reduced to the indirect assessment of glomerular filtration rate (GFR) by the measurement of plasma urea and, more accurately, serum creatinine in blood. These waste products of nitrogen metabolism, however, are insensitive markers of GFR and are heavily modified by many factors and by dilution with the administration of intravenous fluids.[7] Furthermore, they start becoming abnormal only after more than 50% of GFR is lost and do not reflect dynamic changes in GFR. The use of creatinine clearance (2- or 4-hour collections) or of calculated clearance by means of formulae may be a more accurate reflection of GFR but rarely changes clinical management and is, therefore, uncommonly performed. The use of more sophisticated radionuclide-based tests is only useful for research purposes.

DIAGNOSIS AND CLINICAL CLASSIFICATION

The most practically useful approach to the aetiological diagnosis of AKI is to divide its causes according to the probable source of renal injury: pre-renal, renal (parenchymal or intrinsic) and post-renal.

PRE-RENAL RENAL FAILURE

This form of AKI is by far the most common in the ICU and is considered, at least in its initial phases, to be *functional* in nature (i.e. there are no histopathological changes to renal tissue). The term indicates that the kidney malfunctions predominantly because of systemic factors outside the kidney, which decrease GFR (decreased cardiac output, hypotension, sepsis and the like). If the systemic cause of AKI is rapidly removed or corrected, renal function improves and relatively rapidly returns to near normal levels. However, if intervention is delayed or unsuccessful, renal injury may become established and AKI may persist for several days or weeks. Several urine tests (measurement of urinary sodium, fractional excretion of sodium and other derived indices) have been promoted to help clinicians identify the development of such 'established' AKI. Unfortunately, their accuracy is doubtful[8] and their clinical utility is negligible. Furthermore, pre-renal AKI and established AKI are part of a continuum, and their separation has limited clinical implications.[9] More recently, other diagnostic tests have been developed which rely on the identification of molecules which are released in the urine as a consequence of renal injury. Such novel renal injury biomarkers[2,3] appear in the urine before changes in serum creatinine take place and have good to excellent accuracy for the prediction on subsequent increases in serum creatinine. Their commercialisation and

ABSTRACT

Acute kidney injury (AKI) is a major complication of critical illness typically characterised by oliguria and increased blood concentrations of nitrogen waste products. It is now defined by presence of consensus criteria and is associated with increased mortality. Its clinical subdivision into pre-renal, renal and post-renal causes provides a useful diagnostic framework of reference. More recently, the discovery of biomarkers of renal injury has helped identify at-risk patients earlier and may make preventive interventions more successful. The pathophysiology of AKI, however, is likely complex and remains poorly understood. For septic AKI (the most common type of AKI in intensive care unit [ICU]), changes in microvascular flow may be particularly important. For other unique syndromes (rhabdomyolysis and hepatorenal syndrome), specific factors are likely to be responsible for loss of renal function.

Prevention relies upon early recognition, treatment or removal of the likely cause, avoidance or removal of nephrotoxins, and optimisation of systemic haemodynamics (cardiac output and blood pressure). The non-dialytic management of AKI is also focused on preventing or rapidly treating the complications of AKI (hyperkalaemia, acidosis, fluid overload). Such treatment may ultimately require renal replacement therapy (RRT) in some patients. Although most patients recover renal function once their illness resolves, some do not. Moreover, an episode of AKI carries significant risk of subsequent chronic kidney disease, highlighting the importance of prevention.

PARENCHYMAL (INTRINSIC) RENAL FAILURE

This term is used to define a syndrome where the principal source of damage is within the kidney and where *structural* changes can be seen on microscopy. Disorders which affect the glomeruli or renal tubules can be responsible (Box 47.1).

Among these, nephrotoxins are particularly important, especially in hospital patients. The most common nephrotoxic drugs affecting ICU patients are listed in Box 47.2. Many cases of drug-induced AKI rapidly improve upon removal of the offending agent. Accordingly, a careful history of drug administration is *mandatory* in all patients with AKI. In some cases of parenchymal AKI, a correct working diagnosis can be obtained from history, physical examination and radiological and laboratory investigations. In such patients, one can proceed to a therapeutic trial without the need to resort to renal biopsy. However, if immunosuppressive therapy is considered, renal biopsy is recommended.

Box 47.1 Causes of intrinsic (parenchymal) acute kidney injury

- Glomerulonephritis
- Vasculitis
- Interstitial nephritis
- Malignant hypertension
- Pyelonephritis
- Bilateral cortical necrosis
- Amyloidosis
- Malignancy
- Nephrotoxins
- Cholesterol embolism

Box 47.2 Drugs which may contribute to acute kidney injury in the intensive care unit

- Radiocontrast agents
- Starch continuing fluids
- Aminoglycosides
- Amphotericin
- Non-steroidal anti-inflammatory drugs
- β-lactam antibiotics (interstitial nephropathy)
- Sulphonamides
- Acyclovir
- Methotrexate
- Cisplatin
- Cyclosporin A
- Tacrolimus
- Sirolimus

More than a third of patients who develop AKI in the ICU have chronic renal dysfunction due to factors such as age-related changes, long-standing hypertension, diabetes or atheromatous disease of the renal vessels. Such chronic renal dysfunction may be manifest by a raised serum creatinine. However, this is not always the case. Often, what may seem to the clinician to be a relatively trivial insult, which does not fully explain the onset of AKI in a normal patient, is sufficient to unmask lack of renal functional reserve in another patient.

Beyond all the above considerations, however, the most common type of so-called intrinsic AKI falls under the traditional name of acute tubular necrosis (ATN). The term ATN is often used to describe a form of 'intrinsic' AKI, which follows from severe and persistent pre-renal AKI. It is assumed that such ATN results from such continued hypoperfusion. This approach is widely accepted and used by textbooks and clinicians, but is likely misleading and inaccurate.[10] This is because the term ATN conflates a histological diagnosis (tubular necrosis) that is rarely confirmed by biopsy with a complex clinical syndrome (typically AKI of >72 hours from multiple causes). Such syndrome, in many cases, has *not* been convincingly linked with the specific histopathological appearance of ATN either in animal experiments or in human disease.[10,11] Moreover, ATN is believed to represent the consequence of sustained or severe pre-renal azotemia. Unfortunately, the term 'pre-renal azotemia' is, like ATN, conceptually flawed[12,13] because it implies that clinicians can know with a sufficient degree of certainty, by taking a history, examining the patient and performing urine and blood tests, that there is no histopathological injury to the tubules. Finally, all such concepts are biologically flawed because they imply that AKI does not represent (like all other diseases known to man) a continuum of injury but rather a yes-or-no phenomenon in terms of histological damage. For these reasons, terms like pre-renal azotemia and ATN are increasingly being challenged.[9,12] In addition to the above syndromes, the specific clinical syndrome of 'intrinsic' AKI deserves special attention.

HEPATORENAL SYNDROME

This condition is a form of AKI, which occurs in the setting of severe liver dysfunction in the absence of other known causes of AKI.[14] Typically, it presents as progressive oliguria with a very low urinary sodium concentration (<10 mmol/L). Its pathogenesis is not well understood. New consensus definitions, however, now define HRS as any development of AKI in the setting of advanced liver disease that is not due to other intrinsic causes. Thus, sepsis, paracentesis-induced hypovolaemia, raised intra-abdominal pressure due to tense ascites, diuretic-induced hypovolaemia, lactulose-induced hypovolaemia, and any combination

of these, which in the past were used to exclude HRS, are now acknowledged triggers of this condition.[14] The avoidance of hypovolaemia by albumin administration in patients with spontaneous bacterial peritonitis has been shown to decrease the incidence of HRS.[15] More importantly, multiple observational studies, several controlled trials, and growing clinical experience have led to the acceptance and widespread use of terlipressin to improve GFR in this condition.[16]

RHABDOMYOLYSIS-ASSOCIATED ACUTE KIDNEY INJURY

This condition accounts for close to 5%–10%[17] of cases of AKI in the ICU depending on the setting. Its pathogenesis involves pre-renal, renal and post-renal factors. It is now typically seen following major trauma, drug overdose with narcotics, vascular embolism and in response to a variety of agents, which can induce major muscle injury. The principles of treatment are based on retrospective data. They include prompt and aggressive fluid resuscitation, elimination of causative agents, correction of compartment syndromes, alkalinisation of urine (pH >6.5), and maintenance of polyuria (>300 mL/h).

POST-RENAL RENAL FAILURE

Obstruction to urine outflow is the most common cause of functional renal impairment in the community,[18] but is uncommon in the ICU. The clinical presentation of obstruction may be acute or acute-on-chronic in patients with long-standing renal calculi. It may not always be associated with oliguria. If obstruction is suspected, ultrasonography can be easily performed at the bedside. However, not all cases of acute obstruction have an abnormal ultrasound and, in many cases, obstruction occurs in conjunction with other renal insults (e.g. staghorn calculi and severe sepsis of renal origin). Assessment of the role of each factor and overall management should be conducted in conjunction with an urologist. Finally, the sudden and unexpected development of anuria in an ICU patient should always suggest obstruction of the urinary catheter as the cause. Appropriate flushing or changing of the catheter should be implemented in this setting.

PATHOGENESIS OF ACUTE KIDNEY INJURY

The pathogenesis of obstructive AKI involves several humoral responses as well as mechanical factors. The pathogenesis of parenchymal renal failure as seen with glomerulonephritis is typically immunological. It varies from vasculitis to interstitial nephropathy and involves an extraordinary complexity of immunological mechanisms. The pathogenesis of pre-renal AKI is of greater direct relevance to the intensivist.

The overwhelming majority of our conceptions of the pathophysiology of pre-renal AKI are derived from animal models[19,20] using ischemia by the acute and complete occlusion of the arterial vascular supply to the kidney. Unfortunately, the clinical relevance of such models is limited, and is negligible to conditions like sepsis,[21,22] now the most common trigger of AKI in hospital and ICU patients. However, models of septic AKI, which fully resemble the human phenotype, are difficult to develop. When a hyperdynamic sepsis phenotype with AKI is produced in large animals, renal blood flow actually increases to supranormal levels and renal histopathology is essentially normal.[23,24] Moreover, kidney adenosine triphosphate (ATP) levels are highly preserved in animal models of septic shock (Fig. 47.1). If experimental septic AKI can occur in the setting of increased renal blood flow and preserved ATP levels, it is impossible to know for sure that this does not also happen in humans, where histopathological assessment remains confined to rapid postmortem assessment, and assessment of renal blood flow is similarly extremely difficult and confined to invasive techniques.

Despite all of the above observations, activation of the renin-angiotensin system (RAAS), activation of the renal sympathetic system,[25] and activation of the tubulo-glomerular feedback (TGF) system may play a role.[26] However, it remains unclear which particular pathway of injury has *primacy* in terms of *importance or timing* or *both*. Finally, recent evidence suggests that intrarenal shunting contributes to decreased GFR and ischemia of the renal medulla.[27,28] Such shunting may also be coupled with changes in the microcirculation, suggesting that even if one could measure global renal blood flow with reasonable accuracy, unless the microcirculation is also assessed, our understanding of AKI will remain poor.

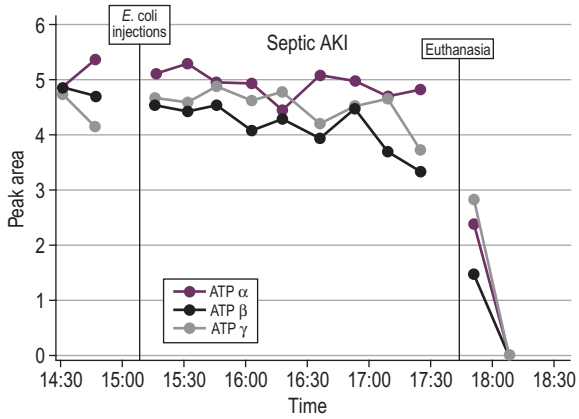

Figure 47.1 Graphic representation of the changes in magnetic resonance spectroscopy-derived ATP levels in the kidney during experimental septic shock. There are no significant changes until euthanasia is performed. *AKI*, Acute kidney injury.

THE CLINICAL PICTURE

The most common clinical picture seen in the ICU is that of a patient who has sustained/is experiencing a major systemic insult (trauma, sepsis, myocardial infarction, severe haemorrhage, cardiogenic shock, major surgery and the like). When the patient arrives in the ICU, resuscitation should typically be well under way or surgery may have just been completed. Despite such efforts, the patient may already be anuric or oliguric, the serum creatinine may be rising and a metabolic acidosis may be developing. Potassium and phosphate levels may be rising as well. Mechanical ventilation and need for vasoactive drugs is common in this setting. Fluid resuscitation is typically undertaken in the ICU under the guidance of invasive haemodynamic monitoring. Vasoactive drugs are often used to restore mean arterial pressure (MAP) to 'acceptable' levels (typically >65–70 mm Hg). The patient may improve over time and urine output may return with or without the assistance of diuretic agents. If urine output does not return, however, renal replacement therapy (RRT) needs to be considered. Once the cause of AKI has been removed and the patient has become physiologically stable, slow (days to weeks) recovery typically occurs. If the cause of AKI has not been adequately remedied, the patient remains gravely ill, the kidneys do not recover and death from multiorgan failure may occur.

PREVENTING ACUTE KIDNEY INJURY

The fundamental principle of AKI prevention is to treat its cause. If pre-renal factors contribute, these must be identified and haemodynamic resuscitation quickly instituted.

RESUSCITATION

Intravascular volume must be maintained or rapidly restored, and this is often best done using invasive haemodynamic monitoring (central venous catheter, arterial cannula, and pulmonary artery catheter or pulse contour cardiac output catheters, or echocardiography in some cases). Oxygenation must be maintained. An adequate hemoglobin concentration (at least >70 g/L) must be maintained or immediately restored. Once intravascular volume has been restored, some patients remain hypotensive (MAP <70 mm Hg). In these patients, autoregulation of renal blood flow may be lost. Restoration of MAP to near normal levels may increase GFR. Such elevations in MAP, however, require the addition of vasopressor drugs.[29] The nephroprotective role of additional fluid therapy in a patient with a normal or increased cardiac output and blood pressure is questionable. Despite these resuscitation measures, AKI may still develop if cardiac output is inadequate. This may require a variety of interventions from the use of inotropic drugs to the application of ventricular assist devices.

NEPHROPROTECTIVE DRUGS

Following haemodynamic resuscitation and removal of nephrotoxins, it is unclear whether the use of additional pharmacological measures is of further benefit to the kidney.

A phase III trial in critically ill patients showed that low-dose dopamine is as effective as placebo in the prevention of renal dysfunction in ICU patients.[30]

The use of loop diuretics is controversial and not supported by high-quality evidence. Other agents such as *theophylline, urodilatin, anaritide* (a synthetic atrial natriuretic factor), or *fenoldopam* have failed to show consistent benefits.

In patients receiving radiocontrast, saline infusion to maintain intravascular fluid expansion may be helpful in attenuating kidney injury. However, the relevance of such treatment in critically ill patients remains unclear. The benefits of n-acetylcysteine and bicarbonate infusion as protective strategies in this context also remain highly controversial.

DIAGNOSTIC INVESTIGATIONS

An aetiological diagnosis of AKI must always be established. While this may be obvious on clinical grounds, in other cases, investigations including the examination of urinary sediment and exclusion of a urinary tract infection (most if not all patients), exclusion of obstruction when appropriate (some patients) and the careful exclusion of nephrotoxins (all patients) may be needed.

In specific situations, other investigations are necessary to establish the diagnosis, such as creatine kinase and free myoglobin for possible rhabdomyolysis. A chest radiograph, a blood film, the measurement of non-specific inflammatory markers, and the measurement of specific antibodies (anti GBM, anti-neutrophil cytoplasm, anti-DNA, anti-smooth muscle, etc.) may help diagnose vasculitis or certain types of collagen disease or glomerulonephritis. If thrombotic-thrombocytopenic purpura is suspected, the additional measurement of lactic dehydrogenase, haptoglobin, unconjugated bilirubin and free haemoglobin are needed. In some patients, specific findings (cryoglobulins, Bence-Jones proteins) are almost diagnostic. In a few rare patients, a renal biopsy might become necessary.

NOVEL BIOMARKERS OF ACUTE KIDNEY INJURY

Using new search techniques based on proteomics, investigators have identified novel biomarkers of AKI.[31]

The identification of these biomarkers may change our classification and treatment of this condition in the near future. These biomarkers appear to change significantly earlier than changes in serum creatinine.[32] They appear to reflect different aspects of renal injury. For example, cystatin C appears to reflect changes in GFR, while neutrophil gelatinase associated lipocalin (NGAL) appears to reflect tubular stress/injury. They also appear to dynamically change with treatment or recovery, which suggests that they can be used to monitor interventions. They may identify subpopulations of patients who do not have AKI according to creatinine-based criteria, but actually have a degree of kidney stress/injury that can be detected by biomarkers and is associated with worse outcomes.[32] Finally, by identifying possible mechanisms of injury they may increase our understanding of the pathogenesis of AKI. Their therapeutic implications, however, remain unclear.

MANAGEMENT OF ESTABLISHED ACUTE KIDNEY INJURY

The principles of management of established AKI are the treatment or removal of its cause, the avoidance of nephrotoxins, and the maintenance of physiological and, in particular, haemodynamic homeostasis while recovery takes place. Complications such as encephalopathy, pericarditis, myopathy, neuropathy, electrolyte disturbances or other major electrolyte, fluid or metabolic derangement should never occur in a modern ICU. Their prevention may include several measures, which vary in complexity from fluid restriction to the initiation of extracorporeal RRT.

Nutritional support should be started early and should contain adequate calories (20–30 Kcal/kg/day) as a mixture of carbohydrates and lipids. Adequate protein (at least 1 g/kg/day) should be administered. There is no evidence that specific renal nutritional solutions are useful. Vitamins and trace elements should be administered at least according to their recommended daily allowance. The role of newer immunonutritional solution remains controversial. The enteral route is preferred to the use of parenteral nutrition.

Hyperkalaemia (>6 mmol/L) must be promptly treated either with insulin and dextrose administration, the infusion of bicarbonate if acidosis is present, the administration of nebulised salbutamol, or all of the above together. If the 'true' serum potassium is greater than 7 mmol/L or electrocardiographic signs of hyperkalaemia appear, calcium gluconate (10 mL of 10% solution IV) should also be administered. The above measures are temporising actions while RRT is being set up. The presence of hyperkalaemia is a major indication for the immediate institution of RRT.

Metabolic acidosis is almost always present but rarely requires treatment per se. Anaemia requires correction to maintain a haemoglobin level of at least greater than 70 g/L. More aggressive transfusion needs individual patient assessment. Drug therapy must be adjusted to take into account the effect of the decreased clearances associated with loss of renal function. Stress ulcer prophylaxis is advisable. Assiduous attention should be paid to the prevention of infection.

Fluid overload can be prevented by the use of loop diuretics in polyuric patients. However, if the patient is oliguric, the only way to avoid fluid overload is to institute RRT at an early stage (see specific chapter). Marked azotemia ([urea] >40 mmol/L or [creatinine] >400 µmol/L) is undesirable and should probably be treated with RRT unless recovery is imminent or already under way and a return towards normal values is expected within 24–48 hours. It is recognised, however, that no randomised controlled trials (RCTs) exist to define the ideal time for intervention with artificial renal support. Moreover, recent trials have reported controversial findings.[33,34]

PROGNOSIS

The mortality of critically ill patients with AKI remains high (40%–50% depending on case-mix). It is frequently stated that patients die with renal failure rather than of renal failure. However, much indirect evidence supports a careful and proactive approach to the treatment of patients with AKI, which is based on the prevention of uncontrolled uraemia and the maintenance of low-urea levels throughout the patient's illness. Finally, ICU patients with AKI typically recover to baseline or near baseline function even when suffering from severe AKI and long-term dialysis is an uncommon complication.[35] However, it is now clear that even a single episode of AKI is associated with a significantly increased risk of subsequent chronic kidney disease.[36,37] Accordingly, it seems advisable to refer patients treated in the ICU for severe AKI to follow-up nephrology care.

Renal replacement therapy

Rinaldo Bellomo

INTRODUCTION

When acute kidney injury (AKI) is severe, resolution can take several days or weeks. During this time, the kidneys may be unable to maintain homeostasis of fluid, potassium, metabolic acid and waste products. If this pathophysiological state is prolonged, life-threatening complications frequently develop. In these patients, extracorporeal techniques of blood purification become necessary to prevent such complications. These techniques broadly referred to as renal replacement therapy (RRT) include continuous haemofiltration (HF) and its technical variations, intermittent haemodialysis (IHD), and peritoneal dialysis (PD) – each with its technical variations. All of these techniques rely on the principle of removing unwanted solutes and water through a semipermeable membrane, which is either biological (peritoneum) or artificial (haemodialysis or HF membranes), and each technique offers several advantages, disadvantages and limitations.

PRINCIPLES

The principles of RRT have been extensively studied and described.[1-3] Here we summarise several key aspects, which are relevant to the critical care physician.

WATER REMOVAL

The removal of unwanted solvent (water) is therapeutically probably as important as the removal of unwanted solutes (acids, uraemic toxins, potassium, and the like). During RRT, water is removed through a process called *ultrafiltration*. This process is essentially the same as that performed by the glomerulus. It requires a driving pressure to move water across a semipermeable membrane because such fluid would normally be kept within the circulation due to oncotic pressure. This pressure is achieved by:

1. Generating a *transmembrane pressure* though the pumping of blood (as in HF or during IHD) through the semipermeable membrane. This positive pressure is greater than the oncotic pressure that would retain water in the circulation, and generates ultrafiltration.
2. Increasing osmolarity of the dialysate (as in PD), which then draws water across the semipermeable membrane (the peritoneum).

SOLUTE REMOVAL

The removal of unwanted solutes (uraemic toxins, nitrogen waste products, and organic acids) can be achieved by:

1. Creating an electrochemical gradient across the membrane using a flow-past system with toxin-free dialysate (*diffusion*) as in IHD and PD.
2. Creating a transmembrane pressure driven 'solvent drag', where solutes move together with solvent (*convection*) across the membrane, are discarded together with the solvent, and then replaced with toxin-free replacement fluid as in HF.

The rate of diffusion of a given solute depends on its molecular weight (MW), the porosity of the membrane, the blood flow rate, the dialysate flow rate, the degree of protein binding and its concentration gradient across the membrane. If synthetic high-flux membranes are used (cut-off at 10–20 kilo Daltons [kD] MW in vivo) molecules with a MW below these values can be removed. However, with these membranes, convection is superior to diffusion in achieving the clearance of middle molecules (those with a MW >1000).

INDICATIONS FOR RENAL REPLACEMENT THERAPY

In the critically ill patient, RRT can be initiated early, prior to the development of complications. Fear of early RRT stems from historical experience with the adverse effects of conventional IHD, especially haemodynamic instability, and from the risks and limitations of continuous or intermittent PD.[4,5] However, continuous renal replacement therapy (CRRT)[6,7] or slow low efficiency daily dialysis (SLEDD)[8] minimise these effects. The criteria for the initiation of RRT in patients with chronic renal failure may not be appropriate in many critically ill patients.[9,10] A set of modern criteria, which can be considered sufficient for the initiation of RRT in the intensive care unit (ICU) is presented in Box 48.1.

ABSTRACT

In the intensive care unit (ICU) setting in patients with acute kidney injury (AKI), renal replacement therapy (RRT) becomes necessary when renal function is insufficient to preserve adequate control of fluid, acid-base and waste product homeostasis. The principles of RRT are based on solute and solvent movement across a semipermeable membrane. These principles apply to all modalities of RRT from intermittent haemodialysis (IHD) to continuous haemofiltration, from slow low efficiency daily dialysis (SLEDD) to peritoneal dialysis. Continuous RRT (CRRT) is the dominant form of RRT in developed countries, especially in haemodynamically unstable patients. IHD is typically used in stable patients or in the recovery phase just before and after general ward transfer. CRRT circuit anticoagulation is often challenging. However, regional anticoagulation with citrate is emerging as the safest and most effective option. Although large, randomised, controlled trials have made it possible to have strong evidence to guide intensity selection, several aspects of RRT remain to be explored, especially the timing of its initiation.

7. Uncompensated metabolic acidosis (pH <7.1)
8. (Na^+) <110 and >160 mmol/L
9. Temperature >40°C
10. Uraemic complications (encephalopathy/myopathy/neuropathy/pericarditis)
11. Overdose with a dialyzable toxin (e.g. lithium).

*Please be aware of differences between plasma versus serum measurement in your laboratory.

If one criterion is present, RRT should be considered. If two criteria are simultaneously present, RRT is strongly recommended.

RRT, Renal replacement therapy.

With either IHD, or CRRT or SLEDD, there are limited data on what is the 'adequate' intensity of dialysis. However, the concept of dialytic adequacy should include the maintenance of homeostasis at all levels[10] and better uraemic control may translate into better survival.[11,12] An appropriate target urea might be 15–25 mmol/L, with a protein intake around 1.5 g/kg/day. This can be easily achieved using CRRT at urea clearances of 20–25 mL/kg/h depending on the catabolic rate. If intermittent therapy is used, daily and extended treatment as described with SLEDD may be desirable in the ICU.[13]

MODALITY OF RENAL REPLACEMENT THERAPY

There is a great deal of controversy as to which modality of RRT is 'best' in the ICU due to the lack of randomised, controlled trials comparing different modalities (IHD or CRRT). In their absence, modalities of RRT may be judged on the basis of the following criteria:

1. Haemodynamic side effects
2. Ability to control fluid status
3. Biocompatibility
4. Risk of infection
5. Uraemic control
6. Avoidance of cerebral oedema
7. Ability to allow full nutritional support
8. Ability to control acidosis
9. Absence of specific side effects
10. Cost.

In relation to the above criteria, CRRT and SLEDD offer many advantages over PD and conventional IHD (3–4 h/day, 3–4 times/week),[13] and, therefore, CRRT or SLEDD are almost exclusively used in Australia and New Zealand ICUs,[14] with IHD only being used prior to discharge or after discharge to the general wards. Irrespective of the choice of modality, some salient aspects of CRRT, IHD and PD require discussion.

CONTINUOUS RENAL REPLACEMENT THERAPY

First described in 1977, CRRT has undergone several technical modifications. It is now performed using double-lumen catheters and peristaltic blood pumps with control of the ultrafiltration rate. If no dialysate is used and effluent is replaced with substitution solutions, the technique is called continuous veno-venous haemofiltration (CVVH). During CVVH, ultrafiltration rates of 2 L/h yield urea clearances of approximately 25 mL/kg/h in the average 80 kg patient (Fig. 48.1).

In a veno-venous system, dialysate can also be delivered countercurrent to blood flow (continuous veno-venous haemodialysis – CVVHD) to achieve either almost pure diffusive clearance (Fig. 48.2) or as a mixture of diffusive and convective clearance (continuous veno-venous haemodiafiltration – CVVHDF) (Fig. 48.3).

No matter what technique is used, the following outcomes are predictable:

1. Continuous control of fluid status
2. Haemodynamic stability
3. Control of acid-base status
4. Ability to provide protein-rich nutrition while achieving uraemic control
5. Control of electrolyte balance, including phosphate and calcium balance
6. Prevention of swings in intracerebral water
7. Minimal risk of infection
8. High level of biocompatibility.

However, CRRT mandates the presence of specifically trained nursing and medical staff 24 hours a day and the issues of continuous circuit anticoagulation or the potential risk of bleeding have been of concern.

CIRCUIT ANTICOAGULATION DURING CONTINUOUS RENAL REPLACEMENT THERAPY

The flow of blood through an extracorporeal circuit causes activation of the coagulation cascade and promotes clotting of the filter and circuit itself. In order to delay this and achieve acceptable operational lives (approximately 24 hours) for the circuit, anticoagulants are frequently used.[15] However, circuit anticoagulation increases the risk of bleeding. Therefore, the risks and benefits of more or less intense anticoagulation and alternative strategies (Box 48.2) must be considered.

In the vast majority of patients, low-dose heparin (<500 IU/h) is sufficient to achieve adequate (approximately 24 hours) circuit life; it is easy and cheap to

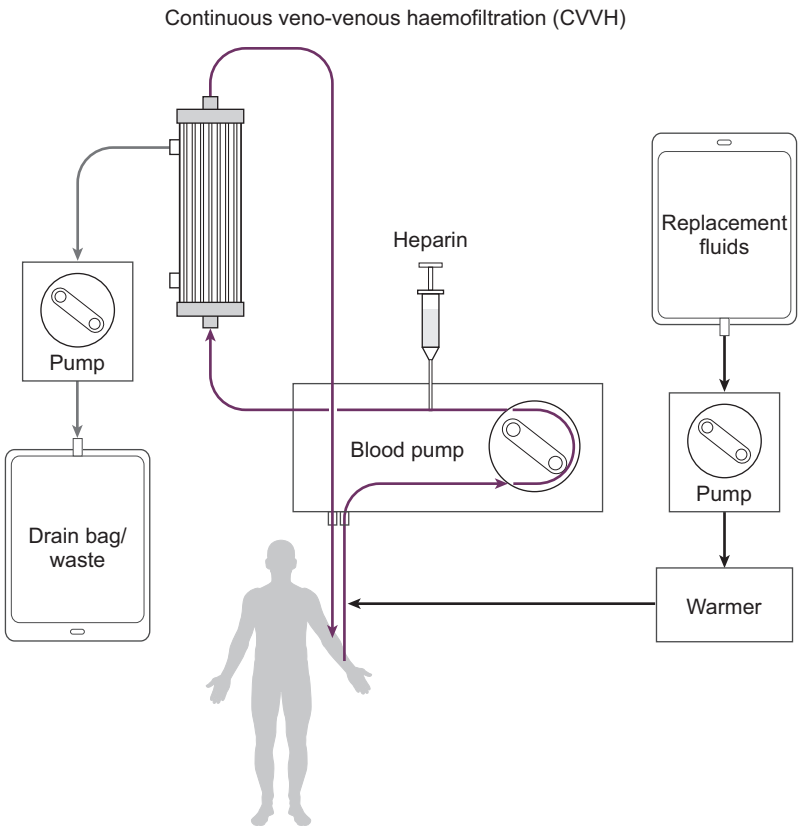

Figure 48.1 Diagram illustrating a continuous veno-venous haemofiltration circuit (CVVH).

Box 48.2 Strategies for circuit anticoagulation during continuous renal replacement therapy

1. No anticoagulation
2. Low-dose pre-filter heparin (<500 IU/h)
3. Regional citrate anticoagulation (pre-filter citrate and post-filter calcium and magnesium – special calcium free dialysate needed or citrate containing replacement fluid delivered pre-filter)
4. Medium-dose pre-filter heparin (500–1000 IU/h)
5. Full heparinisation
6. Regional anticoagulation (pre-filter heparin and post-filter protamine usually at a 100 IU to 1 mg ratio) (1500 IU/h) of heparin pre-filter and 15 mg/h of protamine post-filter
7. Low-molecular-weight heparin
8. Prostacyclin
9. Heparinoids

administer, and has almost no effect on the patient's coagulation tests. In some patients, a higher dose (800–1000 IU/h) is necessary. In others (pulmonary embolism, myocardial ischaemia) full heparinisation may actually be concomitantly indicated.

Regional citrate anticoagulation is very effective, but requires a special dialysate or replacement fluid.[16] Nonetheless, several randomised, controlled trials have now established that citrate anticoagulation is the safest and most effective way of achieving anticoagulation.[17,18] However, although it is safe and effective in patients who do not have significantly impaired liver function, in these patients citrate may accumulate and induce coagulopathy. The biochemical signs of citrate accumulation are an increasing base deficit, an increasing requirement for calcium administration to maintain the target level of calcaemia and widening of the total calcium to ionised calcium ratio. Magnesium supplementation is also needed. Due to the development of commercially available dialysate and replacement fluids to facilitate citrate anticoagulation and new CRRT machine technology to enable such anticoagulation to be performed with minimal risk, the use of citrate anticoagulation is now rapidly expanding.[17,18]

Regional heparin/protamine anticoagulation is also somewhat complex, but is simpler than citrate anticoagulation, and may be useful if frequent filter clotting occurs and further anticoagulation of the patient is considered dangerous.[18] Low MW heparin is also easy to administer, but is more expensive. If enoxaparin is

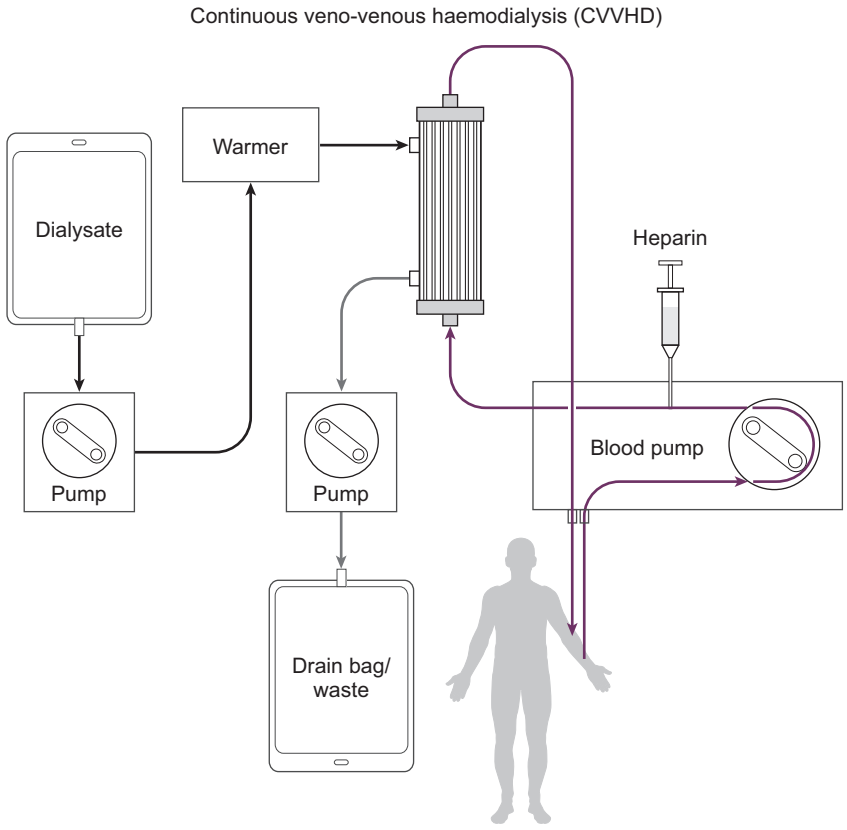

Figure 48.2 Diagram illustrating a continuous veno-venous haemodialysis circuit (CVVHD).

used, its dose should be adjusted for the loss of renal function. Heparinoids and prostacyclin may be useful if the patient has developed heparin-induced thrombocytopoenia and thrombosis. Finally, in perhaps 10%–20% of patients, anticoagulation of any kind is best avoided because of endogenous severe coagulopathy or recent surgery or inability to metabolise citrate. In such patients, adequate filter life can be achieved provided that blood flow is kept at about 200 mL/min and vascular access is reliable.[19]

Many circuits clot for *mechanical reasons* (inadequate access, unreliable blood flow from double-lumen catheter depending on patient position, kinking of catheter).[20] Responding to frequent filter clotting by simply increasing anticoagulation without making the correct aetiological diagnosis (checking catheter flow and position, taking a history surrounding the episode of clotting, identifying the site of clotting) is often futile and exposes the patient to unnecessary risk. Particular attention needs to be paid to the adequacy/ease of flow through the double lumen catheter. Smaller (11.5 Fr) catheters in the subclavian position are a particular problem. Larger catheters (13.5 Fr) in the femoral position or internal jugular position appear to perform more reliably.[21]

CONTINUOUS RENAL REPLACEMENT THERAPY TECHNOLOGY

The increasing use of veno-venous CRRT has led to the development of a field of CRRT technology, which offers different kinds of machines to facilitate its performance.[22] Some understanding of these devices is important to the successful implementation of CRRT in any ICU. These machines are safer and have much more sophisticated pump control systems, alarms and graphic displays. They are much more user friendly, especially with the set-up procedure. They provide information on outflow pressure (the suction pressure applied to the outflow lumen of the dialysis catheter and a marker of its performance), the transmembrane pressure (a marker of membrane fouling and clotting) and inflow pressure (a marker of resistance to inflow). Such pressures are often useful is assessing catheter function and the aetiology of circuit loss.[20]

The choice of membrane is also a matter of controversy. There are no controlled studies to show that one of them confers a clinical advantage over the others. The AN 69 is the most commonly used CRRT membrane in Australia. The issue of membrane size is also controversial as no controlled studies have compared

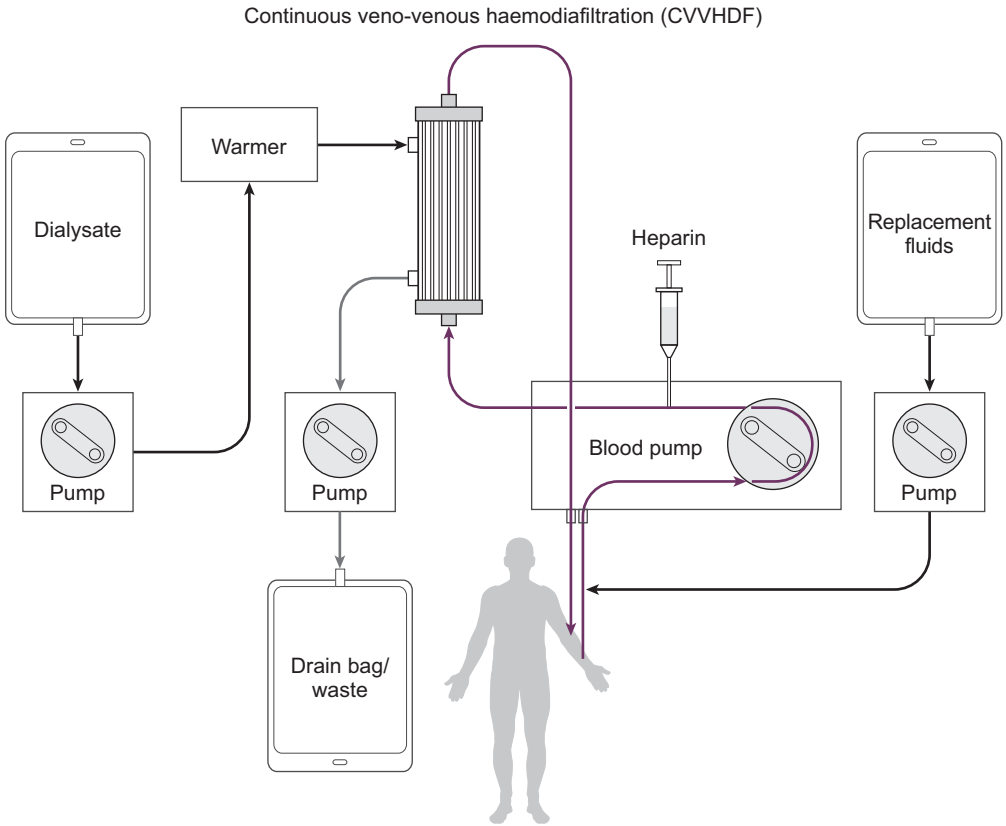

Figure 48.3 Diagram illustrating a continuous veno-venous haemodiafiltration circuit (CVVHDF).

different membrane surface sizes. However, if high-volume haemofiltration is planned the membrane surface needs to be in the 1.6–2 m^2 range.

INTENSITY OF CONTINUOUS RENAL REPLACEMENT THERAPY

The optimal dose (expressed at effective effluent/kg/h) of CRRT has been the subject of controversy for almost a decade. Several studies had initially suggested that a higher dose may translate into a better outcome.[23–25] However, such studies had been single centre in nature and were considered to require confirmation in multicentre, randomised, controlled trials. Two trials, completed in 2008[26] and 2009[27], showed no difference with increasing the intensity of RRT indicating that, in current practice, the prescribed dose of RRT should be equivalent to 25–30 mL/kg/h to take into account the impact of 'down time' on the delivered dose. Moreover, essentially all AKI patients on vasopressor support received CRRT in the Acute Renal Failure Trial Network (ATN) and Randomized Evaluation of Normal vs Augmented Level renal replacement therapy (RENAL) trials. Thus, by practice consensus, CRRT has now been become the de facto standard of care in haemodynamically unstable patients. Renal recovery was much greater in the RENAL trial (with essentially exclusive use of CRRT) than in the ATN trial (with substantial use of IHD), suggesting that the use of CRRT might facilitate renal recovery – a finding supported by large observational data.[28]

INTERMITTENT HAEMODIALYSIS

Acute vascular access for IHD is typically by double lumen catheter as in continuous HF. The circuit is also the same. Countercurrent dialysate flow is used as in CVVHD. The major differences are that standard IHD uses high dialysate flows (>400 mL/min) and generates dialysate by mixing purified water and concentrate. Treatment is conventionally applied for short periods of time (3–4 hours), usually every second day. These differences have important implications. First, volume has to be removed over a short period of time and this may cause hypotension. Repeated hypotensive episodes may delay renal recovery.[4,28] Secondly, solute removal is episodic. This translates into inferior uraemic[29] and acid-base control. Limited fluid and uraemic control imposes unnecessary limitations on nutritional support. Finally, rapid solute shifts increase brain water content and raise intracranial pressure.[30]

The limitations of applying 'standard' IHD to the treatment of AKI has led to the development of new approaches (so-called 'hybrid techniques'), such as slow low efficiency daily dialysis –SLEDD.[13] These techniques seek to adapt IHD to the clinical circumstances, decrease the rate of volume removal, decrease the rate of solute removal and thereby increase tolerance and overall clearances. However, the uptake of SLEDD has remained limited.[26] The multiple techniques of RRT and their complex names and many abbreviations (CVVHD, CVVH, CVVHDF, SLEDD, IHD) can lead to confusion and miscommunication. Accordingly, recent consensus statements on principles and nomenclature for RRT have been published for reference.[31,32]

PERITONEAL DIALYSIS

This technique is now uncommonly used in the treatment of adult AKI in developed countries, but remains relatively common in children and in patients with AKI in developing countries.[23] This is because it may be a cheap and adequate technique in developing countries, or in children where the peritoneal membrane has a greater relative surface or where alternatives are considered too expensive, too invasive or are not available. Typically, access is by the insertion of an intraperitoneal catheter. Glucose rich (hypertonic) dialysate is then inserted into the peritoneal cavity and acts as the 'dialysate'. After a given 'dwell time' it is removed and discarded with the extra fluid and toxins that have moved from the blood vessels of the peritoneum to the dialysate fluid. Machines are also available that deliver and remove dialysate at higher flows, providing intermittent treatment or higher solute clearances. Several major shortcomings make PD suitable for chronic dialysis but relatively unsuited to the treatment of adult AKI:

1. Limited and sometimes inadequate solute clearance
2. High risk of peritonitis
3. Unpredictable hyperglycaemia
4. Fluid leaks
5. Protein loss
6. Interference with diaphragm function.

In developed countries, there have not been any reports of the sole use of PD for the treatment of adult patients with AKI in the last 15 years. A randomised trial comparing PD to CVVH found that PD was associated with increased mortality.[23]

OTHER BLOOD PURIFICATION TECHNIQUES

HAEMOPERFUSION

During haemoperfusion, blood is circulated through a circuit similar to one used for CVVH. However, a charcoal cartridge is perfused with blood instead of a dialysis membrane. In some cases, an ion exchange resin (Amberlite) has been used. Charcoal microcapsules effectively remove molecules of 300–500 D in molecular weight including some lipid-soluble and protein-bound substances. Heparinisation is necessary to prevent clotting. Also, attention must be paid to changes in intravascular volume at the start of therapy because of the large priming volume of the cartridge (260 mL). Glucose absorption is significant and the monitoring of blood glucose is necessary to avoid hypoglycaemia. Also, thrombocytopoenia is common, and can be marked. The role of haemoperfusion is controversial as no controlled trials have ever shown it to confer clinically significant advantages. However, it may be useful in patients with life-threatening theophylline overdose because it removes the agent effectively.

PLASMAPHERESIS OR PLASMA EXCHANGE

With this technique, plasma is removed from the patient and exchanged with fresh frozen plasma (FFP) and a mixture of colloid and crystalloid solutions. This technique also can be performed in an ICU familiar with CRRT techniques. A plasmafilter (a filter that allows the passage of molecules up to 500 kD) instead of a haemofilter is inserted in the CVVH circuit, and the filtrate (plasma) is discarded. Plasmapheresis can also be performed with special machines using the principles of centrifugation. The differences, if any, between centrifugation and filtration technology are unclear. Replacement (post-filter) will occur as in CVVH, using a 50/50 combination of FFP and albumin, for example. Plasmapheresis has been shown to be effective treatment for thrombotic thrombocytopenic purpura (TTP) and for several diseases mediated by abnormal antibodies (Guillain-Barré syndrome, cryoglobulinaemia, myasthenia gravis, Goodpasture syndrome, etc.) in which antibody removal appears desirable. Its role in the treatment of sepsis remains uncertain.[33]

BLOOD PURIFICATION TECHNOLOGY OUTSIDE OF ACUTE KIDNEY INJURY

There is growing interest in the possibility that blood purification may provide a clinically significant benefit in patients with severe sepsis/septic shock by removing circulating 'mediators'. A variety of techniques, including plasmapheresis, high-volume HF, very-high volume HF, coupled plasma filtration adsorption and large pore HF are being studied in animals and in phase I/II studies in humans.[34–36] Initial experiments supported the need to continue exploring this therapeutic option. However, a recent multicentre, randomised, controlled trial of high volume haemofiltration in septic shock failed to show any benefit.[37] Also, albumin-based dialysis has been developed

Table 48.1 Drug dosage during dialytic therapy

DRUG	CRRT	IHD
Aminoglycosides	Normal dose q. 36 h	50% normal dose q. 48 h–2/3 re-dose after IHD
Cefotaxime or ceftazidime	1 g q. 8–12 h	1 g q. 12–24 h after IHD
Imipenem	500 mg q. 8 h	250 mg q. 8 h and after IHD
Meropenem	500 mg q. 8 h	250 mg q. 8 h and after IHD
Metronidazole	500 mg q. 8 h	250 mg q. 8 h and after IHD
Co-trimoxazole	Normal dose q. 18 h	Normal dose q. 24 h after IHD
Amoxycillin	500 mg q. 8 h	500 mg daily and after IHD
Vancomycin	1 g q. 24 h	1 g q. 96–120 h
Piperacillin	3–4 g q. 6 h	3–4 g q. 8 h and after IHD
Ticarcillin	1–2 g q. 8 h	1–2 g q. 12 h and after IHD
Ciprofloxacin	200 mg q. 12 h	200 mg q. 24 h and after IHD
Fluconazole	200 mg q. 24 h	200 mg q. 48 h and after IHD
Acyclovir	3.5 mg/kg q. 24 h	2.5 mg/kg/d and after IHD
Gancyclovir	5 mg/kg/d	5 mg/kg/48 h and after IHD
Amphotericin B	Normal dose	Normal dose
Liposomal amphotericin	Normal dose	Normal dose
Ceftriaxone	Normal dose	Normal dose
Erythomycin	Normal dose	Normal dose
Milrinone	Titrate to effect	Titrate to effect
Amrinone	Titrate to effect	Titrate to effect
Catecholamines	Titrate to effect	Titrate to effect
Ampicillin	500 mg q. 8 hourly	500 mg daily and after IHD

The above values represent approximations and should be used as a general guide only. Critically ill patients have markedly abnormal volumes of distribution for these agents, which will affect dosage. CRRT is conducted at variable levels of intensity in different units also requiring adjustment. The values reported here relate to CVVH at 2 L/h of ultrafiltration. Vancomycin is poorly removed by CVVHD. IHD may also differ from unit to unit. The values reported here relate to standard IHD with low-flux membranes for 3–4 hours every second day.
CRRT, Continuous renal replacement therapy; *d*, day; *h*, hours; *IHD*, intermittent haemodialysis; *q,* frequency.

to deal with protein-bound toxins in patients with liver failure. This system – known as MARS (molecular adsorption re-circulating system) – has shown benefits in patients' elevated intracranial pressure and/or acute or chronic liver failure, but not in patients with fulminant liver failure.[38] More recently, new techniques based on advanced sorbents with high adsorption capabilities for cytokines have been developed and are being used in small studies with promising biological effect.[39]

DRUG PRESCRIPTION DURING DIALYTIC THERAPY

Acute renal failure and RRT profoundly affect drug clearance. A comprehensive description of changes in drug dosage according to the technique of RRT, residual creatinine clearance, and other determinants of pharmacodynamics is beyond the scope of this chapter and can be found in specialist texts.[40] Table 48.1 provides general guidelines for the prescription of drugs commonly used in the ICU.

AREAS OF ONGOING CONTROVERSY AND CLINICAL RESEARCH

In the area of RRT, the area of greater controversy and clinical research priority relates to the timing of the initiation of such RRT.[41]

This issue has been recently addressed by two important trials.[42,43] Unfortunately, these two studies (one from France and the other from Germany) had

opposing findings, leaving the issue unresolved. Accordingly, a definitive, very large (>2000 patients) international, randomised, controlled trial has just started and will be randomising patients over the next 3–4 years.[44] Its findings will likely shape RRT practice in the next decade, much as the ATN[26] and RENAL[27] trials have done over the last decade.

SUMMARY

The field of RRT has undergone remarkable changes over the last 10 years and is continuing to evolve rapidly. Technology is being improved to facilitate the clinical application, and new areas of research are developing. CRRT is now firmly established throughout the world as perhaps the most commonly used form of RRT. However, conventional dialysis, which was slowly losing ground, is reappearing in the form of extended, slow-efficiency treatment, especially in the United States. Two large phase III trials (>1000 patients) have been completed in the United States and in Australia and New Zealand to define the optimal dose of RRT in ICU patients; the results indicate that a dose of 25 mL/kg/h of effluent generation provides appropriate therapy in this setting. In the meantime, the use of novel membranes, sorbents and different intensities of treatment are being explored in the area of sepsis management and liver support.

Disorders of consciousness

Hayden White, Balasubramanian Ventakesh

NEUROANATOMY AND PHYSIOLOGY OF WAKEFULNESS

A normal level of consciousness depends on the interaction between the cerebral hemispheres and the rostral reticular activating system (RAS) located in the upper brainstem. Although the RAS is a diffuse projection, the areas of RAS of particular importance to the maintenance of consciousness are those located between the rostral pons and the diencephalon. In contrast, however, consciousness is not focally represented in any of the cerebral hemispheres and is in many ways related to the mass of functioning cortex. Thus anatomical bilateral hemispheric lesions or brain stem lesions may result in an altered conscious state.[1] Large unilateral hemispheric lesions may produce impairment of consciousness by compression of the upper brainstem. In addition, metabolic processes may result in coma from the interruption of energy substrate delivery or alteration of neuronal excitability. Disorders of consciousness are characterised either by an alteration in the level or content of consciousness (Box 49.1). **These are also illustrated in Fig. 49.1.**[2]

The last three conditions described in Box 49.1 are a frequent source of confusion and require further discussion (Table 49.1). These neurological states are seen more frequently in modern day clinical practice, partly because of the advances in therapy of severe brain injury and in intensive care, which have led to the survival of many patients who would have otherwise died.

DIFFERENTIAL DIAGNOSIS OF COMA

Although the aetiology of coma is invariably multifactorial, the differential diagnosis of coma can be broadly grouped into three classes:

1. Diseases that produce focal or lateralising signs
2. Coma without focal or lateralising signs, but with signs of meningeal irritation
3. Coma without focal or lateralising signs or signs of meningeal irritation.

These are considered in greater detail in Table 49.2.

CLINICAL EXAMINATION OF THE COMATOSE PATIENT

The neurological examination of the comatose patient is of crucial importance to assess the depth of the coma and to locate the site of the lesion. Although the detailed neurological examination, which can be carried out in a conscious patient, is not possible in a comatose individual, useful information can be obtained by performing a thorough general examination and a neurological examination, particularly evaluating the level of consciousness, brainstem signs and motor responses in coma.

GENERAL EXAMINATION

General examination of the patient may point to the aetiology of coma. Skin changes may be seen in carbon monoxide poisoning (cherry red discolouration of skin), alcoholic liver disease (telangiectasia, clubbing), hypothyroidism (puffy facies) and hypopituitarism (sallow complexion). The presence of cutaneous petechiae or ecchymoses may point to meningococcemia, rickettsial infection or endocarditis as possible causes of coma. Needle puncture marks may suggest substance abuse. Bullous skin lesions are a feature of barbiturate overdose. An excessively dry skin may indicate diabetic ketoacidosis or anticholinergic overdose.

Periorbital haematomas (raccoon eyes) indicate an anterior basal skull fracture, particularly if there is associated cerebrospinal fluid rhinorrhoea. The other signs of a basal skull fracture include Battle's sign and cerebrospinal fluid otorrhoea. Nuchal rigidity may be seen in meningoencephalitis and subarachnoid haemorrhage (SAH), although this sign may not be present in the elderly and in patients in a deep coma.

The presence of hepatomegaly or stigmata of chronic liver disease may suggest hepatic encephalopathy. Bilateral enlarged kidneys may indicate polycystic kidney disease and should prompt one to consider SAH as a possible aetiology of coma. The breath may smell of alcohol or other poisons (organophosphates). The smell of ketones in the breath is an unreliable sign and hepatic and uraemic foetor are rare.

ABSTRACT

An altered level of consciousness is a common finding in the intensive care unit (ICU) population. Although often induced by clinicians to facilitate patient management, cerebral functioning is altered by a number of disease processes commonly found in the ICU, both brain specific (e.g. acute brain injury), or as a consequence of systemic disease (e.g. sepsis-induced encephalopathy). While significant progress has been made in understanding the impact of disease on the brain, many questions still remain. What is clear is that altered cerebral function has a significant impact on morbidity and mortality. This is evidenced by the poor outcomes demonstrated in patients suffering from delirium in the ICU, and has led to a number of attempts to increase clinician awareness of the impact of ICU management on the brain, and investigate more 'brain friendly' treatment options. It is hoped that as technology advances, monitoring of cerebral function will improve and lead to a better understanding of cerebral dysfunction in the ICU environment.

Box 49.1 Disorders of consciousness

Consciousness	An awake individual demonstrates full awareness of self and environment
Confusion	Inability to think with customary speed and clarity, associated with inattentiveness, reduced awareness and disorientation
Delirium	Confusion with agitation and hallucination
Stupor	Unresponsiveness with arousal only by deep and repeated stimuli
Coma	Unarousable unresponsiveness
Locked-in syndrome	Total paralysis below third cranial nerve nuclei; normal or impaired mental function
Persistent vegetative state	Prolonged coma >1 month, some preservation of brainstem and motor reflexes
Akinetic mutism	Prolonged coma with apparent alertness and flaccid motor tone
Minimally conscious state	Preserved wakefulness, awareness and brainstem reflexes, but poorly responsive

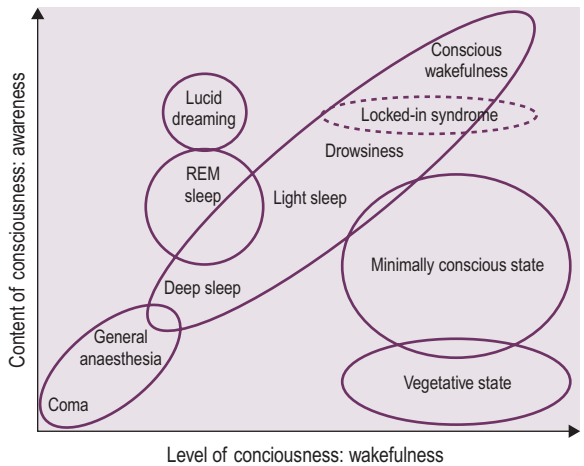

Figure 49.1 Disorders of consciousness are characterised by an alteration in either the level or content of consciousness. *REM*, Rapid eye movements. *With permission from Gosseries O, Vanhaudenhuyse A, Bruno MA, et al. Disorders of consciousness: coma, vegetative and minimally conscious states. In: Cvetkovic D, Cosic I, eds.* States of Consciousness: Experimental Insights into Meditation, Waking, Sleep and Dreams. *Berlin: Springer; 2011.*

LEVEL OF CONSCIOUSNESS

This is assessed by the Glasgow Coma Scale (GCS), which takes into account the patient's response to command and physical stimuli. The GCS (Box 49.2), which was originally developed to grade the severity of head injury and prognosticate outcome, has now been extended for all causes of impaired consciousness and coma. Whilst it is a simple clinical score easily performed by both medical and nursing staff by the bedside, there are a number of caveats:

Box 49.2 Glasgow coma scale

EYE OPENING	POINTS
Spontaneous	4
To speech	3
To pain	2
Nil	1
BEST VERBAL RESPONSE	
Oriented	5
Confused	4
Inappropriate	3
Incomprehensible	2
Nil	1
Intubated	T
BEST MOTOR RESPONSE	
Obeys commands	6
Localises to pain	5
Withdraws to pain	4
Abnormal flexion	3
Extensor response	2
Nil	1

1. The GCS should always be determined prior to administration of sedative drugs or endotracheal intubation
2. It should also be defined with regard to patient's vital signs, namely blood pressure, heart rate and temperature
3. The GCS must be interpreted in light of previous or concomitant drug therapy
4. The presence of alcohol in the breath or in the serum should always be documented
5. Because of the considerable interobserver variation in scoring, it is important to define the responses in descriptive terms rather than emphasising the numerical score associated with each response
6. The measurement of awareness by the GCS is limited. Subtle changes in brainstem reflexes are not adequately assessed by the GCS.

To overcome the limitations of the GCS in assessing brainstem activity, the FOUR (Full Outline of UnResponsiveness) score was proposed by Wijdicks et al.[8,9] The components of the FOUR score include eye movements, motor score, brainstem reflexes and respiration.

Table 49.1 Coma-like syndromes and related states

SYNDROME	FEATURES	SITE OF LESION	EEG	METABOLISM (% OF NORMAL)[3]	COMMENTS
Locked-in syndrome[4] (de-efferented state)	Alert and aware, vertical eye movements present, and able to blink. Quadriplegic, lower cranial nerve palsies, no speech, facial or pharyngeal movements	Bilateral anterior pontine lesion which transects all descending motor pathways, but spares ascending sensory and RAS systems	Normal	90%–100%	Similar state seen with severe polyneuropathies, myasthenia gravis and neuromuscular blocking agents
Persistent vegetative state (PVS)[5] (apallic syndrome, neo-cortical death)	Previously comatose, who now appear to be awake. Spontaneous limb movements, eye movements and yawning seen. However, patient inattentive, no speech, no awareness of environment and total inability to respond to commands	Extensive damage to both cerebral hemispheres with relative preservation of the brainstem	Polymorphic delta or theta waves, sometimes alpha	40%–60%	When vegetative state lasts longer than 4 weeks, it is termed persistent. PVS lasting for longer than 2 weeks implies a poor prognosis
Akinetic mutism[6] (coma vigile)	Partially or fully awake patient, immobile and silent	Lesion in bilateral frontal lobes or hydrocephalus or third ventricular masses	Diffuse slowing	40%–80%	Abulia is the term applied to milder forms of akinetic mutism
Catatonia	Awake patients, sometimes a fixed posture, muteness with decreased motor activity	Usually of psychiatric origin	Non-specific EEG patterns associated with associated medical conditions	Variable metabolic changes in prefrontal cortex	May be mimicked by frontal lobe disease and drugs
Minimally conscious state[7]	Globally impaired responsiveness, limited but discernible evidence of self and environment	Global neuronal damage	Theta & alpha waves	40%–60%	Differs from PVS in that patients diagnosed with minimally conscious state have some level of awareness

EEG, Electroencephalography; *RAS*, reticular-activating system.

Each subcomponent is scored out of a maximum of four and therefore the maximum score is 16. It does not include verbal response and may be more suitable in the intubated patient.

PUPILLARY RESPONSES IN COMA

The presence of normal pupils (2–5 mm and equal in size and demonstrate both direct and consensual light reflexes) confirms the integrity of the pupillary pathway (retina, optic nerve, optic chiasma and tracts, midbrain and third cranial nerve nuclei and nerves).[10]

The size of the pupil is a balance between the opposing influences of both sympathetic (causing dilatation) and parasympathetic (causing constriction) systems. Pupillary abnormalities have localising and diagnostic value in clinical neurology (Table 49.3). When the pupils are miosed, the light reaction is difficult to appreciate and may require a magnifying glass.

OPHTHALMOSCOPY IN COMA

The pupils *should never be dilated pharmacologically* without prior documentation of the pupillary size and

Table 49.2 Differential diagnosis of coma

CATEGORY	SPECIFIC DISORDER	FEATURES IN HISTORY AND EXAMINATION	INVESTIGATIONS	COMMENTS
COMA WITH FOCAL SIGNS	*Trauma* – extradural, subdural and parenchymal haemorrhage, concussions	History of trauma, findings of fracture base of skull, scalp haematoma, other associated body injuries	Usually an abnormal CT	Exclude coexisting drug or alcohol ingestion
	Vascular – Intracerebral haemorrhage	Sudden onset, history of headaches or hypertension, neck stiffness may be present	Abnormal CT scan	Consider causes of secondary hypertension in young hypertensives
	Vascular – thromboembolic	Sudden onset, atrial fibrillation, vascular bruits, endocarditis	An abnormal CT after a few days	Consider echocardiography to diagnose cardiac sources of emboli
	Brain abscess	Subacute onset, look for ENT and dental sources of infection	Abnormal CT and CSF	Consider infective endocarditis and suppurative lung disease as sources of sepsis
Coma without focal signs, but with meningeal irritation	Infection Meningitis, encephalitis	Onset of illness over a few hours to days, neck stiffness, rash of meningococcemia	Abnormal CSF	Consider underlying immunosuppressive states
	Subarachnoid haemorrhage	Onset usually sudden, subhyaloid haemorrhages on fundoscopy	Abnormal CT and CSF	Consider polycystic kidney disease in subarachnoid haemorrhage
Coma without focal signs and no meningeal irritation	Metabolic causes Hyponatraemia Hypoglycaemia, hyperglycaemia Hypoxia Hypercapnia Hypo- and hyperthermia Hyper- and hypo-osmolar states	History might point to the cause of metabolic disturbance, asterixis a feature of hypercapnia-induced coma	Abnormal blood results	Rapid correction of hyponatraemia and osmolality should be avoided
	Endocrine causes Myxoedema Adrenal insufficiency Hypopituitarism	Puffy facies, may be hypothermic	Abnormal electrolyte profile, hypoglycaemia	Multiple disorders may be present in the same patient
	Seizure disorders	History typical	Abnormal EEG, check anticonvulsant levels	CT scan to exclude an underlying space occupying lesion
	Organ failure Hepatic Renal	History of jaundice, chronic alcohol ingestion, stigmata of liver disease, asterixis	Abnormal hepatic and renal functions	Presence of A-V fistula may be a pointer to chronic renal failure
	Toxic/drug Sedatives Narcotics Alcohol Psychotropic Carbon monoxide Poisons	History, may be hypothermic at presentation except in psychotropic drug overdose	Metabolic screen is usually normal	Rapid improvement in conscious states with antidotes
	Behavioural Sleep deprivation Pseudocoma	No typical features	No specific diagnostic tests	Diagnosis of exclusion

A-V, Arteriovenous; *CSF*, cerebrospinal fluid; *CT*, computed tomography; *EEG*, electroencephalography; *ENT*, ear, nose and throat.

Table 49.3 Pupillary abnormalities in coma

ABNORMALITY	CAUSE	NEUROANATOMICAL BASIS
MIOSIS (<2 MM IN SIZE)		
Unilateral	Horner's syndrome	Sympathetic paralysis
	Local pathology	Trauma to sympathetics
Bilateral	Pontine lesions	
	Thalamic haemorrhage	Sympathetic paralysis
	Metabolic encephalopathy	
	Drug ingestion	
	Organophosphate	Cholinesterase inhibition
	Barbiturate	
	Narcotics	Central effect
MYDRIASIS (>5 MM IN SIZE)		
Unilateral fixed pupil	Midbrain lesion	Third nerve damage
	Uncal herniation	Stretch of third nerve against the petroclinoid ligament
Bilateral fixed pupils	Massive midbrain haemorrhage	Bilateral third nerve damage
	Hypoxic cerebral injury	Mesencephalic damage
	DRUGS	
	Atropine	Paralysis of parasympathetics
	Tricyclics	Prevent local reuptake of catecholamines by nerve endings
	Sympathomimetics	Stimulation of sympathetics

the light reflex. The presence of papilloedema suggests the presence of intracranial hypertension, but is frequently absent, when the lesion is acute. Subhyaloid and vitreous haemorrhages are seen in patients with SAH.[11]

EYE MOVEMENTS IN COMA[12]

Horizontal eye movements to the contralateral side are initiated in the ipsilateral frontal lobe and are closely coordinated with the corresponding centre in the contralateral pons. To facilitate conjugate eye movements, yoking of the third, fourth and sixth nerve nuclei is achieved by the medial longitudinal fasciculus.

To look to the left, the movement originates in the right frontal lobe and is coordinated by the left pontine region and vice versa. In contrast to horizontal gaze, vertical eye movements are under bilateral control of the cortex and upper midbrain.

The position and movements of the eyes are observed at rest. The presence of spontaneous roving eye movements excludes brainstem pathology as a cause of coma. In a paralytic frontal lobe pathology, the eyes will deviate towards the side of the lesion, while in pontine pathologies, the eyes will deviate away from the side of the lesion. Ocular bobbing, an intermittent downward jerking eye movement, is seen in pontine lesions due to loss of horizontal gaze and unopposed midbrain controlled vertical gaze activity.[13] Skew deviation (vertical separation of the ocular axes) occurs with pontine and cerebellar disorders.[14]

The presence of full and conjugate eye movements in response to oculocephalic and oculovestibular stimuli demonstrates the functional integrity of a large segment of the brainstem. Corneal reflexes are preserved until late in the coma. Upward rolling of the eyes after corneal stimulation (Bell's phenomenon) implies intact midbrain and pontine function.

LIMB MOVEMENTS AND POSTURAL CHANGES IN COMA

Restlessness, crossing of legs and spontaneous coughing, yawning, swallowing and localising movements suggest only a mild depression of the conscious state. Choreoathetotic or ballistic movements suggest a basal ganglion lesion. Myoclonic movements indicate a metabolic disorder usually of post anoxic origin. Asterixis is seen with metabolic encephalopathies. Hiccup is a non-specific sign and does not have any localising value.

Decerebrate rigidity is characterised by stiff extension of the limbs, internal rotation of the arms and plantar flexion of the ankles. With severe rigidity, opisthotonos and jaw clenching may be observed. These movements may be unilateral or bilateral, and spontaneous or in response to a noxious stimulus. Whilst animal studies suggest that the lesion is usually in the midbrain or caudal diencephalon (leading to exaggeration of antigravity reflexes), in humans such posturing may be seen in a variety of disease states: midbrain lesion, certain metabolic disorders (e.g. hypoglycaemia, anoxia, hepatic coma) and in drug intoxication.

Box 49.3 Disorders of respiratory rate and pattern in coma

ABNORMALITY	SIGNIFICANCE
Bradypnoea	Drug-induced coma, hypothyroid coma
Tachypnoea	Central neurogenic hyperventilation (midbrain lesion), metabolic encephalopathy
Cheyne Stokes respiration	Deep cerebral lesions, metabolic encephalopathy (hyperpnoea alternating regularly with apnoea)
Apneustic breathing (an inspiratory pause)	Pontine lesions
Ataxic breathing (ataxic breathing normally progresses to agonal gasps and terminal apnoea)	Medullary lesions

Decorticate posturing is characterised by the flexion of the elbows and wrists and extension of the lower limbs. The lesion is usually above the midbrain in the cerebral white matter.

RESPIRATORY SYSTEM[15]

Abnormal respiratory rate and patterns have been described in coma, but their precise localising value is uncertain. As a general rule, at lighter levels of impaired consciousness tachypnoea predominates, while respiratory depression increases with the depth of coma. Some of the commonly observed respiratory abnormalities are summarised in Box 49.3. Respiratory failure in comatose patients may result from hypoventilation, aspiration pneumonia and neurogenic pulmonary oedema, a sympathetic nervous-system-mediated syndrome seen in acute brain injury.

BODY TEMPERATURE IN COMA

The presence of altered core body temperature is a useful aid in the diagnosis of coma. Hypothermia (<35°C) is frequently observed with alcohol or barbiturate intoxication, sepsis with shock, drowning, hypoglycaemia, myxoedema coma and exposure to cold. Severe hyperthermia may be seen in pontine haemorrhage, intracranial infections, heat stroke and anticholinergic drug toxicity.

RECOGNITION OF BRAIN HERNIATION[16–18]

When patients with an impaired level of consciousness deteriorate, it is important to consider brain herniation as a possible cause of worsening. Several herniation syndromes have been described. Subfalcine herniation usually results from the lateral displacement of the brain and is identified by the horizontal shift of the pineal gland. Ischaemia of the medial aspect of the cerebral hemispheres can result from compression of the pericallosal and the marginal arteries. Transtentorial herniation results from the downward displacement of the upper brainstem (central herniation) with or without involvement of the uncus (lateral herniation). The clinical signs of a central herniation are progressive obtundation, Cheyne-Stokes respiration, small pupils followed by extensor posturing and medium-sized fixed dilated pupils. Uncal herniation differs from central herniation in that pupillary dilatation occurs early in the process because of third nerve compression. The traditional Cushing's response of hypertension and bradycardia is not always a feature of herniation and any heart rhythm may be present. Tonsillar herniation is the protrusion of the cerebellar tonsils through the foramen magnum resulting in caudal medullary compression and obstruction of the fourth ventricle.

DIFFERENTIATING TRUE COMA FROM PSEUDOCOMA

Patients feigning coma resist passive eye opening and may even hold their eyes tightly closed. They may blink in response to a threat and do not demonstrate spontaneous roving eye movements. In contrast, they move the eyes concomitantly with head rotation; with cold caloric testing, they may wake up or demonstrate preservation of the fast component of nystagmus. They also demonstrate avoidance of 'self-injury'. In addition, the pattern of clinical 'abnormalities' does not fit any specific neurological syndromes.

MANAGEMENT OF THE COMATOSE PATIENT

EMERGENT THERAPEUTIC MEASURES

Irrespective of the aetiology of coma, certain emergent therapeutic measures apply to the care of all patients. These take precedence over any diagnostic investigation.

1. Ensuring adequate airway and oxygenation
2. Securing intravenous access and maintain circulation
3. Administering 50% dextrose after drawing a sample of blood for serum glucose levels. Although there are theoretical concerns about augmentation of brain lactic acid production[19,20] in anoxic coma, the relatively good prognosis for hypoglycaemic coma when treated expeditiously far outweigh any potential risks of glucose administration

4. Thiamine must always be administered in conjunction with dextrose to prevent precipitation of Wernicke's encephalopathy
5. Consideration should be given to administering naloxone, when there is a suspicion of narcotic overdose with impending respiratory arrest
6. If hypertension, bradycardia and fixed dilated pupils are present at the time of the initial presentation, suggestive of marked intracranial hypertension and tentorial herniation, 20% mannitol at a dose 0.5–1 g/kg body weight should be administered. Consideration should be given to the emergency placement of an external ventricular drain
7. Treat suspected meningitis with antibiotics even if cerebrospinal fluid results are not available. A combination of penicillin and ceftriaxone is usually recommended for a community-acquired bacterial meningitis
8. Control of seizures must be achieved as outlined in the chapter on Status Epilepticus
9. Treat extreme body temperatures
10. Stabilisation of the cervical spine if trauma is suspected.

INVESTIGATIONS

The order of investigation depends on the clinical circumstance. In the majority of cases, history and examination will provide enough information to be able to perform specific cause-related investigation. In general, the investigations can be grouped as follows.

ROUTINE INVESTIGATIONS

Measurements of serum glucose, electrolytes, arterial blood gases, liver and renal function tests, osmolality, blood count and blood film are part of the routine investigations. When drug overdose is suspected, a toxicology screen for alcohol, paracetamol, salicylates, benzodiazepines and tricyclic antidepressants should be performed. A sample of serum should be stored for later analysis for uncommon drug ingestions.

NEUROIMAGING

COMPUTED TOMOGRAPHY SCAN

The most commonly used radiological investigation for evaluation of the comatose patient is computed tomography (CT) scan of the brain. This is useful for diagnosing central nervous system (CNS) trauma, SAH and intracerebral haemorrhage, haemorrhagic and non-haemorrhagic strokes, cerebral oedema, hydrocephalus and the presence of space-occupying lesion (SOL). Frequently, a CT is performed prior to a lumbar puncture (LP) to exclude rather than confirm the presence of severe cerebral oedema or a SOL. Its other advantages include lower cost, easy availability, short examination time and safety in the presence of pacemakers, surgical clips and other ferromagnetic substances. The advent of helical CT whereby multiple images are possible has reduced scanning times and is suitable for the uncooperative patient. The limitations of a CT scan include:

1. the need to transfer the patient to a site where resuscitation and monitoring facilities are limited
2. the need to sedate and possibly endotracheally intubate patients who are agitated
3. its low sensitivity to demonstrate an abnormality in the acute phase of a stroke
4. its low sensitivity for detecting brainstem lesions
5. the need to administer intravenous (IV) contrast agents. The two major side effects of IV contrast include anaphylaxis (with an approximate death rate of 1 in 40,000) and renal failure. The use of N-acetylcysteine, sodium bicarbonate and haemodialysis has been reported to reduce the incidence of contrast-induced nephropathy, although data in critically ill patients are minimal).[21]

MAGNETIC RESONANCE IMAGING

Magnetic resonance imaging (MRI) scans provide superior contrast and resolution of the grey and white matter compared to CT scans, thus facilitating easy identification of the deep nuclear structures within the brain. MRI is more sensitive than CT for the detection of acute ischaemia, diffuse axonal injury and cerebral oedema, tumour and abscess. Brainstem and posterior fossa structures are better visualised. The other advantage of MRI is the use of non-ionising energy. The use of gadolinium, a paramagnetic agent as a contrast agent, permits sharp definition of lesions. Magnetic resonance coupled with angiography may enable the diagnosis of vascular lesions. However, MRI is limited by:

1. the need for special equipment
2. long imaging times
3. the need to transfer the patient to a site where resuscitation and monitoring facilities are limited
4. the need to sedate and possibly endotracheally intubate patients who are agitated
5. the risk of dislodgement of metal clips on blood vessels and the resetting of pacemakers.

POSITRON EMISSION TOMOGRAPHY AND SINGLE PHOTON EMISSION WITH COMPUTERISED TOMOGRAPHY SCANS

Newer nuclear medicine scans such as SPECT (single photon emission with computerised tomography) and PET (positron emission tomography) are useful for the assessment of cerebral blood flow and oxygenation and in the prognostication of neurotrauma, but have little role to play in the management of acute disorders of consciousness. In PET scans, positron emitting isotopes, such as ^{11}C, ^{18}F and ^{15}O, are incorporated into biologically active compounds, such as deoxyglucose or fluorodeoxyglucose, which are metabolised in the

body. By determining the concentration of the various tracers in the brain and constructing tomographic images, cerebral blood flow and metabolism can be measured by PET scanning.

SPECT scans use iodine containing isotopes incorporated into biologically active compounds and, like PET scans, their cranial distribution is determined after a dose of tracer. Information on cerebral blood flow and metabolism can be obtained from SPECT scans. The advantage of a PET scan is that it does not require a cyclotron for the generation of isotopes. Despite their many advantages, both these technologies continue to be research tools and are not routinely available in many medical centres.

OPTIC NERVE DIAMETER[22]

While the gold standard for detecting changes in intracranial pressure (ICP) involves the intracranial placement of a catheter, a non-invasive technique has emerged that may allow emergency non-invasive detection of intracranial hypertension. This involves the bedside measurement of optic nerve sheath diameter (ONSD) using ultrasonography. Various measures have been described. One technique is using a 7 MHz probe to measure the ONSD at 3 mm behind the optic nerve head. A recent study comparing ONSD with ICP demonstrated that the ONSD value of 5.205 mm was 95.8% sensitive and 80.4% specific in detecting raised ICP. An ONSD of 5.47 mm in the traumatic group yielded 94.4% sensitivity and 95.2% specificity. This information may help augment management of the comatose patient especially in regions where invasive ICP monitoring is not available.

TRANSCRANIAL DOPPLER[23]

Transcranial Doppler (TCD) is a non-invasive technique that can be used for both diagnostic and management purposes in the comatose patient. The technique involves using a 2 MHz probe to determine intracranial blood velocities and flow patterns via a number of 'cranial windows'. The commonest employed is the trans-temporal window where it may be possible to view the entire circle of Willis. By combining the flow velocities with certain indices it may be possible to detect a variety of pathological processes, including raised intracranial pressure, cerebral vasospasm, loss of cerebral autoregulation, cerebral embolism etc. Furthermore, TCD can be invaluable in detecting cerebral circulatory arrest in patients suspected of brain death. Although this cannot be used legally to determine brain death, it may direct the timing of further investigations, such as cerebral angiography.

LUMBAR PUNCTURE[24]

Cerebrospinal fluid is most commonly obtained by means of a LP. This should be performed after ensuring that raised ICP has been excluded clinically or radiologically. The major use of an LP is to diagnose an intracranial infection and to detect abnormal cytology in cases of suspected malignant meningeal infiltration. The advent of CT scans has diminished the role of LP in the diagnosis of SAH. Some of the commonly reported complications post-LP include post-puncture headache (12%–39%) and traumatic tap (15%–20%). Brain herniation is a rare potential complication seen with conditions associated with raised ICP due to an SOL.

Box 49.4 Usefulness of electroencephalography in coma

Identification of non-convulsive status epilepticus
Diagnosis of hepatic encephalopathy
- presence of paroxysmal triphasic waves

Assessing severity of hypoxic encephalopathy
- presence of theta activity
- diffuse slowing
- burst suppression (seen with more severe forms)
- alpha coma (seen with more severe forms)

Herpes encephalitis
- periodic sharp spikes

Monitoring of therapy (e.g. thiopentone infusion for status epilepticus)

ELECTROENCEPHALOGRAPHY IN COMA[25–27]

The usefulness of electroencephalography (EEG) in coma is summarised in Box 49.4. Continuous EEG monitoring in the ICU has been reported to be useful in the identification of acute cerebral ischaemia and non-convulsive seizures, and for monitoring therapy used in an induced coma, such as thiopentone infusion for refractory status, and to assess level of sedation.

EVOKED POTENTIALS

Visual, brainstem and somatosensory evoked potentials test the integrity of neuroanatomical pathways within the brain and the spinal cord. They may be used in the diagnosis of blindness in comatose patients and in the assessment of locked-in states. There are data to suggest that they have better prognostic value than clinical judgement in patients with anoxic coma.[28,29]

BIOCHEMICAL ABNORMALITIES[30–33]

A number of biomarkers of brain injury have been evaluated as predictors of the severity of the brain injury and to assess the progression of injury severity from traumatic and non-traumatic aetiologies. These include

neuron-specific enolase (cytoplasm of neurons), S-100B protein (astroglial cells), CK-BB fraction (astrocytes), glial fibrillary acidic protein (glial origin) calpain and caspase. Whilst early studies showed S-100B as a reliable marker of traumatic brain injury, concerns remain about their sensitivity and specificity for the assessment of severity and prediction of outcome.

CARE OF THE COMATOSE PATIENT

AIRWAY

As mentioned before, assessment of airway adequacy should take precedence over any diagnostic investigation in comatose patients. This is best done by assessing the patient's response to command and physical stimulation, and whether a gag reflex is present. Securing the airway will depend on the level of consciousness. This may entail simple manoeuvres, such as jaw thrust, chin lift, the use of oropharyngeal airways or – in the comatose patient – mandate endotracheal intubation. All of these patients are at risk of pulmonary aspiration and there must be a low threshold for establishing a definitive airway.

As a general rule, patients presenting with medical causes of coma may be nursed on their side (coma position, if the airway is adequate). However, all traumatised patients should be assumed to have a potential cervical spine injury and must be nursed with the cervical spine in the neutral position and/or with a rigid collar until an injury is excluded by definitive radiological views. All patients with disordered consciousness must receive supplemental oxygen.

VENTILATION

It is important to ensure optimal gas exchange and avoid hypoxia and hypercapnia. Generally a Pa_{O_2} of >10 kPa and P_{CO_2} of 4.7–5.3 kPa is desirable. If spontaneous ventilatory efforts are not adequate to achieve these levels of arterial blood gases, mechanical ventilatory support may be necessary.

CIRCULATION

Adequacy of circulation should be assessed by conventional clinical endpoints. The goals of circulatory therapy in coma include prompt restoration of appropriate mean arterial blood pressure, correction of dehydration and hypovolaemia, and urgent attention to life-threatening causes of shock.

SPECIFIC TREATMENT

This will depend on the underlying aetiology of the coma and is discussed in the relevant chapters. Avoidance of secondary insults is of paramount importance in the management of these patients.[34,35]

NURSING CARE

Meticulous eye and mouth care, regular changes in limb position, limb physiotherapy, bronchial toilet and psychological support are mandatory. Nosocomial infections and iatrogenic complications are associated with an increased mortality and morbidity in these patients and must be promptly diagnosed and treated. The rational use of daily investigations, invasive procedures and antibiotic prescription is essential.

OTHER THERAPY

Stress ulcer and deep vein thrombosis prophylaxis should be instituted. Early establishment of enteral feeding via a nasoenteric tube is preferable. It is important to exclude a basal skull fracture before the insertion of a nasoenteric tube.

ANOXIC COMA/ENCEPHALOPATHY

Cardiac arrest is the third leading cause of coma resulting in ICU admission after trauma and drug overdose. The symptomatology and clinical outcome of patients with anoxic brain damage depend on the severity and duration of oxygen deprivation to the brain. A number of criteria have been developed to prognosticate outcome in anoxic coma. Although a number of laboratory and imaging criteria contribute to the prognostic assessment, clinical signs still have major prognostic impact. The important clinical predictors of outcome are listed in Box 49.5. However, there are data to suggest that electrophysiological studies using evoked potential have far greater prognostic accuracy compared to clinical assessment.[32] It is important to note that the clinical criteria of poor prognosis were developed in the pre-hypothermia era. The optimal time for prognostication following hypothermia is unclear.[37]

Targeted temperature management (TTM) has proven a game changer in managing patients post-cardiac arrest. Although there exists controversy over whether patients should be cooled to 33°C or 36°C, it is clear that TTM is now the standard of care. As such, there is now some evidence that the original criteria published in 2006 by the American Academy of Neurology, which predicted poor outcome following cardiac arrest, may be less applicable in the post-TTM era.[38] By 2010, a series of isolated reports questioned the usefulness of a number of clinical and laboratory criteria previously employed in predicting poor outcomes. Reports of patients surviving with good outcomes despite absent motor responses on day 3, neuron-specific enolase levels above 33 µg/L and absent N20 evoked potentials, to name a few.[39] Furthermore, since a landmark study in 1994, the presence of myoclonic status epilepticus post-cardiac arrest was universally considered to predict dismal outcome. Many patients

Box 49.5 Clinical and laboratory predictors of unfavourable prognosis in anoxic coma

CLINICAL PREDICTOR	UNFAVOURABLE PROGNOSIS
Duration of anoxia (time interval between collapse and initiation of CPR)	8–10 min
Duration of CPR (time interval between initiation of CPR and ROSC)	>30 min
Duration of postanoxic coma	>72 h
Pupillary reaction	Absent on day 3
Motor response to pain (absent = a motor response worse than withdrawal)	Absent on day 3
Roving spontaneous eye movements	Absent on day 1
Elevated neuron specific enolase	>33 mcg/L
SSEP recording	Absent N20

CPR, Cardiopulmonary resuscitation; *ROSC*, return of spontaneous circulation; *SSEP*, somatosensory evoked potentials.
See references 23, 27, 36.

were given do-not-resuscitate orders based on this finding. However, in 2015, Seder et al. published a retrospective review of 2532 cardiac arrest survivors, 88% of which underwent TTM, and 471 exhibited myoclonus.[40] A good outcome at hospital discharge was found in 9% of patients with myoclonus, although they tended to be younger with shorter ischemic time and more witnessed arrests. Better evidence is therefore required before firm criteria indicating poor neurological outcome can be developed.

In the absence of strong evidence, Sandroni et al. suggest using the most robust predictors of outcome following 72 hours of absent motor responses first.[41] These include bilaterally absent pupillary reflexes for greater than 72 hours from return of spontaneous circulation and bilaterally absent SSEP N20 wave after rewarming. This may be combined with absent corneal reflexes. The predictors have a false positive rate of less than 5% and 95% confidence interval of less than 5% in patients treated with controlled temperature. They suggested using a prognostication strategy as outlined in Fig. 49.2.

THE CONFUSED/ENCEPHALOPATHIC PATIENT IN THE INTENSIVE CARE UNIT

Encephalopathy is a term used to describe the alteration in the level or content of consciousness due to a process extrinsic to the brain. Metabolic encephalopathy, particularly of septic aetiology, is the most common cause of altered mental status in the ICU setting.[3,42] A number of processes can lead to metabolic encephalopathy (Box 49.6). A number of features in the history and examination help to differentiate metabolic from structural causes of altered conscious states (Table 49.4).

Box 49.6 Aetiology of metabolic/toxic encephalopathy

Hepatic failure
Renal failure
Respiratory failure
Sepsis
Electrolyte abnormalities: Hyponatraemia, hypernatraemia, hypercalcaemia
Hypoglycaemia and hyperglycaemia
Acute pancreatitis
Endocrine – Addisonian crisis, myxoedema coma, thyroid storm
Drug withdrawal – Benzodiazepine, opiates
Hyperthermia
Toxins: Alcohols, glycols, tricyclic antidepressants
ICU syndrome
D-Lactic Acidosis

ICU, Intensive care unit.
See references 43–45.

Owing to their increased frequency in and exclusiveness to the critical care setting, two types of encephalopathy will be considered in detail: septic encephalopathy and ICU syndrome.

Sepsis associated encephalopathy (SAE) has been reported to occur in 8%–80% of patients with sepsis.[46] The criteria to diagnose SAE include the presence of impaired mental function, evidence of an extracranial infection and absence of other obvious aetiologies for the altered conscious state. Although the precise mechanism of damage to the brain has not been delineated, the pathogenesis of the encephalopathy is thought to be multifactorial: alteration in cerebral blood flow induced by mediators of inflammation, generation of free radicals by activated leucocytes resulting in erythrocyte sludging in the microcirculation, breakdown of the blood–brain barrier resulting in cerebral oedema, reduced brain oxygen consumption induced by endotoxin and cytokines, neuronal degeneration and increased neuronal apoptosis, increases in aromatic amino acids resulting in altered neurotransmitter function and increased GABA-mediated neurotransmission leading to general inhibition of the CNS. Hypotension may contribute to the encephalopathy.[47,48] The asterixis, tremor and myoclonus – features of other metabolic encephalopathies – are uncommon in sepsis. The presence of lateralising signs is extremely rare in SAE and warrant exclusion of other causes, such a stroke. The mortality of patients with SAE is higher than in those

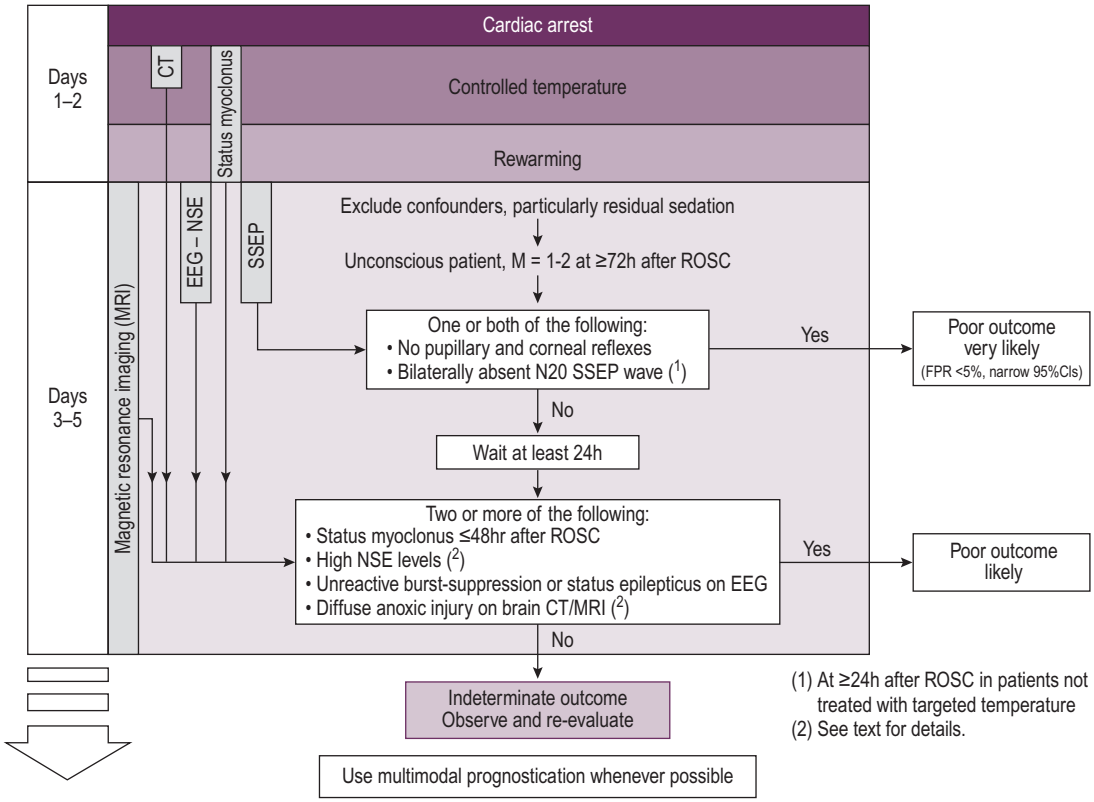

Figure 49.2 Suggested prognostication algorithm. The algorithm is entered ≥72 hours after ROSC if, after the exclusion of confounders (particularly residual sedation), the patient remains unconscious with a Glasgow Motor Score of 1 or 2. The absence of pupillary and corneal reflexes, and/or bilaterally absent N20 somatosensory evoked potentials (SSEP) wave indicates that a poor outcome is very likely. If neither of the features is present, wait at least 24 hours before reassessing. At this stage, two or more of the following indicate that a poor outcome is likely: status myoclonus ≤48 hours; high neuron-specific enolase values; unreactive EEG with burst suppression or status epilepticus; diffuse anoxic injury on brain CT and/or MRI. If none of these criteria is met, consider continuing to observe and re-evaluate. *CT*, Computed tomography; *EEG*, electroencephalography; *FPR*, false positive rate; *MRI*, magnetic resonance imaging; *NSE*, neuron specific enolase; *ROSC*, return of spontaneous circulation. *With permission from Sandroni C, Cariou A, Cavallaro F, et al. with sepsis without encephalopathy.[49] Therapy is largely directed at the underlying septic process.

INTENSIVE CARE UNIT ENCEPHALOPATHY OR INTENSIVE CARE UNIT SYNDROME[50,51]

This is a term used to describe behavioural disorders that develop in patients 5–7 days after admission to the ICU. Clinically, this may present as agitation, restlessness and frank delirium. The causes are multifactorial: prolonged ventilation sleep deprivation,[52,53] distortion of perception with loss of day–night cycles, immobilisation, noisy environment and monotony. These coupled with the administration of multiple sedatives and neurological consequences of the underlying disease can precipitate psychotic behaviour in the ICU. It is important to bear in mind that *this is a diagnosis of exclusion and that all other reversible causes are looked for (Table 49.4)* before this diagnostic label is applied. Tools to assess delirium, such as the CAM-ICU, have been developed and validated for the critical care setting.[54]

Abnormal behaviour can increase patient morbidity (self-extubation, ripping of catheters, soft tissue damage, etc.). Episodes of delirium in the ICU are also associated with increased mortality.[55] Postoperative delirium after cardiac surgery has also been associated with a significant decline in cognitive ability during the first year after cardiac surgery.[56] It is important to identify the underlying cause of the abnormal behaviour to institute appropriate therapy. Management of this condition may require the use of restraints, sedation

Table 49.4 Distinguishing features of structural and metabolic encephalopathy

FEATURE	STRUCTURAL	METABOLIC
State of consciousness	Usually fixed level of depressed conscious state, may deteriorate progressively	Milder alteration of conscious state, waxing and waning of altered sensorium
Fundoscopy	May be abnormal	Usually normal
Pupils	May be abnormal, either in size or response to light	Usually preserved light response (although pupil shape and reactivity affected in certain overdoses – see above)
Eye movements	May be affected	Usually preserved
Motor findings	Asymmetrical involvement	Abnormalities usually symmetrical
Involuntary movements	Not common	Asterixis, tremor, myoclonus frequently seen

Plum F. Sustained impairment of consciousness. In: Bennett C, ed. *Cecil Textbook of Medicine*. Philadelphia, PA: W.B. Saunders; 1996:1970–1978.

and major tranquilisers. Improvement of sleep quality (minimising interruption of nocturnal sleep, adjusting lighting in the ICU), reducing patient boredom by the use of television and music, and better communication with the patient may reduce the incidence and severity of this syndrome. Regular administration of haloperidol has not been shown to reduce the incidence of delirium coma.[57] However, dexmedetomidine has been advocated as an agent to minimise delirium in the critically ill patient.[58] More recent evidence suggests that the introduction of dexmedetomidine among patients with agitated delirium results in more ventilator-free hours at 7 days when compared with standard care.[59] Other evidence suggests that the introduction of ABCDE bundles may reduce delirium by up to 50%.[60] More work in this area is needed.

PROGNOSIS IN COMA

Drug-induced comas usually have a good prognosis unless hypoxia and hypotension have resulted in severe secondary insults. Coma following head injury has a statistically better outcome compared to non-traumatic coma (coma occurring during the course of a medical illness). In non-traumatic coma lasting for 6 hours or more, only 15% of the patients make a meaningful recovery to be able to return to their pre-morbid state of health.[61] The prognosis following anoxic coma has been described in a separate section. Within the non-traumatic coma category, coma resulting from infection, metabolic causes and multiple organ dysfunction syndrome have a better outcome compared to anoxic coma.[62] A number of outcome scales have been developed to assess neurological recovery following brain injury.[63] These include the Barthel index, Rankin scale and the Glasgow outcome scale (GOS). The GOS is widely used to assess recovery after traumatic brain injury. It has five broad categories: 1 = good recovery, 2 = moderate disability, 3 = severe disability, 4 = persistent vegetative state and 5 = death. It is simple, easy to administer and has been reported to have good inter-rater agreement.

TREATMENT OPTIONS IN DISORDERS OF CONSCIOUSNESS[64]

No effective standardised treatment exists for these patients. Currently, evaluated interventions can be divided into pharmacological and non-pharmacological measures. Pharmacological measures include the use of progesterone, levodopa and amantadine. Initial trials reported some recovery response in terms of reduction in spasticity and improved cognitive behaviour and communication, such as following simple commands. Giacino et al. found a significant improvement in the Disability Rating Scale following administration of amantadine in patients with traumatic brain injury who were in a vegetative or minimally conscious state.[65] However, the administration of progesterone was not associated with improved GOS following traumatic brain injury (TBI).[66,67] Zolpidem has also been trialled in patients with traumatic and anoxic aetiologies of reduced consciousness, and results have been variable. While some investigators report enhanced verbal, motor and cognitive functions, these have not been reproduced in other small trials. Moreover, the duration of the effects of zolpidem is short. Bromocriptine and intrathecal baclofen have also been tried, but no large-scale studies have been reported.

Non-pharmacological measures include deep brain stimulation, extradural cortical stimulation, spinal cord stimulation and median nerve stimulation. Thibaut et al. demonstrated that the application of left dorsolateral prefrontal cortex transcranial direct current stimulation transiently improved signs of consciousness in patients in a minimally conscious state, although the overall outcome did not change.[68] While reports of improved responsiveness have been published, the evidence is largely anecdotal, and data from large studies are lacking.

Status epilepticus

Helen I Opdam

STATUS EPILEPTICUS

Status epilepticus (SE) is a neurological emergency involving prolonged seizure activity that requires prompt intervention to prevent the development of irreversible brain damage.

DEFINITION AND CLASSIFICATION

SE is continuous or recurrent clinical and/or electrographic seizure activity that lasts more than 5 minutes. Seizures of this duration are unlikely to remit spontaneously and require urgent treatment.[1,2]

An international taskforce on the classification of SE emphasised two time points: (1) when treatment should be initiated; and (2) after which there is a risk of long-term consequences including neuronal death (5 and 30 minutes, respectively, for convulsive status epilepticus [CSE]).[3]

Refractory SE (RSE) is defined as persistent seizures resistant to first-line and second-line anticonvulsant therapy, usually necessitating general anaesthesia.[4,5] RSE develops in about one in five patients with SE and is associated with a worse prognosis.[6,7]

Continuation or recurrence of SE beyond 24 hours of anaesthetic therapy has been termed super RSE.[8]

SE may be classified according to clinical presentation, aetiology, electroencephalography (EEG) and age.[3] Key clinical features include whether prominent motor symptoms are present and the degree of impaired consciousness. This chapter will focus on two forms of SE most commonly encountered in intensive care that involve the acutely ill patient with impaired mental status:

- CSE (also known as tonic-clonic SE), and
- non-convulsive status epilepticus (NCSE) with coma.

The incidence of SE is U-shaped, being greatest under 1 year and over 60 years of age.[9]

PATHOPHYSIOLOGY

Ongoing or recurrent seizures result from failure of normal seizure terminating mechanisms or the initiation of mechanisms causing seizures to persist.[3]

The major inhibitory mechanism in the brain is gamma-aminobutyric acid (GABA) receptor-mediated inhibition. With ongoing seizure activity, GABA receptors undergo cellular internalisation and subsequent degradation, leading to the loss of endogenous inhibition and the persistence of seizures. This reduction in synaptic GABA receptors explains the progressive pharmacoresistance to GABAergic anticonvulsants, such as benzodiazepines.[10]

Mechanisms that induce persistent seizures are predominantly excitatory via glutamine acting on *N*-methyl-D-aspartate (NMDA) receptors. NMDA receptors increase on synapses during ongoing epileptic activity, facilitating neuronal excitability and sustainability of seizures. This, in contrast, explains the efficacy of NMDA antagonists, even late in the course of SE.

The pathophysiological effects of seizures on the brain are thought to result from both direct excitotoxic neuronal injury and secondary injury due to systemic complications, such as hypotension, hypoxia and hyperthermia. Ongoing excitation leads to neuronal injury and death, predominantly through intracellular calcium influx and mitochondrial dysfunction. Experimental models and anecdotal human evidence also suggest that SE is epileptogenic.[10,11]

AETIOLOGY

SE may occur following acute or remote central nervous system (CNS) or systemic illness (approximately 60% of presentations) or less commonly in a previously diagnosed epileptic.[3,9] In the situation where RSE does not have a clear cause, more unusual conditions should be considered as their diagnosis may lead to a specific therapy. These include autoimmune conditions,

ABSTRACT

Status epilepticus (SE) is prolonged (>5 minutes) clinical and/or electrographic seizure activity that requires urgent treatment to prevent neuronal injury. The forms commonly encountered in acutely unwell patients requiring intensive care include convulsive SE (CSE) and non-convulsive SE (NCSE) with coma. CSE is the most serious form and treatment involves rapid termination of seizures using benzodiazepines, followed by loading with anticonvulsant medications and, if seizures persist (refractory SE), general anaesthesia. NCSE can evolve from CSE when motor manifestations subside and electrical seizures persist, or may arise de novo and be under-recognised in critically ill patients. Although NCSE also requires prompt treatment, attempts to control seizures whilst avoiding general anaesthesia may be warranted. Causes of SE include acute central nervous system pathology (e.g. infection, stroke), systemic illness (e.g. sepsis, organ failure, autoimmunity) or pre-existing epilepsy. Diagnosis of the precipitant is important as some causes require specific treatment.

KEYWORDS

Status epilepticus

anticonvulsant
treatment

Box 50.1 Causes of status epilepticus in adults

Low antiepileptic drug levels – poor compliance, recent dose reduction or discontinuation (most common cause in patients with epilepsy)
Stroke – vascular occlusion or haemorrhage
Metabolic disturbances – electrolyte abnormalities (hyponatraemia, hypocalcaemia, hypomagnesaemia, hypophosphataemia), hyperglycaemia, hypoglycaemia
Organ failure – uraemia, hepatic encephalopathy
CNS infection – bacterial meningitis, viral encephalitis, cerebral toxoplasmosis, tuberculosis, other
Cerebral hypoxia/anoxia
Alcohol – withdrawal or intoxication
Head trauma
Drug toxicity – cephalosporins, isoniazid, tranexamic acid, tacrolimus, cyclosporine, tricyclic antidepressants, olanzapine, phenothiazines, theophylline, cocaine, amphetamine, antiepileptic drugs, other
CNS tumours – primary or secondary
Temporally remote causes (previous CNS injury) – stroke, trauma, tumour, meningitis
Cortical dysplasias
Hypertensive encephalopathy, eclampsia
Autoimmune disorders – paraneoplastic syndromes, Hashimoto's encephalopathy, anti-NMDA receptor encephalitis (may have associated ovarian tumour), anti-voltage-gated potassium channel receptor encephalitis, cerebral lupus, thrombotic thrombocytopenic purpura, multiple sclerosis, other
Mitochondrial diseases
Metabolic disorders – porphyria, ornithine transcarbamylase deficiency, other
Cryptogenic, including new-onset refractory status epilepticus (NORSE)

CNS, Central nervous system; *NMDA*, *N*-methyl-D-aspartate.
See references 3, 9, 12–14.

unusual infections and mitochondrial diseases.[12] The aetiologies of SE are given in Box 50.1.[3,9,12–14]

CONVULSIVE STATUS EPILEPTICUS

CSE is the most common and dangerous type of SE. There is impairment of consciousness and abnormal muscle contraction, which may be sustained (tonic) and/or interrupted (clonic). The seizures may be primary generalised or have a focal onset evolving into bilateral convulsive SE.

CLINICAL

Patients are unresponsive with rhythmic jerking movements. With time, the clinical manifestations may become subtle and patients have only small-amplitude twitching movements of the face, hands or feet, or nystagmoid jerking of the eyes (late or subtle CSE). Later still, some patients will have no observable motor activity and the detection of ongoing seizures requires EEG. Most authors classify these subtle or electrical forms as NCSE.[1–3,15] Such patients are still at risk of CNS injury and require prompt treatment.

Walton NY. Systemic effects of generalized convulsive status epilepticus. *Epilepsia*. 1993;34(suppl 1):S54–S58.

ELECTROENCEPHALOGRAPHY CHANGES

Just as there is a progression from overt to increasingly subtle motor manifestations, there is also a predictable sequence of EEG changes during untreated CSE. Initially, discrete electrographic seizures merge to a waxing and waning pattern of seizure activity, followed by continuous monomorphic discharges, which become interspersed with increasing periods of electrographic silence and, eventually, periodic epileptiform discharges on a relatively flat background.[16] The presence of any of these EEG patterns should suggest the diagnosis of SE.

ENDOCRINE AND METABOLIC EFFECTS

Early in CSE there is a marked increase in plasma catecholamines, producing systemic physiological changes that resolve if SE is stopped early (Box 50.2). However, if seizures continue, many of these early physiological changes reverse, and the resultant hypotension and hypoglycaemia may exacerbate neurological injury.[17]

Hyperthermia is due to both muscle activity and central sympathetic drive, and thus may still occur when paralysing agents prevent motor activity. In early SE, both cerebral metabolic activity and cerebral blood flow (CBF) are increased. In late SE, although

Box 50.3 Features suggestive of pseudoseizures

Lack of stereotyped seizures, with behavioural manifestations varying from event to event
Lack of sustained convulsive activity – 'on-off' appearance
Increase in movement if restraint is applied
Degree of interaction or responsiveness, such as movements modifiable with suggestion
Resistance to eye opening and gaze aversion
Poor response to treatment, RSE
Absence of pupillary dilatation
Normal tendon reflexes and plantar responses immediately after convulsion
Lack of metabolic consequences despite some hours of apparent fitting

Box 50.4 Investigations in status epilepticus

Initial studies
Blood glucose, electrolytes (sodium, potassium, calcium, magnesium), urea
Arterial blood gases
Anticonvulsant drug levels
Full blood count
Urinalysis
Further investigations after stabilisation
Liver function tests, lactate, creatine kinase
Toxicology screen
Lumbar puncture
Electroencephalogram
Brain imaging with computed tomography or magnetic resonance imaging

cerebral metabolic activity remains high, CBF may fall owing to hypotension and loss of cerebral autoregulation leading to cerebral ischaemia.

PSEUDOSEIZURES

An important differential diagnosis of convulsive epilepsy is pseudoseizures, also known as psychogenic non-epileptic seizures.[18,19] The vast majority are not deliberate and they can occur in patients with or without a history of epilepsy.

Clinical features suggestive of pseudoseizures are listed in Box 50.3. Distinction between the two may be extremely difficult, and pseudoseizures are best confirmed using EEG monitoring where there is an absence of ictal EEG changes with events. Pseudostatus, misdiagnosed as true SE, is often refractory to initial therapy and can lead to patients receiving general anaesthesia and mechanical ventilation.

NON-CONVULSIVE STATUS EPILEPTICUS WITH COMA

There is altered consciousness and EEG evidence of seizures with minimal or no convulsive movements. NCSE may evolve from CSE when electrical seizure activity continues with the loss of motor manifestations.

The diagnosis of NCSE should be considered in any patient with an unexplained altered conscious state, particularly those with CNS injury, metabolic disturbance, hepatic encephalopathy or sepsis. Its incidence is probably underestimated because of failure to recognise the condition. Series where EEG has been performed in critically ill patients with an unexplained depressed conscious state have found a high incidence of seizures (8%–18%).[20–22] Seizures will usually be detected within the first 30 minutes of EEG monitoring in such patients, although the presence of epileptiform discharges increases the likelihood of seizures being detected with more prolonged monitoring.[23]

NCSE may be mistaken for other conditions, such as persisting sedative effects, metabolic encephalopathy and post-ictal confusion. A high index of suspicion must therefore be present to trigger investigation with an EEG. EEG monitoring is required in patients with CSE who do not recover consciousness after resolution of overt convulsive activity; in one study more than 14% of such patients had NCSE.[15]

As NCSE includes a heterogeneous group of aetiologies, there is variable response to treatment. The outcome is largely determined by the underlying cause.[24–26]

EPILEPTIFORM ENCEPHALOPATHIES

In many advanced coma stages, the EEG exhibits continuous or periodic EEG abnormalities, but in such situations it is unclear whether the abnormal discharges are responsible for, or contribute to, the altered consciousness, or are merely a reflection of a severe cerebral insult.[27]

Some consider myoclonic SE that follows an anoxic insult as part of this category, rather than as a form of SE.[27]

INVESTIGATIONS

Not all of the investigations listed in Box 50.4 need to be performed in every patient, and they should be guided by the presentation.

NEUROIMAGING

Most patients with SE should have a computed tomography (CT) scan of the brain performed, although this

may not always be necessary if another episode of SE occurs in a patient with established epilepsy who has previously been thoroughly evaluated. Magnetic resonance imaging may occasionally reveal abnormalities not visualised on CT scans and should be considered for non-emergency imaging. Imaging should only be performed after patient stabilisation.[28]

LUMBAR PUNCTURE

In any patient, especially in young children with fever and SE, CNS infection and lumbar puncture along with blood cultures should be considered.[29] Meningitis is an uncommon cause of SE in adults, and brain imaging should usually be performed before a lumbar puncture. If meningitis is suspected and a lumbar puncture cannot be performed expediently, antibiotics should be administered immediately rather than delayed. Approximately 20% of patients have a modest CSF white cell count pleocytosis after SE, and treatment for meningitis should be given until the diagnosis is excluded.

MANAGEMENT

CONVULSIVE STATUS EPILEPTICUS

An accurate history should be obtained – with particular emphasis on eye-witness accounts of the onset and nature of the seizures – and a full physical examination performed. However, neither should delay the initial management. Rapid control of seizures is crucial to prevent brain injury and the development of RSE. There is evidence that the longer SE goes untreated the harder it is to control with drugs.[5,30,31]

Management of SE involves the termination of seizures, treating the precipitating causes and underlying conditions, and the prevention of complications and recurrence of seizures.

There are few controlled data to support the use of any particular agents and existing randomised, controlled trials (RCTs) have recently been reviewed.[32] One double-blind RCT for treatment of CSE found that lorazepam, phenobarbital or diazepam followed by phenytoin are all acceptable as an initial treatment, but that phenytoin alone was not as effective as lorazepam.[31]

There are few data to guide the treatment of RSE, for which anaesthetising agents, such as thiopental, propofol or midazolam infusions, are commonly used.[32] The only RCT in RSE, which compared propofol versus barbiturates, was terminated after 3 years with only 24 of the required 150 patients recruited.[6]

The EEG goal of treatment for RSE remains controversial as to whether seizure suppression is sufficient or therapy should be escalated to achieve burst suppression (periods of high-voltage electrical activity 'bursts' alternating with periods of suppression).[4,11]

There are various protocols for SE management including a recent evidence-based guideline issued by the American Epilepsy Society.[1,2,4,30,33] One approach is outlined in Box 50.5.

NON-CONVULSIVE STATUS EPILEPTICUS

There is considerable debate as to whether NCSE presents the same degree of risk of neurological injury as CSE. Prompt treatment is generally recommended and the use of additional non-anaesthetising anticonvulsants, such as valproate, levetiracetam and phenobarbital, has been suggested prior to embarking upon general anaesthesia.[1,26,34]

The side-effects of aggressive treatment (hypotension, immobility, immunosuppression) need to be balanced against the potential neurological morbidity of NCSE and so treatment tailored according to the aetiology.[35,36] Particularly in elderly patients, aggressive treatment may be associated with more risk than benefit and a worse outcome.[25,35,37]

DRUGS FOR STATUS EPILEPTICUS

BENZODIAZEPINES

Benzodiazepines are fast-acting antiseizure drugs and thus preferred as initial therapy. They act mainly by enhancing the neuroinhibitory effects of GABA. The efficacy of benzodiazepines diminishes with the duration of SE as prolonged seizures result in a reduction in synaptic GABA receptors.[10]

The choice of benzodiazepine will depend upon its efficacy, the setting and the available formulations.

Diazepam, as with other benzodiazepines, is highly lipid-soluble with rapid CNS penetration.

Diazepam, however, has a short redistribution half-life (1 hour) compared with midazolam (2 hours) and lorazepam (14 hours), and therefore a short duration of action.[32] It can be administered intravenously or by the rectal route, which is useful in the pre-hospital setting and when vascular access is delayed.

Intravenous lorazepam has a longer duration of action and appears better than diazepam in both stopping seizures and preventing recurrence.[32]

Midazolam can be administered via intramuscular, buccal and intranasal routes as well as intravenously. Intramuscular midazolam appears as safe and efficacious as intravenous lorazepam in both adults and children, and it can be administered more reliably in the pre-hospital setting.[38,39]

Midazolam, by bolus and infusion, may terminate seizures when other agents have failed, and it is used in RSE. Unlike other benzodiazepines, it does not accumulate with prolonged infusion.[40]

Clonazepam has a longer duration of action than diazepam, and early reports suggested superior

Box 50.5 Protocol for management of status epilepticus

1. Assess A, B, C, GCS.
2. Give O_2 and consider need for intubation/ventilation.
3. Monitor blood pressure, ECG, pulse oximetry.
4. Obtain IV access, perform bedside blood sugar level and draw blood for investigations.
5. If patient is hypoglycaemic give glucose:
   adults: give thiamine 100 mg IV and 50 mL of 50% glucose IV.
   children: give 2 mL/kg of 25% glucose IV.
6. Seizure control*:
   A. Give a benzodiazepine (first-line),† for example:
      diazepam: 0.2 mg/kg IV at 5 mg/min, max 10 mg/dose, may repeat once.
      lorazepam: 0.1 mg/kg IV at 2 mg/min, max 4 mg/dose, may repeat once.
      clonazepam: 0.015 mg/kg IV at 1 mg/min, may repeat up to 4 mg.
      If diazepam stops the seizures, phenytoin should be given next to prevent recurrence.
   B. If seizures persist, give a second-line agent,†† for example:
      phenytoin: 20 mg/kg IV (adults ≤50 mg/min; children ≤1 mg/kg/min) or fosphenytoin 20 phenytoin equivalents (PE) mg/kg IV (adults ≤150 mg/min; children ≤3 mg/kg/min). May give a further dose of 5 mg/kg IV for persistent seizures.
      valproate: 40 mg/kg IV single dose, max 3000 mg.
      levetiracetam: 60 mg/kg IV single dose, max 4500 mg.
   C. If seizures persist (RSE), intubate and ventilate patient. Give third-line therapy intravenously, either:
      propofol: slow bolus 1–2 mg/kg, repeat every 3–5 minutes until seizure control, followed by infusion 2–5 mg/kg/h§, *or*
      midazolam: slow bolus 0.1–0.2 mg/kg, repeat every 3–5 minutes until seizure control, followed by infusion 0.1–3 mg/kg/h, *or*
      thiopental: slow bolus 3–5 mg/kg, repeat 1 mg/kg every 3–5 minutes until seizure control, followed by infusion 1–5 mg/kg/h, *or*
      pentobarbital: slow bolus 5–15 mg/kg, repeat 5 mg/kg every 3–5 minutes until seizure control, followed by infusion 1–5 mg/kg/h.
      Titrate doses to achieve seizure control or until burst suppression pattern is achieved on EEG.
      A combination of agents (e.g. propofol and midazolam) may be required for seizure control.
   D. Insert nasogastric tube and administer maintenance doses of long acting anticonvulsant medication(s); continue after withdrawal of anaesthesia.
   E. Beware of ongoing unrecognised seizures.
      Use continuous EEG monitoring until seizures are controlled, during withdrawal of anaesthesia and preferably during the maintenance phase.
      Avoid muscle relaxants (use continuous EEG if giving repeated doses of muscle relaxants).
   F. Reduce anaesthesia 24–48 hours after seizure control using continuous EEG monitoring. If seizures recur, reinstate the infusion and repeat this step at 24-hour intervals or longer. Consider adjunctive therapies including ketamine (see text).
   In addition:
   Look for and treat underlying cause and precipitant.
   Look for and treat complications: hypotension, hyperthermia and rhabdomyolysis.

*First-line therapy should be initiated after 5 minutes of seizures, second-line therapy at the 20- to 40-minute time point and third-line within 40–60 minutes of onset of SE.

†If none of these three options are available, give IV phenobarbital 15–20 mg/kg, single dose. If IV access is not obtainable, consider rectal diazepam (0.2–0.5 mg/kg, single dose, max 20 mg), IM midazolam (10 mg for > 40 kg, 5 mg for 13–40 kg, single dose), buccal midazolam, intranasal midazolam, or IM fosphenytoin.

††If none of these three options are available, give IV phenobarbital 15–20 mg/kg, single dose, if not already given.

§High infusion rates for prolonged periods require caution.

efficacy and fewer side effects though there are no published comparisons.

PHENYTOIN

Phenytoin is useful for maintaining a prolonged antiseizure effect after rapid termination of seizures with a benzodiazepine, or when benzodiazepines fail. It has lower efficacy than benzodiazepines when used alone as initial therapy.[31]

The recommended intravenous loading dose is 20 mg/kg. The common practice of giving a standard loading dose of 1000 mg may provide inadequate therapy for some adults.

When phenytoin is infused at the maximal adult recommended rate of 50 mg/min, hypotension occurs in up to 50% of patients, and cardiac rhythm disturbance occurs in 2%. These adverse effects are more common in older patients and those with cardiac disease, and are due to the phenytoin itself as well as the propylene glycol diluent. Blood pressure and the electrocardiogram (ECG) should be monitored and the infusion slowed or stopped if cardiovascular complications occur.

Intramuscular phenytoin is not recommended due to erratic absorption and local tissue reactions.

Fosphenytoin, a water-soluble prodrug of phenytoin, can be administered at rates up to 150 phenytoin

equivalents (PE) mg/min since it is not formulated with propylene glycol. Despite this, studies have not demonstrated a faster onset of action than phenytoin. Systemic side effects are similar, although infusion site reactions are less common. Fosphenytoin can be administered intramuscularly, which is useful when intravenous access is not possible.

VALPROATE

Intravenous valproate may be used in both CSE and NCSE in adults and children, and is the preferred second-line agent in children with primary generalised epilepsy.[2] It is non-sedating, appears as effective as phenytoin and may be better tolerated with few reports of hypotension or respiratory depression.[41]

LEVETIRACETAM

There is some evidence for the use of levetiracetam as second-line therapy and in situations where it is desirable to avoid intubation, such as in NCSE and treatment in the elderly.[5,34,42] Levetiracetam may have particular utility in controlling seizures after cerebral hypoxia.[5]

BARBITURATES

Phenobarbital is a potent anticonvulsant with a long duration of action. Although it has equal efficacy to benzodiazepines as first-line therapy, its slower rate of infusion makes it an alternate rather than preferred initial therapy.[33] It may also be used as second-line therapy but only if other recommended agents are unavailable due to it having higher adverse events.[33]

Thiopental is an intravenous anaesthetic agent used for RSE. Following intravenous bolus, the drug is rapidly redistributed into peripheral fat stores and an infusion is required for the ongoing suppression of seizures. Once lipid stores are saturated, the duration of action is prolonged and recovery may take hours to days. Side effects include hypotension, myocardial depression and immunosuppression with increased infection risk.

Pentobarbital (the first metabolite of thiopental) is available in the United States as the alternative to thiopental.

PROPOFOL

Propofol (2,6-diisopropylphenol) is an anaesthetic agent that has become increasingly popular for the treatment of RSE. Recommended infusion rates in RSE vary within 1–10 mg/kg/h.[4,40] High doses may be required to attain seizure control, although this increases the risk of refractory bradycardia/asystole, metabolic acidosis, rhabdomyolysis, lipaemia and death (propofol-related infusion syndrome).[43]

KETAMINE

Ketamine acts as an antagonist at the NMDA receptor and has a theoretical advantage over standard anaesthesia agents, which act on the GABA receptor and therefore may be less effective in prolonged RSE. Its reported use is mostly in super RSE, although it may be a promising alternative or adjunctive therapy used earlier in the treatment of RSE.[4] Suggested dose ranges include a loading intravenous bolus of 0.5–3 mg/kg followed by an infusion of 1–10 mg/kg/h.[4,8,44,45] Case series also report improvement in haemodynamic stability with reduced vasopressor requirement.[45] Ketamine may increase intracranial pressure (ICP) so caution is required in at-risk patients.

OTHER AGENTS OF POTENTIAL USE IN REFRACTORY STATUS EPILEPTICUS

Magnesium is the drug of choice in eclamptic seizures and is also effective in seizures due to hypomagnesaemia, but there is little evidence to support its use in other forms of SE. Nonetheless, given that infusing magnesium is relatively safe, it may be used as adjunctive treatment in super RSE.[8,40]

Lacosamide is a new anticonvulsant drug. Small case series have suggested utility as an adjunctive treatment in RSE when seizures persist after traditional second-line antiepileptic agents or with anaesthetic agents.[11]

Inhalational anaesthesia has been used in RSE. Limitations include difficulties with administration in intensive care, seizure recurrence with discontinuation and adverse effects (e.g. hypotension, ileus), including concerns about neurotoxicity.[11]

OTHER TREATMENTS FOR REFRACTORY STATUS EPILEPTICUS

Neuromuscular-blocking agents are indicated if uncontrolled fitting causes difficulty with providing adequate ventilation or severe lactic acidosis. Paralysis should be used only if EEG monitoring is available, as the clinical expression of seizure activity is abolished.

Hypothermia (32°C–35°C) is utilised for super RSE in several centres, although there are only a small number of case reports suggesting benefit.[40] Targeted temperature management with avoidance of fever as a general neuroprotective strategy has been recommended pending the results of large clinical trials.[4]

Immunotherapy (high-dose steroids, immunoglobulins and/or plasma exchange) has been used in super RSE arising from paraneoplastic aetiologies or autoimmune encephalitis.[4,11] Small case series have also suggested benefit in super RSE from unknown cause – cryptogenic or new-onset RSE (NORSE).[11,46,47]

A ketogenic diet has been reported to be useful in super RSE that is unresponsive to other therapies in

Box 50.7 Causes of status epilepticus in children

Febrile
Acute symptomatic – meningitis, encephalitis, cerebrovascular disease, trauma, metabolic derangement, hypoxia, sepsis, drug related
Remote symptomatic causes – previous traumatic brain injury or insult, CNS malformation, cerebral palsy
Progressive neurological conditions – tumours, degenerative, autoimmune diseases
Congenital and genetic disorders
Cryptogenic, including FIRES

CNS, Central nervous system; *FIRES*, febrile infection-related epilepsy syndrome.
See references 28, 29, 48.

children (mostly with febrile infection-related epilepsy syndrome [FIRES]) and in adults.[11,48]

Surgery has had some success in carefully selected cases of RSE. Techniques include focal cortical resection, multiple subpial transection, corpus callosotomy, hemispherectomy and vagus nerve stimulation.[8,49]

INTENSIVE CARE MONITORING

Pulse oximetry, capnography, intra-arterial and ECG monitoring should be used in patients at risk of cardiorespiratory compromise. Indications for EEG monitoring are listed in Box 50.6.[15,50] Cerebral function monitors are useful in titrating doses of anaesthetic agents to EEG background suppression, but may not be sufficiently sensitive to detect seizure activity. ICP monitoring should be considered if elevated ICP is present owing to the underlying brain pathology.

OUTCOME

The prognosis of patients with SE is related to age, aetiology, degree of impairment of consciousness at presentation and duration of SE.[9,14] RSE is associated with a worse prognosis and prolonged super RSE an even higher mortality. However, where no underlying irreversible brain damage is present, good recovery is possible even after weeks of SE.[8,30]

Children have a much lower mortality of 3%,[51] whereas those aged over 65 years have a mortality rate of 30%.[24,52]

SE precipitated by low antiepileptic drug levels, alcohol abuse or systemic infection has a very low mortality, whereas SE secondary to an acute CNS insult, such as stroke or infection, has a higher mortality.[9,52] SE associated with hypoxic brain injury is most often fatal. NCSE in comatose critically ill patients, despite recognition and treatment, has a poor outcome.[22,37]

The consequences of SE include brain damage resulting in permanent neurological deficits, and the development of focal epilepsy. Multiorgan failure and death can result from uncontrolled seizures, the underlying illness or complications of treatment.

STATUS EPILEPTICUS IN CHILDREN

Most paediatric SE is in very young children with 80% below 4 years of age.[51] The majority are convulsive and generalised.[28] The distribution of causes is highly age-dependent with febrile SE, which is usually self-limiting, and with that due to acute neurological disease (e.g. CNS infection) being more common in children under 4 years. Remote symptomatic causes and SE in a child with previously diagnosed epilepsy are more common in older children.[51] The most frequent aetiologies of SE in children are listed in Box 50.7.[28,29,48,51]

The likelihood of bacterial meningitis is much higher in febrile children presenting with a first-ever episode of SE (12%) as opposed to a brief seizure (1%).[51]

A rare, severe form of SE, called FIRES, usually occurs in school-age children who within weeks of a minor febrile illness develop RSE.[48] The syndrome possibly may have an inflammatory or autoimmune mechanism, and immune treatment and the ketogenic diet may help. The outcome is poor with most children left with significant cognitive disability and refractory epilepsy. Features are similar to NORSE in adults, and there may be a common pathophysiology.

Treatment of SE in children is essentially the same as in adults.[33,53] In addition, pyridoxine should be administered to young children presenting with SE, who may have an inborn error of metabolism of pyridoxine; in these patients lifelong supplementation is required. Pyridoxine-responsive super RSE has also been described in children in whom the genetic test was negative and who only needed immediate and not

ongoing treatment. Given the infusion is without significant side effects, it is now commonly recommended that pyridoxine be routinely given to young children with super RSE.[2,8,40]

The underlying cause is the main determinant of mortality, which is negligible for prolonged febrile seizures other than FIRES and 12%–16% for acute symptomatic causes.[54] Similarly, the risk of subsequent epilepsy is low in neurologically normal children, but is higher than 50% in those with acute or remote symptomatic causes.[54]

Acute cerebrovascular complications

Thearina de Beer

Cerebrovascular disease is common and its acute manifestation – stroke – produces considerable morbidity and mortality. Stroke is defined as an acute focal neurological deficit caused by cerebrovascular disease, which lasts for more than 24 hours or causes death before 24 hours. Transient ischaemic attack (TIA) also causes focal neurology, but this resolves within 24 hours. Stroke is the fourth largest cause of death in the United Kingdom, the second largest worldwide and is the most common cause of physical disability in adults.[1] Stroke can be categorised as ischaemic or haemorrhagic (Table 51.1).

The main risk factors are increasing age, hypertension, ischaemic heart disease, atrial fibrillation, smoking, diabetes, obesity, some oral contraceptives and raised cholesterol or haematocrit.

PROGNOSIS IN ACUTE CEREBROVASCULAR DISEASE

Mortality after stroke averages 30% within a month, with more patients dying after subarachnoid haemorrhage (SAH) or intracerebral haemorrhage than after cerebral infarction, although survival to 1 year is slightly better in the haemorrhagic group. In all types of stroke, about 30% of survivors remain disabled to the point of being dependent on others. Risk of stroke increases with age and doubles every decade over the age of 55.[1] Thus stroke is often accompanied by significant age-related medical co-morbidity. In the past, this may have been partially responsible for a relatively non-aggressive approach to the treatment of stroke patients, so the gloomy prognosis of stroke becomes a self-fulfilling prophecy. The challenge for intensivists is to identify those patients who are most likely to survive, and not to offer aggressive therapy to those who are not. Stroke should be regarded as a medical emergency. Patients should initially be treated in a stroke unit as there is good evidence of reduction in both mortality and dependency compared with those treated in a general ward. The UK National Institute for Health and Clinical Excellence (NICE) has published guidelines aimed at ensuring early diagnosis and aggressive therapy.[2]

CEREBRAL INFARCTION

Infarction of cerebral tissue (ischaemic stroke) occurs as a result of inadequate perfusion from occlusion of cerebral blood vessels (large or small) in association with inadequate collateral circulation. It may occur due to cerebral thrombosis or embolism.

AETIOLOGY AND PATHOLOGY

CEREBRAL THROMBOSIS

Atherosclerosis is the major cause of major arterial occlusion and most often produces symptoms if it occurs at the bifurcation of the carotid artery or the carotid syphon. Progressive plaque formation causes narrowing and forms a nidus for platelet aggregation and thrombus formation. Ulceration and rupture of the plaque exposes its thrombogenic lipid core, activating the clotting cascade. Hypertension and diabetes mellitus are common causes of smaller arterial thrombosis. Rarer causes of thrombosis include any disease resulting in vasculitis, vertebral or carotid artery dissection (either spontaneous or post-traumatic) or carotid occlusion by strangulation or systemic hypotension after cardiac arrest. Cerebral venous thrombosis, responsible for less than 1% of strokes, may occur in hypercoagulable states, such as dehydration, polycythaemia, thrombocythaemia, some oral contraceptive pills, protein C or S deficiency, or antithrombin III deficiency or vessel occlusion by tumour or abscess. Cerebral infarction may also result from sustained systemic hypotension from any cause, particularly if associated with hypoxaemia.

CEREBRAL EMBOLISM

Embolism commonly occurs from thrombus or platelet aggregations overlying arterial atherosclerotic plaques, but 30% of cerebral emboli will arise from thrombus in the left atrium or ventricle of the heart. This is very likely in the presence of atrial fibrillation, left-sided valvular disease, recent myocardial infarction, chronic atrial enlargement or ventricular aneurysm. The

ABSTRACT

Stroke, whether it is ischaemic or haemorrhagic, is an acute medical emergency, and great strides have been made in its treatment in the last 10 years. It still remains a high-ranking cause of death worldwide, but outcomes have improved with the newer treatments. When a stroke is suspected, a computed tomography scan of the brain needs to be performed within an hour of presentation, and what type of stroke it is will determine further management. Stroke patients should be treated in hyperacute stroke centres with neurosurgical support. Subarachnoid haemorrhage patients should be in a neurosurgical centre with access to interventional neuroradiologists. With rehabilitation, the stroke survivors can make a significant recovery.

Table 51.1 Classification of stroke

ISCHAEMIC STROKE CAN BE DIVIDED INTO FIVE TYPES:	HAEMORRHAGIC STROKE CAN BE DIVIDED INTO TWO TYPES:
1. Large-artery atherosclerosis	1. Intracerebral haemorrhage (ICH)
2. Cardioembolism	2. Subarachnoid haemorrhage (SAH)
3. Small-vessel occlusion	
4. Stroke of other determined aetiologies	
5. Stroke of undetermined aetiology	

presence of a patent foramen ovale or septal defects allows paradoxical embolism to occur. Iatrogenic air embolism may occur during cardiopulmonary bypass, cardiac catheterisation or cerebral angiography. Embolisation may also occur as a complication of attempted coil embolisation of cerebral aneurysms or arteriovenous malformations (AVMs) after SAH.

CLINICAL PRESENTATION

In cerebral thrombosis, there is initially no loss of consciousness or headache, and the initial neurological deficit develops over several hours. Cerebral embolism may be characterised by sudden onset and rapid development of complete neurological deficit. No single clinical sign or symptom can reliably distinguish a thrombotic from an embolic event.

Where infarction occurs in a limited arterial territory the clinical signs are often characteristic. The commonest site involves the middle cerebral artery, which classically produces acute contralateral brachiofacial hemiparesis with sensory or motor deficits, depending on the precise area of infarction. Infarction of the middle cerebral territory leads to a dense contralateral hemiplegia, contralateral facial paralysis, contralateral hemianopia and ipsilateral eye deviation. Dominant left-hemisphere lesions result in language difficulties from aphasia, dysphasia, dysgraphia and dyscalculia. Non-dominant right hemispheric lesions cause the patient to neglect the left side, and failure to communicate with anyone approaching from that side. In strokes involving the posterior fossa, the precise pattern of symptoms depends on the arterial territories involved and the presence or absence of collaterals. The onset of symptoms, such as gait disturbance, headache, nausea, vomiting and loss of consciousness, may be very rapid. Venous thrombosis may occur, particularly in the cerebral veins, sagittal or transverse dural sinuses, causing headache, seizures, focal neurology and loss of consciousness. Other cognitive effects of stroke include memory impairment, anxiety, depression, emotional lability, aprosody and spatial impairment. Bilateral brainstem infarction after basilar artery thrombosis may produce deep coma and tetraparesis. Pontine stroke may produce the 'locked-in' syndrome. The precise clinical presentation depends on the size of the infarcted area and its position in the brain. Vascular lesions, such as carotid dissection, can present with ipsilateral Horner syndrome with facial pain, a painful Horner's from local stellate ganglion damage or if there is significant ischaemia from impaired flow or emboli, then with contralateral signs consistent with infarction.[3]

INVESTIGATIONS

A full history and examination of the patient will produce a differential diagnosis that will require specific investigations. The aim is to make the diagnosis, establish the nature, size and position of the pathology, so that correct treatment can target the effects of the primary injury, and prevent extension of the lesion or complications occurring.

BLOOD TESTS

A blood glucose test should be done to exclude diabetes and rule out hypoglycaemia as a cause for symptoms. A full blood count should be taken to look for polycythaemia, infection or thrombocythaemia. A raised erythrocyte sedimentation rate or C-reactive protein level may indicate vasculitis, infection or carcinoma, warranting further appropriate investigations. Cardiac enzymes and troponin should be taken after an electrocardiogram (ECG). Urea and electrolytes, as well as creatinine and liver function tests, should be taken to rule out a metabolic component. A coagulation screen should also be taken together with serum cholesterol, triglyceride and syphilis serology. Specific investigation for thrombophilia due to protein C, protein S, Leiden factor V and antithrombin III abnormalities should be undertaken in patients with venous thrombosis or patients with otherwise unexplained cerebral infarction or TIA. A pregnancy test should be performed on females under the age of 55.

ELECTROCARDIOGRAPHY

This may demonstrate atrial fibrillation, other arrhythmia or recent myocardial infarct.

ECHOCARDIOGRAPHY

Either transthoracic or transoesophageal echocardiography (TOE) may demonstrate mural or atrial appendage thrombus as a source of embolism. TOE is more effective in detecting patent foramen ovale, aortic arteriosclerosis or dissection. Base the decision to perform echocardiography on history, ECG or physical findings.[2]

IMAGING

New guidelines suggest a computed tomography (CT) brain scan within 1 hour of presentation with

a suspected stroke.[2] These techniques are used to distinguish infarction from haemorrhage. Tumour, abscess or subdural haematoma may also produce the symptoms and signs of stroke. Early scanning is vital if interventional treatment, such as thrombolysis, thrombectomy, anticoagulation, antiplatelet therapy or surgery, is planned.

The CT scan may be normal or show only minor loss of grey/white matter differentiation in the first 24 hours after ischaemic stroke, but haemorrhage is seen as areas of increased attenuation within minutes. After a couple of weeks, the CT appearances of an infarct or haemorrhage become very similar and it may be impossible to distinguish them if CT is delayed beyond this time. CT angiography (CTA) will often demonstrate vascular abnormalities and vasospasm but multimodal magnetic resonance imaging (MRI), a combination of diffusion and perfusion-weighted MRI and magnetic resonance angiography (MRA), is much more sensitive in demonstrating small areas of ischaemia. Timing from the onset of symptoms and the exclusion of intracranial haemorrhage (ICH) determines the suitability and benefit of thrombolysis.[4] Where cerebral infarction has occurred as a result of venous thrombosis, the best imaging technique is MRA. Any patient with a stroke or TIA in the internal carotid artery territory should have duplex Doppler ultrasonography, which may demonstrate stenosis, occlusion or dissection of the internal carotid. Where trauma is an aetiological factor reconstruction CT bone window views are required to demonstrate any site of fracture-associated vascular injury.

MANAGEMENT

There is strong evidence that admission to a specialised stroke care unit as soon as possible after the occurrence of a stroke provides a cost-effective reduction in long-term brain damage and disability.[2] In general, only those patients with a compromised airway due to a depressed level of consciousness or life-threatening cardiorespiratory disturbances require admission to medical or neurosurgical intensive care units (ICUs). In either case, attention to basic resuscitation, involving stabilisation of airway, breathing and circulation, is self-evident.

AIRWAY AND BREATHING

Patients with Glasgow Coma Scores (GCS) of 8 or less, or those with absent gag or defects of swallowing (both of which may occur at higher GCS), will require intubation to preserve their airway and to prevent aspiration. Where this requirement is likely to be prolonged, early tracheostomy should be considered. Adequate oxygenation and ventilation should be confirmed by arterial blood gas analysis, and supplemental oxygen prescribed if there is any evidence of hypoxia. If hypercarbia occurs then ventilatory support to achieve normocarbia is necessary to prevent exacerbation of cerebral oedema. A multicentre international study demonstrated that ICU mortality was 37% and hospital mortality was 45% for ventilated stroke patients; it also demonstrated a longer ventilation time and higher tracheostomy rate than non-neurological patients.[5]

CIRCULATORY SUPPORT

A large number of stroke patients will have raised blood pressure (BP) on admission, presumably as an attempt by the vasomotor centre to improve cerebral perfusion. Hypertensive patients may have impaired autoregulation and regional cerebral perfusion may be very dependent on BP. The patient's clinical condition and neurological status should determine treatment rather than an arbitrary level of BP. Current recommendations are that emergency administration of antihypertensive agents should be withheld unless the systolic pressure is >220 mm Hg or the diastolic pressure is >120 mm Hg. Aggressive lowering of BP is not without risk and may result in the progression of ischaemic stroke, so reduction should be monitored closely (not exceeding 15% of normal BP).[6] It would seem reasonable on physiological grounds to avoid drugs that cause cerebral vasodilatation in that they may aggravate cerebral oedema, although there is no hard evidence for this. Cardiac output should be maintained and any underlying cardiac pathology, such as failure, infarction and atrial fibrillation, treated appropriately.

METABOLIC SUPPORT

Both hypo- and hyperglycaemia have been shown to worsen prognosis after acute stroke; therefore blood sugar levels should be maintained in the normal range (<8.6 mmol/L).[7] In the long term, nutritional support must not be neglected, and early enteral feeding should be instituted by nasogastric intubation if needed. In the longer term, particularly where bulbar function is reduced, percutaneous endoscopic gastrostomy may be necessary.

ANTICOAGULATION

The routine use of prophylactic heparin in immobile stroke patients should be avoided as the risk of intracerebral bleeding is high. Intermittent pneumatic compression should be used for 30 days or until mobile.[2] Anticoagulation can only be recommended in individuals where there is a high risk of recurrence, such as in those patients with prosthetic heart valves, atrial fibrillation with thrombus or those with thrombophilic disorders. A CT scan must be obtained prior to commencing therapy to exclude haemorrhage, and careful monitoring used. In patients with large infarcts, there is always the risk of haemorrhage (haemorrhagic conversion) into the infarct and early heparinisation is best avoided. Aspirin 160–300 mg should be given within 48 hours after thrombolysis and continued for 2

weeks while antithrombotic therapy is commenced. If the patient is intolerant of aspirin, an alternative, such as clopidogrel, should be used.[2]

THROMBOLYSIS

Thrombolysis with intravenous recombinant tissue plasminogen activator (rtPA alteplase) is now an established treatment for acute ischaemic stroke.[8] There are specific inclusion and exclusion criteria. Inclusion criteria are a diagnosis of ischaemic stroke causing measurable neurological deficit, age over 18 with an onset of symptoms to treatment time of less than 3 hours. Patients should be excluded if there is a history of head trauma or stroke (ischaemic or haemorrhagic) in the previous 3 months, evidence of subarachnoid or ICH, intracranial neoplasma, AVM or aneurysm, recent intracranial or intraspinal surgery, arterial puncture in a non-compressible site in the past 7 days, any active bleeding or bleeding diathesis including platelet count less than 100,000/mm^3, heparin within 48 hours, current anticoagulant therapy, hypoglycaemia or multilobar infarction (more than one-third of a cerebral hemisphere) on CT scan. Relative contraindications include minor or rapidly improving stroke symptoms, seizure at time of stroke with residual postictal signs, serious trauma or major surgery in the past 14 days, gastrointestinal or urinary tract bleeding in the past 21 days, or myocardial infarction within the past 3 months or pregnancy.

There is some evidence for improved clinical outcome after rtPA use between 3 and 4.5 hours after symptom onset, although the degree of clinical benefit is less.[6] Patients must be in an environment where they can be monitored for potential complications, the most serious of which is ICH. The inclusion criteria must be adhered to, age <80 years, not having a history of diabetes AND stroke, not taking warfarin or other oral anticoagulant (National Institutes of Health Stroke Score, NIHSS), ≤25. This risk is reduced where there is strict adherence to the inclusion and exclusion criteria and the appropriate dose used.

ENDOVASCULAR THERAPY

Several studies have shown positive results with mechanical thrombectomy in immediate and 90-day functional outcome, specifically for patients with a large artery proximal occlusion in addition to thrombolysis and for patients who have contraindications to thrombolysis but not mechanical thrombectomy.[2,9,10] This procedure is available only in specialist neuroradiology departments, which have the support of a neurosurgical centre.

DECOMPRESSIVE CRANIECTOMY

Some patients with malignant middle cerebral artery infarction syndrome (MMCAS) (Fig. 51.1) may benefit from decompressive craniectomy, especially patients with large middle cerebral artery territory infarcts aged <60 years. Decompressive craniectomy must be done within 48 hours of symptom onset. The number needed to treat (NNT) for survival is 2 and for severe disability is 6. Untreated, MMCAS has a mortality of 80% and it is suggested craniectomy can reduce mortality to around 30%, but with residual neurological deficit. This procedure is limited to specialist centres. MMCAS development is predicted by middle cerebral artery (MCA) territory stroke of >50%, a perfusion deficit of >66% on CT, an infarct volume of >145 mL within 14 hours and >82 mL within 6 hours of onset. Electroencephalography (EEG) and tissue cerebral tissue oxygenation have been used to predict cerebral oedema; intracranial pressure (ICP) monitoring has not been proven to change the outcome. Craniectomy has to be large enough to extend past the margins of the infarct. This seems to be well tolerated even after thrombolysis. There is no difference in outcome whether dominant or non-dominant hemispheres are involved. The patients who survive after craniectomy have moderate to severe disability and may have a high incidence of psychological complications. A recent study has shown benefit in this procedure for patients over 60 years.[11] Whether this is acceptable to patients has not been studied.[12]

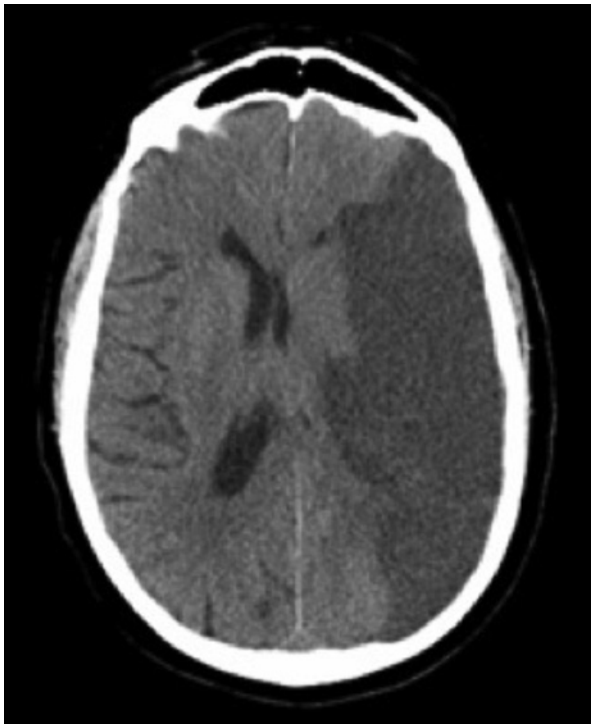

Figure 51.1 Malignant MCA infarct.

Other forms of surgical intervention proven to be effective in making more intracranial space and reducing ICP are drainage of secondary hydrocephalus by extraventricular drain (EVD) insertion or evacuation

of haemorrhage into infarcted areas, resulting in new compressive symptoms. This is especially useful in the posterior fossa where the room for expansion of mass lesions is limited by its anatomy.

COMPLICATIONS

Local complications include cerebral oedema, haemorrhage into infarcted areas or secondary hydrocephalus. General complications include bronchopneumonia, aspiration pneumonia, deep-vein thrombosis, urinary tract infections, pressure sores, contractures and depression. Stroke patients who are ventilated seem particularly susceptible to ventilator-acquired pneumonia.[13] A team approach of specialist nursing, physiotherapists, occupational and speech and language therapists is best able to avoid these complications.

SPONTANEOUS INTRACRANIAL HAEMORRHAGE

Spontaneous ICH producing stroke may occur from either intracerebral haemorrhage (10%) or SAH (5%).

INTRACEREBRAL HAEMORRHAGE

The incidence of intracerebral haemorrhage is about 9/100,000 of the population, mostly in the age range of 40–70 years, with an equal incidence in males and females.

AETIOLOGY AND PATHOLOGY

The commonest cause is the effect of chronic systemic hypertension. This results in degeneration of the walls of vessels or microaneurysms, by the process of lipohyalinosis, and these microaneurysms then suddenly rupture. This may also occur in malignant tumour neovasculature, vasculitis, mycotic aneurysms, amyloidosis, sarcoidosis, malignant hypertension, primary haemorrhagic disorders and over-anticoagulation.

Occasionally, cerebral aneurysms or AVMs may cause intracerebral haemorrhage without SAH. Where intracerebral haemorrhage occurs in young patients, the most likely cause is an underlying vascular abnormality. In some areas, this is also associated with the abuse of drugs with sympathomimetic activity, such as cocaine. The rupture of microaneurysms tends to occur at the bifurcation of small perforating arteries. Common sites of haemorrhage are the putamen (55%), cerebral cortex (15%), thalamus (10%), pons (10%) and cerebellum (10%). Haemorrhage is usually due to the rupture of a single vessel, and the size of the haemorrhage is influenced by the anatomical resistance of the site into which it occurs. The effect of the haemorrhage is determined by the area of brain tissue that it destroys. Cortical haemorrhages tend to be larger than pontine bleeds (Fig. 51.2), but the latter are much more destructive owing to the anatomical density of neural tracts and nuclei.

Figure 51.2 Devastating intracerebral haemorrhage.

CLINICAL PRESENTATION

Usually, there are no prodromal symptoms, and a sudden onset of focal neurology or depressed level of consciousness occurs. Headache and neck stiffness will occur in conscious patients if there is subarachnoid extension by haemorrhage into the ventricles. Where intraventricular extension occurs there may be a progressive fall in GCS as secondary hydrocephalus occurs, and this may be accompanied by ocular palsies, resulting in ‘sunset eyes’. Early deterioration is common in the first few hours after haemorrhagic stroke and more than 20% of patients will drop their GCS by two or more points between the initial onset of symptoms and arrival in the emergency department.[14] As with ischaemic stroke, focal neurology is determined by which area of the brain is involved. The only way to differentiate absolutely between ischaemic, intracerebral and SAH is by appropriate imaging. The symptoms relate to tissue destruction, compression and raised ICP, which, if progressive, will result in brainstem ischaemia and death.

INVESTIGATIONS

The general investigations are essentially those listed previously for ischaemic stroke, since it is difficult

to distinguish between the two in the early stages. Patients undergoing treatment with oral anticoagulants, particularly warfarin in atrial fibrillation, mean that anticoagulant-associated ICH is increasing in frequency and a full coagulation screen is essential.[14] CT and/or MRI should be performed at the earliest opportunity. The early deterioration seen in ICH relates to active bleeding and repeat imaging after 3 hours of symptom onset often shows significant enlargement of the initial haematoma. CTA/MRA or venography is very important to determine the cause of the haemorrhage such as AVM, aneurysm or tumour neovasculature. Lumbar puncture may be performed to exclude infection if mycotic aneurysm is suspected, but only after CT has excluded raised ICP or non-communicating hydrocephalus.

MANAGEMENT

The general management principles are identical to those for ischaemic stroke. There is, of course, no place for anticoagulation or thrombolysis, and reversal of any coagulation defect, either primary or secondary to therapeutic anticoagulation, must be undertaken as a matter of urgency. A full coagulation screen must be performed and the administration of vitamin K, fresh frozen plasma, cryoprecipitate, etc., directed by the results. Where emergency decompressive surgery is indicated, warfarin-induced coagulopathy should be corrected using prothrombin complex concentrate (Beriplex or Octaplex). Intraventricular extension occurs in around 45% of cases and the insertion of an EVD may increase the conscious level, particularly in the presence of secondary hydrocephalus. The EVD level should be set so that the cerebrospinal fluid (CSF) drains at around 10 mm Hg. The normal production of CSF should produce an hourly output and a sudden fall in output to zero should alert staff to the possibility that the drain has blocked. This is particularly likely if the CSF is heavily blood-stained. The meniscus of the CSF within the drain tubing should be examined for transmitted vascular pulsation or the level of the drain temporally lowered by a few centimetres to see if drainage occurs. If the drain is blocked, secondary hydrocephalus will recur. Because of the risk of introducing infection and causing ventriculitis, the drain must be unblocked in a sterile manner by the neurosurgeons. Blood in the CSF acts as a pyrogen, but the patient's high temperature should never be ascribed to this alone, and regular blood cultures and CSF samples are required as part of sepsis surveillance. Operative decompression of the haematoma should be undertaken only in neurosurgical centres, and safe transfer must be assured if this is considered. The administration of mannitol prior to transfer should be discussed with the neurosurgical unit. There is some evidence that patients with supratentorial intracerebral haemorrhage less than 1 cm from the cortical surface benefitted from surgery within 96 hours, although this finding did not reach statistical significance.[15] Current recommendations of the American Heart Association/American Stroke Association (AHA/ASA) are: 'Patients with cerebellar hemorrhage who are deteriorating neurologically or who have brainstem compression and/or hydrocephalus from ventricular obstruction should undergo surgical removal of the hemorrhage as soon as possible'.[14] The management of hypertension following spontaneous intracerebral haemorrhage may be difficult as too high a BP may provoke further bleeding, whereas too low a BP may result in ischaemia. Current recommendations of the AHA/ASA are: 'ICH patients presenting with SBP between 150 and 220 mm Hg and without contraindication to acute BP treatment, acute lowering of SBP to 140 mm Hg is safe and can be effective for improving functional outcome'.[14] This should be done for 7 days.[2] The adoption of these guidelines may have significant resource implications regarding access to ICU beds to provide the required levels of monitoring. There is no place for steroids, and hyperventilation to $PaCO_2$ of 30 mm Hg (4 kPa) or less to control raised ICP will have detrimental effects on cerebral blood flow in other areas of the brain.

SUBARACHNOID HAEMORRHAGE

SAH refers to bleeding that occurs principally into the subarachnoid space and not into the brain parenchyma. The incidence of SAH is around 6/100,000; the apparent decrease, compared with earlier studies, is due to more frequent use of CT scanning, which allows exclusion of other types of haemorrhage. Risk factors are the same as for stroke, but SAH patients are usually younger, peaking in the sixth decade, with a female-to-male ratio of 1.24:1. The only modifiable risk factors for SAH are smoking, heavy drinking, the use of sympathomimetics (e.g. cocaine) and hypertension, which increase the risk odds ratio by 2 or 3. Overall mortality is 50%, of which 15% die before reaching hospital, with up to 30% of survivors having residual deficit-producing dependency. High-volume centres (>60 cases per year) have shown a much improved outcome over that of low-volume centres (<20 cases per year).[16]

AETIOLOGY AND PATHOLOGY

The majority of cases of SAH are caused by ruptured saccular (berry) aneurysms (85%), the remainder being caused by non-aneurysmal perimesencephalic haemorrhage (10%) and rarer causes, such as arterial dissection, cerebral or dural AVMs, mycotic aneurysm, pituitary apoplexy, vascular lesions at the top of the spinal cord and cocaine abuse. Saccular aneurysms are not congenital, almost never occur in neonates and young children and develop during later life. It is not

known why some adults develop aneurysms at arterial bifurcations in the circle of Willis and some do not. It was thought that there was a congenital weakness in the tunica media, but gaps in the arterial muscle wall are equally as common in patients with or without aneurysms and, once the aneurysm is formed, the weakness is found in the wall of the sac and not at its neck.[17] The association with smoking, hypertension and heavy drinking would suggest that degenerative processes are involved. Sudden hypertension plays a role in causing rupture, as shown by SAH in patients taking crack cocaine or, rarely, high doses of decongestants, such as pseudoephedrine.

CLINICAL PRESENTATION

Classically, there is a 'thunderclap' headache developing in seconds, with half of the patients describing its onset as instantaneous. This is followed by a period of depressed consciousness for less than 1 hour in 50% of patients, with focal neurology in about 30% of patients. About one-fifth of patients recall similar headaches and these may have been due to sentinel bleeds; this increases the chances of early rebleed 10-fold. The degree of depression of consciousness depends upon the site and extent of the haemorrhage. Meningism – neck stiffness, photophobia, vomiting and a positive Kernig's sign – is common in those patients with higher GCS. A high index of suspicion is needed for patients presenting with the classical headache; a non-contrast CT is recommended and, if negative, a lumbar puncture should be done 12 hours after ictus. If that is also negative, consider CTA.

The clinical severity of SAH is often described by a grade, the most widely used being that described by the World Federation of Neurological Surgeons (WFNS), which is summarised in Table 51.2. This grading, together with the extent of the haemorrhage and the age of the patient, gives some indication of the prognosis, in that the worse the grade the bigger the bleed, and the older the patient the less likely is a good prognosis. Another scale [Prognosis on Admission of Aneurysmal Subarachnoid Hemorrhage (PAASH) scale] has been validated for SAH prognosis, and has shown some benefits over WFNS; however WFNS is currently the most used and recommended scale.[18] Other poor prognostic signs are pre-existing severe medical illness, clinically symptomatic vasospasm, delayed multiple cerebral infarction, hyperglycaemia, fever, anaemia and medical complications, such as pneumonia and sepsis. Anatomical risk factors may increase periprocedural risk of complications. On the other hand, better outcomes seem to be associated with treatment in a high-volume neurosurgical centre.

COMPLICATIONS

The clinical status of the patient may be complicated by factors other than the physical effect of the initial bleed. Factors, such as acute hydrocephalus, early rebleeding, cerebral vasospasm, parenchymal haematoma, seizures and medical complications, must be considered.

Table 51.2 Clinical neurological classification of subarachnoid haemorrhage

GRADE	SIGNS
I	Conscious patient with or without meningism
II	Drowsy patient with no significant neurological deficit
III	Drowsy patient with neurological deficit – probably intracerebral clot
IV	Deteriorating patient with major neurological deficit (because of large intracerebral clot)
V	Moribund patient with extensor rigidity and failing vital centres

WFNS GRADE	*GCS*	*MOTOR DEFICIT*
I	15	Absent
II	14–13	Absent
III	14–13	Present
IV	12–7	Present or absent
V	3–6	Present or absent

GCS, Glasgow Coma Score; *WFNS*, World Federation of Neurological Surgeons.

REBLEEDING

This may occur within the first few hours after admission and 15% of patients may deteriorate from their admission status. They may require urgent intubation and resuscitation, but not all rebleeds are unsurvivable, and as such deterioration should be treated. The chance of rebleeding is dependent on the site of the aneurysm, the presence of the clot, the degree of vasospasm and the age and sex of the patient. Although most studies quote an incidence for rebleeding of 4% in the first 24 hours, more recent studies suggest an incidence of 9%–17% with most cases occurring within 6 hours. A few small studies have shown that antifibrinolytics, such as tranexamic acid, can be used early and short term (<72 hours) in patients who do not have a pre-existing high risk for thrombotic events, for the prevention of rebleeding while awaiting securing of the aneurysm. It is an off-licence use of antifibrinolytics.[16]

ACUTE HYDROCEPHALUS

This may occur within the first 24 hours post ictus and is often characterised by a drop in the GCS, sluggish pupillary responses and bilateral downward deviation of the eyes ('sunset eyes'). If these signs occur, a CT scan should be repeated and, if hydrocephalus is

confirmed or there is a large amount of intraventricular blood, then a ventricular drain may be inserted. This is recommended by the AHA/ASA.[19]

DELAYED CEREBRAL ISCHAEMIA

Vasospasm is the term used to describe the narrowing of the cerebral blood vessels in response to the SAH seen on angiography. It occurs in up to 70% of patients, but not all of these patients will have symptoms. Delayed cerebral ischaemia (DCI) refers to the onset of focal neurological deficit, a drop in GCS by 2 or more points, and/or cerebral infarction that occurs typically 4–12 days post SAH unrelated to aneurysm treatment or other causes of neurological deficit, such as hydrocephalus, cerebral oedema or metabolic disorder.[20] The use of transcranial Doppler (TCD) to estimate middle cerebral artery blood velocity has shown that a velocity of more than 120 cm/s correlates with angiographic evidence of vasospasm. This technology allows diagnosis in the ICU and provides a means of monitoring the success of treatment to reduce DCI, which is undertaken to reduce the severity of delayed neurological deficit secondary to vasospasm. The problem is that not all patients who have angiographic vasospasm or high Doppler velocities have symptoms. If there is evidence of a depressed level of consciousness in the absence of rebleeding, hydrocephalus or metabolic disturbances, but there is evidence of DCI clinically, on TCD or angiogram, then it would seem appropriate to initiate treatment. If vasospasm occurs at the time of angiography or coiling, then intravascular vasodilators, such as papaverine or nimodipine have been used. CTA is the imaging modality of choice unless intracerebral therapy is planned, then digital subtraction angiography (DSA) is recommended as first-line imaging.

PARENCHYMAL HAEMATOMA

This may occur in up to 30% of SAH following aneurysm rupture and has a much worse prognosis than SAH alone. If there is mass effect with compressive symptoms then evacuation of haematoma and simultaneous clipping of the aneurysm may improve outcome.

MEDICAL COMPLICATIONS

Medical complications will occur in 40% of SAH patients. The mortality due to medical complications is almost the same as that due to the combined effects of the initial bleed, rebleeds and DCI. The types of medical complication seen are shown in Table 51.3.

Table 51.3 Types of medical complication seen in patients with subarachnoid haemorrhage

MEDICAL COMPLICATION	INCIDENCE (%)
Arrhythmias	35
Liver dysfunction	24
Neurogenic pulmonary oedema	23
Pneumonia	22
ARDS and atelectasis	20
Renal dysfunction	5

ARDS, Acute respiratory distress syndrome.

INVESTIGATIONS

The general investigations for stroke should be performed, and early CT imaging is mandatory. Blood appears characteristically hyperdense on CT and the pattern of haemorrhage may enable localisation of the arterial territory involved (Fig. 51.3). Very rarely, a false-positive diagnosis may be made if there is severe generalised oedema resulting in venous congestion in the subarachnoid space. Small amounts of blood may not be detected, and the incidence of false-negative reports is around 2%.[19] It may be difficult to distinguish between post-traumatic SAH and primary aneurysmal SAH, which precipitates a fall in the level of consciousness that provokes an accident or fall. MR scanning is particularly effective for localising the bleed after 48

Figure 51.3 Subarachnoid haemorrhage on computed tomography scan of the head.

hours when extravasated blood is denatured, and provides a good signal on MRI.

Lumbar puncture is still necessary in those patients where the suspicion of SAH is high despite a negative CT, or there is a need to exclude infection. There must be no raised ICP and at least 12 hours should have passed to give time for the blood in the CSF to lyse, enabling xanthochromia to develop.

Angiography via arterial catheterisation is still the most commonly used investigation for localising the aneurysm or other vascular abnormality prior to surgery. It is generally performed on patients who remain, or become, conscious after SAH. It is not without risk and aneurysms may rupture during the procedure, and a meta-analysis has shown a complication rate of 1.8%. Other methods under investigation include CTA and MRA. DSA is the diagnostic tool of choice in cases where CTA is still inconclusive.[19]

ICP monitoring is of limited use in SAH patients except in those where hydrocephalus or parenchymal haematoma is present, and early detection of pressure increases may be the trigger for drainage or decompressive surgery.[21]

Multimodal monitoring: TCD studies may be useful in detecting vasospasm or those patients in whom autoregulation is impaired.[19] The technique is dependent on there being a 'window' of thin temporal bone allowing insonation of the Doppler signal along the middle cerebral artery. It is very user dependent and 15% of patients do not have an adequate bone window. Continuous EEG monitoring, cerebral blood flow monitoring, jugular venous oximetry, brain tissue oxygen oximetry and cerebral microdialysis have all been used to diagnose DCI.[22]

MANAGEMENT

The initial management of SAH is influenced by the grading, medical co-morbidity or complications, and the timing or need for surgery. Patients with decreased GCS may need early intubation and ventilation, simply for airway protection, whereas those with less severe symptoms require regular neurological observation, analgesia for headache and bed rest prior to investigation and surgery. Other management options are stress ulcer prophylaxis, deep-vein thrombosis prophylaxis using compression stockings or boots, and seizure control with phenytoin or barbiturates. If the patient is sedated and ventilated, the use of an analysing cerebral function monitor should be considered to detect subclinical seizure activity.

Hyponatraemia is a common finding and adequate fluid therapy with normal saline is required with electrolyte levels maintained in the normal range. Occasionally, as in other types of brain injury, excessive natriuresis occurs and may result in hyponatraemic dehydration – cerebral salt-wasting syndrome (CSWS).[23] Its aetiology is not known, but some suggest increased levels of atrial natriuretic peptide. It usually occurs within the first week after insult and resolves spontaneously in 2–4 weeks. Failure to distinguish CSWS from the syndrome of inappropriate secretion of antidiuretic hormone (SIADH) could lead to inappropriate treatment by fluid restriction, which would have adverse effects on cerebral perfusion. Urine sodium concentrations are usually elevated in both SIADH and CSWS (>40 mmol/L) but urinary sodium excretion, urine sodium concentration [Na mmol/L] × urine volume [L/24 hours] is high in CSWS and normal in SIADH. If CSWS does not respond to fluid replacement with saline or is not self-limiting then fludrocortisone therapy may be useful. Euvolaemia is crucial to help prevent and not exacerbate DCI.

BLOOD PRESSURE CONTROL

Elevation of BP is commonly seen after SAH and there are no precise data on what constitutes an unacceptably high pressure that is likely to cause rebleeding. Equally, there are no precise data on a minimum level of pressure below which infarction is likely to occur, since this will depend on the patient's normal pressure, the degree of cerebral oedema and the presence or absence of intact autoregulation. One observational study has demonstrated reduced rebleeding, but higher rates of infarction, in newly treated compared with untreated post-SAH hypertensive patients. Although there are no precise data on specific BP controls, the AHA guidelines recommend that systolic BP is kept <160 mm Hg or mean arterial pressure of <110 mm Hg in a person with an unsecured aneurysmal SAH.[19] Beta-adrenergic blockers or calcium antagonists are the most widely used agents, since drugs producing cerebral vasodilation may increase ICP. The choice is less important than the titratability of the drug, as the balance between the increased risk of rebleed and cerebral perfusion needs to be maintained. If nimodipine causes severe hypotension, timing and dose need to be changed too (i.e. 30 mg 2-hourly instead of 60 mg 4-hourly). If nimodipine still remains a problem, consider omitting doses until the patient is more cardiovascularly stable while maintaining euvolaemia.

DELAYED CEREBRAL ISCHAEMIA

Angiographic demonstration of vasospasm may be seen in about 70% of SAH patients, but only about 30% develop cerebral symptoms related to vasospasm, hence the change of nomenclature.

Symptoms tend to occur between 4 and 14 days post-bleed, which is the period when cerebral blood flow is decreased after SAH.

PREVENTION

One method of pre-empting vasospasm is oral nimodipine at 60 mg given 4-hourly for 21 days, which has been shown to achieve a reduction in the risk of ischaemic stroke of 34%. Intravenous nimodipine should be used in the patients who are not absorbing enterally, but it must be titrated against BP to avoid hypotension. Aspirin, clazosentan, enoxaparin, erythropoietin, fludrocortisone, magnesium, methylprednisolone, nicardipine and statins have been in trials but have not been shown to prevent DCI.[22]

TREATMENT

Low cerebral blood flow is known to worsen outcome and this resulted in the development of prophylactic hypertensive hypervolaemic haemodilution – so-called triple-H therapy. This has been shown to cause harm. The focus now is on euvolaemia and, if this is indicated and the BP is not already raised, hypertension is induced with vasopressors. This needs to be done in a stepwise fashion with assessment of neurological function at each step.[22] Cerebral angioplasty or direct intracerebral vasodilators should be considered if induced hypertension is not reversing the DCI symptoms. Where symptoms develop it is important to exclude other causes, such as rebleeding, hydrocephalus or metabolic disorder. Poor-grade SAH patients who are sedated or have low GCS are clinically difficult to assess; multimodal monitoring is recommended to look for deterioration.[22]

SEIZURES

Seizure occurs in up to 26% of SAH sufferers. The evidence for prophylactic use of anticonvulsants is poor and not recommended. Some prognostic indicators for the development of seizures have been identified: increased intracerebral blood, poor-grade SAH, rebleeding infarction and MCA aneurysm. Patients should be observed for seizure activity and treated appropriately. A patient with poor-grade SAH who is not improving or is deteriorating neurologically, from an unknown cause, should have continuous EEG monitoring.[16]

SURGERY

Clipping of the aneurysm is the surgical treatment of choice, with wrapping, proximal ligation or bypass grafting being used if the aneurysm is inaccessible to Yasargil clipping. The timing of surgery remains debatable. Recommendations by the AHA are to secure the aneurysm within 48 hours of ictus or 48 hours of presentation. Large intracerebral haematomas associated with the SAH and middle cerebral artery aneurysms should be strongly considered for surgery. There is no good level-one evidence for the use of induced hypertension or hypothermia during clipping, but in certain patients it could be considered. What is clear is that hypotension and hyperglycaemia should be avoided.[19]

ENDOVASCULAR COILING

In patients with ruptured intracranial aneurysms suitable for both surgery and endovascular coiling treatments, endovascular coiling is more likely to result in independent survival at 1 year than neurosurgical clipping; the survival benefit continues for at least 7 years. The risk of late rebleeding is low, but is more common after endovascular coiling than after neurosurgical clipping as well as retreatment of up to 20%.[24] Additional complications of coiling include rupture during catheter placement in the aneurysm, coil embolisation and vasospasm. Not all aneurysms, particularly those with wide necks, multiple filling vessels or giant aneurysms, are suitable for coiling. Aneurysms that are amenable to either surgery or coiling should be coiled; if patients are elderly (>70 years) or have poor-grade SAH then coiling is preferred. Stenting of acute SAH carries a worse prognosis.[19]

THERAPY OF MEDICAL COMPLICATIONS

This is specific to the type of complication. Pneumonia may require continuous positive airway pressure or ventilatory support together with directed antimicrobial therapy; acute respiratory distress syndrome requires lung-protective/recruitment ventilatory strategies; and renal failure necessitates an appropriate means of renal replacement therapy. Arrhythmias require correction of trigger factors, such as hypovolaemia and electrolyte or acid-base disturbances prior to the appropriate antiarrhythmic drug or direct current cardioversion. Cardiac function should be evaluated in patients with cardiovascular deterioration, by means of serial enzymes and echocardiography. Cardiac output monitoring should be considered. Neurogenic pulmonary oedema may be associated with severe cardiogenic shock, which may require inotropic support or even temporary intra-aortic balloon counterpulsation. The cardiogenic shock is reversible and patients can make a good recovery despite the need for aggressive support.[25]

Hyper- and hyponatraemia are frequently seen, with hyponatraemia occurring in up to 30% of cases, and it is implicated in the development of DCI. The aim is for euvolaemia; if it cannot be achieved because of a persistent negative fluid balance as a result of CSWS, then fludrocortisone should be considered. Hyponatraemia should be corrected by no more than 0.5 mmol/L per hour with a maximum of 8 mmol/L per day (if it is chronic; i.e. of more than 48 hours' duration) during which 4-hourly sodium levels should be taken. This may be achieved by using intravenous fluid that has more sodium than the serum concentration of the patient. In patients who are resistant to vasopressors, hypothalamic dysfunction should be considered and

hydrocortisone should be administered, but no more than 300 mg/day.

Blood glucose should be kept at 4.4–11.1 mmol/L (80–200 mg/dL), as higher and lower levels of blood glucose have been shown to be detrimental to the outcome.

Fever should be controlled by antipyretics as the first-line treatment, especially when DCI is suspected. Cooling devices should be considered if first-line antipyretics have failed, but care should be taken to monitor for pressure ulcers and venous thrombotic events. Shivering needs to be addressed as this will be counterproductive to therapy by increasing oxygen consumption.

Deep-vein thrombosis prophylaxis should be instituted as soon as possible in the form of graduated compression devices; heparin (unfractionated or low molecular weight) should be started 24 hours after securing the aneurysm.[16]

Anaemia should be minimised by limiting the amount of blood taken for blood tests. A transfusion trigger of 8 g/dL in patients without DCI and 9–10 g/dL in patients with DCI has been recommended.[22]

Cerebral protection

Colin Andrew Eynon

'The chief function of the body is to carry the brain around.'

Thomas A. Edison

'The human brain has 100 billion neurons, each neuron connected to 10 thousand other neurons. Sitting on your shoulders is the most complicated object in the known universe.'

Michio Kaku

CEREBRAL PHYSIOLOGY AND ANATOMY

The brain receives around 15% of the cardiac output (50 mL/100 g/min) and utilises around 3–5 mL O_2/min per 100 g tissue and 5 mg glucose/min per 100 g tissue. The grey matter of the brain, which consists primarily of the neuronal cell bodies and synapses, has a higher blood flow compared with the white matter, which consists largely of fibre tracts. Critical cerebral blood flow (CBF) is around 20 mL/100 g/min, with the electroencephalogram (EEG) becoming isoelectric at 15 mL/100 g/min.

The anterior cerebral circulation is provided by the two internal carotid arteries which subdivide into the anterior and middle cerebral arteries. These provide around 70% of the cerebral circulation supplying the frontal, parietal and temporal lobes and the anterior diencephalon (basal ganglia and hypothalamus). The two vertebral arteries join to form the basilar artery which supplies the posterior circulation; the brainstem, cerebellum, occipital lobes and the posterior diencephalon (thalamus). The two circulations (anterior and posterior) are joined by communicating arteries to form the circle of Willis at the base of the brain. As the circle facilitates collateral flow, obstruction to one of the four principle arteries (right and left internal carotid, right and left vertebral) supplying the brain may be clinically insignificant. Damage to the intracerebral vessels, however, often results in significant damage due to the lack of anatomical reserve. The areas between those supplied by the principle cerebral arteries are supplied by the leptomeningeal arteries. These areas are potential watershed areas that are particularly at risk in conditions of low- or no-flow such as cardiac arrest, severe sepsis or following major trauma (Fig. 52.1).

CEREBRAL PERFUSION

Cerebral perfusion is controlled in part by the perfusion pressure across the brain (cerebral perfusion pressure or CPP). CPP is the difference between the cerebral arterial pressure and cerebral venous pressure. As these pressures are difficult to measure, systemic mean arterial pressure (MAP) and intracranial pressure (ICP) are used as surrogates.

$$CPP = MAP - ICP$$

MAP can be estimated as equal to diastolic blood pressure + 1/3 pulse pressure. In adults, the normal resting ICP is 0–10 mm Hg. ICP can rise to 50 mm Hg or higher during straining or sneezing with no impairment in cerebral function. It is not, therefore, an elevated ICP alone that is important in pathological conditions. CPP is around 60 mm Hg in the normal state.

CEREBRAL METABOLISM

The energy requirements of the brain are large, in order to maintain membrane integrity and to support the transmembrane ion gradients required for electrical activity and cell survival. Energy is also required for the synthesis, storage and release of neurotransmitters. Neurones produce adenosine triphosphate almost entirely by the oxidative metabolism of glucose and ketone bodies. Over 85% of the glucose used by the brain undergoes oxidative metabolism with brain tissue having only very limited ability for anaerobic metabolism. Consciousness is lost rapidly if the supply of either oxygen or glucose is restricted. Loss of consciousness will occur in less than 10 seconds following acute decompression at 50,000 ft, with the time delay resulting from the transit time of deoxygenated blood from the lungs to the brain.[1] Similarly, unconsciousness occurs swiftly following intravenous administration of high doses of insulin.[2]

ABSTRACT

The brain is arguably the most important organ in the body and also one of its most vulnerable. Primary brain injury may result from conditions such as trauma, stroke or intracerebral haemorrhage (ICH), or it may be secondarily injured most commonly due to circulatory or respiratory disease. Cerebral protection is the application of often simple, therapeutic interventions with the intention of limiting or preventing further neuronal injury and thus improving the patient's ultimate neurological outcome. The key to cerebral protection is early intervention, as neuronal damage can occur within minutes of an insult. Prevention of hypoxia, hyper- and hypocarbia, hyper- and hypoglycaemia, seizures and maintenance of adequate cerebral perfusion and osmolarity are all important. Although many therapeutic agents have been studied to try and reduce neuronal damage, very few have been successfully transferred into clinical practice.

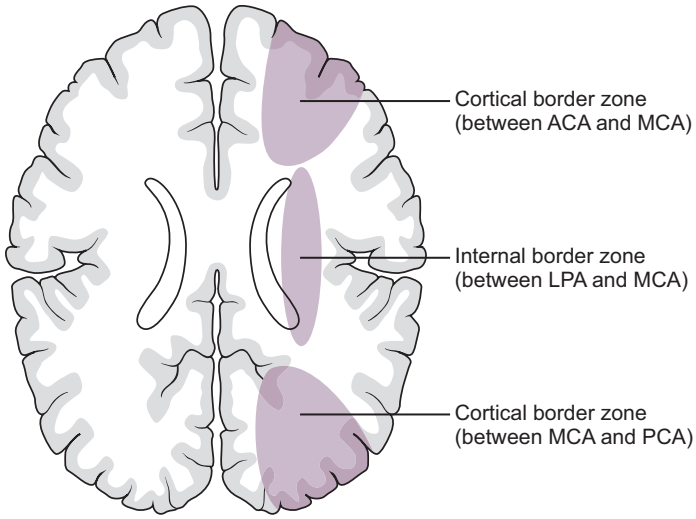

Figure 52.1 Axial view of the brain showing the major arterial territories. Watershed infarcts may occur at the border between the major cerebral arterial territories in conditions of low blood flow. These may be (a) cortical border zone infarcts (infarction of the cortex and neighbouring subcortical white matter at the border of the ACA and the MCA and/or the MCA and the PCA), or (b) internal border zone infarction of deep white matter (between the LPA and the deep cortical branches of the MCA or at the border zone of deep white matter branches of the MCA and the ACA). *ACA,* Anterior cerebral artery; *LPA,* lentriculostriate perforating arteries; *MCA,* middle cerebral artery; *PCA,* posterior cerebral artery.

LOCAL CONTROL OF CEREBRAL BLOOD FLOW

AUTOREGULATION (MYOGENIC REGULATION)

Autoregulation ensures that CBF remains constant between MAPs from 60 to 160 mm Hg. The stimulus for autoregulation is CPP. Autoregulation is thought to be a myogenic mechanism with reflex vasoconstriction of cerebral vessels occurring in response to increases in CPP and vascular wall tension, and vasodilatation occurring in response to decreases in CPP and reduction in wall tension.[3] Outside the values where autoregulation is effective, the relationship between CBF and MAP is linear and CBF is pressure dependent (Fig. 52.2). The range at which autoregulation can operate varies with age and in certain pathological conditions. The range is shifted to the left in early life and to the right in chronic hypertension. A rapid reduction in the blood pressure of a patient with chronic hypertension risks inadequate perfusion of the brain, heart and/or the kidneys. Autoregulation may be also impaired by hypoxia, ischaemia, hypercapnia, trauma and certain anaesthetic agents.

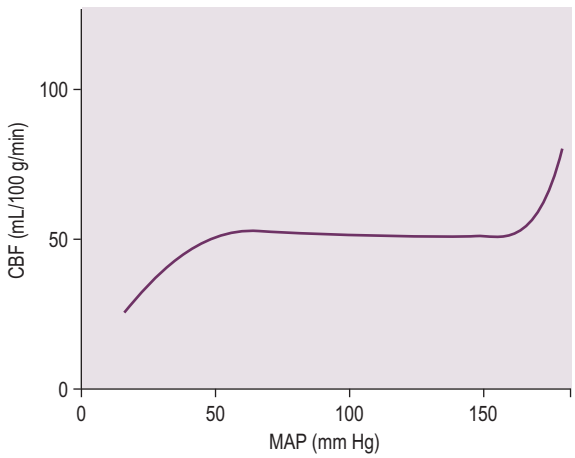

Figure 52.2 The relationship between mean arterial pressure *(MAP)* and cerebral blood flow *(CBF)* under normal circumstances, illustrating the range of autoregulation.

Rapid rises in systemic blood pressure are also poorly tolerated. Hypertensive emergencies occur in an estimated 1–2/100,000 patients per year and may be associated with retinopathy, papilloedema or encephalopathy. Hypertensive encephalopathy results from cerebral oedema due to increased hydrostatic pressures and can cause drowsiness, coma, seizures and ICH. Posterior reversible encephalopathy syndrome (PRES) may present with seizures, disturbed vision, headache and altered mental state.[4] It is strongly linked to conditions that co-exist in patients with renal disease, such as hypertension, vascular and autoimmune diseases, immunosuppression, and organ transplantation. More than 70% of patients are

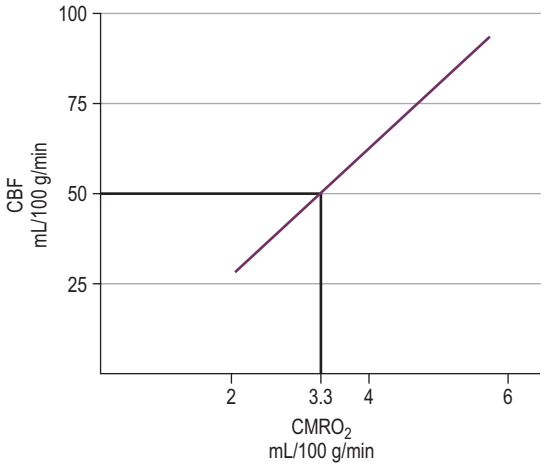

Figure 52.3 Flow-metabolism coupling. As the cerebral metabolic rate for oxygen *($CMRO_2$)* increases there is proportional increase in cerebral blood flow *(CBF)*. Normal CBF is around 50 mL/100 g/min.

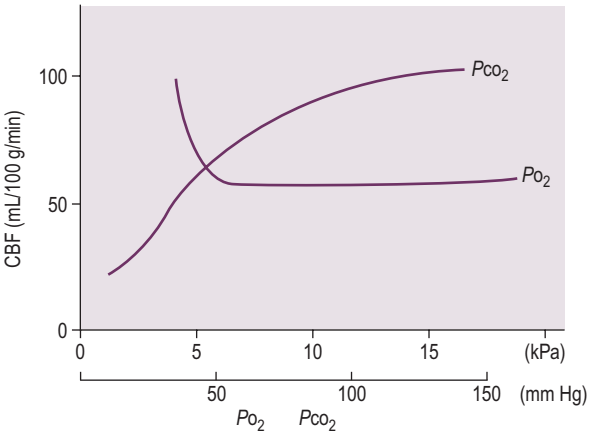

Figure 52.4 The relationship between the partial pressure of oxygen and carbon dioxide and cerebral blood flow *(CBF)*.

hypertensive. Typical magnetic resonance imaging (MRI) findings are of reversible, symmetrical, posterior subcortical vasogenic oedema.[5] If promptly treated and managed, symptoms often resolve within a few days to weeks.

FLOW–METABOLISM COUPLING

Flow–metabolism coupling is the direct relationship of the metabolic activity of the brain to CBF. Increases in metabolic demand are met rapidly by increases in CBF and delivery of substrates (Fig. 52.3). The exact mechanisms that control flow–metabolism coupling are unknown but may involve a variety of mediators such as neurokinin-A, nitric oxide and substance P. It is not clear how the diameter of cerebral vessels upstream to the area of activity can be altered so rapidly by metabolic products which are being washed downstream. It is thought that there may be control neurons that act on specific cerebral vessels that control local blood flow.[6] Regional variations in cerebral metabolism can now be visualised using techniques such as positron emission tomography scanning, although the hypothesis that such variations existed dates as far back as 1890.[7]

SYSTEMIC CONTROL OF CEREBRAL BLOOD FLOW

CARBON DIOXIDE

CBF increases by 3%–4% for each mm Hg increase in $PaCO_2$. A doubling of $PaCO_2$ doubles CBF and conversely a halving of $PaCO_2$ will halve CBF (Fig. 52.4). The responses to changes in $PaCO_2$ occur rapidly, within 30s, and are thought to relate to changes in extracellular or interstitial hydrogen ion concentrations. Tight control of $PaCO_2$ is essential if CPP is critical; increases in CO_2 cause vasodilatation and increased ICP, whereas decreases in $PaCO_2$ below 4 kPa have been shown to result in vasoconstriction sufficient to precipitate critical cerebral ischaemia.[8] Impaired CO_2 reactivity is associated with poor outcomes in patients with severe head injury.[9]

OXYGEN

CBF is not affected by changes in Pa_{O_2} within the normal range, but levels <50 mm Hg (6.65 kPa) result in cerebral vasodilatation and increases in CBF. Below 30 mm Hg (4 kPa), CBF is roughly doubled with a consequent increase in ICP (see Fig. 52.4).

TEMPERATURE

The cerebral metabolic rate for oxygen ($CMRO_2$) is reduced by around 8% for each degree Celsius reduction in temperature. Mild hypothermia remains recommended for the management of patients who are resuscitated from cardiac arrest.[10] More profound cooling enables patients to withstand prolonged periods of low CBF during cardiopulmonary bypass. Application of cooling to unselected patients with traumatic brain injury is now thought to be ineffective.[11] Avoidance of hyperthermia in cerebral injury remains important as $CMRO_2$ is increased by a similar amount for every degree Celsius increase in temperature.

CEREBRAL INJURY

Cerebral injury is commonly divided into primary and secondary. Primary injuries include traumatic,

ischaemic or hypoxic and may be focal or global. Secondary injuries may be initiated as a consequence of the primary injury and can contribute significantly to the ultimate outcome of the patient.

Primary traumatic brain injury may result in four main pathological conditions which can all co-exist: brain contusions, axial and extra-axial haematomas (subdural, extradural and intracerebral), traumatic subarachnoid haemorrhage (SAH) and diffuse axonal injury (DAI). DAI results from dynamic deformation of the brain with resultant shearing forces, affecting the blood vessels and axons. Areas commonly affected include axons in the brainstem, the parasagittal white matter near the cerebral cortex, and the corpus callosum.[12]

Focal hypoxic or ischaemic insults often occur acutely such as in acute stroke. If the area supplied by the affected artery has a good collateral supply, injury may be modest. If, however, the area is poorly supplied, cell death will occur within minutes without reperfusion. Around areas of infarction there is an ischaemic penumbra. Interventions to preserve function in the penumbral area are the key to optimising outcome.

Global hypoxic-ischaemic conditions are often secondary to respiratory or cardiovascular insufficiency, seen most severely in cardiorespiratory arrest. Recovery depends on rapid reversal of the primary cause. MRI examination of patients with persistent disorders of consciousness following resuscitation from cardiac arrest have shown regions of pathological white matter signals in the frontal and occipital lobes and in the periventricular regions.[13] The total volumes of the lesions have been associated with the severity of the patients' outcomes. These patterns demonstrate the different vulnerabilities of particular areas of the brain to ischaemia-hypoxia.

Secondary injury may be initiated as a consequence of the primary injury. The duration and severity of secondary insults can have a significant effect on patient outcome and present an opportunity for prevention or early clinical intervention.[14–17] Intracranial secondary injury may be caused by expansion of intracranial haematomas or the development of cerebral oedema causing pressure effects on more distant parts of the brain, distortion of blood supply or further axonal shearing. Shift of vital structures can ultimately lead to herniation of the brain. Secondary seizure activity can rapidly deplete the brain's supply of metabolites.

Systemic secondary insults include hypoxia, hypotension, hyper- or hypocarbia, hyperthermia, hyper- and hypoglycaemia, anaemia and electrolyte disturbances. Many studies have demonstrated the importance of the duration and severity of secondary insults on the outcome from traumatic brain injury (Table 52.1).

Table 52.1 Effects of secondary injuries on outcome from traumatic brain injury

INSULT	IMPACT ON MORTALITY	IMPACT ON GLASGOW OUTCOME SCORE
Duration of SBP <90 mm Hg	Yes	Yes
Duration of Sa_{O_2} <90%	Yes	No
Duration of temp >38°C	Yes	No
Duration of ICP >30 mm Hg	Yes	No
Duration of CPP <50 mm Hg	Yes	No

CPP, cerebral perfusion pressure; *ICP*, intracranial pressure; *SBP*, systolic blood pressure.

Although hyperventilation of patients with severe brain injury has previously been recommended as a short-term measure to manage elevated ICP before more definitive measures can be employed, there is now evidence of the effects of hypocarbia on cerebral vasculature with vasoconstriction and secondary ischaemia/hypoxia. Levels of $PaCO_2$ below 4 kpa should be avoided.[8]

Anaemia has been associated with poorer outcomes in traumatic brain injury (TBI), aneurysmal SAH, ICH and ischaemic stroke. Transfusion improves brain oxygenation in some patients with TBI.[18] Most critical care units now adopt a restrictive strategy to red cell transfusion using a trigger haemoglobin around 7–8 g/dL. In patients with TBI, neither administration of erythropoietin nor maintaining a haemoglobin concentration >10 g/dL have resulted in improvement in neurological outcome and the 10 g/dL threshold was associated with a greater incidence of adverse events.[19]

The brain is particularly vulnerable to disturbances of osmolality.[20,21] Under physiological conditions, brain osmolality is in equilibrium with extracellular fluid osmolality. When hyponatraemia occurs, the reduction in plasma osmolality causes water movement into the brain along the osmotic gradient, causing cerebral oedema. Cerebral volume increases by around 7% for every three milli-osmolar reduction in osmolality.

METABOLIC AND BIOCHEMICAL PROCESSES IN CEREBRAL INJURY

The pathophysiology of brain injury is complex (Fig. 52.5). Even brief disturbances in CBF and delivery of substrates can initiate a cascade of events leading to cellular death.[22] Different areas of brain have differing thresholds for damage, with the cell bodies (grey matter) being more resilient than the white matter (axons). Anaerobic metabolism results in intracerebral acidosis with accumulation of lactic acid and hydrogen ions. Loss of the normal homeostatic mechanisms responsible for the maintenance of ion gradients results in abnormal sodium, potassium, calcium and chloride movements and the failure of glutamate reuptake into

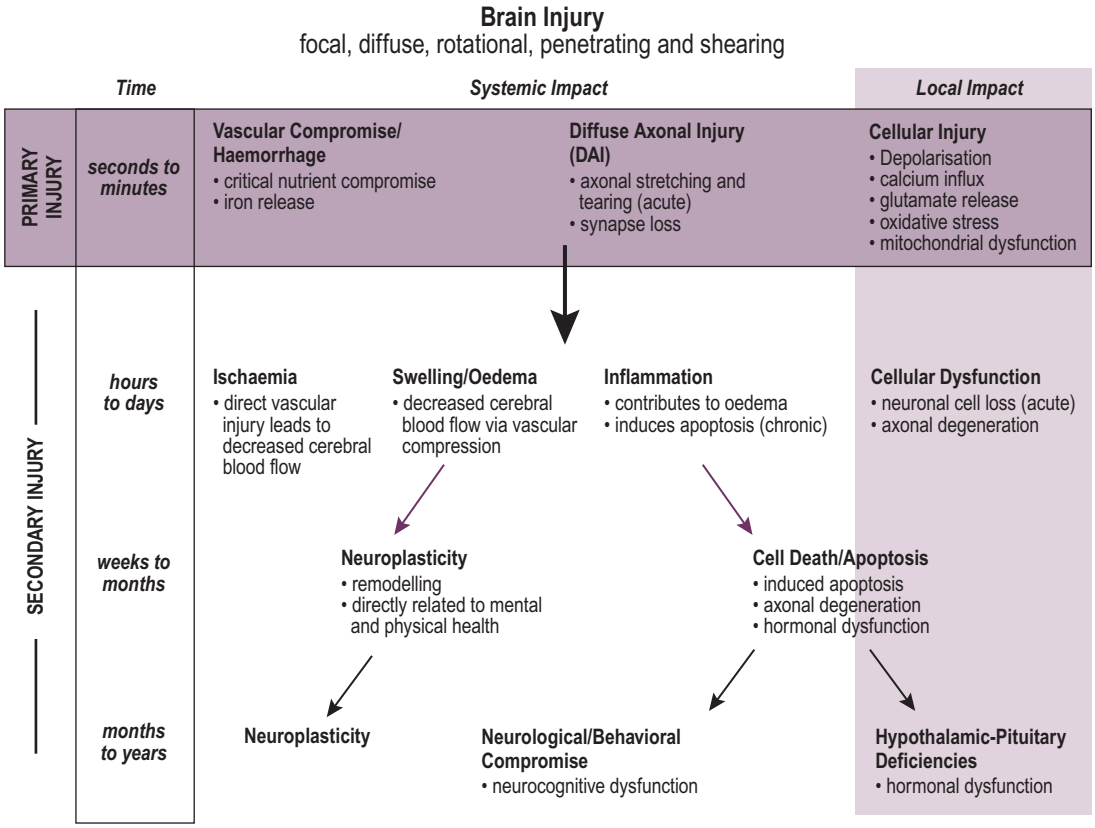

Figure 52.5 Hypothesised model for progression from primary to secondary injury after trauma to the central nervous system. *Modified from Reifschneider K, Auble BA, Rose SR. Update of endocrine dysfunction following paediatric traumatic brain injury.* J Clin Med. *2015;4(8):1536–1560 (with permission).*

cells. Glutamate and aspartate are the main excitatory neurotransmitters in the brain. When uptake mechanisms fail, toxic levels of glutamate can accumulate in the extracellular space, causing a surge of neuronal activity and membrane depolarisation. The increases in intracellular calcium and sodium activate pathways mediated by Ca^{2+} dependent enzymes. The restriction of oxygen and substrates to mitochondria induces a cellular metabolic crisis with disruption of cell membranes and organelles, activation of cellular apoptosis, activation of macrophages and platelet aggregation causing secondary disturbances of the microvasculature. Cytotoxic oedema occurs due to failure of ionic pumps with subsequent ion and fluid shifts. Vasogenic oedema is due to mediator release with damage to endothelium, basement membranes and glial cells with breakdown of the blood-brain barrier.

CEREBRAL PROTECTIVE STRATEGIES

For all patients, including those with brain injury, the priorities are the assessment and management of airway, breathing and circulation (ABC) over assessment of the neurological status (D – disability). For patients who have sustained major trauma, control of catastrophic haemorrhage is now included before ABC (C-ABC). Cerebral protective strategies must start pre-hospital to maximise the opportunities for a good neurological outcome.

AIRWAY

Recommendations regarding securing of the airway in patients with brain injury include those patients with the following[23]:

- Glasgow Coma Score ≤8, or with a significantly deteriorating conscious level (i.e. fall in motor score of ≥ two points)
- Loss of protective laryngeal reflexes
- Hypoxia (Pa_{O_2} <13 kPa on oxygen)
- Hypercarbia ($PaCO_2$ >6 kPa)
- Spontaneous hyperventilation causing $PaCO_2$ <4.0 kPa
- Bilateral fractured mandible or copious bleeding into the mouth (e.g. from skull base fracture)
- Seizures

The projected clinical course of the patient should also be considered. Those requiring transfer for definitive care or who are likely to require surgery for other conditions may require early intubation.

OXYGEN

The National Confidential Enquiry into Patient Outcome and Death (NCEPOD) report, 'Trauma: who cares?' published in 2007 found that administration of oxygen was only documented to have occurred in 78% of patients with neurological injury and that peripheral oxygen saturations of <95% occurred in 28% of patients pre-hospital.[24] In mechanically ventilated patients with TBI, avoidance of hypoxia may require application of positive end-expiratory pressure (PEEP) especially in patients with polytrauma. Although there is a theoretical risk that the increase in intrathoracic pressure can cause increased cerebral blood volume (CBV) and ICP, application of PEEP up to 15 cm H_2O has been used successfully in cases of refractory hypoxaemia.[25] National Institute for Health and Clinical Excellence (NICE) recommendations are that patients with acute stroke should have supplemental oxygen if the peripheral oxygen saturations fall below 95%.[26]

CARBON DIOXIDE

Tight control of $PaCO_2$ is required for all mechanically ventilated patients with acute cerebral injury. This can create difficulties in patients with co-existent lung disease or acute respiratory distress syndrome (ARDS) where a balance needs to be struck between the effects of a raised $PaCO_2$ on the brain and lung-protective strategies.[27–29] As detailed earlier, a target $PaCO_2$ of 4.5–5 kPa is usual in the acute stages of injury.

CEREBRAL PERFUSION (BLOOD PRESSURE TARGETS)

Cerebral perfusion depends on MAP and ICP. If the ICP is elevated due to the presence of intracranial haemorrhage or swelling, MAP must be increased to maintain CPP. Many patients with isolated acute intracranial injury have an initial period of arterial hypertension. Generally this will reduce spontaneously or with simple measures such as analgesia, relieving hypoxia or hypercarbia, and ensuring that the patient does not have other systemic disturbances such as urinary retention. There have been concerns that reducing the blood pressure acutely may risk the perfusion of penumbral areas and worsen the clinical outcome. Recent studies have shown benefit with intensive management of elevated blood pressure for patients with spontaneous ICH and in the early phase of management of SAH before the aneurysm is secured.[30] In patients with acute ischaemic stroke, the blood pressure needs to be less than 185/110 mm Hg prior to administration of thrombolytic therapy and controlled <180/105 mm Hg for the next 24 hours thereafter.

For patients who are unconscious following traumatic brain injury, it is generally recommended that the MAP target should be >80 mm Hg with the presumption that ICP is at least 20 mm Hg. This can present a challenge, especially with multiply injured patients. A patient who is hypotensive despite resuscitation should not be transported to specialist care until the cause has been identified and the patient stabilised. Persistent hypotension will significantly adversely affect the neurological outcome.

FLUIDS

Isotonic crystalloid and blood (if required) are the mainstays of fluid replacement in patients with cerebral injury; 0.9% saline is the only isotonic crystalloid solution that is commonly available. Gelatins, albumin, Ringer's lactate (compound sodium lactate), Ringer's acetate and Plasma-Lyte should be avoided as all are hypotonic when real osmolality (mosm/kg) is measured. The Brain Trauma Foundation (BTF) recommends that the sodium be kept >140 mmol/L for patients with TBI.[31] This avoids the risk of worsening cerebral oedema. Hyperosmolar therapy such as mannitol (2 mL/kg of a 20% solution) or hypertonic saline are often used when ICP is critically elevated. Despite clear effectiveness on measured ICP, there remains little evidence of improvement in clinical outcomes.[32]

POSITIONING 30 DEGREE HEAD UP (WITH SPINAL PRECAUTIONS)

Measures such as elevating the head of the bed by 30 degrees, ensuring the head is in a neutral position and in alignment with the body are important, simple steps that can reduce ICP. For patients with potential spinal injuries, the whole bed should be tilted.

TEMPERATURE CONTROL

Pyrexia is common following acute brain injury. Vigilance for possible infective sources, drug reactions or physical causes such as venous thromboembolism is essential. Central (neurogenic) fever can occur, thought due to disturbance of temperature regulation in the hypothalamus. It is uncommon and characterised by a constant fever which is often >40°C. As the normal regulatory point has been altered, patients characteristically have an absence of the measures normally taken to mitigate hyperthermia, such as sweating.[33] Maintenance of normothermia is common practice in specialist intensive care units (ICUs). Although therapeutic hypothermia has been shown to reduce ICP in patients with TBI, its widespread use has not been found to be beneficial in clinical trials.[11] Targeted temperature

management remains recommended for patients who remain unresponsive after resuscitation from cardiac arrest.[10]

SEDATION/ANALGESIA

Patients requiring intubation for cerebral protection are usually managed using a rapid sequence induction technique (with in-line stabilisation of the cervical spine for those with potential trauma). The use of an opiate is recommended to mitigate rises in ICP. The induction agent and dose used should be chosen to ensure maintenance of an adequate MAP. Commonly, barbiturates or propofol are used. Ketamine may be useful in haemodynamically unstable patients. The concerns regarding potential increases in ICP and cerebral metabolic rate with ketamine appear to be clinically unfounded.[34,35] Following intubation and ventilation, sedation in brain-injured patients is commonly maintained with continuous intravenous infusions of propofol or midazolam. Both reduce the cerebral metabolic rate for oxygen and CBF. High doses are often required to decrease the ICP. Use of continuous infusions of an opiate may help in reducing the amount of sedative required especially if there are concerns regarding propofol infusion syndrome.

SEIZURE CONTROL

Risk factors for early seizures following trauma (within 7 days of injury) include: Glasgow Coma Score (GCS) ≤10; immediate seizures, post-traumatic amnesia >30 minutes, linear or depressed skull fracture, penetrating head injury, subdural, epidural, or intracerebral haematoma, cerebral contusions, age ≤65 years, or chronic alcoholism.[31] Post-traumatic epilepsy is defined as recurrent seizures occurring more than 7 days following injury. The BTF recommends the use of phenytoin to decrease the incidence of early seizures when the overall benefit is felt to outweigh the potential complications associated with treatment.[31]

Seizures occur at the time of bleeding in around 7% of patients with SAH.[36] Another 10% will develop seizures over the first few weeks. Risk factors for early seizures include middle cerebral artery (MCA) aneurysm, thickness of acute subarachnoid clot, associated ICH, re-bleeds, cerebral infarction, poor neurological grade and mode of treatment with endovascular treatment having a lower risk of seizures.[36] The European Stroke Organisation recommends antiepileptic treatment only for those patients with overt seizures. The American Heart Association (AHA)/American Stroke Association guidance states that prophylactic anticonvulsants may be considered in the immediate post-haemorrhagic period.[37] Seizures occur in <16% of patient within 1 week after ICH. A cortical location of the ICH is the most important risk factor for early seizures. Prophylactic anticonvulsant medication has not been shown to be beneficial and the AHA recommends only treatment of clinical seizures.[38]

GLUCOSE CONTROL

Hyperglycaemia has been associated with poorer outcomes for a wide range of acute neurological conditions including TBI, SAH, ICH and acute ischaemic stroke.[39] Studies of tight glycaemic control have been disappointing and guidelines recommend the avoidance of both hyperglycaemia and hypoglycaemia.

SPECIFIC PHARMACOLOGICAL INTERVENTIONS

Although many potential neuroprotective agents have been tried, most clinical studies have failed to show outcome benefits.[22] Nimodipine is used to prevent cerebral vasospasm following aneurysmal SAH.[40] The lack of evidence regarding pharmacological interventions emphasises the importance of the adoption of simple protective measures and rapid access to specialist care.

SPECIALIST MONITORING

INTRACRANIAL PRESSURE

The major intracranial contents are the brain, blood (both arterial and venous), and cerebrospinal fluid (CSF). When a new intracranial mass is introduced (haemorrhage, hydrocephalus or cerebral oedema), a compensatory change in volume must occur through a reciprocal decrease in venous blood or CSF to maintain a constant total intracranial volume. This is the Monro-Kellie doctrine. In young children, with open fontanelles and whose sutures have not yet fused, the cranium can expand to physically accommodate extra volume. In the normal situation, changes in intracerebral volume produce little or no change in ICP and the compensatory reserve is good. If compensatory reserve is poor, any changes in intracerebral volume produce a rapid rise in ICP.

Although there is a lack of Class 1 evidence to support the measurement of ICP and the targeting of CPP in severe head injury, there is good evidence that measurement of these as part of a guideline of care on specialist units results in improvements in mortality and functional outcomes following brain injury.[31] Measurement of ICP may be of use in a number of other neurological conditions.[41] The value of ICP-based management for non-traumatic conditions is even less clear than in traumatic brain injury.

The devices commonly used to measure ICP are intraventricular and intraparenchymal catheter tip microtransducer catheters. Intraparenchymal monitors are most commonly placed by making a small incision in the scalp, screwing a bolt into the skull and then passing a spinal needle through the lumen of the bolt,

puncturing the dura. The monitor is then zeroed to atmospheric pressure before the transducer is passed through the bolt and into the brain parenchyma. The transducer is usually placed into the non-dominant frontal lobe or the dominant frontal lobe if the non-dominant lobe is the primary site of injury. The drift over time of modern intraparenchymal monitors is insignificant, the rates of infection are low and there is no need to routinely change the monitor. Pressure transducers in the subdural or subarachnoid space are now rarely used.

Intraventricular catheters are the gold standard for monitoring ICP and also allow drainage of CSF if the ICP is raised. External ventricular devices (EVDs) can be placed during craniotomy procedures or via a burr hole in similar manner to the intraparenchymal devices. If the ventricles are compressed, placement can be facilitated using ultrasound or stereotactic computed tomography (CT) guidance. The pressure monitor is zeroed to the level of the external auditory meatus. The risks from EVDs include a rate of <5% for placement-associated ICH (although the need for neurosurgical evacuation is far smaller) and <20% for catheter-related infections. Infection rates increase with the duration of placement and can be reduced by strict attention to asepsis during manipulation or use of antibiotic or silver-impregnated catheters.

Non-invasive methods of measuring ICP include transcranial Doppler (TCD), measurement of optic nerve sheath diameter and tympanic membrane displacement. Operator experience and reproducibility have limited the clinical applications of these techniques.

INTRACRANIAL PRESSURE IN NORMAL AND PATHOLOGICAL CONDITIONS

The normal ICP trace looks similar to an arterial trace (Fig. 52.6A). The three peaks are: P1 – the percussion wave caused by arterial pressure transmitted from the choroid plexus to the ventricle; P2 – the tidal wave thought to be due to brain compliance; and P3 – the dicrotic wave resulting from closure of the aortic valve. If the intracranial volume is increased, the ICP waveform shows an initial increase in amplitude, although the mean ICP remains largely unaltered. As the brain compliance reduces further, the P2 component of the wave exceeds P1 and the wave becomes broader (see Fig. 52.6B).

In 1960, Lundberg described fluctuations in ICP waves (Fig. 52.7).[42] Lundberg A waves or plateau waves are slow vasogenic waves seen in patients with critical cerebral perfusion. These waves can reach 50–100 mm Hg and last between 5–20 minutes before spontaneously subsiding. Plateau waves cause critical cerebral ischaemia within minutes and are thought to result from spontaneous reductions in MAP, resulting in cerebral vasodilatation. This results in increased ICP and further reduction in CPP until maximal cerebral vasodilatation occurs and the wave plateaus. Early termination of Lundberg A waves can occur if MAP is increased, thus restoring CPP. Plateau waves are always pathological and indicative of reduced cerebral compliance. Lundberg B waves are smaller changes in ICP that occur every 30 seconds to a few minutes and can be seen in normal individuals. ICP rises to levels 20–30 mm Hg above baseline before falling. Lundberg C waves are of little clinical importance. They are of low amplitude and occur with a frequency of 4–8/min and are associated with variations in blood pressure.

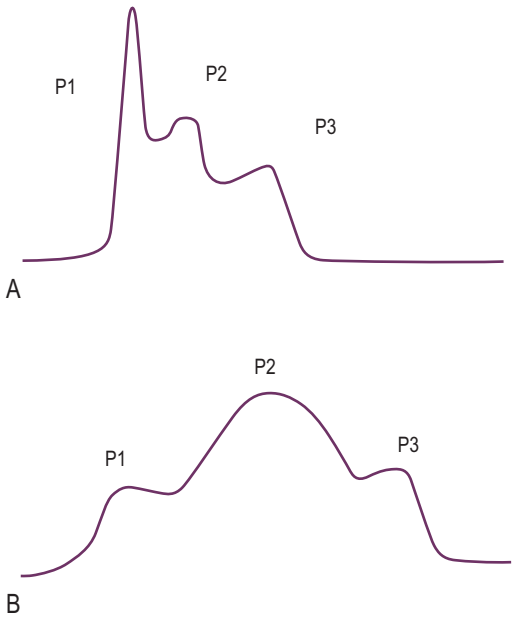

Figure 52.6 Intracranial pressure waveforms in (A) the normal state and (B) when brain compliance is reduced.

OTHER FORMS OF NEUROLOGICAL MONITORING

Patients with neurological illness can be monitored using a wide range of different techniques depending upon the condition and the institution where they are treated. In many specialist ICUs these techniques may be combined, often known as multimodality monitoring (MMM). Despite widespread use in specialist centres, there is limited evidence to support their effectiveness in improving outcomes.[43,44]

CEREBRAL OXYGENATION

Brain tissue oxygenation can be assessed using invasive or non-invasive methods. Intraparenchymal probes are available that measure brain oxygen content (Pbt_{O_2})

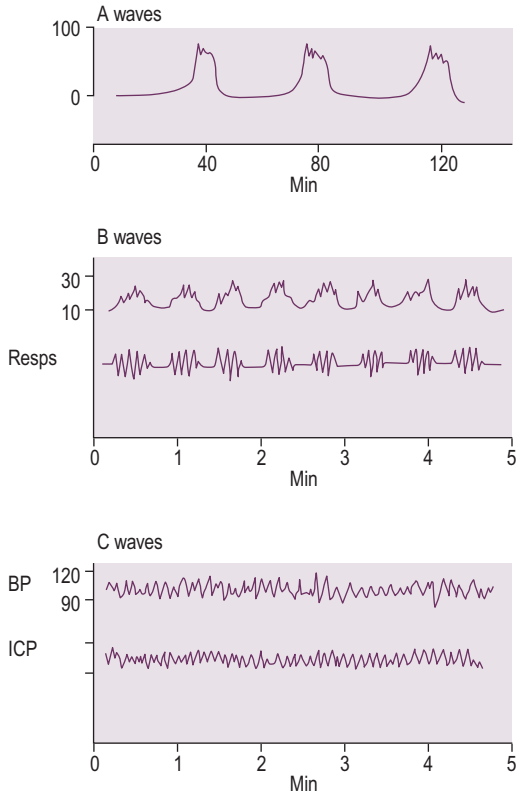

Figure 52.7 Lundberg waves. *A waves* are plateau waves of 50–100 mm Hg lasting 5–20 minutes that compromise CPP. *B waves* are smaller changes in ICP that occur every 30 seconds to a few minutes and may be associated with variations in partial pressure of oxygen and carbon dioxide due to changes in breathing patterns. *C waves* are of low amplitude, occur with a frequency of 4–8/min and are associated with variations in blood pressure. *BP*, blood pressure; *ICP*, intracranial pressure.

in the adjacent white matter. $P\text{bt}_{O_2}$ is the product of CBF and the arteriovenous tension of oxygen; brain oxygenation depends on both the adequate supply of oxygen and its extraction. The normal range of $P\text{bt}_{O_2}$ is 20–35 mm Hg. A level below 20 mm Hg has been suggested as the threshold for therapeutic intervention with increased morbidity and mortality associated with levels less than 10 mm Hg.

Jugular bulb venous oxygen saturation ($S\text{jv}_{O_2}$) provides information on the global utilisation of oxygen by the brain. A catheter is placed into the dominant internal jugular vein and advanced into the jugular bulb. Normal values for $S\text{jv}_{O_2}$ are between 55% and 75%. Low levels of $S\text{jv}_{O_2}$ are indicative of ischaemia resulting either from reduced oxygen delivery or increased demand. High levels of $S\text{jv}_{O_2}$ may indicate hyperaemia, reduced demand or tissue death.

Near-infrared spectroscopy (NIRS) measures regional cerebral oxygen saturation by measuring near-infrared light that is reflected from brain chromophores, the most commonly used of which is oxygenated haemoglobin. The changes in the concentration of near-infrared light are measured as it passes through these compounds and these allow calculation of their oxygenation status. Although NIRS has proved useful in vascular and cardiothoracic surgery, its value in the ICU has not been proven.

MICRODIALYSIS

Brain metabolism can be monitored using cerebral microdialysis probes. Dialysis fluid is passed through the catheter which has a semipermeable membrane. This allows molecules below the size of the membrane to equilibrate along the concentration gradient. The technique analyses substrates such as lactate, pyruvate, glucose, glutamate and glycerol in the extracellular fluid of subcortical white matter. Glutamate is an excitatory neurotransmitter that is associated with injury and inflammation. Glycerol is a lipid-rich component of neurons and is indicative of irreversible cell death when levels are elevated. Lactate, pyruvate and the lactate/pyruvate ratio are used as markers of hypoxia or ischaemia.

CEREBRAL BLOOD FLOW

Invasive measurement of regional CBF can be achieved using thermal diffusion probes or laser Doppler flowmetry. The thermal conductivity of brain tissue varies in proportion to CBF. The most commonly used CBF catheter introduces heat in subcortical white matter and calculates the rate of temperature dissipation at a set distance, allowing calculation of local CBF. Laser Doppler flowmetry involves placement of a small Doppler probe within the brain tissue. Doppler change of laser light is used to measure the movement of red cells within the cerebral microcirculation. Both techniques are limited to the assessment of a small area of cerebral tissue.

TCD ultrasound measures blood flow velocity in the major intracranial vessels. Although TCD measures velocity rather than flow, it can be used to assess relative changes in CBF. TCD is most widely used to assess vasospasm following SAH, high flow velocity being indicative of a reduction in vessel diameter. Comparison of the velocities in the MCA and the external carotid artery (the Lindegaard ratio) can help distinguish between vasospasm and hyperaemia.

ELECTROENCEPHALOGRAPHY

The EEG represents the summation of the brain's electrical activity as recorded from the scalp. It can be used to detect seizure activity, especially when there

is concern regarding non-convulsive status epilepticus, to monitor the response to antiepileptic therapy and to help to prognosticate in patients with persistent coma.[45] EEG monitoring is also useful in diagnosing pseudo-status epilepticus due to psychogenic problems, allowing rapid withdrawal of inappropriate drug therapies.

TIMELINESS OF SPECIALIST CARE

There is a wide body of evidence supporting the care of brain-injured patients in specialist facilities which are often distant to the hospital of first attendance.[46–50] Although many secondary preventive measures can be successfully applied pre-hospital or in a regional hospital prior to transfer to definitive care, rapid diagnosis and transfer is essential to optimise outcomes. The Society of British Neurosurgeons recommends the evacuation of acute extradural or subdural haemorrhages within 4 hours. Major trauma networks advocate direct transfer to specialist care if patients are within a certain time of the specialist centre. Automatic admission criteria have been developed to facilitate rapid transfer from other hospitals without waiting for 'permission' to transfer.[51]

The primary treatment of SAH is occlusion of any identifiable aneurysm that has ruptured. Up to 15% of patients re-bleed within a few hours of the initial bleed, often before definitive treatment can be undertaken. The European Stroke Organisation recommends that the aneurysm should be treated as early as possible to reduce the risk of re-bleeding, ideally within 72 hours of onset of first symptoms.[36] The volume of cases treated and the availability of endovascular services and neurological intensive care are also important determinants of outcome from SAH. The American Heart Association recommends that low-volume hospitals (<10 SAH cases per year) should consider early transfer of patients to high-volume centres (>35 SAH cases per year) with experienced neurovascular surgeons, endovascular specialists, and neuro-intensive care services.[37] Similarly, ICH is a medical emergency that needs to be diagnosed and managed swiftly. Expansion of the haematoma and clinical deterioration are common in the first few hours. Among patients undergoing head CT within 3 hours of ICH onset, up to 38% have expansion of more than one third of the initial haematoma volume on follow-up CT.[38] While awaiting transfer for specialist care, it is important to minimise the risk of haematoma expansion by fully reversing any prescription anticoagulants and reducing elevated blood pressure.[52]

In several countries, acute stroke care has also been centralised, creating specialist centres to which patients are taken rather than going to the nearest hospital.[53,54] This has increased access to specialist care and thrombolysis. With the advent of other time-critical therapies such as intra-arterial thrombectomy,[55] it is likely that there will be continued centralisation of care for acute stroke.

REHABILITATION

Early access to specialist rehabilitation that continues into the community is essential to maximise the recovery following neurological injury. Early mobilisation has been shown to enhance recovery and improve functional outcomes for patients in acute and intensive care settings including neurosciences ICU.[56] There is now a substantial body of evidence to support the effectiveness and cost-effectiveness of specialist rehabilitation.[57] Despite a longer length of stay, the cost of providing early specialist rehabilitation is offset by longer-term savings in the cost of community care.[58]

Brain death

Martin Smith

Death has important medical, legal and societal implications, making it imperative that its determination is accurate, reliable and certain. It was historically defined only by confirmation of cessation of cardiorespiratory function, but the concept of brain death, now more accurately referred to as the determination of death by neurological criteria, was introduced into clinical practice almost 50 years ago. From a legal and scientific perspective, brain death is a definable event which is established as a legitimate definition of death in most countries in the world. Its confirmation provides a professional and legal framework for the withdrawal of life-sustaining therapies from an individual who can no longer derive benefit from them, and additionally allows the retrieval of organs for transplantation.

BRAIN DEATH EPIDEMIOLOGY AND PATHOPHYSIOLOGY

The incidence of brain death is related to several factors including national rates of catastrophic brain injury, access to intensive care and neurosurgical services, the presence of organ donation and transplantation systems, and patterns of professional practice. The true international incidence of brain death is unknown, although it is estimated to account for 1%–2% of all deaths in countries with advanced health care systems and 5%–10% of deaths in comatose patients admitted to intensive care units.[1] Rates of brain death are declining as the incidence of catastrophic brain injury reduces in some parts of the world, and brain injury management improves.

The principal causes of brain death in adults are severe traumatic and haemorrhagic brain injury and cerebral hypoxia–ischaemia. Brain death results from a sustained rise in intracranial pressure above systemic arterial pressure leading to the irreversible cessation of brain activity due to permanent loss of blood flow and oxygen supply to the brain. Brainstem reflexes are lost sequentially in a craniocaudal direction; this process may take several hours to complete but finally results in apnoea due to failure of the medulla oblongata. Because of the fundamental controlling role of the brainstem, cardiovascular and other systemic organ system functions deteriorate after the onset of brain death resulting in profound physiological instability and ultimately asystolic cardiac arrest.[2]

DEVELOPMENT OF BRAIN DEATH CRITERIA

A state of unconsciousness, brainstem areflexia and absence of spontaneous respiration in patients supported by mechanical ventilation was first reported in 1959 by Mollaret and Goulon who described this state as 'le coma dépasse' – literally, a state beyond coma. Almost 10 years later, in 1968, *ad hoc* Committee of the Harvard Medical School in the United States developed and published the first widely accepted standard for the definition and confirmation of brain death.[3] Because the brainstem is responsible for consciousness, breathing and circulatory regulation, and conduction of virtually all throughput to and from the brain, it is loss of brainstem function that is fundamental to the state of irreversible coma described in the Harvard criteria.[4] This concept was incorporated into the United Kingdom criteria for the diagnosis of brain (stem) death which was first published in 1976.[5] A 2008 update retains the key components of those original criteria and emphasises that a clinical diagnosis is sufficient for the determination of brainstem death subject to the fulfilment of essential preconditions and exclusion of reversible causes of coma and apnoea.[6]

Unlike in the United Kingdom, the 1981 Uniform Determination of Death Act (UDDA) defined brain death in the United States as the irreversible cessation of functions of the *entire* brain.[7] The UDDA specified that, like death determined by cessation of cardiorespiratory function, the determination of brain death should be made in accordance with accepted medical standards. The American Academy of Neurology published practice parameters in 1995, updated in 2010, which have become the accepted medical standards for the determination of brain death in the United States.[8]

WHOLE BRAIN AND BRAINSTEM DEATH

There is broad consensus, particularly in Western cultures, that human death is ultimately death of the brain and that this crucially involves the irreversible loss of

ABSTRACT

Death was historically defined only by confirmation of cessation of cardiorespiratory function, but the concept of brain death, now more accurately referred to as the determination of death by neurological criteria, was introduced into clinical practice almost 50 years ago. From a legal and scientific perspective, brain death is a definable event which is established as a legitimate definition of death in most countries in the world. Practice guidelines for the determination of brain death are widely available but there is large international variation in their content and application. Clinical determination is the gold standard for the diagnosis of brain death in many countries, but ancillary investigations are required in some. The clinical determination of brain death incorporates three sequential but interdependent steps – fulfilment of essential preconditions, exclusion of reversible causes of coma and apnoea, and confirmation of brainstem areflexia and apnoea.

the capacity for consciousness combined with loss of the capacity to breathe. Taken together, these elements represent the most basic manner in which human beings can interact with their environment. Despite this consensus, debate continues over the extent of brain functions that must cease in order to satisfy a definition of brain death which, as outlined above, is defined in two different ways based on 'whole' brain and 'brainstem' formulations.

The determination of whole brain death requires confirmation, in theory at least, of the loss of *all* brain function, including, but not limited to, the brainstem. The diagnosis of brainstem death on the other hand requires confirmation of absence of brainstem function; it does not require that all other brain functions have ceased, only that any functions that might persist should not indicate any form of consciousness. The whole brain formulation is the standard for the determination of death by neurological criteria in many parts of the world, including the United States and most European countries, whereas the United Kingdom retains the brainstem formulation. The clinical determination of whole brain and brainstem death is identical, and highlighting differences between them is an unnecessary cause of confusion and controversy.[9]

Death is not a single event but a process that leads progressively to the failure of all functions that constitute the life of the human organism.[10] Once a threshold of irreversibility has been reached, and permanent cessation of cardiorespiratory function or brain death (however defined) marks such a point, it is not necessary to wait for the death of the whole organism for the inevitable consequence of its biological death to be certain. It is universally accepted that cessation of cardiorespiratory function marks the death of an individual, but nobody would claim that the whole human organism is dead at this point. The same is not yet the case for brain death. Reports of brain dead patients 'being kept alive on a ventilator' are familiar, and elements of the public continue to refuse to accept that brain dead patients are actually dead.[11] In a 2015 international survey, 57% of physician respondents also did not believe that brain death equates to death defined by cardiorespiratory criteria.[12] To minimise such confusion, it has been recommended that death should no longer be defined anatomically using terms such as cardiac or brain death, which inaccurately imply death of an individual organ, but functionally based on confirmation of permanent non-function of the brain subsequent to circulatory arrest or catastrophic brain injury.[1]

VARIABILITY IN BRAIN DEATH PRACTICES

Although confirmation of brain death is legally accepted as the death of an individual in the majority of countries, there are major differences between, and even within, countries in the procedures for its determination.[12] Some of these arise because of legal, religious and cultural differences, whereas others relate to different approaches to the clinical determination of brain death and variable requirements for ancillary investigations. In addition, there are well-documented failures to adhere to clinical practice guidelines for the determination of death by neurological criteria.[13,14] Another factor contributing to practice variability is that, unlike circulatory death which is relatively easily diagnosed, the determination of brain death is a much more complex process which requires expertise, familiarity and diligence.[7]

The variability in brain death practices risks adversely influencing public and professional trust, and an international standard for the diagnosis of brain death would reduce such variability and increase public and professional confidence in the credibility of the determination of death by neurological criteria.[10] While it is by no means certain that a true international consensus can ever be reached, there are fundamental components that are common to the determination of brain death in all countries (Box 53.1).[1]

Box 53.1 Areas of consistency in international guidelines for the determination of brain death

- Unresponsive coma with an established aetiology
- Absence of reversible conditions
- Absence of cortical or brainstem-mediated motor responses
- Absent brainstem reflexes
- Loss of the capacity to breathe

GENERAL PRINCIPLES FOR THE CLINICAL DETERMINATION OF BRAIN DEATH

The majority of countries have followed the lead of the United States and United Kingdom in specifying that a clinical diagnosis of brain death is sufficient for the determination of death in adults. Three sequential but interdependent steps form the diagnostic criteria – fulfilment of essential preconditions, exclusion of reversible causes of coma and apnoea, and clinical confirmation of brainstem areflexia and apnoea (Fig. 53.1). While the third step, the clinical examination, demonstrates the absence of brainstem function, it is the first two that determine irreversibility and which require a greater degree of expertise to interpret.[15]

PRECONDITIONS

The patient's comatose condition and apnoea must be due to irreversible brain damage of known aetiology. This is established by clinical examination and cranial imaging that confirms a catastrophic brain injury.

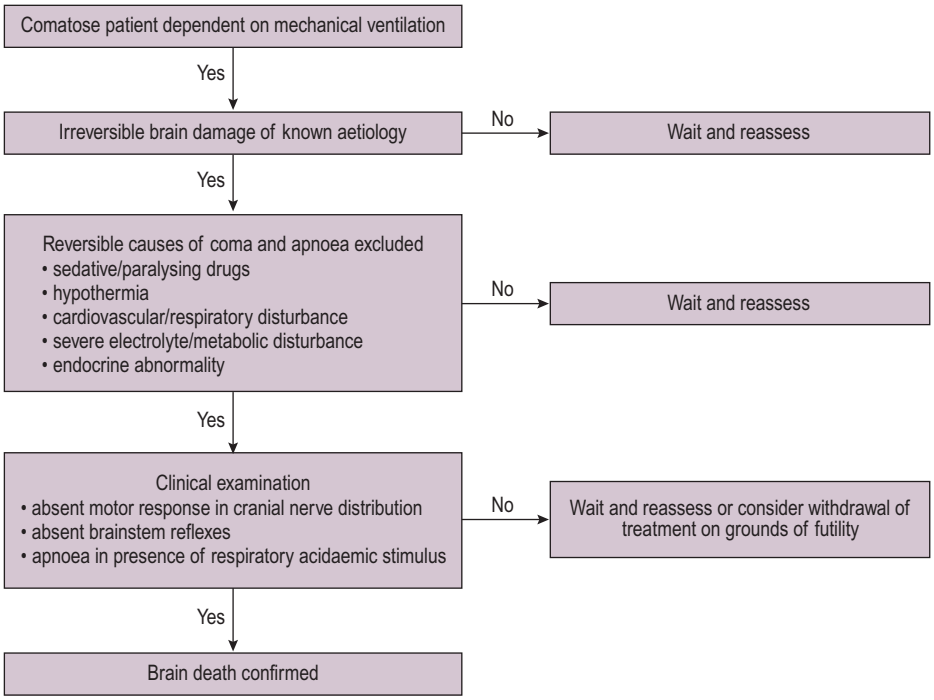

Figure 53.1 The three sequential but interdependent steps that form the criteria for the clinical determination of death by neurological criteria.

Irreversibility might be obvious within a relatively short period of time after severe traumatic brain injury or intracranial haemorrhage, but it may take longer to establish the diagnosis and be confident of prognosis in patients with hypoxic-ischaemic brain injury.

EXCLUSION OF POTENTIALLY REVERSIBLE CAUSES OF COMA AND APNOEA

Following confirmation of a diagnosis that is compatible with brain death, potentially reversible causes of coma and apnoea must be excluded (Table 53.1). The confounding effects of hypothermia, depressant drugs and severe electrolyte abnormalities are consistently cited in all clinical guidelines, but the thresholds vary between them.[12,16]

DRUG EFFECTS

The effects of sedative and paralysing drugs must be excluded as a cause of the patient's unresponsive state. Sufficient time must be allowed for sedative drugs to be metabolised and excreted; five half-lives in the presence of normal hepatic and renal function are usually considered appropriate. However, the presence of hypothermia as well as hepatic or renal dysfunction brings significant confounders to the confident exclusion of residual drug effects. The serum concentration of some sedatives can be measured, but be difficult to interpret because of the unpredictable effects on consciousness of a given drug concentration in a critically ill brain-injured patient. Administration of specific antagonists to exclude opioid or benzodiazepine effects can also be considered. Ancillary investigations may be used to confirm the diagnosis of brain death in some jurisdictions when sedation drug effects cannot be excluded. Residual pharmacological paralysis should be excluded by 'train-of-four' stimulation to confirm the absence of neuromuscular blockade.

HYPOTHERMIA

Although brainstem reflexes are likely to be absent only if body temperature falls below 28°C, temperatures between 32°C and 34°C have occasionally been associated with impaired consciousness. Most guidelines recommend that core temperature should be at or near normal at the time of the clinical examination.[12,16]

ELECTROLYTE AND ENDOCRINE DISTURBANCE

All guidelines require that there should be no evidence of severe electrolyte or endocrine disturbance, but 'severe' is rarely defined. Diabetes insipidus-related hypernatraemia is a common consequence of brain death and a particular problem. Many guidelines recommend a target plasma sodium concentration, while others acknowledge that delay in clinical testing because of strict adherence to a predetermined plasma sodium concentration is inappropriate in the

Table 53.1 Exclusion of potentially reversible causes of coma and apnoea during the determination of death by neurological criteria

VARIABLE	REQUIREMENTS

Drugs	• No residual sedative drug effects
	  • serum drug levels should be measured where assays are available
	  • no consensus regarding the minimal concentration at which brain death can be diagnosed
	  • consider specific opioid or benzodiazepine antagonists
	• No residual effects of neuromuscular-blocking drugs
	  • presence of deep tendon reflexes
	  • train-of-four present on peripheral nerve stimulation

Hypothermia	• Temperature at or near normal
Cardiorespiratory	• Systolic blood pressure consistently >100 mm Hg • SpO_2 >95%
Electrolytes	• Sodium –120 to 160 mmol/L (guidelines vary) • Normoglycaemia
Endocrine	• Hormonal assays if suspicion of myxoedema or Addisonian crisis

presence of other stigmata of brain death and when the hypernatraemia can be confidently excluded as a cause (rather than a result) of the clinical state. Blood glucose concentration should be normalised prior to and during the clinical examination(s).

Several endocrine abnormalities can be associated with impaired consciousness or present as acute coma, but are rare and unlikely to co-exist in the presence of known primary intracranial pathology. Hormone assays are generally only recommended if there is any clinical suspicion of endocrine disturbance.

CARDIORESPIRATORY DISTURBANCES

The onset of brain death is accompanied by intense circulatory and respiratory disturbance. Oxygen saturation should be maintained greater than 95% and systolic blood pressure above 100 mm Hg before and throughout the clinical examination.

CLINICAL EXAMINATION

The clinical examination is designed to confirm the absence of brainstem reflexes and presence of persistent apnoea, and should be performed only after preconditions have been met and reversible causes of coma excluded.

Box 53.2 Components of the cranial nerve examination to confirm brain death

- Pupils non-reactive to bright light
  - absent pupillary response to sharp changes in the intensity of incident light
  - pupils do not need to be maximally dilated, simply unresponsive
- Corneal reflexes absent
- Oculovestibular reflexes absent
  - no eye movements during or following slow injection of 50 mL ice-cold water over 1 min into each external auditory meatus
  - clear access to tympanic membrane must be confirmed by direct inspection prior to testing
  - head at 30 degrees to the horizontal unless contraindicated by unstable spine injury
- Oculocephalic reflexes absent
  - not required in all jurisdictions
  - eyes remain in mid-position during brisk turning of the head from side to side ('doll's eyes')
  - tested only if cervical-spine integrity ensured
- No facial movement to adequate stimulation in the trigeminal areas
  - usually firm pressure over the supraorbital area or temporomandibular joint
- No facial movement to noxious stimuli in all four limbs
  - spinal reflex limb responses are permissible
- Cough reflex absent
  - no response to tracheal suctioning
- Gag reflex absent
  - no response to stimulation (under direct vision) of the posterior pharynx

Apnoea test

- Absence of respiratory effort observed for >5 min despite a respiratory acidaemia
- $PaCO_2$ must rise to specified target (guidelines vary – most require that $PaCO_2$ should be greater than 8.0 kPa or have increased more than 0.5–2.5 kPa above a baseline of 6.0 kPa > 6.5 kPa)
- SpO_2 >95% throughout
- cardiovascular stability during the test (systolic blood pressure >100 mm Hg)

CRANIAL NERVE EXAMINATION

Assessment of brainstem reflexes is common to all guidelines for the clinical confirmation of brain death (Box 53.2). In most jurisdictions the diagnosis is not invalidated if pupil response, corneal reflex and oculovestibular reflex are not assessable on one side because of injury or disease. Ancillary investigations should be considered if bilateral assessment is impossible. Absence of the oculocephalic reflex ('doll's-eye' movements) is a required component of the clinical diagnosis of brain death in some countries. It can also be used

as a 'screening' test; the presence of eye movements indicates that brainstem function persists.

APNOEA TEST

Confirmation of apnoea is fundamental to the determination of brain death in all guidelines, although end-points differ.[12] While the overall aim is to produce an acidaemic respiratory stimulus, fewer than 60% of jurisdictions specify a $PaCO_2$ target for the end-point of the apnoea test.[16] In others there is no guidance whatsoever or only a stipulation that the ventilator should be disconnected for a defined period of time. The apnoea test should be performed only after brainstem areflexia has been confirmed, and using a technique that minimises the risk of significant hypoxaemia, excessive hypercarbia or changes in mean arterial blood pressure.

The UK guidance provides a structured approach for conduct of the apnoea test which maintains physiological stability and allows successful completion in most circumstances. The patient should be preoxygenated with 100% oxygen for at least 10 minutes, and arterial blood gases measured to correlate $PaCO_2$ with end-tidal carbon dioxide ($ETCO_2$). The ventilation rate is then reduced to allow a slow rise in $ETCO_2$. When $ETCO_2$ rises above 6.0 kPa, arterial blood gases are checked to confirm that $PaCO_2$ is at least 6.0 kPa and pH less than 7.40. In patients with chronic CO_2 retention, $PaCO_2$ can be allowed to rise above 6.5 kPa to generate a pH less than 7.40. The patient is then disconnected from the ventilator, oxygen insufflated at 5 L/min via an endotracheal catheter, and the patient observed for respiratory effort. The ventilator should always be disconnected during the apnoea test because autocycling can incorrectly suggest the presence of spontaneous respirations. Apnoea is confirmed following visual inspection for at least 5 minutes, and after documentation of the absence of spontaneous respiratory activity in the presence of $PaCO_2$ that has increased to the target level. This varies between jurisdictions; most require that it should be greater than 8.0 kPa or have increased by more than 0.5–2.5 kPa above a baseline of 6.0 kPa. The ventilator is then reconnected and minute volume adjusted to allow a gradual return of arterial blood gases to pre-test levels. SpO_2 should be maintained above 95% and systolic blood pressure above 100 mm Hg throughout the apnoea test. If adequate oxygenation proves difficult, a prior recruitment manoeuvre and continuous positive airway pressure via an appropriate circuit (e.g. Mapleson B) minimises the risk of desaturation during the test.

TIMING AND REPETITION OF CLINICAL TESTS

There is no evidence to define a minimum period of observation between the onset of apnoeic coma and clinical examination to ensure irreversibility. Some countries recommend a minimum of 6 hours in all cases, whereas no minimum time is stipulated in others.[16] A period of observation of at least 24 hours is usually required in coma related to hypoxic-ischaemic brain injury.

Two clinical examinations are required to confirm brain death in many jurisdictions, although there is no evidence that a second examination is necessary. A large study of brain dead adults showed that the second examination added nothing to the first, delayed the declaration of death, and reduced organ donation rates.[17] The clinical diagnosis of brain death using standard criteria is robust,[8] and there is an increasing trend towards a requirement for only a single examination. Where two examinations are required, there is often no specified time interval between them. In the United Kingdom, for example, the second examination can be undertaken as soon as arterial blood gases have returned to baseline after the first apnoea test. The legal time for certification of death is usually at the initial confirmation of brain death but, in Australia, the time of death is that of the second confirmatory examination.

The number of doctors required to determine brain death also varies. In most jurisdictions a single doctor is sufficient, but in the United Kingdom, Australia and some states in the United States at least two medical practitioners are required. The base specialty of doctors confirming brain death is stipulated in some countries whereas, in others, relevant competencies are defined.[12] To avoid any conflict of interest, the determination of brain death should not be made by a physician involved with organ transplantation.

ANCILLARY TESTS

Clinical determination is the gold standard for the diagnosis of brain death in many countries, but ancillary investigations are mandatory in some.[18] They are also useful if only a limited clinical examination is possible or when confounding or special conditions are present.[19] Ancillary investigations fall into two main categories assessing brain blood flow or electrophysiological activity, but there are limited data to confirm the applicability and reliability of any ancillary test for any particular circumstance.[20]

ASSESSMENT OF CEREBRAL BLOOD FLOW

Absence of blood flow to the brain is widely accepted to be consistent with brain death. Methods to confirm the absence of cerebral blood flow are less affected by confounding factors such as residual sedation, metabolic disturbance or hypothermia than electrophysiological methods, and are preferred.

CEREBRAL ANGIOGRAPHY

Four-vessel digital subtraction cerebral angiograph (DSA) is the gold-standard confirmatory test for brain

death in some jurisdictions.[18] Following bilateral injection of contrast into vertebral and carotid arteries, absence of flow beyond the foramen magnum in the posterior circulation and beyond the petrosal portion of the carotid artery in the anterior circulation is accepted to be indicative of brain death. DSA is reliable and easy to interpret, but invasive, time-consuming and often available only in neuroscience units. It also requires administration of contrast agents which may adversely affect graft function in donated kidneys.

Non-invasive vascular techniques such as computed tomography (CT) cerebral angiography (CTA) are increasingly employed. CTA has high sensitivity for the confirmation of brain death in individuals who fulfil clinical diagnostic criteria but there is insufficient evidence to support its use as a screening tool.[21] A significant proportion of patients meeting clinical criteria for brain death retain some evidence of contrast in the proximal intracranial arteries with all angiographic techniques. False-negative results occur, particularly after decompressive craniectomy and in the presence of cerebrospinal fluid drains or low arterial blood pressure. Systolic blood pressure should be maintained above 100 mm Hg during blood flow confirmation of brain death.[18]

PERFUSION IMAGING

Contrast-enhanced CT cerebral perfusion techniques are widely available, although there is little evidence of advantages over CTA. Positron emission tomography measures regional cerebral metabolic rate for glucose in addition to regional blood flow. It has theoretical advantages as an ancillary investigation in the diagnosis of brain death but there are currently no data to support its use in this situation. Nuclear imaging techniques are also able to confirm absent cerebral perfusion; an 'empty skull' appearance in which no intracranial contrast is visible is indicative of brain death.[18] False positives are rare, and no contrast agent is required.

TRANSCRANIAL DOPPLER ULTRASONOGRAPHY

Transcranial Doppler (TCD) is a non-invasive bedside investigation that can be used as a confirmatory test during the diagnosis of brain death.[22] When intracranial pressure exceeds mean arterial blood pressure, TCD assessment of blood flow velocity in basal cerebral vessels reveals systolic spikes with reversal of diastolic flow. Absence of a TCD waveform should never be taken as confirmation of absent cerebral blood flow because at least 10% of patients have no acoustic bone window. TCD examination has high sensitivity (86%) and specificity (98%) for the diagnosis of brain death when compared to clinical examination, with very few false-positive cases reported in the literature.[18] There is significant operator dependence, and previous surgery or open ventricular drains make TCD waveform interpretation difficult.

ELECTROPHYSIOLOGY

Electroencephalography (EEG) remains widely used in the diagnosis of brain death despite substantial disadvantages and a requirement for specialist interpretation. The absence of cortical electrical activity during high-sensitivity recordings from 16 or 18 channels over 30 minutes is often taken as confirmatory evidence of brain death. However, an isoelectric cortical EEG does not exclude activity in the brainstem or other deep structures, and electrical activity in some cortical cells does not confirm that the whole brain is functioning.[18] EEG examination is a mandatory part of a brain death diagnosis in many European countries and strongly recommended in some states in the United States where loss of whole brain function must be confirmed. However, EEG is affected by hypothermia and sedation, and therefore of limited value in circumstances where a confirmatory investigation might be required. Some experts argue that the substantial disadvantages of EEG mean that it should no longer be used as an ancillary test for the diagnosis of brain death.[20]

Evoked potentials (EPs) monitor the integrity of discrete sensory pathways and are able to assess components of brainstem function. EP monitoring is feasible in the setting of hypothermia and sedation but, like EEG, requires specialist expertise for interpretation. Because EPs rely on the integrity of the whole sensory pathway, a lesion affecting any point of the monitored pathway can result in an absent EP and false-positive result.[18] EPs can also be transiently absent after a hypoxic/ischaemic insult making them unreliable as an ancillary test for brain death.

DIAGNOSING BRAIN DEATH IN SPECIAL CIRCUMSTANCES

Although there are no published reports of recovery of neurological function after a clinical diagnosis of brain death using standard criteria, there are numerous case reports highlighting situations or conditions that may mimic brain death and lead to erroneous conclusions if unrecognised.[23] Such diagnostic errors invariably involve failure to identify preconditions and exclude reversible factors.

HYPOTHERMIA AND SEDATIVE DRUGS AND HYPOTHERMIA

The effects of high-dose sedative or opioid infusions may persist for several days after discontinuation, particularly in the presence of hypothermia. In one report of misdiagnosed brain death, the potential confounding effects of a very high cumulative dose of fentanyl in a patient with renal and hepatic impairment who had been treated with therapeutic hypothermia after a cardiac arrest appear to have been dismissed.[24] This

case illustrates the crucial importance of adherence to a sequential approach to the clinical determination of brain death, with confident exclusion of confounding factors before proceeding to the clinical examination. As noted earlier, ancillary tests may have a role if the clinical diagnosis of brain death is complicated by the effects of prolonged sedation, particularly in the context of hypothermia.

INABILITY TO COMPLETE THE APNOEA TEST

In patients with high spinal cord injury, the possibility that apnoea might be related to the cord injury can bring some uncertainty to the diagnosis of brain death. The degree of any cord injury should be quantified clinically, structurally and functionally by meticulous clinical examination, magnetic resonance imaging and electrophysiological investigation prior to consideration of a brain death diagnosis. In other situations, such as after polytrauma, it may not be possible to attempt or complete the apnoea test because of haemodynamic instability or poor oxygenation. However, in the vast majority of cases the apnoea test can be safely completed using an oxygen diffusion technique as described earlier.[25] Most guidelines consider the apnoea test to be a fundamental component of the clinical determination of death by neurological criteria, although in Australia and New Zealand brain death can be confirmed by demonstration of absent intracranial blood flow if the apnoea test cannot be completed.

OTHER CONDITIONS

Other brain death 'mimics', including baclofen and valproic acid overdose, organophosphate intoxication and some neurological conditions such as fulminant Guillain-Barré syndrome or Miller-Fisher variant, have been reported.[23] Importantly, the preconditions for the diagnosis of brain death are not met in any of these conditions which should therefore never be mistaken for brain death.[7]

EXTRACORPOREAL MEMBRANE OXYGENATION

There are a few case reports of patients who are clinically brain dead while supported on extracorporeal membrane oxygenation (ECMO). Because use of this technology will increase and up to 20% of patients on ECMO may become brain dead, protocols for conduct of the apnoea test in this situation are required.[7]

CHILDREN

The clinical determination of brain death in infants and children can be more problematic than in adults because of difficulties performing the clinical examination and the relative immaturity of some brainstem reflexes.[26] The majority of countries have separate guidelines for the determination of brain death in infants and children, but clinical examination remains paramount in all.[27] In those over 2 months of age, the general criteria are the same as for adults but the period of observation is often longer and ancillary investigations are required in some countries. A higher $PaCO_2$ target is also recommended during the apnoea test. As in adults, the clinical confirmation of brain death must be undertaken by two competent physicians but, in the case of young children, one should be a paediatrician and the other not directly involved in the child's clinical care. Two clinical examinations, separated by an observation period that varies with age, are required to establish brain death in children in most countries.[27]

BRAIN DEATH AND ORGAN DONATION

Development of the original Harvard brain death criteria was driven in part by advances in organ transplantation and the associated importance of determining death prior to organ retrieval. Recent calls for an international standard for brain death determination are also based as much on a need to improve the availability of organs for transplantation as they are on a desire to establish a consensus for its determination. Transplantation networks increasingly operate across national borders, arguing for consistency in the determination of death in potential donors. Despite the inescapable link between brain death and organ donation and transplantation policies, it is vitally important that, in the clinical setting, there is an inviolable separation between brain death and organ donation. The primary reason for confirming brain death is to ensure professional, legal and societal acceptability for the withdrawal of treatment, including mechanical ventilation, from a patient who can no longer derive benefit from it, and to bring closure for family and friends. Confirmation of brain death is therefore in an individual's best interests irrespective of any subsequent potential for organ donation.[9] After brain death has been confirmed, donation should of course be considered in all appropriate patients.[2]

SUMMARY

From a legal and scientific perspective brain death, more accurately referred to as the determination of death by neurological criteria, is a definable event which is established as a legitimate definition of death in most countries in the world. Practice guidelines for the determination of brain death are widely available. Although there is large international variation in their content and application, there are fundamental components that are common to the determination of brain

death in all jurisdictions. A clinical diagnosis of brain death is sufficient for the determination of death in adults in many countries, although ancillary investigations are required in some.

Meningitis and encephalomyelitis

Michel Toledano, Nicholas WS Davies

INTRODUCTION

Infections of the cranial contents can be divided into those affecting the meninges (meningitis; empyema) and those affecting the brain parenchyma (encephalitis; abscess). Involvement of the spinal cord is termed myelitis. Chronic, insidious or rare infections are beyond the scope of this chapter, which will focus on acute bacterial and viral causes of meningitis, encephalomyelitis, and abscess/empyema in adults.

The crucial diagnostic questions to be considered for an individual patient with a neurological infection are to determine why this individual, in this place, has developed this disease at this time.[1]

All patients presenting with symptoms or signs suggestive of meningitis or encephalitis warrant immediate testing for human immunodeficiency virus (HIV) infection.

DEFINITIONS

- *Meningitis:* is inflammation of the meninges and subarachnoid space, which may be caused by infection. Infection can be caused by viruses, bacteria, fungi or protozoa. Meningeal inflammation may also be caused by subarachnoid haemorrhage, vaccination or be a manifestation of other multiorgan diseases such as systemic lupus erythematosus, sarcoidosis, lymphoma or meningeal micrometastases from a disseminated carcinoma.
- *Aseptic meningitis:* is a generic term for cases of meningitis in which bacteria cannot be isolated from the cerebrospinal fluid (CSF). The differential diagnosis includes: (1) viral meningitis, (2) partially treated bacterial meningitis, (3) tuberculosis (TB) meningitis, (4) fungal meningitis, (5) lymphoma, (6) sarcoidosis, (7) drug-induced meningitis, and (8) other collagen vascular diseases. The most common causes of aseptic meningitis are viral infections.
- *Encephalitis:* is inflammation of the brain parenchyma, which can be due to infection or immune-mediated processes. Patients may have a history of focal symptoms including preceding seizures together with cognitive or behavioural symptoms.
- *Tuberculous meningitis:* causes subacute lymphocytic meningitis. Patients may have a non-specific prodromal phase, including symptoms such as headache, vomiting and fever.
- *Subdural empyema:* a suppurative process in the space between the pia and dura maters.
- *Brain abscess:* a collection of pus within the brain tissue.

BACTERIAL MENINGITIS

Bacterial meningitis is an inflammatory response to infection of the leptomeninges and subarachnoid space. This is characterised by the clinical syndrome of fever, headache, neck stiffness and CSF pleocytosis. Despite antibiotic therapy, some patients continue to suffer significant morbidity and mortality.

Bacterial organisms are usually not confined to the brain and meninges and frequently cause systemic illness, for example severe sepsis, shock, acute respiratory distress syndrome, and bleeding disorders such as disseminated intravascular coagulation (DIC).[2,3]

A variety of other pathogens cause meningeal inflammation, resulting in very similar clinical presentations. Bacterial infections must be treated urgently and appropriately to limit ongoing central nervous system (CNS) damage. It is also important to treat the complications of meningitis such as seizures and raised intracranial pressure (ICP).

Where possible, spinal fluid examination following a lumbar puncture is required in order to confirm the diagnosis and establish the pathogenic organism responsible.[4] A CSF examination may be contraindicated if there are signs of raised ICP including:

- papilloedema
- focal neurological signs
- seizures
- Glasgow Coma Scale (GCS) ≤12

These features raise the possibility of an undiagnosed cerebral mass lesion or malignant cerebral oedema, which could cause cerebral herniation should lumbar puncture be performed. A computed tomography (CT) brain scan is required prior to

ABSTRACT

Infections of the central nervous system can be divided into those that affect the meninges (meningitis and empyema) and those that affect the brain parenchyma (encephalitis and abscess). Here we focus on the diagnosis and treatment of common viral, bacterial and fungal acute meningeal and brain infections, as well as on the management of common complications.

KEYWORDS

Meningitis
encephalitis
brain abscess
subdural empyema
epidural infection

CSF examination in order to rule out this possibility and lessen, but not obviate, the risk of cerebral herniation. Even if the CT brain scan is normal, ICP may be raised. The importance of performing a safe CSF examination must be balanced against the need to commence immediate treatment in each individual patient.[4–6]

PATHOGENESIS

All three main causes of bacterial meningitis (see later) are spread by droplet infection or exchange of saliva. Bacterial meningitis may occur when pathogenic organisms colonise the nasopharynx and reach the blood–brain barrier. It can also occur as a consequence of infection in the middle ear, sinus or teeth leading to secondary meningeal infection. Most bacteria obtain entry into the CNS via the haematogenous route. As the organisms multiply, exponentially, they release cell wall products and lipopolysaccharide, which can generate a local inflammatory reaction that itself also releases inflammatory mediators. The net result of the release of cytokines, tumour necrosis factor and other factors is associated with a significant inflammatory response. Vasculitis of CNS vessels, thrombosis, cell damage and exudative material all contribute to vasogenic and cytotoxic oedema, altered blood flow and cerebral perfusion pressure. Later on, infarction and raised ICP occur.[4,7]

The inflammatory events seen with infection are summarised in Fig. 54.1.

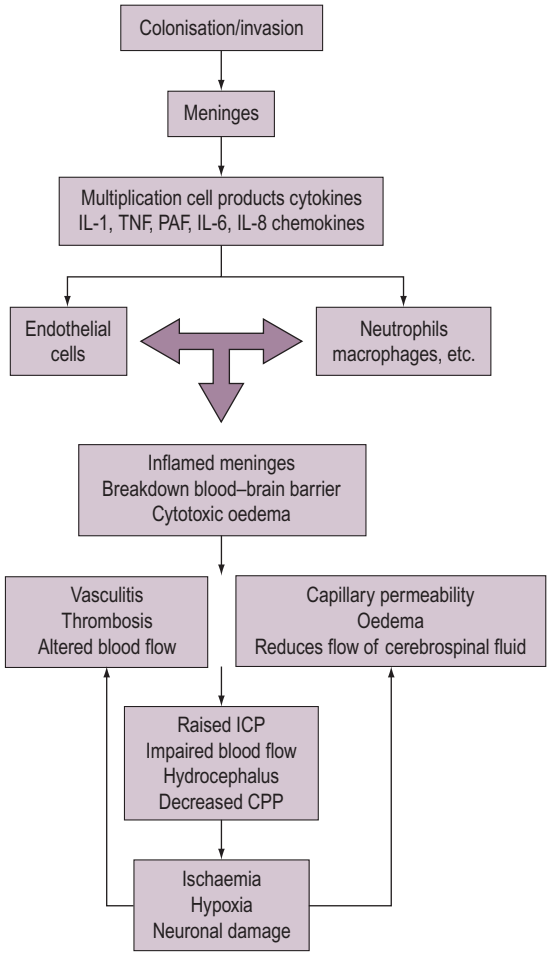

Figure 54.1 Cascade of events in meningitis. *CPP*, Cerebral perfusion pressure; *ICP*, intracranial pressure; *IL*, interleukin; *PAF*, platelet-activating factor; *TNF*, tumour necrosis factor.

AETIOLOGIES

Acute bacterial meningitis can be caused by many species of bacteria, although two organisms are commonly reported in resource-rich settings:

- *Streptococcus pneumoniae*
- *Neisseria meningitidis*

Until the advent of the meningitis vaccination programme, *Haemophilus influenzae* type B was the most common cause of bacterial meningitis. *S. pneumoniae* and *N. meningitidis* remain the most common causes of bacterial meningitis in adults worldwide.[4] *Listeria monocytogenes* can occur in the elderly, immunocompromised, or those with chronic illnesses such as alcohol dependency, diabetes, or malignancy. The emergence of pneumococcal strains resistant to penicillin has also influenced the epidemiology of meningitis.[8]

NOSOCOMIAL INFECTIONS

Common systemic nosocomial pathogens such as *Staphylococcus* species (spp.) *Escherichia coli*, *Pseudomonas* spp., *Klebsiella* and *Acinetobacter* spp. account for a high percentage of nosocomial infections of the meninges.

IMMUNOCOMPROMISED HOSTS

In the immunocompromised patient with meningitis (e.g. HIV or organ transplanted patients), fungal (cryptococcal), viral (cytomegalovirus [CMV]) and mycobacterial meningitis should be considered.[9]

NEUROSURGERY AND TRAUMA

Infections following skull trauma are frequently caused by *Staphylococcus aureus* and *Staphylococcus epidermis*, which should be considered in those with shunts or other intracranial devices.

CLINICAL PRESENTATION

The history may reveal evidence of trauma or infection. Meningitis usually presents with an acute onset of:

Table 54.1 Cerebrospinal fluid changes in meningitis

	NORMAL	BACTERIAL	VIRAL
Appearance	Clear	Turbid/purulent	Clear/turbid
White cell count	<5 per mm^3 mononuclear	200–10,000 per mm^3 predominantly polymorphonuclear	<500 per mm^3 mainly lymphocytes
Protein	0.2–0.4 g/L	0.5–2.0 g/L	0.4–0.8 g/L
CSF: blood glucose ratio	0.6	Normal or ≤0.6	Usually normal
CSF Lactate	<3.5 mmol/L	>3.5 mmol/L	<3.5 mmol/L

CSF, Cerebrospinal fluid.

- fever
- headache
- neck stiffness
- photophobia
- altered level of consciousness
- irritability
- seizures (paediatric).

However, in the immunocompromised, elderly or infant patient, non-specific features such as a low-grade fever or mild behavioural change may be all that is apparent. Many of the classic symptoms are late manifestations of meningitis and are preceded by early symptoms such as leg pain or cold hands, which may not immediately suggest the more serious underlying diagnosis.

If the presenting symptoms are highly suggestive of pyogenic bacterial meningitis, empirical administration of a third-generation cephalosporin such as cefotaxime or ceftriaxone should be given.

It is important to identify from the history any reports of preceding trauma, upper respiratory tract infection or ear infection. Symptoms may develop over hours or days. Specific infections relate partly to an individual's age.

Neurological signs can be present with meningitis, but signs such as nuchal rigidity, stiffness and a positive Kernig's sign (pain and hamstring spasm resulting from attempts to straighten, e.g. with the hip flexed) are not always present; a number of studies have shown that the classic triad of signs were present in less than 50% of cases. There may be focal neurological signs. Systemic signs occur most often in meningococcal disease where a haemorrhagic, petechial or purpuric rash may be observed. Digital gangrene or skin necrosis may occur. Some patients present severely septic with acute respiratory distress syndrome and DIC.

Approximately 25% of patients have a seizure during the course of the illness. Differential diagnoses include subarachnoid haemorrhage, migraine, encephalitis and tumour.

INVESTIGATIONS

The patient with suspected bacterial meningitis requires immediate blood cultures and collection of ethylenediaminetetraacetic acid (EDTA) blood sample for diagnostic polymerase chain reaction (PCR) studies.[4] Thereafter they should be given empirical intravenous (IV) antibiotics if there is likely to be any delay in further assessment (Table 54.1).

CEREBROSPINAL FLUID FINDINGS

A CSF examination is a vitally important investigation that will definitively confirm the diagnosis of bacterial meningitis. Its value should, in this regard, not be dismissed. Concern about the risks of coning following lumbar puncture should be considered in the context of patients' symptoms where the presence of coma, seizures, focal neurological signs and papilloedema may suggest raised ICP. Neuroimaging may not always predict whether it is safe to lumbar puncture a patient, although it may provide some level of reassurance that it is safe to proceed. A young patient who is alert, orientated, immune competent and without focal signs can safely have a lumbar puncture without prior imaging.

Bacterial meningitis is suggested when there is:

- polymorphic leucocytosis
- low CSF glucose relative to the plasma value
- raised CSF protein concentration
- elevated CSF lactate (>3.5 mmol/L).

An urgent Gram stain and microbiological culture are mandatory. The Gram stain is positive in approximately 50%–60% of cases. A CSF examination shortly after empirical antibiotics may, but does not necessarily, decrease the diagnostic sensitivity of CSF culture. Bacterial latex agglutination tests applied to CSF have no greater sensitivity than Gram stain and may give non-specific results; care should be taken with their interpretation and they should not be used alone to limit the spectrum of antimicrobial cover. PCR techniques can now be used to detect the presence of different organisms. A throat swab should be routinely taken. The clinical decision-making process to determine whether a patient does or does not have bacterial meningitis cannot be modelled easily and is reliant on both clinical and laboratory findings as well as patient observations over time.

Table 54.2 Empirical antibiotics for meningitis

INDICATION	ANTIBIOTIC	DOSE
<60 years	Ceftriaxone *or* cefotaxime	2 g IV 12-hourly, 2 g IV 6-hourly
>60 years or impaired cell immunity	Ceftriaxone *or* cefotaxime AND Ampicillin *or* amoxicillin	2 g IV 12-hourly, 2 g IV 6-hourly 2 g IV 4-hourly
Drug-resistant *Streptococcus pneumoniae**	Ceftriaxone AND Vancomycin *or* Rifampicin	2 g IV 12-hourly 15–20 IV mg/kg 12-hourly 600 mg IV or po 12-hourly
Neurosurgery shunt infection	Vancomycin AND Meropenem	15–20 IV mg/kg 12-hourly 2 g IV 6-hourly

*Add in IV vancomycin or rifampicin if penicillin resistance is suspected such as if the patient has travelled in the preceding 6 months to a country with high prevalence of penicillin-resistant pneumococci.
IV, Intravenous.

As spread is haematogenous, blood cultures comprise an important investigation in meningitis, and a number of sets of cultures should be sent. It is advisable to routinely check a full blood count, clotting profile (to exclude DIC) and biochemistry including blood glucose level. A chest radiograph and blood gases should be performed to identify systemic involvement. Relevant areas such as infected sinuses or ears should be examined if there is any indication they are implicated.

MANAGEMENT

Broad-spectrum antibiotics should be started as early as possible and continued until bacterial identification is made (Table 54.2). Antibiotic selection is influenced by the clinical situation in conjunction with known allergies or local patterns of antibiotic resistance and the CSF findings. The patient's travel history, exposure risks and level of immunocompetence are key to determining empirical antibiotic treatment. Delay in administering antibiotics is a significant risk factor for a poor prognosis. Adults with suspected meningitis should receive empirical treatment with ceftriaxone 2 g IV every 12 hours *or* 2 g cefotaxime IV every 6 hours (Table 54.3).[4]

If the patient has within the last 6 months been to a country where resistant pneumococci are present, IV vancomycin 15–20 mg/kg should be added (*or* 600 mg rifampicin 12-hourly IV or orally). Up-to-date information regarding antibiotic resistance in travellers can be obtained from the World Health Organization (http://bit.ly/1rOb3cx and http://bit.ly/1rOb3cx).

Those aged over 60 or immunocompromised (including diabetics and those with a history of alcohol misuse) should receive 2 g IV ampicillin *or* amoxicillin *in addition* to a cephalosporin.

Table 54.3 Alternative antibiotic choices for empirical treatment of meningitis

ORGANISM	ANTIBIOTIC	DOSE
<60 years	Chloramphenicol	25 mg/kg 6-hourly
>60 years or impaired cell immunity	Chloramphenicol AND Co-trimoxazole 10–20 mg/kg (of the trimethoprim component)	25 mg/kg 6-hourly In four divided daily doses

Always check local sensitivity as resistance patterns are variable.

It is more difficult to select an appropriate empirical antibiotic in the immunocompromised patient. Discussion with local microbiology services is recommended. When the organism has been identified and sensitivity results are available, it will probably be necessary either to change or to rationalise the antibiotics being given.[10] Meningitis caused by Gram-negative organisms is rare but multidrug resistance amongst enterobacteriaceae is increasing.[4] If there is a high suspicion that an extended spectrum beta lactamase organism might be present then meropenem 2 g IV 8-hourly should be given (instead of cephalosporin with or without amoxicillin/ampicillin).

In all cases, it is important to monitor the clinical response; antibiotics should be reviewed and appropriately altered once antibiotic sensitivities are known or if a patient is not improving. A repeat CSF

examination should be performed if there is concern about antibiotic sensitivity or selection. In those with penicillin-resistant pneumococcal meningitis, a CSF examination 48 hours after presentation is recommended to ensure bacteriological improvement. Antibiotics should be given for 5 days for *N. meningitidis*; 10–14 days for fully sensitive *S. pneumonia*; and 21 days for *L. monocytogenes*. Intrathecal antibiotics are not recommended.[4]

STEROID ADMINISTRATION

The benefit of steroid administration in adult meningitis has been debated, but clear guidance is now available to support its routine use as the Cochrane Database of 4121 adults and children demonstrated significantly lower rates of hearing loss and neurological sequelae in those treated with corticosteroids.[11] Decreased mortality was only observed in those with pneumococcal meningitis. Concern remains that corticosteroids may reduce CSF penetration of antibiotics, although this has not been demonstrated in studies conducted in humans. For reasons that remain unclear, these effects are only observed in high-income countries with multiple studies showing no benefit to adjunctive corticosteroid therapy in low-income settings.

RECOMMENDATIONS IN ADULTS

Dexamethasone 10 mg is an adjuvant treatment and should be given in adults IV shortly before or with the first of antibiotics and continued 6-hourly for 4 days. Dexamethasone should be halted if a microbiological cause for meningitis other than *S. pneumoniae* is identified.[4]

ANTICONVULSANTS

Focal or generalised seizures should be treated immediately with IV benzodiazepines to stop the seizures, with subsequent IV loading with phenytoin or levetiracetam. The possibility of the following should be considered:

- raised ICP
- cerebritis
- cerebral abscess
- septic venous thrombosis.

The development of seizures may be indicative of a poor prognosis.

INTRACRANIAL PRESSURE

Intracranial hypertension is a common complication of meningitis. ICP monitoring may be required and standard measures such as hyperventilation, mannitol infusion or CSF drainage should be considered. Depending upon the particular circumstance, serial lumbar punctures or external ventricular drainage should be implemented.

GENERAL MANAGEMENT CONSIDERATIONS

CRITICAL CARE

Intensive care teams should be involved early in patients with rapidly evolving rash, evidence of limb ischaemia, cardiovascular instability, acid/base disturbance, hypoxia, respiratory compromise, frequent seizures or altered mental state. Patients with a rapidly evolving rash, GCS ≤12 (or a drop of >2 points), those requiring monitoring or specific organ support, or those with uncontrolled seizures should be transferred to critical care facilities.[4]

Normal haemodynamics should be maintained. Inappropriate antidiuretic hormone secretion may occur in meningitis. Those with severe shock or profound coma may require a secure airway and respiratory support. Intubation should be strongly considered in those with GCS less than 12. Attention should be paid to management of the unconscious patient with appropriate mouth and eye care. Physiotherapy will be required in order to prevent the onset of pressure sores. Surgical evaluation may be needed for skin necrosis.[12,13]

PUBLIC HEALTH

Meningitis prophylaxis is recommended for close (kissing contacts) associates and for those medical personnel with close contact in cases of probable or confirmed meningococcal meningitis only. Ciprofloxacin 500 mg po stat should be given to adults (alternative rifampicin 600 mg twice-daily for 2 days).[4] Meningococcal vaccination may also be considered. Procedures should be in place to alert the infectious disease team and public health authorities. In many countries the latter is a statutory obligation for the treating physician.

PROGNOSIS

Untreated bacterial meningitis is usually fatal. Appropriate therapy significantly reduces the mortality rate but studies still show that the overall mortality is approximately 18%. Mortality is slightly higher in those who have seizures, when there have been delays introducing treatment, and if the patient is either elderly or very young (see Table 54.3).[13,14]

CRYPTOCOCCAL MENINGITIS

Cryptococcus neoformans is a yeast that can cause a chronic meningitis that is clinically similar to tuberculous meningitis. It is most frequently found in those who are immunocompromised, such as with HIV infection. A lumbar puncture should be obtained if the diagnosis is suspected and the opening pressure should be measured. India ink evaluation and cryptococcal

antigen testing can help establish the diagnosis, but culturing the organism from the spinal fluid remains the gold standard. Serum cryptococcal antigen testing is useful for evaluation of patients with HIV infection, although a negative result cannot be used to rule out cryptococcal meningoencephalitis. Initial treatment is with amphotericin B and 5-fluorocytosine followed by consolidation therapy with fluconazole. Management of the raised ICP may necessitate daily lumbar punctures or CSF diversion.

VIRAL MENINGITIS

The majority of cases of viral meningitis are benign, usually self-limiting conditions that are often caused by enteroviruses (which include Coxsackie viruses), herpes simplex virus (HSV) type 2 and varicella zoster virus (VZV). In endemic regions, some are caused by arthropod-borne viruses (arboviruses), such as West Nile virus. The same viruses that produce meningitis can also cause encephalitis. HSV type 1 usually produces encephalitis but rarely causes meningitis. Other viruses causing CNS infections include echoviruses, mumps, Toscana virus and HIV (particularly at the time of seroconversion). Patients with migrainous headaches often receive a lumbar puncture to rule out viral meningitis, which paradoxically may prolong their hospital stay with a post-lumbar-puncture headache and migraine.

CLINICAL PRESENTATION

Patients usually present with symptoms of meningeal irritation, fever, headache, neck stiffness, retrobulbar pain, photophobia, vertigo, nausea and vomiting that are less severe than those with bacterial meningitis. The presence of intellectual impairment, focal neurological symptoms or seizures suggests that the brain parenchyma is involved often due to meningoencephalitis. A detailed travel history should be obtained, as this may alter the differential diagnosis in terms of the likely organism. True viral meningitis develops over hours to days but rarely lasts longer than 7–10 days. Occasionally it can have a thunderclap presentation. A variety of associated symptoms, such as nausea, vomiting and generalised malaise, may accompany this condition.[15]

INVESTIGATIONS

A CSF examination is important and usually shows:

- a mild to moderate lymphocytic pleocytosis (can be neutrophilic initially)
- a mildly elevated CSF protein concentration
- normal glucose concentration
- normal CSF lactate.

Staining for microorganisms, including bacteria, *Mycobacterium tuberculosis* and cryptococci is necessary. Sites for viral culture include the mucous membranes, throat, skin and rectum.

MANAGEMENT

Acute viral meningitis is usually a self-limiting condition and only supportive therapy is required with analgesia and bedrest. Viral meningitis caused by HSV or VZV may require IV acyclovir, especially where it occurs in the immunosuppressed. Acute HIV infection causing meningitis responds to antiretroviral therapy.

ENCEPHALITIS

Encephalitis refers to inflammation of the brain. When secondary to an infectious organism, it can be caused by direct infection or by post-infectious, immune-mediated mechanisms. Autoimmune encephalitis can also occur independent of infection. HSV type 1, the most common and serious cause of focal encephalitis, usually affects the temporal and frontal lobes. There are a large number of arboviruses that cause epidemics of encephalitis. Encephalitis acts as a sentinel for new and emerging infections, including Japanese encephalitis, Nipah virus, Hendra virus, a variety of bat-associated viruses as well as West Nile and some tick-borne encephalitides such as Murray Valley encephalitis.

West Nile virus is now the most common cause of epidemic viral encephalitis in some countries. Although, on neuroimaging, changes in the basal ganglia may suggest the diagnosis, a CSF pleocytosis may be a more obvious diagnostic finding. Specific CSF antibodies can be sent for West Nile virus. There are also a variety of antibody-mediated encephalitides that target synaptic proteins. These include *N*-methyl-D-aspartate receptor (NMDAR) antibodies and voltage-gated K^+ channel antibodies.[16] Occasionally the former can be a sequela of HSV encephalitis.

CLINICAL PRESENTATION

The key clinical pointer to encephalitis is the presence of focal neurological symptoms indicating involvement of brain parenchyma. In particular, the presence of speech disturbance, seizures, altered cognition and disturbance of conscious level suggest this.

Diagnosis can be difficult.

- Abnormalities on cranial imaging such as T2-weighted magnetic resonance imaging (MRI) may support this diagnosis (Fig. 54.2).
- Electroencephalogram (EEG) studies may show slow-wave activity or epileptiform discharges in the temporal lobe. The presence of extreme delta brush pattern is specific for NMDAR encephalitis. EEG may also exclude non-convulsive status epilepticus that can mimic or be a complication of encephalitis.

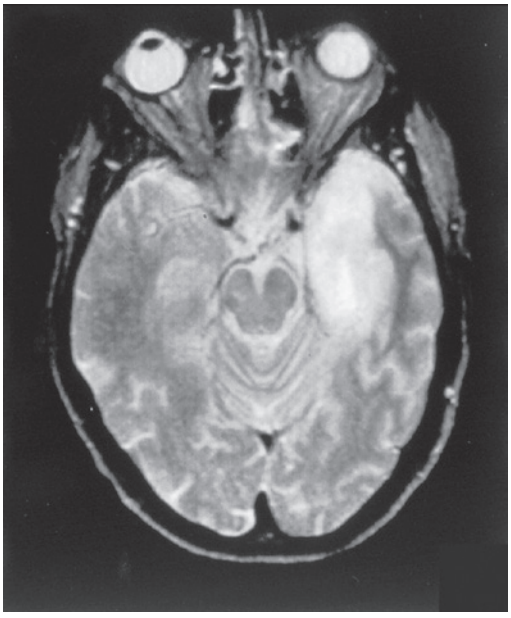

Figure 54.2 Temporal lobe following herpes simplex encephalitis.

- PCR examination of the CSF examination may confirm the virus.

A systematic approach to the investigation of those with encephalitis has been proposed and national guidelines developed to reduce the proportion of unidentified cases.[17]

TREATMENT

Understanding, and if at all possible identifying, the specific aetiological cause of an individual's encephalitis may ultimately have the greatest influence on the successful management of individual patients.[18]

Specific treatment for HSV encephalitis requires IV aciclovir at a dose of 30 mg/kg per day in three divided doses for at least 14 days; some recommend repeating the lumbar puncture, ensuring that the CSF is HSV DNA negative before halting aciclovir.[17] Untreated, the mortality of HSV encephalitis is approximately 70% but there is still 10%–20% mortality in patients treated with optimal therapy, and patients can be left with significant disability due to cognitive dysfunction or seizures. Most patients with significant cerebral oedema receive empirical steroids, although there are no clinical trials to support this therapy. Aciclovir can cause renal impairment and the patient should be hydrated intravenously and renal function monitored.[19] Aggressive treatment of seizures is important.

CMV infection requires antiviral therapy with ganciclovir or valganciclovir. CMV can cause a ganglionitis and polyradiculitis, which may suggest this diagnosis clinically in an immunocompromised patient.

Most CNS viruses cause neuronal damage but chronic John Cunningham (JC) virus infection in oligodendrocytes causes the syndrome of progressive multifocal leucoencephalopathy (PML). This condition presents with a subacute onset of confusion, weakness and visual symptoms, usually in an immunosuppressed individual. The MRI scan is usually suggestive but CSF examination with PCR amplification of the JC virus particles may be required. Currently, no specific therapy for PML exists. Initiation of combined antiretroviral therapy in HIV patients with associated PML significantly improves survival but can be associated with paradoxical clinical worsening due to transient inflammation, a phenomenon known as immune reconstitution inflammatory syndrome (IRIS).[20]

Viral infection with HIV, measles and rubella can also cause chronic CNS infection leading to chronic encephalitides. *Mycoplasma* infection can give rise to post-infectious encephalitis.

A number of systemic neurological conditions (e.g. lymphoma, Lyme disease, sarcoidosis and vasculitides such as Behçet disease) may present with aseptic meningitis. It is therefore important to consider these systemic conditions in those presenting with viral meningitis or encephalitis.

TUBERCULOUS MENINGITIS

Meningitis caused by *M. tuberculosis* (TBM) has a variable natural history with a range of different clinical presentations. It typically affects adolescents and young persons but is not restricted to these age groups. It is more frequent in the immunosuppressed. This and the lack of specific and sensitive tests hinder the diagnosis of this condition. Approximately 10% of individuals with TB develop meningeal involvement. A variety of risk factors such as HIV, diabetes mellitus and recent use of steroids increases the risk of tuberculous meningitis.[21]

CLINICAL FEATURES

TBM has a very varied clinical presentation. Often, it is heralded by a non-specific prodromal phase, frequently but not necessarily including headache, vomiting and fever. Of one case series that included those admitted to an intensive care unit, only 65% had fever, 52% had focal neurology and 88% had signs of meningism. A variety of cranial nerve palsies can occur, but other presentations include those seen with stroke, hydrocephalus and tuberculoma.

DIAGNOSIS

An investigation of the differential diagnosis of TBM is important. A minimum of three serial lumbar punctures should be performed to increase the sensitivity of acid-fast bacilli smear and mycobacterial culture.

The use of PCR amplification of mycobacterial DNA can increase sensitivity further, and some of the newer assays such as the Xpert MTB/RIF, can provide information regarding antibiotic resistance.[22] CSF analysis shows an elevated protein, lymphocytic pleocytosis and hypoglycorrhachia. Those who are immunosuppressed can have an atypical CSF appearance, including normal CSF examinations in occasional HIV individuals. TB culture from CSF is required but may take up to 6 weeks before a positive culture result is available. Imaging studies may show a basal meningitis and hydrocephalus but these features are non-specific.[23]

Current advice suggests that in adults the first 2 months of treatment should comprise quadruple therapy:

- Isoniazid oral/IV 300 mg daily
- Rifampicin oral/IV 450 mg (<50 kg) and 600 mg (≥50 kg)
- Pyrazinamide oral 1.5 g (<50 kg) and 2 g (≥50 kg)
- Ethambutol oral 15 mg/kg

Fluoroquinolones (moxifloxacin or levofloxacin) may represent an effective fourth agent. Streptomycin is used rarely. Agent toxicity must be monitored in terms of renal and liver function and the effect on other organs, such as the eye. It is strongly recommended that advice is sought from local experts or networks with experience in management of TB.

Corticosteroids are recommended in HIV seronegative patients with TBM. The initial steroid dose is guided by the patient's GCS and is tapered over 4–6 weeks.[24,25] There is increasing multidrug-resistant tuberculous meningitis, especially in the HIV-positive population, reiterating the importance of culturing *M. tuberculosis* from clinical specimens in order to obtain sensitivities. Patients with TB meningitis frequently deteriorate over the weeks following initiation of appropriate chemotherapy and steroid regimens. Neurosurgical intervention for the treatment of hydrocephalus is sometimes required.

SUBDURAL EMPYEMA

This is a collection of pus between the dural and arachnoid space and usually is a consequence of middle ear or sinus disease. It may follow cranial osteomyelitis related to previous neurosurgery. Head trauma can also be responsible.

Individuals present acutely with headache, fever, neck stiffness, seizures and focal neurological symptoms. Meningeal signs and evidence of hemispheric dysfunction with sinusitis should suggest the diagnosis.

DIAGNOSIS

CT and MRI are both effective in demonstrating a fluid collection.

Surgical intervention, drainage and appropriate antibiotic regimens are required. Both Gram-positive (*S. aureus* and *Streptococcus* species), and Gram-negative organisms may be implicated. Initial broad-spectrum (Ceftriaxone 2 g IV 12-hourly and Metronidazole 500 mg IV 8-hourly) cover should be narrowed to targeted treatment when the organism or organisms are known.

PROGNOSIS

This condition if left untreated is invariably fatal. With treatment, mortality is in the order of 20% but neurological sequelae are common.

EPIDURAL INFECTION

Cranial and spinal epidural abscess is an infection between skull or spinal column and dura often as a consequence of osteomyelitis or malignancy. There is an occasional incidence following epidural anesthesia. It is similar to subdural empyema. The organism involved where a catheter or drain is implicated is often the same as that found at the skin; hence, *S. aureus* is frequently responsible.

PRESENTATION

Inflammation is commonly (but not always) present on the back, and is usually generalised to the area of the back involved. There may be local tenderness over the site associated with redness of the catheter insertion site. Fever is common. Initially mild neurological deficit may rapidly progress leading to para/quadriparesis.

Blood cultures may be positive and may indicate the organism.

DIAGNOSIS

CT and MRI are both effective in diagnosis.

Spinal decompression and drainage are urgently required. This is usually a nosocomial infection and therefore resistant organisms are commonly found. Antibiotics should be specific for the organisms involved and may need to be continued for prolonged periods, often weeks, to eradicate the infection.

Where there have been neurological symptoms and signs prior to surgery, residual deficit is common. In one series, the recovery rate for patients with paresis/plegia after lumbar epidural abscess was 50%, whereas no patients with paresis/plegia following a thoracic abscess recovered. The majority of long-term survivors had severe neurological deficits.

CEREBRAL VENOUS AND SAGITTAL SINUS THROMBOSIS

Venous and sinus thrombosis may occur in the context of infection – in particular meningitis, and epidural or

subdural abscess. It may also be secondary to facial or dental infection. It may have no septic aetiology but can occur either as an isolated event or in association with prothrombotic problems such as diabetic ketoacidosis, 3,4-methlenedioxy-methamphetamine (MDMA) (ecstasy) abuse, oral contraceptives and hereditary prothrombotic conditions in pregnancy.[26]

Clinical signs at presentation include:

- headache
- focal neurological deficits in particular cranial nerves
- seizures
- papilloedema.

The diagnostic sensitivity of CT, MRI and digital subtract angiography are 59%, 86% and 100%, respectively, but MRI with magnetic resonance angiography or CT venography reaches 96% (Fig. 54.3).

TREATMENT

- Treat the primary infection if present.
- Anticoagulants are the mainstay of treatment. Paradoxically there are often areas of intracerebral haemorrhage in patients with sinus thrombosis. The presence of such haemorrhages is not a contraindication to anticoagulation.

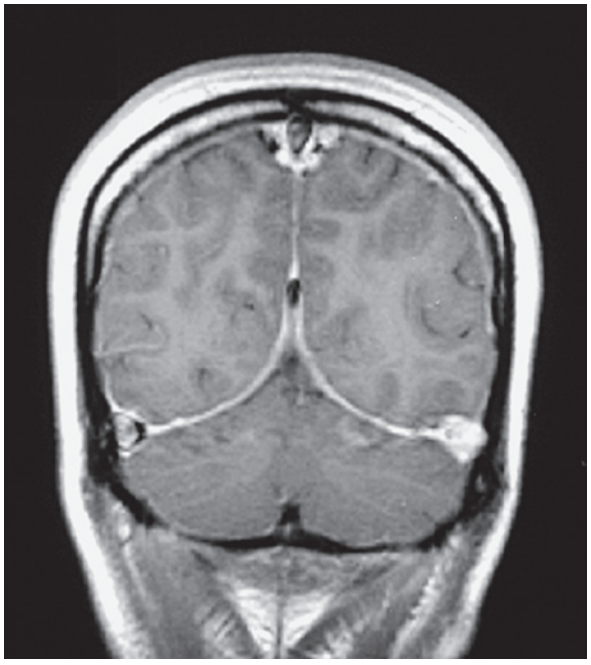

Figure 54.3 Magnetic resonance imaging (MRI) of superior sagittal sinus thrombosis: coronal T1-weighted post-contrast MRI; patient developed a sinus thrombosis following protracted labour and delivery.

BRAIN ABSCESS

AETIOLOGY

Direct spread from bone or dura or may be via haematogenous spread. Predisposition includes cranial trauma, neurosurgery, chronic ear or sinus disease, suppurative lung disease, congenital heart disease and recurrent sepsis. Immunological compromise may predispose to more exotic organisms, but more common organisms include *S. aureus* (associated with local and haematogenous) spread; and *Streptococcus* spp., *Bacteroides fragilis* and Gram-negative bacteria, which are common with lung disease or recurrent sepsis.

PRESENTATION

Severe headache, vomiting, obtundation, seizures and focal neurological signs. Neck stiffness is often absent. Clinical sepsis may not be obvious.

DIAGNOSIS

- An obvious primary source of infection
- Evidence of raised ICP
- Focal cerebral or cerebellar signs.

INVESTIGATIONS

- Lumbar puncture is low yield and potentially dangerous if there is significant mass effect
- CT scan – contrast will usually show a ring-enhancing lesion (Fig. 54.4)
- MRI
- Assessment of the patient's immune status
- Blood cultures
- Echocardiogram – where infective endocarditis suspected
- Specific blood tests such as HIV and toxoplasma serology.

TREATMENT

Indications for surgery include large single lesions, relief of raised ICP and the need for tissue diagnosis.

Antibiotics are the mainstay of therapy. If the organism is known, then the treatment should be specific. In the absence of a definitive organism, ceftriaxone 2 g IV 12-hourly *or* cefotaxime 2 g IV 6-hourly *with* metronidazole 500 mg IV 8-hourly. If there is a recent history of trauma or neurosurgery, then a regimen that will cover *Staphylococcus* should be used. Antibiotics should be continued for 3–6 weeks.

Supportive therapy limits morbidity, which is nevertheless high. Mortality from cerebral abscesses is still 10%–20%.[27]

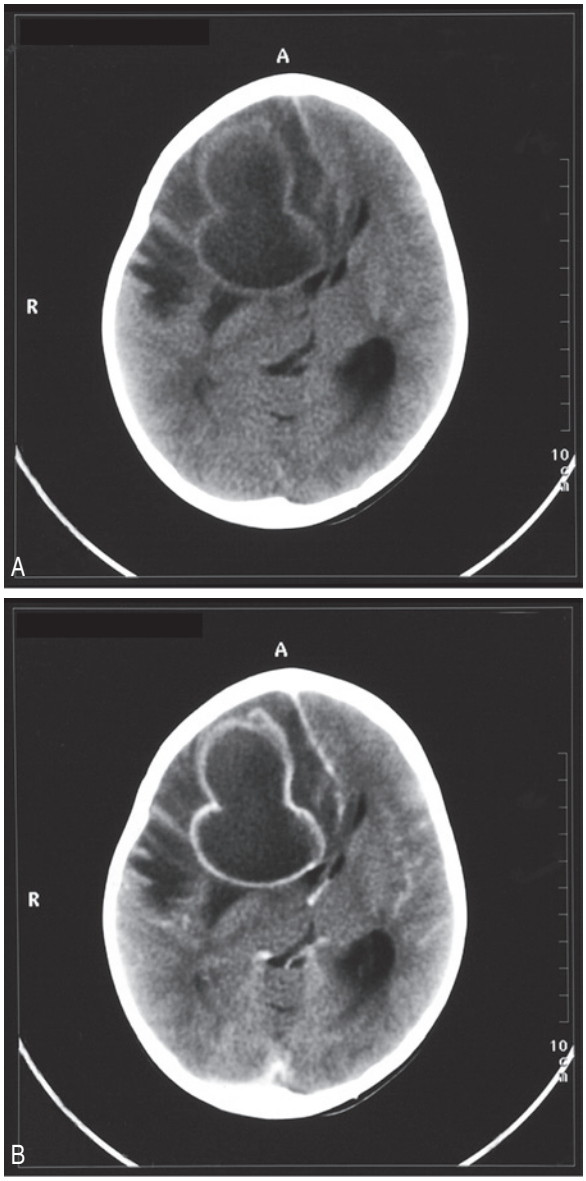

Figure 54.4 Abscess: (a) pre-contrast and (b) post-contrast.

LYME DISEASE

This is a tick-borne multisystem disease with dermatological, cardiological, rheumatological and neurological effects caused by the spirochaete *Borrelia burgdorferi*.

A history of potential exposure should be sought but is not always found. The disease may present in a variable fashion neurologically including as a cranial neuropathy (commonly a facial palsy) or as meningoencephalitis or radiculopathy. It may also cause lymphocytic meningitis and may have been diagnosed as 'viral' meningitis in the past. A variety of longer-term neurological sequelae have been described.[28]

INVESTIGATIONS

CEREBROSPINAL FLUID

White cell count is equivocal but may be raised. Protein is normal or marginally raised and sugar is normal or marginally low. Demonstration of intrathecal production of antibodies against *B. burgdorferi* establishes the diagnosis. PCR has very low sensitivity, as well as low positive and negative predictive value.

TREATMENT

Practice parameters for the treatment of nervous system Lyme disease state that nervous system infection responds favourably to penicillin, ceftriaxone, cefotaxime and doxycycline. The optimal duration of treatment is not known, but 10–21 days is recommended.[29] Prolonged treatment with antibiotic appears to have no benefit in preventing post-Lyme syndrome.

OTHER DISEASES

There are several other diseases that may have an encephalopathic component. Cerebral malaria is dealt with elsewhere. *Legionella* may lead to subclinical or clinical neurological manifestations, ranging from headache to coma or encephalopathy usually seen in conjunction with pneumonia, in addition to possible renal impairment. Similarly, *Mycoplasma* has been associated with an encephalitic picture characterised by impaired consciousness and seizures, and by normal or non-specific neuroradiological findings. Occasionally, symmetrical lesions in the putamen and its external surrounding areas have been seen.

SEPTIC ENCEPHALOPATHY

Septic encephalopathy has been described as a common complication in the critically ill, presenting in a panoply of ways, from the agitated confused state seen in acute sepsis through to profound loss of consciousness. The aetiology is almost certainly multifactorial involving changes in cerebral blood flow, alteration in oxygen extraction, cerebral oedema, disruption of the blood–brain barrier, the presence and effects of diverse inflammatory mediators and abnormal neurotransmitter activity; deranged liver and renal function contribute. It is a syndrome of exclusion based on observation and circumstantial evidence. The EEG is usually abnormal with decreased fast activity and an increase of slow-wave activity, but the findings are not pathognomonic. There are no specific treatments. In general terms, outcome appears to correlate with the management of the underlying sepsis.[30]

Tetanus

Jeffrey Lipman

Tetanus is a preventable, often Third-World disease frequently requiring expensive First-World technology to treat. It is an acute, often fatal disease caused by exotoxins produced by *Clostridium tetani,* and is characterised by generalised muscle rigidity, autonomic instability and sometimes convulsions.

EPIDEMIOLOGY

Recently, tetanus has become a disease of the elderly and debilitated in developed countries, as younger people are likely to have been immunised.[1,2] In the United States, its incidence decreased from 0.23 per 100,000 in 1955 to 0.04 per 100,000 in 1975, and remained stable thereafter.[1] In England and Wales, the annual incidence has been reported as 0.2 per million population, with the highest incidence in patients older than 64 years.[2] It is reported that 1 million people annually are afflicted with tetanus, signifying a global incidence of about 18 per 100,000 population, with an estimated world mortality of more than 200,000 per year.[2,3] It is geographically prevalent in rural areas with poor hygiene and medical services. Thus, tetanus remains a significant public health problem in the developing world, primarily because of poor access to immunisation programmes. In addition, modern management requires intensive care unit (ICU) facilities, which are rarely available in the most severely afflicted populations[4]; therefore, tetanus will continue to afflict developing populations in the foreseeable future.

PATHOGENESIS

C. tetani is an obligate anaerobic, spore-bearing, Gram-positive bacillus. Spores exist ubiquitously in soil and in animal and human faeces. After gaining access to devitalised tissue, spores proliferate in the vegetative form, producing the toxins tetanospasmin and tetanolysin. Tetanospasmin is extremely potent; an estimated 240 g could kill the entire world population,[5] with 0.01 mg being lethal for an average human. Tetanolysin is of little clinical importance.

C. tetani is non-invasive. Hence, tetanus occurs only when the spores gain access to tissues to produce vegetative forms. The usual mode of entry is through a puncture wound or laceration, although tetanus may follow surgery, burns, gangrene, chronic ulcers, dog bites, injections such as with drug users, dental infection, abortion and childbirth. Tetanus neonatorum usually follows infection of the umbilical stump. The injury itself may be trivial, and in 10%–20% of cases there is no history or evidence of a wound.[1,2] Germination of spores occurs in oxygen-poor media (e.g. in necrotic tissue), with foreign bodies, and with infections. *C. tetani* cannot grow in healthy tissue.[2] *C. tetani* infection remains localised, but the exotoxin tetanospasmin is distributed widely via the bloodstream, taken up into motor nerve endings, and transported into the nervous system. Here, it affects motor neuron end-plates in skeletal muscle (to decrease release of acetylcholine), the spinal cord (with dysfunction of polysynaptic reflexes) and the brain (with seizures, inhibition of cortical activity and autonomic dysfunction). Tetanus is not communicable from person to person.

The symptoms of tetanus appear only after tetanospasmin has diffused from the cell body through the extracellular space, and gained access to the presynaptic terminals of adjacent neurons.[1,2] Tetanospasmin spreads to all local neurons, but is preferentially bound by inhibitory interneurons – that is, glycinergic terminals in the spinal cord, and γ-aminobutyric acid (GABA) terminals in the brain.[4] Its principal effect is to block these inhibitory pathways. Hence, stimuli to and from the central nervous system (CNS) are not 'damped down'.

ACTIVE IMMUNOPROPHYLAXIS[1–3,5]

Natural immunity to tetanus does not occur. Tetanus may both relapse and recur. Victims of tetanus must be *actively immunised*. Tetanus toxoid is a cheap and effective vaccine that is thermally stable.[5] It is a non-toxic derivative of the toxin that, nevertheless, elicits and reacts with antitoxic antibody. By consensus, an

ABSTRACT

Tetanus is a preventable disease caused by *Clostridium tetani*, an obligatory anaerobic, spore–bearing, Gram-positive bacillus. Spores produce an exotoxin tetanospasmin which, within the central nervous system, inhibits inhibitory pathways. Tetanus is characterised by generalised muscle rigidity, in severe cases autonomic instability and occasionally convulsions. Without expensive intensive care treatment, the disease is often fatal.

Good wound care with extensive debridement and metronidazole will eradicate the organism and prevent spores releasing tetanospasmin. Human rich tetanus antitoxin neutralises circulating toxin. Trismus is often the presenting symptom and airway control can be lifesaving. The goal of therapy is to block the tetanospasmin's central nervous system effects of overactivity (benzodiazepines, morphine, magnesium, blood pressure management and muscle relaxants in severe cases). Symptomatic intensive care management and prevention of complications allows >90% survival rates. As the disease does not produce immunity, active immunisation with antitetanus toxin must follow.

active immunisation

antibody titre of 0.01 U/mL serum is protective,[2,6] but this thinking comes from very old data.[2] In a damped-down form, tetanus has been reported in a few victims with much higher serum antibody titres.[2]

In adults, a full immunisation course consists of three toxoid doses, given at an optimal interval of 6–12 weeks between the first and second doses, and 6–12 months between the second and third doses. A single dose will offer no immediate protection in the unimmunised, but a full course should never be repeated. Neonates have immunity from maternal antibodies. Children over 3 months should be actively immunised, and need four doses in total. Two or more doses to child-bearing females over 14 years will protect any child produced within the next 5 years. Pregnant females who are not immunised should thus be given two spaced-out doses 2 weeks to 2 months before delivery. Booster doses should be given routinely every 10 years.

Side effects of tetanus toxoid are uncommon and not life threatening. They are associated with excessive levels of antibody due to indiscriminate use.[7] Common reactions include urticaria, angio-oedema and diffuse, indurated swelling at the site of injection.

CLINICAL PRESENTATION[1–3,6,8]

The incubation period (i.e. time from injury to onset of symptoms) varies from 2 to 60 days. The period of onset (i.e. from first symptom to first spasm) similarly varies. Nearly all cases (90%), however, present within 15 days of infection.[8] The incubation period and the period of onset are of prognostic importance, with shorter times signifying more severe disease.

Presenting symptoms are pain and stiffness. Stiffness gives way to rigidity, and there is difficulty in mouth opening – trismus or lockjaw. Most (75%) non-neonatal generalised tetanus cases present with trismus.[8] Rigidity becomes generalised, and facial muscles produce a characteristic clenched-teeth expression called risus sardonicus. The disease progresses in a descending fashion. Typical spasms, with flexion and adduction of the arms, extension of the legs and opisthotonos, are very painful and may be so intense that fractures and tendon separations occur.[1,2] Spasms are caused by external stimuli (e.g. noise and pressure). As the disease worsens, even minimal stimuli produce more intense and longer-lasting spasms. Spasms are life threatening when they involve the larynx and/or diaphragm.

Neonatal tetanus presents most often on day 7 of life,[6] with a short (1-day) history of failure of the infant to feed. The neonate displays typical spasms that can be easily misdiagnosed as convulsions of another aetiology. In addition, because these infants vomit (as a result of the increased intra-abdominal pressure) and are dehydrated (because of their inability to swallow), meningitis and sepsis are often considered first.

Autonomic dysfunction occurs in severe cases,[8–10] and begins a few days after the muscle spasms. (The toxin has further to diffuse to reach the lateral horns of the spinal cord.) There is increased basal sympathetic tone, manifesting as tachycardia and bladder and bowel dysfunction. Also, episodes of marked sympathetic overactivity involving both α- and β-receptors occur. Vascular resistance, central venous pressure and, usually, cardiac output are increased, manifesting clinically as labile hypertension, pyrexia, sweating and pallor and cyanosis of the digits.[9] These episodes are usually of short duration and may occur without any provocation. They are caused by reduced inhibition of postsynaptic sympathetic fibres in the intermediolateral cell column, as evidenced by very high circulating norepinephrine (noradrenaline) concentrations.[1,10] Other postulated causes of this variable sympathetic overactivity include loss of inhibition of the adrenal medulla with increased epinephrine (adrenaline) secretion, direct inhibition by tetanospasmin of the release of endogenous opiates, and increased release of thyroid hormone.[1,4]

The role of the parasympathetic nervous system is debatable. Episodes of bradycardia, low peripheral vascular resistance, low central venous pressure and profound hypotension are seen, and are frequently preterminal.[9] Sudden and repeated cardiac arrests occur, particularly in intravenous drug abusers.[10] These events have been attributed to total withdrawal of sympathetic tone, since it is unresponsive to atropine.[11] However, they may be caused by catecholamine-induced myocardial damage[10,12] or direct brainstem damage.[10] Whatever the mechanism, patients afflicted with the autonomic dysfunction of tetanus are at risk of sudden death.

Local tetanus is an uncommon mild form of tetanus with a mortality of 1%. The signs and symptoms are confined to a limb or muscle, and may be the result of immunisation. *Cephalic tetanus* is also rare. It results from head and neck injuries, eye infections and otitis media. The cranial nerves, especially the seventh, are frequently involved and the prognosis is poor. This form may progress to a more generalised form. Tetanus in heroin addicts seems to be severe, with a high mortality, but numbers are small.[10,13]

DIAGNOSIS

The diagnosis is clinical and often straightforward. Examination and special investigations often exclude other diseases. There are no laboratory tests specific to tetanus. *C. tetani* is cultured from the wound in only a third of cases. The most common differential diagnosis is dystonic reaction to tricyclics. Other differential diagnoses include strychnine poisoning, local

temporomandibular disease, local oral disease, convulsions, tetany, intracranial infections or haemorrhage and psychiatric disorders.

MANAGEMENT

Initial objectives of treatment are to neutralise circulating toxin (i.e. passive immunisation) and prevent it from entering peripheral nerves (i.e. wound care), as well as eradicating the source of the toxin (i.e. extensive surgery, hygiene, wound care and antibiotics). Treatment then aims to minimise the effect of toxin already bound in the nervous system, and to provide general supportive care.

PASSIVE IMMUNISATION[1,3,14]

Human antitetanus immunoglobulin (HIG) has now largely replaced antitetanus serum (ATS) of horse origin, as it is less antigenic. HIG will at best neutralise only circulating toxin, but does not affect toxins already fixed in the CNS (i.e. it does not ameliorate symptoms already present).

Current recommendations for HIG in tetanus are 500 IU.[3] It has been suggested that unimmunised patients or those whose immunisation status is unknown should be given HIG on presentation with contaminated wounds. No controlled study has shown this to be more effective than wound toilet and penicillin administration.

Intrathecal administration of antitetanus toxin is still controversial,[15–17] with the most recent meta-analysis reporting some benefit.[18] Moreover, suitable intrathecal preparations are not widely available. Side effects of human antitetanus toxin include fever, shivering and chest or back pains. Cardiovascular parameters need to be monitored, and the infusion may need to be stopped temporarily if significant tachycardia and hypotension are present.[1,7,14] If HIG is not available, equine ATS can be used after testing and desensitisation.[1]

ERADICATION OF THE ORGANISM

WOUND CARE

Once HIG has been given, the infected site should be thoroughly cleaned and all necrotic tissue extensively debrided.

ANTIBIOTICS

Tetanus spores are destroyed by antibiotics. The vegetative form (bacillus) is sensitive to antibiotics in vitro. However, in vivo efficacy depends on the antibiotic concentration at the wound site, and large doses may be required. Recommended antibiotic regimens include:

- *metronidazole 500 mg intravenous (IV) 6–8-hourly for 10 days:* the drug has a spectrum of activity against anaerobes, is able to penetrate necrotic tissue, and has been shown to be more effective than penicillin in this situation[17,19]
- *penicillin G 1–3 Mu IV 6-hourly for 10 days:* penicillin is a GABA antagonist in the CNS,[20] and may aggravate the spasms; nevertheless, it is still often used in this situation.

Nowadays, metronidazole is probably the drug of choice.[17]

SUPPRESSION OF EFFECTS OF TETANOSPASMIN

CONTROLLING MUSCLE SPASMS

In the early stages of tetanus, the patient is most at risk from laryngeal and other respiratory muscle spasm. Therefore, if muscle spasms are present, the airway should be urgently secured by endotracheal intubation or tracheostomy. If respiratory muscles are affected, mechanical ventilation should be instituted. In severe tetanus, spasms usually preclude effective ventilation, and muscle relaxants may be required. Any muscle relaxant can be used.[21] Heavy sedation alone may prevent muscle spasms and improve autonomic dysfunction (see below).

MANAGEMENT OF AUTONOMIC DYSFUNCTION

Autonomic dysfunction manifests in increased basal sympathetic activity[22] and episodic massive outpourings of catecholamines.[22–24] During these episodes, norepinephrine and epinephrine may be up to 10 times basal levels.[22,23] The clinical picture is variable.[24] Hypertension, tachycardia and sweating do not always occur concurrently.

Traditionally, a combination of α- and β-adrenergic blockers has been used to treat sympathetic overactivity. Phenoxybenzamine, phentolamine, bethanidine and chlorpromazine have been used as α-receptor blockers. Ganglion blockers and nitroprusside have occasionally been used, but with the safety profile of newer agents, all these drugs are probably outdated.[17] Propranolol and labetalol have had limited success.[25–27] However, unopposed β-adrenergic blockade cannot be advised. Deaths from acute congestive cardiac failure have resulted.[24,25] Removal of β-mediated vasodilatation in limb muscle causes a rise in systemic vascular resistance, and β-blocked myocardium may not be able to maintain adequate cardiac output. Also, with β blockade, hypotension follows when sympathetic overactivity abates. Esmolol, a very short-acting β-adrenergic blocker given IV, has been reported to

be useful.[28] However, although sympathetic crises can be controlled by esmolol, catecholamine levels remain raised.[24] This raises concern because excessive catecholamine secretion is associated with myocardial damage.[12]

From the above, it appears more logical to decrease catecholamine output. This can be done with sedatives. Benzodiazepines and morphine are successfully used.[23] Morphine and diazepam act centrally to minimise the effects of tetanospasmin. Morphine probably acts by replacing deficient endogenous opioids.[1] Benzodiazepines increase the affinity and efficacy of GABA.[1,17] Very large doses of these agents (e.g. diazepam 3400 mg/day[23] and morphine 235 mg/day[29]) may be required, and are well tolerated, although they may cause a metabolic acidosis due to the preservative propylene glycol within benzodiazipines.[17]

Magnesium has been used as an adjunct to sedation,[23,30] now confirmed by a large trial.[31] Magnesium sulphate infusions to keep serum concentrations between 2.5 and 4.0 mmol/L have decreased systemic vascular resistance and pulse rate, with a small decrease in cardiac output.[23,30] In animal studies, magnesium inhibits release of epinephrine and norepinephrine, and reduces the sensitivity of receptors to these neurotransmitters. Magnesium also has a marked neuromuscular-blocking effect, and may reduce the intensity of muscle spasms. Nevertheless, it could not be shown to decrease the need for mechanical ventilation.[31] However, magnesium sulphate can't be used alone and must be used with other sedatives,[17,23] and calcium supplements may be needed when it is infused. Anecdotally, clonidine, a central α_2-stimulant, has successfully produced sedation with control of autonomic dysfunction.[32] It seems sensible to attempt to make use of the central nervous system effects of an α_2-adrenergic agonist, namely sedation and vasodilatation.[33] Intrathecal baclofen has produced similar beneficial results in a series of cases, but significant respiratory depression occurred in a third.[34] When given intrathecally, baclofen can diminish spasms and spasticity, allowing for a reduction in sedative and paralysis requirements.[17,35]

SUPPORTIVE TREATMENT

Steps should be taken to prevent contractures, nosocomial pneumonias and deep-vein thrombosis. The patient (including the mother if a neonate is afflicted) must be actively immunised. Where possible, supportive psychotherapy should be offered to both patient and family.

COMPLICATIONS[1,2,6,8,12,36]

Muscle spasms disappear after 1–3 weeks, but residual stiffness may persist. Although most survivors recover completely by 6 weeks, cardiovascular complications, including cardiac failure, arrhythmias, pulmonary oedema and hypertensive crises, can be fatal. No obvious cause of death can be found at autopsy in up to 20% of deaths. Other complications include those associated with factors shown in Box 55.1.

Box 55.1 Factors contributing to death in tetanus

- Hypoxia
- Complications of mechanical ventilation
- Myoglobinuria and its attendant problems
- Sepsis, particularly pneumonia
- Fluid and electrolyte problems (including inappropriate antidiuretic hormone secretion)
- Deep-vein thrombosis and embolic phenomena
- Bed sores
- Bony fractures

OUTCOME

Recovery from tetanus is thought to be complete. However, in 25 non-neonatal patients followed for up to 11 years,[37] 15 were reported to have one or more abnormal neurological features such as intellectual or emotional changes, fits and myoclonic jerks, sleep disturbance and decreased libido. Of the 10 apparently normal survivors, 6 had electroencephalogram changes. Some of these symptoms resolved within 2 years.

Mortality figures depend on the availability of intensive care. In neonates, the mortality from African countries with no ICU facilities can be up to 80% of cases, but falls to about 10% when artificial ventilation is used. In the USA, mortality in non-neonates relates directly to age, with rates from 0% in patients under 30 years rising to 50% in those 60 years or older. An average of 10% mortality would seem to be reasonable for most ICUs. However, as this disease is easily and completely preventable, loss of life is unacceptable.

Delirium

Marcela Paola Vizcaychipi, Mena Farag, Edward Watson

Delirium is an acute confusional state common in critically ill patients, particularly those who require ventilation. It is an independent predictor of death and long-term cognitive decline. Prompt identification and treatment of delirium in patients aims to improve outcomes, reduce length of stay (LOS), mechanical ventilator days, morbidity and mortality, as well as the associated financial costs in the intensive care unit (ICU).

DEFINITION

Delirium, as defined by the American Psychiatric Association (APA) in the Diagnostic and Statistical Manual of Mental Disorders, 5th edition (DSM-5), is a disturbance in attention, awareness and cognition that develops over a short period of time, fluctuates and is associated with perceptual changes, such as hallucinations (Box 56.1).[1] New to the DSM-5 is the withdrawal of the use of the term 'consciousness' in the revised classification of delirium. Furthermore, it explicitly necessitates that such disturbances are not applicable in the context of a reduced level of arousal (e.g. a comatose state). Omitting consciousness and shifting focus towards attention and awareness is likely a reflection of the challenges encountered in the objective assessment of consciousness.

Three clinical subtypes of delirium are recognised: (1) hypoactive; (2) hyperactive and (3) mixed, each distinguishable by arousal and psychomotor behaviour observed in hospitalised patients. Hypoactive delirium, which is the most common subtype, is often unrecognised or misdiagnosed as depression or sedation. Patients will appear cooperative and docile but will show signs of inattention and be unable to organise thoughts. Pure hyperactive delirium, in contrast, is much less common but more familiar and recognisable to the clinician. Patients can be aggressive and agitated, combative and uncooperative. Patients with hyperactive delirium are more likely to have hallucinations. Mixed delirium exists when patients fluctuate between hypoactive and hyperactive subtypes.

Subsyndromal delirium (SSD) has recently emerged as a distinct yet clinically relevant condition from delirium. SSD has been defined by the presence of one or more symptoms of delirium, but that does not meet the threshold for, nor progress to, delirium.[2,3] Some patients will not present with or progress to full-blown delirium but do have altered mental status. For instance, patients may be able to attend to a conversation whilst experiencing hallucinations. SSD delirium can be diagnosed using the Intensive Care Delirium Screening Checklist (ICDSC).[4] Of note, the presence of a single SSD symptom has been attributed to a significant increase in hospital LOS and functional decline (i.e. it infers a prognostic value).[2] Whilst SSD has been associated with reduced outcomes, prognosis is still better than for those demonstrating the full clinical syndrome.

Delirium tremens (DT) is a subtype of delirium that falls under the clinical spectrum of alcohol withdrawal syndrome. DT onset emerges 48–72 hours following cessation of heavy drinking and is characterised by psychomotor agitation, similar to hyperactive delirium, with symptoms of global confusion, hallucinations and sympathetic nervous system arousal.

HISTORICAL PERSPECTIVE

The first records of delirium are from the 5th century BC by Hippocrates, who described delirium in an acutely confused patient using the terms phrenitis (frenzy) and lethargus. This terminology reflected the belief that the diaphragm governed the 'seat of consciousness' and thus phrenitis – inflammation of the diaphragm – was the underlying pathogenic process.[5] Da Medicina, a 1st century BC treatise by Aulus Cornelius Celsus, used well into the 15th century as a source of medical wisdom, has the first written entry of delirium to describe the acutely confused state. The word delirium is derived from the latin *de* away from + *lira* furrow in a field, hence literally meaning *going away from the ploughed track*. Until relatively recently, those ICU patients who were recognised as delirious were described as either having acute brain failure, ICU psychosis or subacute befuddlement.[6] As per APA recommendations, the term 'delirium' is now uniformly employed in clinical practice to describe this condition of brain dysfunction.

ABSTRACT

Delirium is an acute confusional state that is frequently observed in intensive care unit (ICU) patients. It is characterised by transitory changes in attention, awareness and cognition that develops over a short period of time. ICU delirium is an independent predictor of a longer hospital stay and mortality. Patients who develop this disorder are also at risk of long-term cognitive decline and early dementia. Identification of ICU delirium is feasible through the effective and routine use of delirium screening in daily ICU culture. Regular assessment of cognitive function and sedation will enable early detection of the delirious patient, triggering subsequent prompt intervention and management.

Box 56.1 DSM-5 classification of delirium

A Disturbance in attention (i.e. reduced ability to direct, focus, sustain, and shift attention) and awareness (reduced orientation to the environment).
B The disturbance develops over a short period of time (usually hours to a few days), represents an acute change from baseline attention and awareness, and tends to fluctuate in severity during the course of a day.
C An additional disturbance in cognition (e.g. memory deficit, disorientation, language, visuospatial ability or perception).
D The disturbances in criteria A and C are not better explained by a pre-existing, established or evolving neurocognitive disorder and do not occur in the context of a severely reduced level of arousal such as coma.
E There is evidence from the history, physical examination or laboratory findings that the disturbance is a direct physiological consequence of another medical condition, substance intoxication or withdrawal (i.e. due to a drug of abuse or to a medication), or exposure to a toxin, or is due to multiple aetiologies.

INTENSIVE CARE UNIT INCIDENCE, PREVALENCE AND RELEVANCE

ICU patients have the highest incidence of delirium of all clinical areas in the hospital, including orthopaedic/care of the elderly wards. Delirium can occur in up to 69% of ventilated patients in the United Kingdom (UK).[7] Prevalence rates in the ICU have been reported in prospective observational studies varying from 48% in non-ventilated medical ICU patients to 67% and 73% in ventilated (greater than 24 hours) trauma and surgical ICU patients, respectively.[8,9] Peterson et al.[10] examined delirium subtypes in a cohort of 614 critically ill patients admitted to the ICU. Mixed delirium was the most common subtype detected (54.9%), followed by hypoactive delirium (43.5%) and hyperactive delirium (1.6%).[10] In this study, delirium mainly occurred within the first 48 hours of active monitoring, which justifies and reinforces the importance of monitoring for delirium as part of routine clinical care and practice in the ICU.

ICU delirium is an independent predictor of a longer hospital stay and mortality.[8,11] Compared with case-matched critically ill patients without delirium, those with delirium have a 6-month mortality that is three times greater, following ICU admission.[11] Each day spent in a delirious state has been associated with a 10% increase in risk of death.[8,11] ICU delirium is known to be associated with long-term cognitive decline and early dementia. It results in a threefold increase in the risk of discharge into long-term care.[12] and a ninefold increase in the likelihood of experiencing a degree of cognitive impairment following discharge, compared with non-delirious ICU patients.[11] In specific conditions such as Alzheimer disease, the development of delirium has been shown to accelerate cognitive decline.

While the association between delirium and poor outcome is clear, a causal relationship has yet to be proven. Clearly, delirium has implications for quality of life and the independence of patients and their relatives. Patients with delirium have longer ICU and hospital stays.[8] Furthermore, associated costs are increased for both ICU (1.4 fold) and overall hospital (1.3 fold) stays.[13]

PATHOPHYSIOLOGY

The pathophysiology of delirium is ill-defined, but there are a number of theories regarding the pathological changes in the brain that result in and from delirium. Studies supporting the hypotheses reviewed in this subsection were conducted in populations of non-ICU patients and thus further research is required in order to characterise the intricate interplay between critical illness and delirium in the ICU setting. These hypotheses range from neuroinflammation with tumour necrosis factor-alpha (TNF-α) activation of microglia, impaired oxidative metabolism, altered cerebral blood flow, increased blood–brain barrier permeability, thalamic dysfunction and aberrant levels of large neutral amino acids.[14,15]

It is likely that several mechanisms contribute to the development of delirium, which then results in a common pathway of neurotransmitter imbalance and resultant cholinergic hypoactivity.[16,17] There is then, inevitably, a state of relative dopamine excess, which can also cause deterioration in attention or consciousness. The interlinking role of acetylcholine and dopamine makes it difficult to ascertain which of these imbalances is primarily responsible for delirium.

Other theories relate to the availability of tryptophan, a metabolic precursor of serotonin, which may play a role since both increased and decreased levels of serotonin are seen in delirium. It is also possible that there is a genetic component for developing delirium. Apolipoprotein E4 (Apoε4) genotype, wild-type Apoε3, is a susceptibility factor for Alzheimer disease possibly by being less able to suppress cerebral inflammation than the other isoforms. In all of these mechanisms of the cause of delirium, the data are conflicting.[18,19]

RISK FACTORS

The numerous risk factors for delirium fall into two main categories: predisposing (non-modifiable) and precipitating (both modifiable and non-modifiable) (Box 56.2). It is important to realise that the risk of delirium increases with the number of risk factors to which the patient is exposed,[20] and a frail, elderly

Box 56.2 Risk factors for developing delirium in intensive care

Precipitating	Predisposing
infection	age (especially over 65)
anticholinergic drugs	cognitive impairment
opiates	dementia
pain	depression
immobility	genetic factors
dehydration or constipation	institutionalised residence
sedative drugs	liver impairment
sensory impairment	
hyponatraemia	
hypoxia	
hypercarbia	
acidosis	
polypharmacy	
sleep disturbance	
use of physical restraints	
use of bladder catheter	

patient with many predisposing factors may develop delirium from only a minor precipitating factor.

The PRE-DELIRIC (PREdiction of DELIRium in ICu patients) model described by van den Boogaard et al.[21,22] has been developed to help predict the likelihood that a patient admitted to the ICU will develop delirium based on risk factors. It uses various parameters readily available during the first 24 hours of admission, for example the Acute Physiology and Chronic Health Evaluation score (APACHE-II), metabolic acidosis, urea concentration, use of sedatives, etc. Using this model, the risk factors that confer the highest risk of developing delirium in the ICU are coma (from any cause), infection and sedatives.

Utility of the PRE-DELIRIC model, however, is limited given that it only reliably predicts delirium using data acquired after 24 hours in the ICU. Indeed, patients can develop delirium within the first 24 hours following admission to the ICU,[11] which reinforced the need for a validated model capable of immediately predicting the development of delirium at the time of admission to the ICU. This formed the rationale underlying the multinational prospective cohort study by Wassenaar et al.,[23] which led to the development and validity of the early prediction E-PRE-DELIRIC model. Variables that form the E-PRE-DELIRIC model are consistent with established risk factors for delirium,[24–27] including candidate predictors derived from the original PRE-DELIRIC model.[21,22] This model incorporates the following predictors assessed and readily available at the time of ICU admission: age, cognitive impairment, alcohol abuse, admission category (medical, surgical, trauma, neurology/neurosurgery), urgent admission, mean arterial blood pressure, corticosteroid use, respiratory failure and blood urea nitrogen.[23]

DIAGNOSIS AND SCREENING

Diagnosis of delirium is challenging and difficult, particularly without the use of a diagnostic tool and especially when a patient with delirium presents with hypoactive symptoms. Unfortunately, in practice there is converging evidence to suggest that delirium is under-diagnosed and under-recognised. In one study, nurses detected daily delirium in only 34.8% of cases with doctors detecting delirium in only 28%.[28] In another study that used a semi-structured interview to explore current awareness and practice related to delirium in the ICU setting, only 26.8% of ICU healthcare professionals were found to screen for delirium on a routine basis.[29] The notable disparity between the clinical recognition and the actual disease burden of ICU delirium reinforces the importance of employing recently published clinical practice guidelines from the American College of Critical Care Medicine (ACCM) and Society of Critical Care Medicine (SCCM).[30] These guidelines, which are based on available evidence, emphasise and strongly recommend routine monitoring for the presence of delirium in adult ICU patients.[30]

To date, the American Psychiatric Association recommends the use of observational assessment tools in screening for delirium, yet few of them have been validated for use in ICU with intubated patients. The most widely used screening tools in critical care are the Confusion Assessment Method for ICU (CAM-ICU) (Fig. 56.1)[20] and the ICDSC.[4] These tools are designed for clinical use to identify delirium in a critically ill patient and have been validated for intubated patients. They are non-verbal, simple to use and require minimal training. CAM-ICU is a point-in-time assessment, whereas ICDSC uses information gathered over a nursing shift providing information on delirium occurrence.

These screening tools aim to detect the key features of delirium, which are inattention, disorganised thinking, altered level of arousal (with or without hallucinations) and altered sleep pattern in the case of ICDSC. Specificity and sensitivity for each of these tools in critically ill patients are 81% and 96%, respectively (CAM-ICU)[31] and 99% and 66% (ICDSC).[4] However, a cautionary note was sounded by van Eijk et al., who discovered in a multicentre trial that routine daily use of CAM-ICU by nursing staff has a specificity of 98% but a sensitivity of only 47%.[32] Such differences in sensitivity reporting may be secondary to assessor knowledge and implementation processes, which calls for further research to ascertain whether teaching and training can influence delirium detection rates in the clinical setting.

The ACCM and SCCM guidelines advocate both the CAM-ICU and ICDSC as the most valid and reliable screening tools for detecting and monitoring delirium in adult ICU patients.[30] These tools have

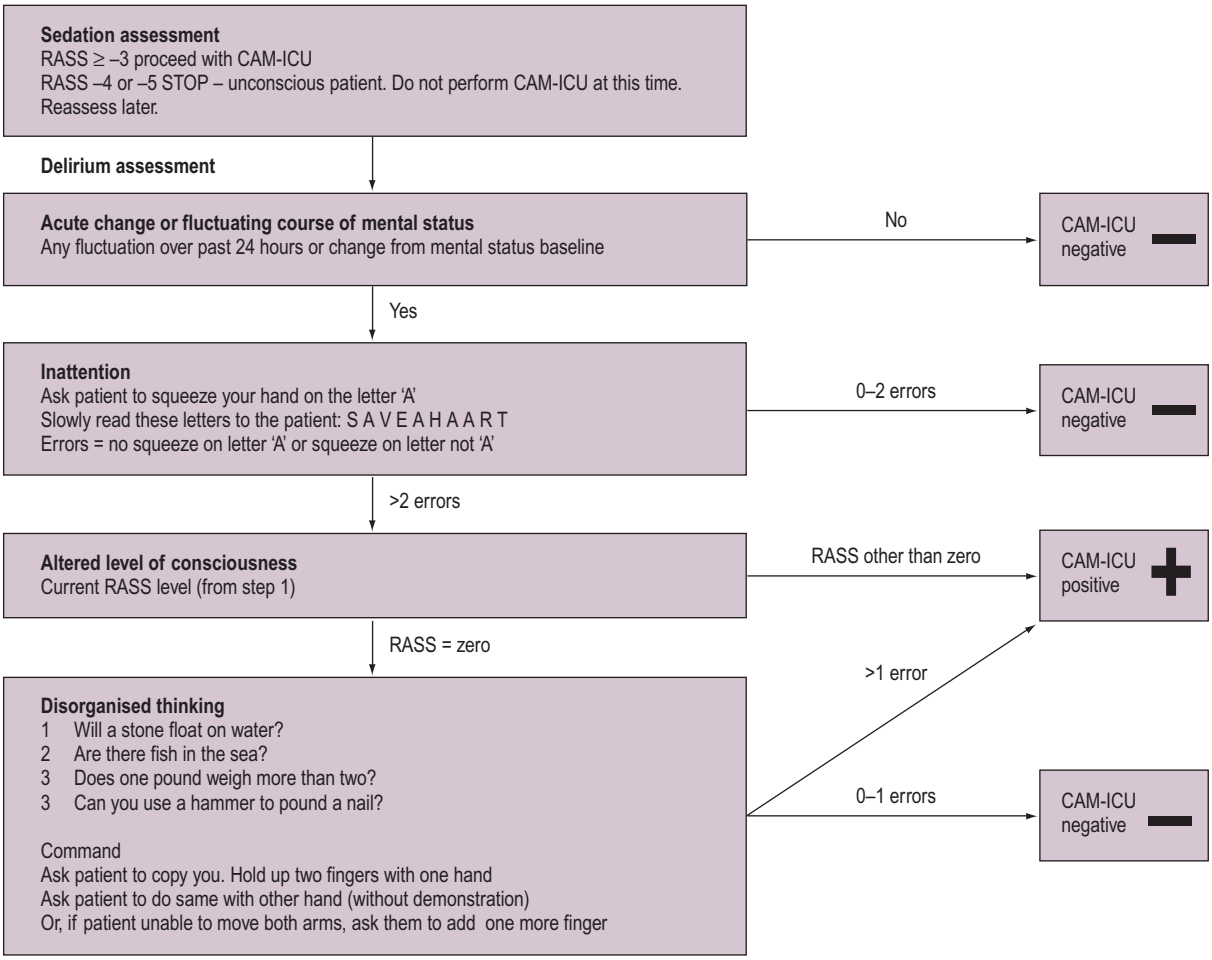

Figure 56.1 Confusion assessment method for intensive care unit *(CAM-ICU)* flow chart. *RASS*, Richmond Agitation–Sedation Scale. *Reproduced with permission from E Wesley Ely, MD MPH.*

high sensitivity, specificity and inter-rater reliability. Identification of ICU delirium is feasible if effective and routine delirium screening is integrated into daily ICU culture, for example, as part of the standard ICU admission clerking.

MANAGEMENT OF DELIRIUM

GENERAL MANAGEMENT

Initial management should aim at correcting the cause of delirium. If a medical condition has triggered delirium, it is likely that the patient will continue to be delirious, with all the associated neuroinflammation, neurotransmitter imbalance and alterations in cerebral blood flow, until the medical condition has successfully been treated. Reversal of the underlying cause is important and necessary examination and investigations should be undertaken, taking into account that there may, of course, be more than one precipitating cause. Management strategies should not only aim to reverse and reduce the duration of ICU delirium, but emphasis should be placed on the prevention. Approaches to prevent the occurrence of ICU delirium can be divided into non-pharmacological and pharmacological interventions.

NON-PHARMACOLOGICAL INTERVENTIONS

There are a multitude of simple, non-pharmacological measures, free from adverse effects, that can be employed with the aim of reducing the severity or preventing delirium.[33] These include clear and firm communication with frequent verbal orientation cues (e.g. date, time and location). Involvement of relatives provides the patient with a sense of control, familiarity and security. It can also provide the clinician with vital collateral information regarding the patient's premorbid mental and functional status. Other factors include

minimising environmental noise and correcting audio and visual sensory impairments.

Reduced sleep quality and interruptions in rapid eye movement (REM) sleep is a postulated contributory factor to the development of ICU delirium.[34] Minimising sleep deprivation and its associated impact on delirium can be achieved through pragmatic steps. Promotion of a normal sleep-wake cycle is important and can be facilitated by reducing night-time disturbances, for example the mindful timing of interventions.

Early mobilisation of critically ill patients has been demonstrated to decrease delirium and improves outcomes.[35] On the basis of a moderate quality of evidence (+1B), the ACCM and SCCM guidelines explicitly promote early mobilisation as a strategy to reduce the duration and incidence of ICU delirium.[30] Physical restraints, rarely used in the United Kingdom, are known to increase the risk of delirium. Use of physical restraints should be avoided. Medical restraints, for example lines, leads and catheters, can also impact the mobility of patients and should be removed as early as is prudent.

Other measures such as controlling febrile episodes, correcting electrolyte and metabolic derangements, setting patient-appropriate blood pressure and oxygenation targets represent essential non-pharmacological strategies to prevent the onset and reduce the duration of delirium in the ICU.

PHARMACOLOGICAL INTERVENTIONS

Sedation is a common and unfortunately requisite element of ICU therapy. All sedative drugs, including fentanyl and propofol, are likely to precipitate delirium. It is essential to have a sedation protocol with routine sedation scoring, sedation targets and daily sedation holds where appropriate.[36] The pharmacological class and dose of the sedative, and patient susceptibility factors, are all important considerations when prescribing and administering central nervous system (CNS) depressants. Daily sedation holds and spontaneous breathing trials, as the patient clinical condition allows, have been shown to decrease mortality.[37] Deep sedation (e.g. RASS –3 [Richmond Agitation–Sedation Scale]) in the first 48 hours of sedation and ventilation in the ICU has been associated with increased time to extubation and mortality.[38] Unless there is a clinical reason to keep a patient sedated, for example in cases of severe or life-threatening asthma, it is suggested that a daily sedation target of RASS 0 to –1 is appropriate.

Pain control in critical care is important. Although opioids can be deliriogenic, higher doses of opiates are associated with a significantly lower risk of delirium in the population of intensive care burns patients.[39] Weighing the risk of opioid-induced delirium against suffering and pain-induced delirium is a difficult balancing act. Pain management can be optimised, however, through routine pain monitoring, for example using structured tools such as the Behavioural Pain Scale (BPS) and the Critical-Care Pain Observation Tool (CPOT), as recommended in the ACCM and SCCM guidelines.[30] Although self-reporting is the gold standard for assessment of pain, the BPS and CPOT are reliable and valid tools that enable assessment of pain in adult ICU patients who are reluctant or unable to self-report.

Pharmacological treatment primarily involves the use of dopamine antagonists – typical and atypical antipsychotics. Clinical trials have attempted to address the question whether antipsychotics can be used to prevent delirium.[40,41] Although these have shown positive effects on delirium, reducing either duration or severity, this has not been translated to an improvement in outcome. Thus, there is currently insufficient robust scientific evidence to recommend the use of prophylactic antipsychotics. In fact, the ACCM and SCCM guidelines openly recommend against pharmacological prophylaxis in view of the low quality of evidence (–2C).[30]

HALOPERIDOL

Haloperidol is a butyrophenone with partial selectivity for dopamine $D\text{-}_2$ receptors. Its licensing is variable in different countries; for example, intravenous (IV) haloperidol is not licensed in the United States. However, in the United Kingdom it is commonly used in monitored, critically ill patients when enteral absorption is impaired.

Side effects include sedation, autonomic effects and, more importantly, extrapyramidal symptoms (e.g. dystonia, excessive salivation). Akathisia, an unpleasant sensation of restlessness, may be mistaken for continuing agitation. Haloperidol should not be given to patients with Parkinson disease or patients with a family history of dystonia.

More serious side effects include neuroleptic malignant syndrome and Torsades de pointes, both potentially life threatening. QT_c prolongation increases the risk of Torsades de pointes; monitoring should be carried out prior to starting haloperidol and daily whilst the patient is receiving the drug. Haloperidol can be used with caution with a QT_c greater than 450 ms and should not be used if greater than 500 ms.

Doses of haloperidol used clinically range from 0.5–10 mg, although 2.5–5 mg is more common; the maximum dose in 24 hours is 18 mg.

OLANZAPINE, QUETIAPINE, RISPERIDONE

Other antipsychotics have lower incidence of extrapyramidal side effects. Olanzapine can be given both intramuscularly and intravenously. It is as effective as haloperidol in critically ill patients[41] and is a useful alternative if haloperidol is contraindicated.[42] The starting dose is usually 5 mg, up to 20 mg daily (10 mg in renal failure). For patients with dementia who are

agitated, quetiapine and risperidone are recommended. Quetiapine has been shown to decrease delirium in a placebo-controlled trial[43] and risperidone was seen to be as effective as olanzapine in managing delirium.[44]

CLONIDINE, DEXMEDETOMIDINE

α_2 adrenergic receptor agonists have a sedative effect without gamma-aminobutyric acid-ergic (GABAergic) activity, potentially reducing the requirements of sedation, which itself can be deliriogenic.

Clonidine is favoured by some clinicians if a patient is requiring large doses of sedatives due to agitation. A starting dose would be 1 μg/kg enterally or diluted with saline and given slowly intravenously. Dexmedetomidine is a more highly selective α_2 agonist and may be beneficial in terms of length of time at targeted level of sedation and less agitated delirium.[45] Of note, the ACCM and SCCM guidelines comment that dexmedetomidine infusions administered for sedation may be associated with a lower prevalence of delirium in mechanically ventilated patients (compared to benzodiazpine sedation) and thus may represent a preferable sedation strategy to adopt in practice.[30]

ANTICHOLINESTERASES

The use of anticholinesterases, including rivastigmine, for treatment of delirium in critically ill patients is not recommended and may be harmful.[46]

BENZODIAZEPINES

Benzodiazepines should be used only for the treatment of delirium tremens resulting from alcohol withdrawal. A Cochrane review of benzodiazepines in delirium treatment concluded that their use is not indicated in non–alcohol-withdrawal agitated delirium.[47] Indeed, a study in critically ill burns patients revealed benzodiazepine exposure to be an independent risk factor, with these patients approximately seven times more likely to develop delirium.[39] However, if agitation is severe and is putting the patient at risk, a *stat* dose of a benzodiazepine might be indicated for rapid control of the incident. Up to 2 mg IV of lorazepam every 4 hours may be of benefit. It has rapid onset, short duration of action and low risk of accumulation. A reduced dose should be prescribed when administering to elderly patients and those with hepatic disease.

PERSISTENT DELIRIUM

Elderly patients may be left with persistent delirium, lasting beyond three months. The use of antipsychotics may be considered in individual cases, although generally care-of-the-elderly physicians avoid antipsychotics in their practice, relying on non-pharmacological interventions.

A possible ICU management protocol is outlined in Fig. 56.2.

REMEMBER THE RELATIVES

ICU admission is already a distressing time for relatives and friends of patients and this is exacerbated by witnessing their loved ones suffering from delirium. Thus, it is good practice to emphasise awareness that mental status changes in the ICU are common and inform them that, although delirium can lead to cognitive impairment, generally any acute psychosis is transient. It is often useful to provide a delirium information leaflet for relatives and reassure them that clinicians are conscientiously vigilant to seek and address underlying treatable causes.

Furthermore, it is prudent to continue to counsel and support the patient after recovery. This may involve affording time to listen to the patient talk about their experience, in particular any vivid hallucinations endured during the delirious episode. Patient diaries have been shown to help fill gaps in memory and rationalise traumatic hallucinations.[48]

SUMMARY

Delirium is commonly encountered in the ICU, is associated with longer ICU and hospital stays, increased mortality and with a long-term cognitive deficit and early dementia. Regular assessment of cognitive function and sedation will enable early detection of the delirious patient, triggering subsequent prompt intervention and management. Delirium primarily requires correction of likely causes (medical or drug related) and minimising known risk factors. First-line treatment of agitated delirium consists of antipsychotics, usually IV haloperidol; olanzapine or quetiapine are useful second-line treatments and the use of benzodiazepines is strongly advised against. Keep friends and relatives, and, whenever possible, the patient informed.

Intensive care unit-acquired weakness

Zudin Puthucheary

The loss of flesh and strength is striking
William Osler 1882

DEFINITION

Intensive care unit-acquired weakness (ICU-AW), first recognised in 1977, is an encompassing functional description of post-critical-illness weakness of all causes (once primary neuromuscular diseases have been excluded). Over time, more than 20 different terms have been used[1] until a definition framework was proposed[1] and later accepted[2] as part of clinical practice guidelines.

We currently consider all generalised new weakness with no alternative explanation to be ICU-AW. In those with documented polyneuropathy and/or myopathy, subcategories exist of:

Critical illness polyneuropathy (CIP): Those with electrophysiological evidence of distal axonal polyneuropathy

Critical illness myopathy (CIM): those with electrophysiological and/or histological evidence of myopathy

Critical illness neuromyopathy (CINM): those with electrophysiological and/or histological evidence of CIM and CIP.

At this current point in time, subcategory diagnoses are not relevant in the acute phase, as no treatments are available. In the setting of long-term follow-up survivor outpatient clinics, these diagnoses may have an important role and implications.

CLINICAL FEATURES

The classical features are that of a symmetrical flaccid weakness, with absent reflexes. Proximal muscle wasting is a hallmark of ICU-AW.[3] The facial muscles are often spared. The presence of distal muscle weakness predominance suggests either an alternative diagnosis or the presence of axonal damage (CIP or overlap).[4]

DIAGNOSTIC CRITERIA

PHYSICAL EXAMINATION

ICU-AW is diagnosed on physical examination using the Medical Research Council (MRC) Sum Score. The MRC sum score was first described in 60 patients with Guillain-Barré syndrome as an assessment tool, as part of the Dutch gamma globulin trial.[5,6] A 90% inter-rater agreement (defined as <10% change in score) was seen in measurements between blinded observers. In 2002, this technique was deployed in a multicentred observational study of 95 critically ill patients following 7 days of mechanical ventilation.[3] Patients were expected to respond appropriately to three of five questions, on two consecutive evaluations with a 6-hour interval, to be considered appropriate for manual muscle testing.

Each limb is scored using the MRC strength scale of 0-5 for proximal and distal muscle groups in regards to the ability to exert force against resistance (5-4), overcome gravity (3), to move once gravity is eliminated (2) or if only fasciculation (1) or no movement (0) is observed (Table 57.1; the score for each limb is then added up to a maximum of 60). An arbitrary cut-off of 48 is used to distinguish weak patients.

Several concerns exist as regards its clinical utility. Whilst excellent inter-rater reliability has been seen in healthy subjects and critical illness survivors, this worsens considerably in the ICU setting.[7,8] Furthermore, 30%–60% of patients have been unable to perform manual muscle testing when assessed.[3,8] Proximal muscle wasting is extremely common[3] and of initial substantial functional importance, but is underrepresented in the MRC Sum Score (Fig. 57.1). Finally, MRC Sum score assessment can detect weakness once it occurs, but is unable to identify those *at risk*.

ELECTROPHYSIOLOGICAL STUDIES

Nerve conduction abnormalities have been demonstrated repeatedly in the critically ill patient, and were first described by Bolton in 1984.[9] Emerging hypotheses for the pathophysiology include acquired channelopathies of voltage-gated sodium channels,

ABSTRACT

Intensive care unit-acquired weakness (ICU-AW), first recognised in 1977, is an encompassing functional description of post-critical-illness weakness of all causes (once primary neuromuscular diseases have been excluded).

Table 57.1 Medical Research Council Sum Score

RIGHT	SCORE	LEFT	SCORE
Shoulder abduction	(0–5)	Shoulder abduction	(0–5)
Elbow flexion	(0–5)	Elbow flexion	(0–5)
Wrist extension	(0–5)	Wrist extension	(0–5)
Hip flexion	(0–5)	Hip flexion	(0–5)
Knee extension	(0–5)	Knee extension	(0–5)
Ankle dorsiflexion	(0–5)	Ankle dorsiflexion	(0–5)
TOTAL	(0–30)	TOTAL	(0–30)

MRC SS = TOTAL of RIGHT AND LEFT SCORES
MRC SS ≤ 48 = ICU-AW

Strength is scored as ability to exert force against resistance (5-4), overcome gravity (3), to move once gravity is eliminated (2), or only fasciculation (1) or no movement (0) is observed.
ICU-AW, Intensive care unit-acquired weakness; *MRC SS*, Medical Research Council sum score.

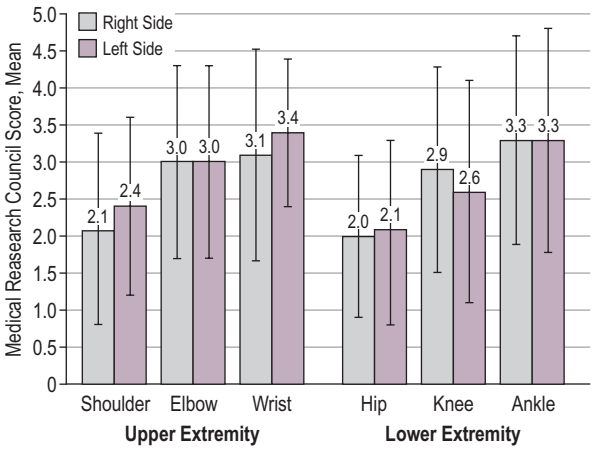

Figure 57.1 Medical Research Score distribution in awake critically ill patients, demonstrating proximal muscle wasting. *From De Jonghe B, Sharshar T, Lefaucheur JP, et al. Paresis acquired in the intensive care unit: a prospective multicenter study*. JAMA. *2002;288(22): 2859–2867*.

localising the defect to the muscle membrane.[10–12] In addition, neuronal tissue architecture disruption has been seen in peripheral nerve biopsies.[13] Quantification and description of these functional defects is done by nerve conduction studies (NCS) and electromyography (EMG).[14] Aside from the technical difficulties of performing and interpreting EMG in the critical care setting, their use in assessing the aetiology or severity of muscle weakness is limited by two factors. Firstly, EMG and NCS abnormalities appear universal in ICU patients and correlate poorly with the severity of muscle function loss.[3,14–17] Secondly, lack of patient cooperation (for instance, due to sedation or pharmacological paralysis) prevents early detection of neuromuscular abnormalities and thus risk of weakness.[1] Whilst severe neuropathy is debilitating, critical illness neuropathy is much less common than *CIM*[3,18,19] and, again, correlates poorly with symptoms of weakness.

Electrophysiological studies are rarely performed in the acute setting. However, neurophysiology is essential for the diagnosis of peripheral nerve injury – both foot drop and entrapment syndromes are common and, if untreated, can lead to functional disability. Further, it can be used to distinguish other less common causes of weakness that are unmasked by critical illness (e.g. motor neurone disease).

Criteria for subcategories of ICU-AW described by Stevens[1] are as follows:

CIP:
- Compound muscle action potential amplitudes are decreased to less than 80% of lower limit of normal in ≥2 nerves
- Sensory nerve action potential amplitudes are decreased to less than 80% of lower limit of normal in ≥2 nerves
- Normal or near-normal nerve conduction velocities without conduction block
- Absence of a decremented response on repetitive nerve stimulation

CIM:
- Sensory nerve action potential amplitudes are greater than 80% of the lower limit of normal in ≥2 nerves
- Needle electromyogram in ≥2 muscle groups demonstrates short-duration, low-amplitude motor unit potentials with early or normal full recruitment with or without fibrillation potentials
- Direct muscle stimulation demonstrates reduced excitability (muscle/nerve ratio >0.5) in ≥2 muscle groups

INCIDENCE

ICU-AW is the most common secondary complication of critical illness. Weakness at awakening can be detected in up to 65% of patients following 5–7 days of ventilation.[3,20–22] This is unsurprising given that a 10% change in muscle mass has significant functional implications[23] and critically ill patients in multiorgan failure waste away at rates between 2% and 3% per day.[24]

Understanding the incidence of CIP, CIM and CINM is less easy as electrophysiological abnormalities are almost universally present in the acute critical illness phase[16] and bear an unclear relationship with the eventual clinical phenotype. Furthermore, the variation in diagnostic methodology and timings vary widely in the literature.[25] In a longitudinal study of 92

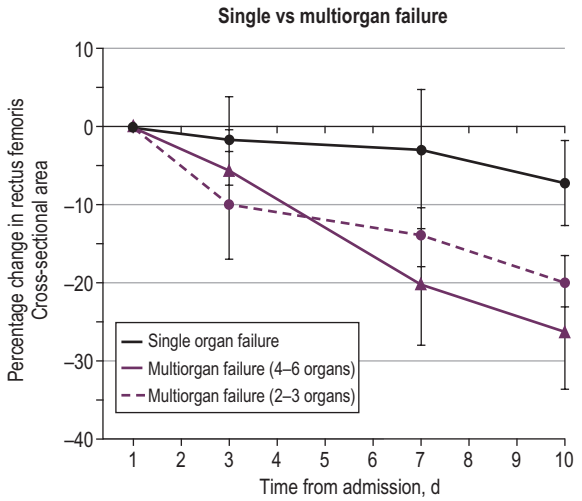

Figure 57.2 Rates of skeletal muscle wasting by organ failure. Organ failure defined as cumulative sequential organ failure assessment scores. *d*, day. *From Puthucheary ZA, Rawal J, McPhail M, et al. Acute skeletal muscle wasting in critical illness.* JAMA. *2013;310(15): 1591–1600.*

patients, 6.5% had CIM, 4.3% CIP and 5.4% CINM[26] on ICU discharge.

PATHOPHYSIOLOGY

LOSS OF MUSCLE MASS

Acute muscle wasting occurs rapidly and early in critical illness. Detectable muscle loss can occur within the first 72 hours. Several studies have suggested that wasting occurs at rates of 2%–3% per day of critical illness.[27] The severity of muscle wasting is directly related to the degree of illness severity; as more organs fail (sequential organ failure assessment [SOFA] score >2 within an organ system), more muscle is lost (Fig. 57.2).[24]

Clinical drivers of muscle wasting have been noted to be the Pa_{O_2} to Fi_{O_2} ratio, and the degrees of acidosis and inflammation. In the only direct study comparing nutritional delivery to change in muscle mass, no interactions were seen with calories delivered, and increased protein delivery was associated with increased muscle wasting.[24] Whilst controversial and should be seen as hypothesis generating currently, the ability of nutritional delivery to affect muscle mass remains contentious (see later).

ALTERED PROTEIN HOMEOSTASIS

Skeletal muscle mass in all vertebral organisms is governed by the principles of protein homeostasis: a balance of muscle protein synthesis (MPS) and muscle protein breakdown (MPB).[28] The two processes are

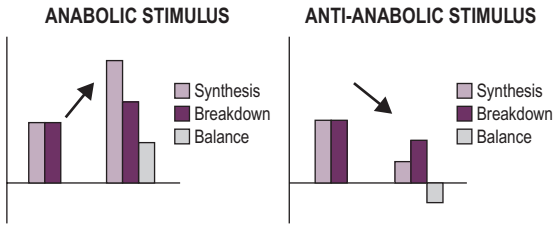

Figure 57.3 Schematic of the protein homeostatic response in humans to anabolic and anti-anabolic stimuli.

linked. In humans (in a completely different fashion from rodents), MPS has been repeatedly shown to be facilitative (the initial responsive process to a physiological stimulus) and MPB *adaptive* (responds to the change in MPS) by decreasing or increasing (but to a lesser amount) alongside MPS (Fig. 57.3).[29a]

Within the critical care environment, patients are exposed to a variety of stimuli that affect this balance (Fig. 57.4).

Muscle protein homeostasis in the critically ill seems to be determined by the time course of illness. Whilst several studies have conflicted as to the altered balance, a longitudinal study demonstrated suppressed MPS on the initial day of critical illness, with variable recovery over the first week.[24] This decrease in MPS resulted in a greater MPB than MPS, resulting in a net catabolic state that was mirrored by activity of the intracellular signalling pathways governing muscle protein homeostasis.[24] This same alteration in protein homeostasis was recently seen in patients ventilated for greater than 10 days, though it was noted that with increasing time, MPS recovered but MPB rose.[29b]

BIOENERGETIC IMPAIRMENT

MPS is a highly energy-dependent process and its depression may be the result of altered metabolism. Mitochondrial numbers[30] and function[31–33] reductions have been described, and intramuscular adenosine triphosphate (ATP) declines during critical illness irrespective of nutritional delivery.[34] This is mirrored by decreases in phosphorylated and total creatine, likely contributed to by the observed myonecrosis (see later). Beta-oxidation additionally declines, rendering fatty acid delivered as part of nutrition or sedation (propofol) relatively inert bioenergetically. Insulin resistance is well described in critical illness, and is in part the result of impaired GLUT-4 translocation, worsening the bioenergetic impairment.[35]

SKELETAL MUSCLE INFLAMMATION

Inflammation is well described as a suppressant of MPS[36] and intramuscular inflammation occurs in critically ill patients, related to altered protein homeostasis.[34] Additionally, this may impede recovery from myonecrosis by affecting macrophage function.

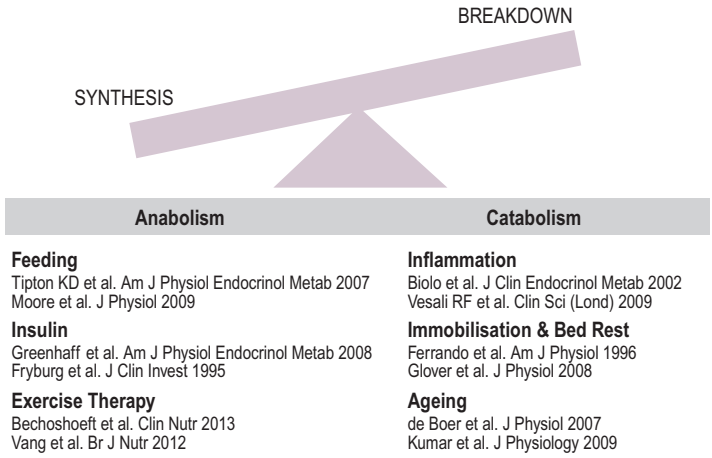

Figure 57.4 Factors affecting muscle protein homeostasis in critically ill patients.

IMPAIRED MUSCLE MEMBRANE EXCITABILITY

ICU-AW was originally described as a distal, axonal neuropathy[9] before observational data revealed the far greater prevalence of muscle wasting.[3,24] However, inflammation in experimental settings has been shown to affect muscle membrane excitability.[12] This is likely to be the result of inactivation of the voltage-gated muscle membrane sodium channels.[37] Additionally, sepsis models have suggested altered contractility secondary to deranged intracellular calcium homeostasis.[38]

In critically ill patients, this was elegantly demonstrated to be clinically relevant by the ability of the compound muscle action potential after direct muscle stimulation to be decreased in critical illness and to be highly predictive of subsequent ICU-AW (Fig. 57.5).[39]

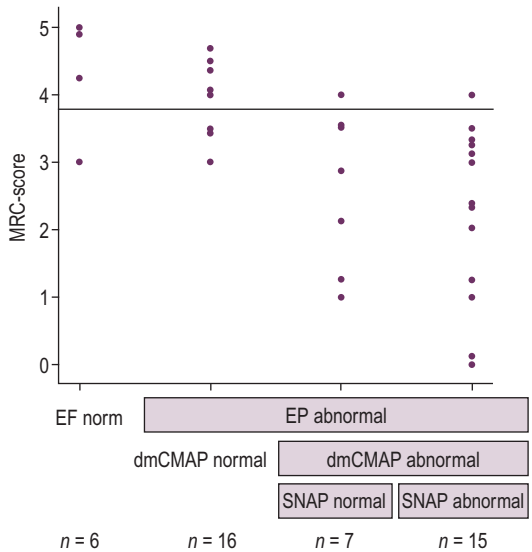

Figure 57.5 Medical Research Council score in the lower limb stratified by abnormal electrophysiology. *dmCMAP*, Direct muscle stimulation; *EP*, electrophysiology; *MRC*, Medical Research Council; *SNAP*, sensory nerve action potentials. (*From Weber-Carstens S, Koch S, Spuler S, et al. Nonexcitable muscle membrane predicts intensive care unit-acquired paresis in mechanically ventilated, sedated patients.* Crit Care Med. *2009;37:2632–2637.*)

LOSS OF MUSCLE QUALITY

In addition to muscle mass loss, loss of muscle quality is seen. Over 40% of patients develop patchy myonecrosis, detectable non-invasively by muscle ultrasound (Fig. 57.6). This necrosis is accompanied by a macrophagic infiltrate, and a fasciitis.[40] The pathological relevance of the macrophages remains unclear, though their presence may reflect clearance of dead tissue in preparation for regeneration.

Regeneration may not, however, be straightforward – a small human study suggests aberrant expression of regenerative genes[41] which may result in a mass/strength mismatch[42] (i.e. larger mass not being associated with greater strength).

AXONAL DEGENERATION

Neuropathies remain poorly understood, given the intrinsic difficulties in tissue analysis. Axonal degeneration may occur secondary to endoneurium microvascular changes,[43] with either neurotoxicity or oedema leading to axonal destruction.[44] Hyperglycaemia may also contribute to axonal damage.[45]

RISK FACTORS

These can be divided into pre-existing and in-ICU risk factors. The pre-existing risk factors of low muscle

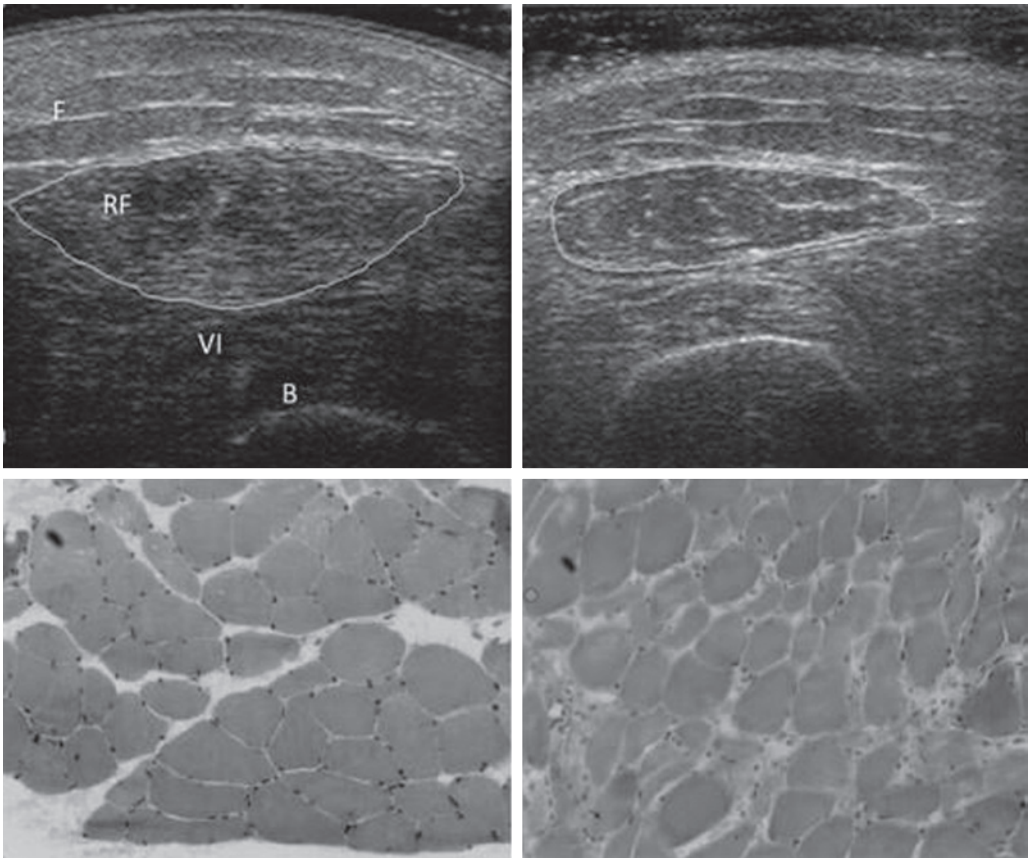

Figure 57.6 Paired ultrasound and haematoxylin and eosin stained sections of a patient on day 1 and day 10, demonstrating the reduction in rectus femoris (RF) cross-sectional area, an increase in RF echogenicity and the presence of myofibre necrosis with cellular infiltrate on day 10. *B*, Femoral bone; *F*, fascial layer; *VI*, vastus intermedius. *Reproduced from Puthucheary ZA, Phadke R, Rawal J, et al. Qualitative ultrasound in acute critical illness muscle wasting.* Crit Care Med. *2015;43(8):1603–1611.*

mass, age and presence of chronic disease have significant overlap, and relative contributions are often hard to dissect, which has led to the translation of the concept of frailty into critical care.

BASELINE MUSCLE MASS

Whilst few studies exist specifically relating baseline muscle mass with subsequent muscle wasting and functional disability, low muscle mass is clearly associated with poor functional status across the spectrum of health and disease. In health, muscle mass is directly related to muscle strength. The loss of further muscle from critical illness can only exacerbate this. Indirect evidence exists within the Nutrition Risk in Critically Ill (NUTRIC) score data where a low body mass index (BMI) is a predictor of mortality.[46] Within the critical illness literature, low skeletal muscle mass[47] and quality[48] are predictors of mortality. The diagnosis of ICU-AW is an independent predictor of mortality too,[3,21] and the combination of these observations allows confidence in the role of low pre-existing muscle mass in subsequent ICU-AW and functional disability.

PRE-EXISTING CHRONIC DISEASE

The presence or absence of chronic disease as a risk factor for ICU-AW is not clear. What is clear is that chronic co-morbidities lead to decreased muscle mass, and decreased function and physical activity post intensive care (compared to those without). A differential response to exercise rehabilitation also exists (Fig. 57.7). Separating the specific contribution of chronic disease states from disuse muscle atrophy is not currently possible. The presence of a chronic

disease state should prompt a detailed functional history to be taken.

AGE

The vast majority of data informing this field is observational, and the effect of age *per se* separated from accompanying chronic diseases and sarcopaenia is difficult to dissect. The use of numerical age alone as a risk factor is controversial but may have a role: anabolic resistance (the inability of MPS in response to resistance exercise and nutrition) is well described in the elderly.[49,50] However, it may be that high-functioning elderly patients are different – research into master athletes clearly demonstrated the dissociation between numerical age and physiology except at the extremes of age (Fig. 57.8).[51]

There exist several large observational studies suggesting that age does matter. For example, contrasting studies of critically ill patients in their 40s[52] and 50s[53] show very different outcome trajectories, with the latter having only 9% alive without functional dependence in one study. In an 8-year follow-up study, older patients had a higher rate of new functional limitations compared to younger patients and a higher decrement in function.

Batt et al.[54] summarise this complex issue of baseline health with '…there appears to be a clear prognostic signal in the elderly in terms of the importance of physiological reserve, burden of chronic organ dysfunction, and nature of the health trajectory before the critical illness for prognostication for survival, function, and Health Related Quality of Life. An emphasis on physiological rather than chronologic age and by inference the degree of fitness and muscle reserve may provide valuable insight into projected outcome.' These interactions hold true in observational studies where age[55] and/or chronic disease[56] were used to stratify functional outcomes.

FRAILTY

The construct of frailty was first described in the geriatric literature,[57] and is defined as *a biologic syndrome of decreased reserve and resistance to stressors, resulting from cumulative declines across multiple physiologic systems, and causing vulnerability to adverse outcomes* (Fig. 57.9). This is therefore separate from disability and chronic disease, though these conditions, as stated above, overlap considerably.

Several forms of assessment for frailty exist. The Clinical Frailty Score has been used repeatedly in observational studies to both assess and grade frailty, and has good construct validity with objective functional measures.[56] Frail patients are highly likely to have low muscle mass, given that a fundamental of the frailty

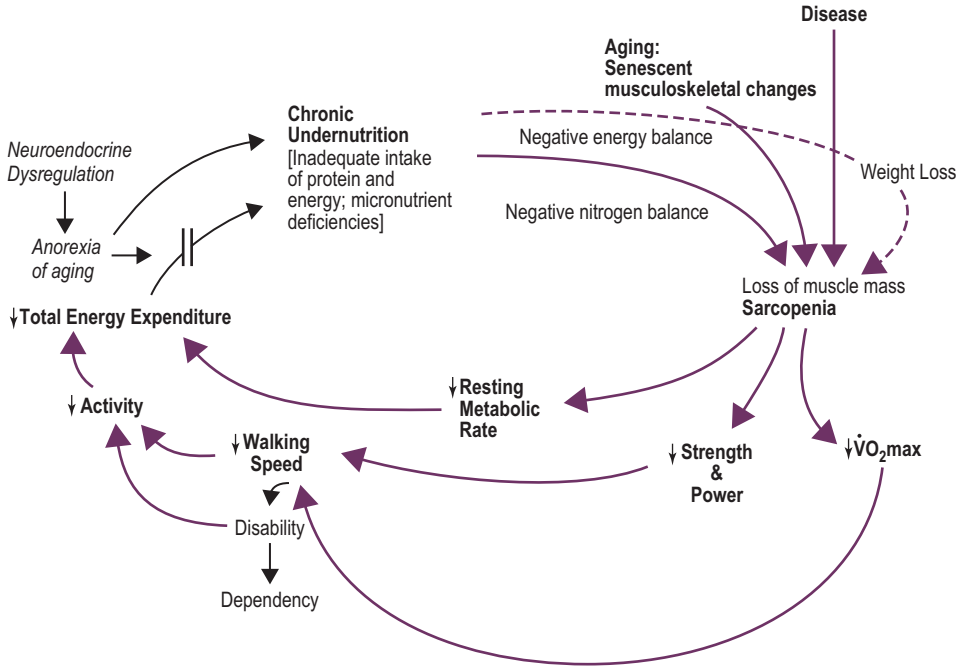

Figure 57.9 The cycle of frailty. *From Fried LP, Tangen CM, Walston J, et al. Frailty in older adults.* J Gerontol A Biol Sci Med Sci. *2001;56(3):M146–M157.*

diagnosis is altered physical function. What is key here is that frailty is a spiral: not only do these patients have low muscle mass, they are unable to increase this, with their default being to continue to lose muscle.

ILLNESS SEVERITY AND LENGTH OF STAY

Muscle wasting is related to severity of illness: patients in single-organ failure seem to lose no appreciable muscle in the first 10 days of critical illness, whilst those in 2–3 organ failure (defined using SOFA scoring) lose 20% in the first 10 days on average, and those in 4–6 organ failure lose more, averaging 26% lost in the same time period (see Fig. 57.2).[26]

INTENSIVE CARE UNIT LENGTH OF STAY

With muscle wasting occurring at rates of 2%–3% per day, it is perhaps unsurprising that the greater the length of stay, the greater the muscle mass lost. Length of stay is also a risk factor for subsequent functional disability as a result.[57]

GLYCAEMIC CONTROL

Insulin resistance secondary to impaired GLUT-4 translocation is well recognised in critically ill patients.[35] Hyperglycaemia results in mitochondrial damage[58,59] and strict glycaemic control improves mitochondrial function.[60] Insulin itself decreased MPB,[61,62] and separating glucose/insulin interactions is difficult.

IMMOBILISATION AND SEDATION

The effects on muscle protein homeostasis and muscle mass of immobilisation have been long established. Whilst bed rest alone results in detectable muscle wasting within 10 days[63] as a result of decreased MPS,[64] immobilisation in critical illness may be worse, given the metabolic effects of bed rest – insulin resistance, decreased aerobic capacity and anabolic resistance.[65]

Sedation remains an unquantified risk factor given the dependent relationship with immobilisation. Direct pharmacological effects of propofol and benzodiazepines on post-synaptic skeletal muscle receptors may attenuate neurotrophic stimulation of muscle mass.[65]

INFLAMMATION

Systemic inflammation is a common feature of critical illness. In human endotoxin experiments, inflammation suppresses MPS.[36] C-reactive protein concentrations are associated with loss of muscle mass[24] and intramuscular pro-inflammatory cytokine concentrations are strongly related to impaired anabolic signalling.[34]

Tumour necrosis factor alpha (TNFα) and its superfamily are the most studied of the pro-inflammatory

cytokines. Circulating levels and TNF receptor activation promotes muscle atrophy via nuclear factor kappa beta pathways. Additionally, apoptosis may be triggered by TNF receptor activation, leading to decreases in mitochondrial density and therefore energy availability,[34] and potentially necrosis.[40]

UNPROVEN RISK FACTORS

Neuromuscular blocking agents (NMBAs) have repeatedly been examined as a risk factor for ICU-AW. An important distinction is that ICU-AW is not prolonged neuromuscular blockade – this being the result of decreased drug clearance.[66] There is a clear lack of associative evidence,[18] and examining the historical context of the association reveals the far greater likelihood that the observed association was the result of concomitant high-dose steroids, use of ventilators without synchronised or spontaneous modes, or both.[67]

The only randomised controlled trial was performed in acute respiratory distress syndrome (ARDS) research and no increase in incidence of ICU-AW was noted with 48-hour infusions of cisatracurium,[68] even in the sub-cohort that received corticosteroids.[69] Importantly, there was a reduction in systemic inflammation[70] – if any conclusion were to be drawn, it might be that NMBAs reduce inflammation and therefore are protective in muscle wasting.

CLINICAL RELEVANCE

Survival and functional disability are rarely discussed acutely on admission to intensive care. However, this is of increasing relevance to patients and families, in the face of a significant year-on-year decrease in mortality worldwide. This survival is not without cost. The facts surrounding survival need to be clearly communicated to patients and families: muscle wasting occurs at rates of 2%–3% per day,[24] and a 10% loss of muscle mass is considered sufficient to affect physical function.[23] This is likely to affect patient and families in four domains.

LONG-TERM FUNCTIONAL DISABILITY

Herridge's landmark observational study in 2003[52] demonstrated the significant functional disability that these survivors suffer from and these findings have been confirmed repeatedly. We now know that although 75% of patients are discharged,[71] long-term impairment of physical function and quality of life are common: substantial functional limitations occur in 70% at 6–12 months, and 30% are carer-dependent.[52,72] One-third of working-age patients never work again.[52] Patients,[73] the National Institute of Clinical Excellence (UK)[71] and researchers[52] recognise muscle wasting and weakness as a major contributor to this functional deficit which may persist for up to 5 years (Fig. 57.10)[74] and in the setting of older age and co-morbidities, worsen[75] over time.

DISCHARGE PLANNING

Functional disability is now accepted as a major consequence of ICU-AW,[76] and often compounded by cognitive impairment,[77] which may recover eventually.[74] Critically ill patients lose muscle mass rapidly, and prolonged stays often result in discharges to intermediate care centres as opposed to home.[78] The elderly and those with pre-existing co-morbidity are often worse affected and less likely to return home. Discharge destination can be predicted by functional outcome assessment by scoring systems such as the Chelsea Critical Care Physical Assessment Tool,[79] which is well used internationally (Fig. 57.11).[80] Interestingly (likely due to the contribution from pre-illness muscle mass and co-morbidities), discharge destination can be predicted very early in the course of critical illness[81] and the likely destination should be communicated early.

LENGTH OF STAY AND VENTILATION

Observational studies have repeatedly demonstrated the association between muscle weakness and increased ICU length of stay, using various methods such as muscle ultrasound,[24] hand-grip strength[21] and the MRC Sum Score.[3] The effect on ventilator dependence has also been demonstrated, with one study seeing 9 days on average longer duration of ventilation, specifically post awakening,[82] which has significant implications for tracheostomy planning and avoidance of complications related to longer critical care (e.g. delirium, sleep deprivation, secondary infections and rehabilitation).

LONG-TERM MORTALITY

Short-term mortality rates from critical illness continue to fall. However, late mortality[53,83–92] remains high: 5-year mortality was 61% amongst 439 survivors of severe sepsis[93] and 58% amongst 300 mixed ICU survivors,[85] data similar to those reported by others.[74,94–97] In studies with careful matching and control for confounding, pneumonia,[7] sepsis,[8] and all-cause critical illness have each been found to increase survivors' risk for late mortality, independent of age and baseline health status. Overall, increased risk of death over 5 years (relative risk 3.4 when compared to the general population)[97] may extend to 15 years or more after discharge.[95] Death from the diseases that led to ICU admission[98–100] or from significant chronic disease pre-dating ICU admission[101,102] tends to occur in the first 6–12 months. Thereafter, for reasons, which are unexplained, malignancy and chronic cardiovascular diseases dominate as causes of death.[98–100] In a study of 156 ARDS survivors,[103] muscle weakness at hospital discharge was independently associated with 5-year mortality regardless of trajectory of recovery (i.e. those with persistent weakness had the same mortality as those with resolving weakness). Swallowing dysfunction,[18] decreased nutritional intake,[18] increased aspiration,[18] and decreased physical activity[19] are all sequelae of muscle weakness. Decreased physical activity may in turn increase risk for cardiovascular events and malignancy. Individually or in combination, these factors may impair MPS, leading to a vicious cycle of maintained cachexia increasing mortality.[20]

With these consequences of surviving critical illness in mind, clinicians need to ascertain physiological reserve, burden of chronic organ dysfunction, and nature of the health trajectory before the critical illness for prognostication for survival, function, and health related quality of life. These facts need to be communicated to families and, whenever possible, the patient.

PREVENTION AND TREATMENT

Nutrition: As a result of our incomplete understanding of the pathophysiology of ICU-AW, to date, trials of additional substrate delivery[104–110] have yet to preserve muscle mass and improve outcomes. Recent pathophysiological data on bioenergetics impairment may explain why conflict exists between data from observational studies demonstrating a clinical benefit from increased nutrition over the *entire* ICU stay[46,111,112] and the lack of benefit seen with *early* targeted nutrition,[104–107] when ATP turnover is impaired.

Glucose control: In a meta-analysis of two large randomised controlled trials of tight glucose control, intensive insulin therapy resulted in a decrease in electrophysiological abnormalities in patients ventilated greater than 1 week.[113] However, the impracticalities of such treatment were demonstrated in the NICE-SUGAR trial where an unacceptable incidence of hypoglycaemia and mortality was noted.[114] Current best practice is to avoid hyperglycaemia.

Neuromuscular electrical stimulation: Multiple trials in the acute setting have failed to demonstrate a benefit on muscle mass.[115–119] Statistically positive trials exist with methodological issues related to mass measurement techniques, which have not been reproduced by the same investigators.

Physiologically electrical stimulation is unlikely to have a beneficial effect in the acute setting in the presence of an impaired anabolic response.[24] Further, resistance exercise is needed for an anabolic stimulus, as opposed to simple muscle contraction. Lastly, non-excitability is predictive of ICU-AW, and by definition, is unaffected by electrical stimulation.[39] There is a high chance for harm – muscle necrosis is common,[40] (see Fig. 57.6) and electrical stimulation results in direct muscle damage.[120] It may be that a more focused approach using functional electrical stimulation will be

successful in maintenance of muscle mass,[121] and trials are ongoing.[122]

ABCDEF: Preventing muscle wasting and subsequent functional disability are intertwined goals. It is unlikely that a single intervention will manage this. The ABCDEF[123] bundle represents the best intervention available, and has been demonstrated to additionally decrease mortality significantly in a cost-neutral fashion. The bundle components are:

ABBREVIATION	INTERVENTION
A	Awakening trials[124]
B	Spontaneous breathing[125]
C	Coordination of care[125]
D	Delirium assessment
E	Early mobilisation[126]
F	Family engagement

Technically the evidence for each of these is related to mortality or ICU/hospital length of stay rather than treating ICU-AW *per se*. However, the evidence includes or requires increases in physical functioning, which, all things being equal, can only be achieved by addressing muscle mass and function. The muscle-specific intervention of early mobilisation is impractical without other aspects of the bundle.

Despite the neutral cost and significant patient and institutional gains from bundle implementation, the ABCDEF bundle has yet to become a standard of care, as a result of workplace cultural issues centred on early mobilisation and coordination of care.[127,128]

POST-DISCHARGE MANAGEMENT

Rehabilitation: As yet no evidence exists that post-discharge rehabilitation leads to increases in physical function or quality of life in critical care survivors, despite a number of high-quality multicentre randomised controlled trials.[129–133] This may be a result of trial methodology[134] and/or a failure to account for baseline function (Fig. 57.7).[56] Nevertheless, physical and exercise rehabilitation remains a recommendation in survivors.[71]

Bone health: Survivors of critical illness have an increased fracture risk.[135,136] This is the result of a combination of pre-existing osteopaenia, and the acute effects of critical illness on bone mineral density and structure.[137] In the setting of low muscle mass and decreased mobility, these patients represent a high falls-and-fracture risk. A comprehensive falls assessment is needed, as is staging of osteopaenia.

Nutrition: Ingestion of protein is mandatory for MPS to occur, preferably following resistance exercise. There is some evidence of poor appetite among critical illness survivors. This couples with functional disability that may limit shopping; financial constraints following loss of income and hospital costs may lead to poor dietary habits, and into the spiral of continued muscle wasting and functional decline.

Small fibre neuropathy: Two studies have described loss of small fibres, resulting in neuropathic pain and non-dermatomal sensory loss.[138,139] These symptoms may be difficult to control, and if non-responsive to first-line neuropathic pain treatments (e.g. gabapentin or amitriptyline), expert advice should be sought and formal diagnosis criteria checked.[140]

Nerve entrapment: Focal compression neuropathies with normal electro-diagnostic testing may occur.[141] In a 1-year follow-up series, this was noted in 7% of patients.[52] Whilst foot drop (a common compression neuropathy) is often recognised and treated by physiotherapists, uncommon compression neuropathies may need specialist neurological diagnostic input.

Patients, families and healthcare professionals need to be made aware of the sequelae of surviving critical illness rather than a pure focus on immediate mortality. Non-intensivists need to be made aware, as this has profound ramifications for their own discussions with patients regarding subsequent/ongoing treatment of complex conditions such as neoplastic disease (chemotherapy having a pre-requisite of good performance status) and complex surgery (recovery of muscle mass and rehabilitation not occurring in the short term). Only in this fashion can patients and families weigh the cost/benefit ratio of intensive care treatment versus subsequent quality of life.

Neuromuscular disorders

Manoj K Saxena

A number of peripheral nerve disorders producing weakness can require admission to the intensive care unit (ICU). These may involve:

- spinal anterior horn cells: motor neuron (or neurone) disease, poliomyelitis
- peripheral nerve conduction: Guillain–Barré syndrome (GBS) and related disorders
- the neuromuscular junction: myasthenia gravis (MG), botulism
- muscle contraction: myopathies, periodic paralysis

Weakness that results from peripheral nerve or muscle lesions as a complication of critical illness ('Intensive Care Unit Acquired Weakness') is covered in Chapter 57.

Box 58.1 lists a differential diagnosis of muscle weakness in critically ill patients.

GUILLAIN–BARRÉ SYNDROME AND RELATED DISORDERS

In 1834, James Wardrop reported a case of ascending sensory loss and weakness in a 35-year-old man, leading to almost complete quadriparesis over 10 days, and complete recovery over several months.[1] In 1859, Landry described an acute ascending paralysis occurring in 10 patients, 2 of whom died. Guillain, Barré and Strohl in 1916 reported two cases of motor weakness, paraesthesiae and muscle tenderness in association with increased protein in the cerebrospinal fluid (CSF)[2]; lumbar puncture for CSF examination was first described in the 1890s.

The many variants of this syndrome and the lack of specific diagnostic criteria have previously resulted in confusion in nomenclature. More recently, clinical, electrical and laboratory criteria for the three predominant variants have been described – acute inflammatory demyelinating polyneuropathy (AIDP), acute motor axonal neuropathy (AMAN) and acute motor and sensory axonal neuropathy (AMSAN).[3,4] GBS is usually preceded by an infection or other immune stimulation that induces an aberrant immune reaction to peripheral nerves and their spine roots. It is probably best regarded as a heterogeneous group of immunologically mediated disorders of peripheral nerve function.

INCIDENCE

Since the incidence of poliomyelitis has markedly declined due to mass immunisation programmes, GBS has become the major cause of rapid-onset flaccid paralysis in previously healthy people, with an incidence of approximately 1.7 per 100,000.[5] The disorder is commoner in males, and up to four times commoner in the elderly. No consistent seasonal or racial predilection has been demonstrated, and it now appears unlikely that GBS occurs after vaccination.[6,7]

AETIOLOGY

Most recent evidence supports the proposition that the AMAN and AMSAN variants of GBS are caused by immunological antibody-mediated nerve injury.[8,9] This antibody-mediated injury is driven by accidental molecular mimicry between surface gangliosides[10,11] on the nerve and an antecedent microbial antigen, such as *Campylobacter jejuni*.[12,13] However, it is important to note that unwanted autoimmunity does not arise in the majority of individuals exposed to *C. jejuni* infection.[14] The immune mechanism underlying AIDP is less well elucidated and this may be because of a greater heterogeneity in antecedent microbial infections or immune stimulation.

Two-thirds of cases are preceded by symptoms suggestive of respiratory or gastrointestinal infection. *C. jejuni* gastroenteritis now appears to be the most common predisposing infection and may be associated with a more severe clinical course; 26%–41% of GBS patients show evidence of recent *C. jejuni* infection. Cytomegalovirus infection accounts for a further 10%–22% of cases.[15] Other infective agents implicated include influenza A, hepatitis E,[16] parainfluenza, *haemophilus*,[17] varicella-zoster, Epstein–Barr, chickenpox, mumps, human immunodeficiency virus,[18] measles virus and *Mycoplasma*. Immunisations against viral infections, tuberculosis, tetanus and typhoid have all been reported to be associated with the onset of GBS, but most of these reports are anecdotal and of

ABSTRACT

Weakness due to disorders of peripheral nerve, the neuromuscular junction and muscle are a small, but important subset of neurological admissions to intensive care units. Several disorders including Guillain-Barré syndrome, myasthaenia gravis and motor neurone disease are discussed in this chapter summarising the epidemiology, pathogenesis, clinical features and management of these conditions. Recent advances include the identification of an increasing number of autoantibodies in Guillain–Barré syndrome and myasthaenia gravis, the consolidation of immunotherapy in the management of these two conditions and the confirmation of the benefit of thymectomy in the management of the latter, particularly for early onset disease. The prognosis of both disorders remains good. Motor neurone disease remains a disease with a poor prognosis and short life expectancy following diagnosis, although early multidisciplinary involvement and the use of noninvasive ventilation, assisted feeding and riluzole may modestly slow the progression of the disease.

KEYWORDS

Intensive care
critical illness
Guillain-Barré syndrome
myasthaenia gravis and motor neurone disease

Box 58.1 Differential diagnosis of muscle weakness in critically ill patients

Brainstem
Lower pontine haemorrhage or infarction (locked-in state)
Spinal cord
Transverse myelitis
Compression by tumour, abscess or haemorrhage
Carcinomatous or lymphomatous meningitis
Peripheral nerve
Intensive care unit acquired neuropathy/neuromyopathy
Phrenic nerve injury during thoracic surgery
Guillain–Barré syndrome
Ingested toxins, including arsenic, thallium, cyanide
Neuromuscular junction
Delayed reversal of neuromuscular blockade
Myasthaenia gravis
Lambert–Eaton syndrome
Botulism
Pesticide poisoning
Skeletal muscle
Acute necrotising myopathy
Steroid myopathy
Severe hypokalaemia, hypophosphataemia, and/or hypomagnesaemia
Acute alcoholic myopathy
Polymyositis or dermatomyositis
Toxic myopathy (colchicine, lovastatin, cocaine, bumetanide, amiodarone and others)
Intensive care unit acquired myopathy/neuromyopathy

questionable aetiological significance.[7] Surveillance data following the 2009 H1N1 influenza epidemic suggested that the risk of GBS following immunisation was only marginally increased over baseline.[6]

PATHOGENESIS

The peripheral nerves of patients who have died of GBS show infiltration of the endoneurium by mononuclear cells, in a predominantly perivenular distribution. The inflammatory process may be distributed throughout the length of the nerves, but with more marked focal changes in the nerve roots, spinal nerves and major plexuses. Electron micrographs show macrophages actively stripping myelin from the bodies of Schwann cells and axons. In some cases, Wallerian degeneration of axons is also seen, and failure of regeneration in these cases may correspond with a poor clinical outcome.[8,9]

Patients with recent *C. jejuni* infection have a high incidence of antibodies to the gangliosides GM1 and GD1a on the axonal surface (AMAN). Antibodies to the ganglioside GQ1b, which is enriched in the extraocular muscles, are described in the Miller-Fisher variant.[11] The basis of the effectiveness of plasma exchange and immunoglobulin therapy is likely to be by blocking or removing these autoantibodies.[19]

CLINICAL PRESENTATION

Most patients describe a minor illness in the 8 weeks prior to presentation, with a peak incidence 2 weeks beforehand. Approximately half the patients initially experience paraesthesiae, typically beginning in the hands and feet. Motor weakness proceeds to flaccid paralysis, which becomes the predominant problem. Objective loss of power and reduction or loss of tendon reflexes usually commence distally and ascend, but a more haphazard spread may occur. Muscle and/or neuropathic pain can be a prominent early feature. Cranial nerves are involved in 45% of cases, most commonly the facial nerve, followed by the glossopharyngeal and vagus nerves. One-third of patients require ventilatory support.

In typical GBS, sensory loss is generally mild, with paraesthesiae or loss of vibration and proprioception, but occasionally sensory loss, pain or hyperaesthesia can be prominent features. Autonomic dysfunction is common, and a major contributor to morbidity and mortality in ventilator-dependent cases. Orthostatic or persistent hypotension, paroxysmal hypertension and bradycardia are all described, as are fatal ventricular tachyarrhythmias. Sinus tachycardia is seen in 30% of cases. Paralytic ileus, urinary retention and abnormalities of sweating are also commonly seen. Progression of symptoms occurs up to 4 weeks after onset and rarely can be longer. Approximately 20%–30% of patients during the progressive phase require mechanical ventilation.

One subgroup of patients presents with a primarily axonal neuropathy (AMAN or AMSAN). In these cases, motor (and sensory) axons appear to be the primary targets of immune attack, rather than myelin. These patients have a more fulminant and severe course, and there is again a strong association with *C. jejuni* infection and anti-GM1 and -GD1a antibodies.

In the Miller–Fisher syndrome, a variant of GBS, cranial nerve abnormalities predominate, with ataxia, areflexia and ophthalmoplegia as the main features.[20] This is strongly associated with recent *C. jejuni* infection and with the presence of GQ1b antibodies.

DIFFERENTIAL DIAGNOSIS

Most of the important alternative diagnoses are listed in Box 58.2. In patients with prolonged illness, the possibility of chronic inflammatory demyelinating polyradiculopathy should be considered.[21] In this condition, preceding viral infection is uncommon, the onset is more insidious and the course is one of slow worsening or stepwise relapses. Corticosteroids and plasma

Box 58.2 Diagnostic criteria for typical Guillain–Barré syndrome

Features required for diagnosis
Progressive weakness in both arms and both legs
Areflexia
Features strongly supportive of the diagnosis
Progression over days to 4 weeks
Relative symmetry of symptoms
Mild sensory symptoms or signs
Cranial nerve involvement, especially bilateral weakness of facial muscles
Recovery beginning 2–4 weeks after progression ceases
Autonomic dysfunction
Pain
High concentration of protein in cerebrospinal fluid protein, with fewer than 10×10^6 cells/L
Typical electrodiagnostic features
Features that should raise doubt about the diagnosis of Guillain-Barré syndrome
Mononuclear cell count in CSF >50 cells per μL
Presence of fever at onset
Severe pulmonary pathology with minimal limb weakness at onset
Persistent bladder or bowel dysfunction
Sharp spinal cord sensory level
Persistent asymmetry of weakness
Slow progression of weakness without respiratory involvement
Purely sensory syndrome, without weakness

Feasby T, Hahn A, Brown W, et al. Severe axonal degeneration in acute Guillain-Barre syndrome: evidence of two different mechanisms? *J Neurol Sci.* 1993;116(2):185–192.

exchange are possibly effective in this disorder, but adequate studies of immunosuppressive drugs have not been carried out.

An intermediate *subacute* polyneuropathy as well as a recurrent form of GBS are also described, and these variants may be part of the spectrum of a single condition.

A purely motor axonal neuropathy (AMAN), which causes seasonal childhood epidemics mimicking classical GBS in China and elsewhere,[22] appears to be a distinct entity. Once again, this is strongly associated with *C. jejuni* infection.

INVESTIGATIONS

In over 90% of patients, CSF protein is increased (greater than 0.4 g/L) within 2 weeks of onset of symptoms. The level does not correlate with the clinical findings. A pleocytosis with lymphocytes and monocytes in the CSF may be seen in a small proportion of patients (<15%), especially later in the disease. Nerve conduction studies may be normal early in the disease and are most useful around 2 weeks after the onset of weakness. Nerve conduction studies can help differentiate between the demyelinating (AIDP) and axonal (AMAN and AMSAN) subtypes and this differentiation may relate to prognosis.

MANAGEMENT

Although the management of the patient with severe and protracted GBS provides a major challenge, the prognosis is generally good if complications can be treated early or avoided.

SPECIFIC THERAPY

Plasma exchange (plasmapheresis) is of value in GBS, and in two trials a reduction in patients requiring mechanical ventilation, reduced duration of mechanical ventilation for those who required it, reduced time to motor recovery and time to walking without assistance were demonstrated.[23,24] Mortality, however, was not altered. Plasma exchange was most effective when carried out within 7 days of onset of symptoms. The currently recommended plasma exchange schedules consist of four exchanges of 1–2 plasma volumes each, over 1–2 weeks.[25] Adverse events are common, and some relate to the disease itself[26]; Fresh frozen plasma is reported to have more side effects than albumin as the replacement fluid.

Immunoglobulin therapy was as effective as plasmapheresis[27] and previous concerns of higher recurrence rates are probably unfounded. Because of its ease of use, many authorities now advocate immunoglobulin as the treatment of choice.[28] A total dose of 2 g/kg body weight intravenously, over 2–5 days, is reasonable.[29]

About 10% of patients relapse after initial treatment with either plasmapheresis or immunoglobulin; most respond well to a further course. There appears to be no benefit in combining plasmapheresis and immunoglobulin treatments, or in crossing over from one to the other.[27]

Low- or high-dose corticosteroids are of no value, and may even slow recovery.[30]

SUPPORTIVE CARE

RESPIRATORY

In the spontaneously breathing patient, chest physiotherapy and careful monitoring of respiratory function are of paramount importance. Regular measurement of vital capacity is probably the best way to predict respiratory failure, and is more reliable than arterial blood gases.[31] Any patient with a vital capacity less than 15 mL/kg or 30% of the predicted level, or a rising arterial $PaCO_2$ (a late sign of respiratory failure) is likely to require mechanical ventilation.

Bulbar involvement should be carefully sought, as there is a significant risk of aspiration of upper airway secretions, gastric contents or ingested food. The cough

reflex may be inadequate, and airway protection by tracheal intubation or tracheostomy is then required. Oral feeding should be stopped in any patient in whom bulbar involvement is suspected.

Mechanical ventilation is mandatory if coughing is inadequate, pulmonary collapse or consolidation develop, arterial blood gases are significantly abnormal, vital capacity is less than predicted tidal volume (approximately 15 mL/kg), or the patient is dyspnoeic, tachypnoeic or appears exhausted. Mechanical ventilation, if necessary, will probably be required for several weeks (although there is wide variation), and early tracheostomy should be considered.

CARDIOVASCULAR

Cardiac rhythm and blood pressure should be monitored. Sinus tachycardia is the commonest autonomic manifestation of GBS and usually requires no active treatment. Induction of anaesthesia appears particularly likely to induce serious arrhythmias. Use of suxamethonium may contribute significantly to this and, as with many other neuromuscular disorders, should be avoided.[32] Endotracheal suctioning has also been associated with serious arrhythmias. Cardiovascular instability may also be exacerbated by several drugs (Box 58.3). These, likewise, should be avoided or used with great care.

Mild hypotension and bradycardia may require no treatment, particularly if renal and cerebral functions are maintained. However, blood volume expansion or inotropic drugs may be required in some cases. Hypertension is often transient, but occasionally requires appropriate drug therapy. Hypoxia, hypercarbia, pain and visceral distension should be excluded as causes.

Box 58.3 Drugs associated with cardiovascular instability in Guillain–Barré syndrome

Exaggerated hypotensive response
Phentolamine
Nitroglycerin
Edrophonium
Thiopentone
Morphine
Furosemide

Exaggerated hypertensive response
Phenylephrine
Ephedrine
Dopamine
Isoprenaline

Arrhythmias
Suxamethonium

Cardiac arrest
General anaesthesia

FLUIDS, ELECTROLYTES AND NUTRITION

Paralytic ileus is not uncommon, especially immediately following the institution of mechanical ventilation, and a period of parenteral nutrition may be required. However, where possible, nasoenteric feeding should be instituted because of its significantly greater safety. Energy and fluid requirements are considerably reduced in these patients.

SEDATION AND ANALGESIA

In non-ventilated patients, sedation should be avoided because of the potential for worsening respiratory and upper airway function. In ventilated patients, sedation becomes less necessary as the patient becomes accustomed to the ventilator, but night sedation may help to preserve diurnal rhythms. Limb pain, particularly with passive movement, is very common and often quite severe. Quinine, non-steroidal analgesics and antidepressant drugs may all be tried, but the pain can be difficult to control and opioids are often required. Methadone, transdermal fentanyl, gabapentin and tramadol have all been advocated.

GENERAL AND NURSING CARE

A comprehensive programme of physiotherapy should be implemented by nurses and physiotherapists, with careful attention to pressure area care, the maintenance of joint mobility and pulmonary function. Nosocomial infection should be actively sought. Sites of vascular access should be inspected frequently, and changed whenever necessary. It may be possible to manage stable long-term patients without venous access. Care should be taken to prevent corneal ulceration and faecal impaction.

Prophylaxis against venous thromboembolism should be given, and enterally administered low-dose warfarin may be preferable to twice-daily heparin injections in long-stay patients. Psychological problems, especially depression, are common, and some patients are helped by antidepressant drugs. Good communication and rapport between the patient and staff, involvement of allied health practitioners, the provision of television, radio and reading aids and, where possible, occasional trips out of the ICU often have great value.

PROGNOSIS

The nadir of the disease is reached within 2–4 weeks, and gradual resolution follows over weeks to months. Of those who survive the acute illness, 70% have recovered to functional independence within 1 year, and a further 20% are left with minor limitations. Poor prognostic features[33] include age over 60 years, rapid progression to quadriparesis in less than 7 days, the need for mechanical ventilation (except for children), and a preceding diarrhoeal illness. Even in patients ventilated for more than 2 months, gradual improvement

may continue for 18 months to 2 years. These severely affected patients require a protracted period of rehabilitation. A substantial proportion of patients have residual pain and fatigue that may be attributed to persistent axonal loss. Many patients adapt their work or daily activities even after substantial recovery.

Overall mortality in well-resourced settings is 5%–8% and is usually due to respiratory complications or because of autonomic instability.

MYASTHAENIA GRAVIS

MG is an autoimmune disorder of skeletal muscle caused by antibodies directed against acetylcholine (ACh) receptors or functionally related molecules in the post-synaptic membrane at the neuromuscular junction.[34] Despite its relative rarity, it is the most studied and best understood clinical disorder of neuroreceptor function, and arguably the best understood organ-specific autoimmune disease. It is characterised clinically by ocular and skeletal muscle weakness and exaggerated fatigability on sustained effort. Intensive care is most commonly required because of severe involvement of the bulbar or respiratory muscles, which may be the result of a spontaneous exacerbation of the disease, a complication of drug therapy, intercurrent illness or surgery, or following surgical thymectomy – a component of treatment for some patients. The diagnosis of MG is based on the combination of symptoms, signs and a positive test for specific autoantibodies, although seronegative forms are recognised.

INCIDENCE

The incidence of MG is approximately 8–10 per million. There is no racial or geographic predilection. Although MG can occur at any age, it is very rare in the first 2 years of life, and the peak incidence is in young adult females. Overall, females are affected about twice as often as males. This gender predilection decreases with increasing age, and there is a smaller, second incidence peak in elderly males.

AETIOLOGY AND PATHOPHYSIOLOGY

In 70% of cases, there is histological evidence of thymic abnormality. Thymic hyperplasia is present in most patients, particularly early onset (<50 years old). Approximately 10% have a thymoma and this is more common in the older age group.

The precise role of the thymus is uncertain, but ACh receptors (AChR) are present in the myoid cells of the normal thymus, and there is evidence that anti-AChR antibody production is mediated by both B and T lymphocytes of thymic origin.

Other organ-specific autoimmune disorders, most commonly thyroid disease[35] but also rheumatoid arthritis and lupus erythematosus, are significantly associated with MG; autoantibodies to other organs may be seen in MG patients without evidence of disease. Other associations include myocarditis and lymphoma.

Children born to mothers with MG demonstrate transient weakness ('neonatal MG') in about 15% of cases.

A number of congenital myasthaenic syndromes exist, in which symptoms develop in infancy, without evidence of autoantibody production.[36] A familial tendency is more common in this group, and structural changes at the neuromuscular junction have been demonstrated.

The stimulus to autoantibody production is not known, but these can be detected in about 90% of patients with generalised myasthaenia. The antibodies may interfere with neuromuscular transmission by competitively blocking receptor sites, by initiating immune-mediated destruction of receptors, or by binding to portions of the receptor molecule that are not part of the AChR site but nevertheless are important in allowing ACh to bind.

CLINICAL PRESENTATION

Ptosis and diplopia are the most common initial symptoms and in 20% of cases the disorder remains confined to the eye muscles (ocular MG); ocular signs are usually asymmetrical. Bulbar muscle weakness is common and may result in nasal regurgitation, dysarthria and dysphagia.[33] Limb and trunk weakness can occur with varying distribution, and is usually symmetrical.

Some patients complain of fatigue rather than weakness and may be misdiagnosed as having psychiatric problems. However, weakness can be elicited by sustained effort of an involved muscle group (e.g. sustained upward gaze is often worse at the end of the day and improves with rest).

Early onset disease tends to be associated with thymic hyperplasia, whereas late onset disease is often associated with thymic atrophy.

INVESTIGATIONS

Impairment of neuromuscular transmission may be confirmed by a positive edrophonium ('Tensilon') test. However, this traditional test has waned in popularity as it has high sensitivity but rather poor specificity. Atropine 0.6 mg is given IV to prevent muscarinic side effects, and this is followed by 1 mg edrophonium. If there is no obvious improvement within 1–2 minutes, a further 5 mg may be given. Some authors recommend the use of a saline placebo injection, and the presence of a second doctor as a 'blinded' observer.

Resuscitation facilities should be available as profound weakness may ensue, especially in patients already receiving anticholinesterase drugs.

The presence of autoantibodies against nicotinic AChR is quite specific, but false positives may occur in patients with penicillamine-treated rheumatoid disease, other autoimmune diseases and in some first-degree relatives of myasthaenic patients.[37] Other antibodies associated with myasthaenia include muscle-specific kinase and lipoprotein receptor related protein antibodies; the former appears to be associated with more severe, treatment-resistant disease. About 15% of patients are seronegative.

Electromyography shows characteristic changes in 90% of patients with generalised MG and also in many patients with ocular symptoms only.

A syndrome of myasthaenic weakness occurs in association with malignancy and other autoimmune diseases (Eaton–Lambert syndrome). Although fatigability is present, the pelvic and thigh muscles are predominantly affected, whereas ocular and bulbar involvement is rare. Tendon reflexes are reduced or absent, and there are specific electromyographic changes.

MANAGEMENT

1. *Symptomatic treatment* is provided by anticholinesterase drugs, which potentiate the action of ACh at receptor sites. Pyridostigmine (Mestinon) is the most commonly used, and is usually commenced at a dose of 60 mg orally three to four times daily. Considerable adjustment of dosage may be required based on symptom relief and side effects (diarrhoea, abdominal pain, cramps, urinary urgency and increased flatus, salivation and sweating).
2. Expert consensus and limited controlled trial data suggest that most patients require immunosuppression with a combination of *Corticosteroids and/or azathioprine*.[38–40] High doses of corticosteroids (e.g. prednisolone 50–100 mg/day) are used initially and may be introduced gradually, before being carefully reduced to the minimal dose (10–40 mg/day) for symptom control. Transient exacerbation upon commencement of steroids is very common, and severely affected patients are often hospitalised for the initiation of therapy with gradually increasing doses. Older patients are more likely to respond, but an average of 4 months' treatment is required to achieve clinical stability and the majority will require continuing treatment indefinitely.[41] *Azathioprine and mycophenolate* are both effective adjuncts to corticosteroid therapy because a combination of corticosteroid with either agent allows a reduced dose of steroid, minimising side effects of steroid therapy and achieving a better functional outcome overall. Azathioprine and mycophenolate are purine synthesis antagonists and have effects on T and B lymphocytes. Thiopurine methyltransferase activity should ideally be tested before treatment with azathioprine because low activity increases the risk of toxic side effects.[42,43] Overall, 80% of patients are improved with a combination of steroid and either azathioprine or mycophenolate, but this may be seen only after some months. A few patients may achieve complete remission.
3. *Ciclosporin (cyclosporine), mycophenolate, tacrolimus and rituximab* are all supported by limited evidence in MG and are occasionally used.[44–46]
4. *Thymectomy* offers the prospect of long-term, drug-free remission and has long been advocated as a mainstay of MG treatment. Thymectomy should be performed in patients with MG and a thymoma. Historical studies suggested that total thymectomy also benefited patients with MG without a thymoma.[47] Recently, this has been confirmed in a clinical trial supporting early total thymectomy for patients with generalised disease, duration of disease of less than 3–5 years and age of less than 65.[48] Thymectomy was associated with symptom reduction, less immunosuppressive drug treatment and fewer exacerbations during the 3-year follow up.

   Preoperative optimisation of neuromuscular function is essential, using anticholinesterase drugs and steroids, supplemented by plasma exchange or immunoglobulin if necessary. Though anticholinesterase requirements are usually reduced in the immediate postoperative period to about three-quarters of the preoperative dose, sustained improvement following thymectomy may not be seen for months or even years. A thoracoscopic approach may achieve equivalent results with less short-term morbidity, but the traditional sternotomy approach continues to be commonly used.
5. *Plasma exchange and intravenous immunoglobulin* are equally effective in producing short-term clinical improvement.[35,49,50] Either approach may be used in myasthaenic crisis or to improve severely affected patients before thymectomy. For *plasma exchange*, five exchanges of 3–4 L each are performed over a 2-week period, and this results in improvement within days. However, the benefits are short-lived, lasting only weeks. *Intravenous immunoglobulin* can be used at a total dose of 1–2 g/kg given over 1–2 days, and occasional patients derive long-term benefit. Interestingly, immunoglobulin has no consistent effect on AChR antibody concentrations, and its mechanism of action is poorly understood.

MYASTHAENIC AND CHOLINERGIC CRISIS

Patients with known MG may undergo life-threatening episodes of acute deterioration affecting bulbar and respiratory muscle function. These may occur spontaneously, or may follow intercurrent infection, pregnancy, surgery, the administration of various drugs (Box 58.4) or attempts to reduce the level of immunosuppression.

Box 58.4 Drugs that may exacerbate myasthaenia gravis

Antibiotics	**Local anaesthetics**
Streptomycin	Procaine
Kanamycin	Lidocaine
Tobramycin	**General anaesthetics**
Gentamicin	Ether
Polymyxin group	**Muscle relaxants**
Tetracycline	Curare
Antiarrhythmics	Suxamethonium
Quinidine	**Analgesics**
Quinine	Morphine
Procainamide	Pethidine

Such episodes, known as myasthaenic crises, usually resolve over several weeks, but occasionally last for months. The incidence of myasthaenic crisis increases markedly with age.

Rarely, a patient may deteriorate due to excessive dosage of anticholinesterase drugs ('cholinergic crisis'). Abdominal cramps, diarrhoea, excessive pulmonary secretions, sweating, salivation and bradycardia may be present, but these can also occur in patients with myasthaenic crisis on high doses of pyridostigmine. Though the two situations may be difficult to distinguish, myasthaenic crisis is far more likely unless extremely large doses of pyridostigmine (at least 120 mg every 3 hours) have been administered.

A Tensilon test is now considered an unreliable method of distinguishing between these two possibilities, may be hazardous, and is generally not recommended.

Patients with myasthaenic crisis should be admitted directly to the ICU, as there is a significant risk of pulmonary aspiration due to bulbar involvement, bacterial pneumonia due to stasis, acute respiratory failure or cardiorespiratory arrest. After initial stabilisation and resuscitation, every effort should be made to identify and correct reversible causes, especially respiratory infections and electrolyte disturbances.

Frequent estimations of vital capacity and maximum inspiratory force should be made and recorded. Tracheal intubation and mechanical ventilation should be considered in patients with significant bulbar involvement or clinical evidence of worsening respiratory failure. As with other neuromuscular disorders, deterioration of blood gases may occur late, and is an unreliable sign of progressive respiratory failure.[31] Aggressive chest physiotherapy, urinary drainage and nasogastric feeding may be required. Hypokalaemia, hypocalcaemia and hypermagnesaemia should be avoided, as all may exacerbate muscle weakness.

If the patient's clinical status cannot be rapidly improved by the adjustment of anticholinesterase dosage, immunosuppressive therapy and aggressive treatment of intercurrent illness, high-dose corticosteroids and plasma exchange or immunoglobulin should be commenced simultaneously, and may produce some benefit within as little as 24 hours.

PERIOPERATIVE MANAGEMENT

MG patients often require intensive care in relation to surgery for intercurrent illness or prior to thymectomy. Unstable patients should be admitted to hospital some days in advance for stabilisation. In severely affected patients, preoperative high-dose corticosteroids and/or plasma exchange may be used to improve the patient's fitness for surgery. It may be prudent to omit premedication, and an anaesthetic technique that avoids the use of non-depolarising muscle relaxants is usually advocated, though vecuronium and atracurium are probably safe in reduced dosage.[51,52] Suxamethonium can be used safely in normal dosage.[53]

Up to one-third of patients require continuing mechanical ventilation postoperatively following thymectomy. Predictive factors include a long preoperative duration of myasthaenia, coexistent chronic respiratory disease, high anticholinesterase requirements (e.g. pyridostigmine >750 mg/day) and a preoperative vital capacity of less than 2.9 L.[54] In those cases requiring mechanical ventilation, some authors advocate temporary cessation of anticholinesterase drugs to reduce respiratory secretions, but generally they should be continued, though dosage requirements must be reassessed carefully and repeatedly.

MOTOR NEURON DISEASE (AMYOTROPHIC LATERAL SCLEROSIS, LOU GEHRIG'S DISEASE)

Motor neuron disease is a heterogeneous progressive, paralytic disorder characterised by gradual generalised degeneration of all types of motor neurons.[55,56] This leads to increasing physical disability and there is now a recognised association with impaired cognition (frontotemporal dementia). There is often a delay in initial diagnosis and death occurs 3–5 years after diagnosis due to respiratory failure.

PATHOGENESIS

The key pathological finding is mixed upper and lower motor neurone death in the motor cortex and spinal cord, accompanied by inflammation and proliferation of astrocytes, microglia and oligodendrocytes. A common finding is aggregation of cytoplasmic proteins in motor neurones. The cerebral cortex as well as the anterior horns of the spinal cord are involved, with shrinkage, degenerative pigmentation and, eventually, disappearance of the affected cells accompanied by gliosis of the lateral columns ('lateral sclerosis'). As

muscles are denervated, there is progressive atrophy of muscle fibres ('amyotrophy'), but sensory neurons as well as those concerned with autonomic function and coordination are all spared.

Over 120 genetic variants of motor neurone disease have been identified and approximately 10% of cases are familial and 90% are sporadic. The disease may arise because of the interplay between genetic and environmental factors, although it is possible that the disease occurs because of mainly complex genetic factors.

CLINICAL PRESENTATION

There are four main clinical phenotypes of motor neurone disease.

- Amyotropic lateral sclerosis (ALS) is the dominant phenotype (70%) and presents with mixed upper and lower motor neurone signs affecting the limbs. This is the most malignant form of the disease and median life expectancy is about 3 years. In North America the term ALS is often used more generically, essentially equivalent to the broader term motor neurone disease.
- Isolated bulbar palsy (4%–8%) presents initially with progressive speech and swallowing difficulty prior to the development of more generalised disease. Median life expectancy is around 4 years.
- Progressive muscular atrophy (5%) presents with pure lower motor neurone signs affecting the limbs. The prognosis may be slightly better than for classic ALS.
- Primary lateral sclerosis presents with pure upper motor neurone signs affecting the lower limbs mainly, with patients having a much slower disease progression and in some cases a normal life expectancy.

As motor neurone disease becomes more generalized, a mixed pattern of upper and lower motor neurone signs affecting limb skeletal muscle evolves (i.e. spasticity and hyperreflexia in addition to gross wasting) with bulbar and respiratory muscles also affected.

Awareness and intellect were previously thought to be preserved, but it is now recognised that up to half the patients have evidence of cognitive dysfunction, manifest as language difficulties and frontal symptoms. Motor neurone disease and frontotemporal dementia are now recognised to be part of a continuum in which pure motor neurone disease and pure frontotemporal dementia form the ends of a clinical and pathological spectrum.

Death occurs in 50% of cases within 3–5 years, usually due to respiratory infection, aspiration or ventilatory failure from profound weakness. However, there is wide variability, and a few patients may survive for many years.

DIAGNOSIS

There are no specific investigations, and the diagnosis must be made on clinical grounds together with electromyogram evidence of generalised denervation. The most important differential diagnosis is multifocal motor neuropathy. The distinction is of clinical importance, as the latter is amenable to treatment. Poliomyelitis can also result in a syndrome of progressive weakness, wasting and fasciculation, beginning many years after the initial illness (the post-polio syndrome), and leading occasionally to respiratory failure and death.[57]

MANAGEMENT

Treatment is essentially symptomatic and supportive. Current evidence suggests that treatment within a multidisciplinary team may improve both quality of life and life expectancy by 7–24 months. Non-invasive ventilation improves both quality of life and survival in patients who do not have severe bulbar dysfunction.[58,59] Regular assessment and management of nutrition status is important and interventions such as nasoenteral feeding tubes or gastrostomy may have a role.[60] Riluzole, a centrally acting glutamate antagonist that also modifies sodium channel activity, has been shown to slow slightly the progression of ALS by 3–6 months.[61–63]

Admission to the ICU is sometimes requested when these patients present with an acute deterioration or intercurrent illness. The intensivist may also be asked to assist with ambulatory or home respiratory support for gradually worsening chronic respiratory failure.

Respiratory support may be given by face mask, nasal mask or, rarely, by tracheostomy using simple, compact ventilators. Some patients require only intermittent support, particularly at night or during periods of acute deterioration due to intercurrent illness. Although home-based non-invasive ventilation has become routine, long-term invasive respiratory support outside the ICU is a major undertaking, requiring specific equipment and extensive liaison with the patient, the family and numerous specialised support services.

RARE CAUSES OF ACUTE WEAKNESS IN THE INTENSIVE CARE UNIT

PERIODIC PARALYSIS[64]

This term describes a group of rare primary disorders, mostly inherited as autosomal dominant traits, producing episodic weakness. They must be distinguished from other causes of intermittent weakness, including electrolyte abnormalities, MG and transient ischaemic attacks. The inherited types are now grouped together with the various forms of myotonia

and susceptibility to malignant hyperthermia. All are classified as congenital defects of skeletal muscle ion channels and there is an association with long QT syndrome and other cardiac channelopathies. Symptoms begin early in life (before age 25), and follow rest or sleep rather than exertion. Alertness during attacks is completely preserved, and muscle strength between attacks is normal. Treatment is usually successful in preventing both the attacks and the chronic weakness, which can develop after many years in untreated patients.

The *hypokalaemic* form of periodic paralysis is predominantly inherited, but can also present sporadically in association with thyrotoxicosis. Involvement of bulbar or respiratory muscles occurs rarely. The degree of hypokalaemia during attacks is mild, but patients rapidly respond to potassium administration. Effective prophylaxis is conferred by acetazolamide, with potassium replacement. Many patients eventually develop established myopathy. Depolarising muscle relaxants should be avoided in these patients.

The *hyperkalaemic* form is milder, almost always inherited and rarely requires intensive care. The serum potassium is modestly elevated at the beginning of attacks, but may be normal at other times. Creatine kinase levels may be elevated during attacks. Attacks respond to carbohydrate administration, sympathomimetics (which activate the sodium/potassium pump) and acetazolamide. Thiazide diuretics or acetazolamide provide effective prophylaxis. Non-depolarising muscle relaxants should be avoided in these patients.

A *normokalaemic* form and several eponymously named congenital syndromes are also included in this group of disorders.

BOTULISM[65]

Botulism is a widespread but very uncommon potentially lethal disease caused by exotoxins produced by *Clostridium botulinum* – an anaerobic, spore-forming Gram-positive bacillus. The vast majority of botulism is *foodborne* and outbreaks are largely due to home-preserved vegetables (type A toxin), meat (type B) or fish (type E), but high-risk foods also include low-acid fruit and condiments. Signs and symptoms are caused by toxin produced in vitro and then ingested.

The first recorded outbreak occurred in Germany in 1817, from ingestion of improperly preserved blood sausage (*Botulus* [Latin] = 'sausage').

Wound botulism arises rarely, when wounds (typically open fractures) are contaminated by soil containing type A or B organisms. Intravenous drug abusers are an increasing source of this condition through infected injection sites.

Infantile botulism arises in infants under 6 months of age, and is due to the active production of toxin by organisms in the gut rather than the direct ingestion of toxin.

Hidden botulism describes the adult equivalent of infantile botulism, and is a rare complication of various gastrointestinal abnormalities.

Inadvertent botulism is the most recently described form, and occurs as a complication of the medical or cosmetic use of botulinum toxin (BoNT).

Inhalational botulism is the form that would occur as a result of aerosolised toxin released in the context of bioterrorism. BoNT is the most potent known neurotoxin, and it has been estimated that as little as 1 g of aerosolised BoNT could lead to the death of over 1.5 million people.

In most cases, exogenously produced exotoxin is absorbed (primarily in the upper small intestine), and carried by the bloodstream to cholinergic nerves at the neuromuscular junction, postganglionic parasympathetic nerve endings and autonomic ganglia, to which it irreversibly binds. The toxin enters the nerve endings to interfere with ACh release.

Most patients become ill about 3 days after ingestion of toxin, with gastrointestinal symptoms (nausea, vomiting, abdominal pain, diarrhoea or constipation), dryness of the eyes and mouth, dysphagia and generalised weakness, which progresses in a symmetrical, descending fashion, with ventilatory failure in severe cases. Cranial nerve dysfunction is a prominent early feature, manifested by ptosis and diplopia, facial weakness and impaired upper airway reflexes. The pupils may be fixed and dilated in severe cases. Patients are usually afebrile and have no sensory involvement.

The differential diagnosis includes food poisoning from other causes, MG and GBS. Botulism can be confirmed by the presence of toxin (either in the patient's serum or stool, or in contaminated food) in about two-thirds of cases. Contact tracing, in the case of food-borne botulism, is of great importance.

Treatment is mainly supportive, with airway protection and mechanical ventilation when required. Mean duration of mechanical ventilation, when required, is 7 weeks. Clearance of toxin from the bowel with enemas and cathartics has been advocated. Guanidine hydrochloride, which enhances the release of ACh from nerve terminals, has been reported to improve muscle strength, especially in ocular muscles, and may be useful in milder cases. Antibiotics have not been clearly shown to be useful. Equine antitoxins are available, but side effects are common and their efficacy is limited. A human-derived antitoxin has been shown to be effective in *infantile botulism*, and the United States Defense Department has a pentavalent antitoxin, which is not available for public use. Antitoxin must be given before the onset of paralysis in order to be effective. In *wound botulism*, antibiotics (penicillin or metronidazole) and aggressive debridement are recommended.

Most patients begin to improve after a week or so, but hospitalisation is usually required for 1–3 months. The mortality is low (5%–8%) with good supportive

care, including mechanical ventilation. Mild weakness and constipation may persist for many months.

Diabetic emergencies

Ayush Sinha

INTRODUCTION

Diabetes, with a global prevalence of 8.5% in adult population, is rising in prevalence as are its associated emergencies. In 2014 approximately 422 million adults were living with diabetes globally,[1] and this is expected to rise to 552 million by 2030.[2] Diabetic emergencies can either be hyperglycaemic or hypoglycaemic. Diabetic ketoacidosis (DKA) and hyperosmolar hyperglycaemic state (HHS) are the two most common hyperglycaemic acute complications of diabetes resulting from absolute or relative insulin deficiency. Its overtreatment – usually with insulin – leads to hypoglycaemia. Both hyperglycaemia or hypoglycaemia are associated with immediate and long-term adverse clinical outcomes and significant economic burden on healthcare. In the United States, the annual cost of managing DKA as estimated by the reimbursements is $2.4 billion.[3,4] DKA, more prevalent in the younger population, has an annual incidence of 14 episodes per thousand patients with diabetes. The hospital admissions in the last decade have gone up by 30%, most likely due to an increase in ketosis-prone type 2 diabetics. HHS represents approximately 1% of primary admissions to hospital with diabetes as compared with DKA. Up to 20% of HHS patients can die, whereas it is observed that mortality in DKA is less than 1% (but remains high in the elderly).[5] However, a recent Scottish study conducted over a 5-year period determining the readmission rates for DKA patients treated in intensive care units revealed that mortality after intensive care unit admission was 8%, 18% and 35% at 1 month, 1 year and 5 years, respectively.[6]

PATHOPHYSIOLOGY

Normal carbohydrate metabolism depends upon the presence of insulin; both DKA and HHS result from a reduction in the effect of insulin, relative or absolute. A concomitant rise of counter-regulatory hormones like glucagon, catecholamines, cortisol and growth hormone results in hormonal imbalance leading to hyperglycaemia.

Hyperglycaemia occurs as a consequence of increased gluconeogenesis, increased glycogenolysis and reduced peripheral glucose utilisation. The increase in glucose production occurs in both the liver and the kidneys as there is high availability of gluconeogenic precursors such as amino acids (protein turnover shifts from balanced synthesis and degradation to reduced synthesis and increased degradation). Lactate and glycerol also become available owing to an increase in skeletal muscle glycogenolysis and an increase in adipose tissue lipolysis, respectively. Lactate, converted to pyruvate in the liver via the Cori cycle, is used to generate glucose. Gluconeogenic enzyme activity, especially phosphoenol pyruvate carboxykinase (PEPCK) is further enhanced by stress hormones. The resultant hyperglycaemia leads to glycosuria, osmotic diuresis and dehydration. The resultant reduction in renal perfusion leads to a progressive decline in glomerular filtration rate and worsens hyperglycaemia.

Insulin deficiency and increased epinephrine levels activate hormone sensitive lipase in adipose tissue, which leads to breakdown of triglycerides into glycerol and free fatty acids (FFA). Increased concentrations of glucagon promote oxidation of FFAs to ketone bodies in the liver. Acetyl–CoA carboxylase is inhibited by glucagon with resultant reduction in synthesis of malonyl-CoA. Decreased levels of malonyl-CoA stimulates ketogenesis by stimulating carnitine O-palmitoyltransferase 1, liver isoform (CPT1-L), thus promoting transesterification of fatty acyl carnitine and oxidation of FFA to ketone bodies.[7] Both cortisol and growth hormone are capable of increasing FFA and ketone levels and experiments conducted on pancreatectomised patients suggest that glucagon is not essential for the development of ketoacidosis but that it may accelerate the onset of ketonaemia and hyperglycaemia in insulin deficiency.[8] In DKA states, the metabolism and clearance of ketone bodies are decreased, leading to a further rise in ketone levels.[9] As ketone bodies are strong acids, a large hydrogen ion load is produced as it dissociates at physiological pH. The need to buffer hydrogen ions depletes the body's alkali reserves and ketone anions accumulate, accounting for the elevated

ABSTRACT

Diabetic emergencies can be either hyperglycaemic or hypoglycaemic. Diabetic ketoacidosis (DKA) and hyperosmolar hyperglycaemic state (HHS) are the two most common hyperglycaemic acute complications of diabetes. Its overtreatment – usually with insulin – leads to hypoglycaemia. Both hyperglycaemic or hypoglycaemic emergencies are associated with immediate and long-term adverse clinical outcomes and can be fatal if not recognised and treated timely. DKA is more common than HHS; however, 20% of patients with HHS can die. The incidence of 'hospital-acquired DKA' is high and a cause for concern. Five-year mortality after an episode of DKA can be as high as 35%. Hypoglycaemia is the most common and frequently underreported sequel to insulin and oral hypoglycaemic agents. Hypoglycaemia in hospitalised patients is seen both in diabetic and non-diabetic patients. There is approximately 66% increased risk of death within 1 year and about 3 days longer stay in patients who experience hypoglycaemia compared to those who don't.

plasma anion gap. High levels of ketone bodies also contribute to osmotic diuresis.

In contrast to DKA, higher levels of basal and stimulated C-peptide in HHS suggest there is enough insulin present in HHS to prevent lipolysis but not enough to promote peripheral glucose utilisation.[10] Albeit in experimental animals, hyperosmolarity has been shown to directly inhibit lipolysis and FFA release from adipose tissue.[11] Ketogenesis, consequently, is usually absent in HHS. Moreover, patients with HHS have reduced levels of FFA, glucagon, cortisol and growth hormone as compared to patients with DKA.

HHS, as compared to DKA, has slower onset and hyperosmolarity, which is a prominent feature, and is caused by the prolonged effect of osmotic diuresis with impaired ability to take adequate fluids; even when well, patients who have suffered from HHS have impaired thirst reflexes. However, the hyperosmolarity seen in about one-third of patients with DKA results from a shorter osmotic diuresis and to variable fluid intake due to nausea and vomiting, which is often ascribed to the brainstem effects of ketones.

Hyperglycaemia is a proinflammatory state with a direct correlation between high blood glucose and increased mortality.[12] Both in DKA and non-ketotic hyperglycaemia, there is a significant rise of pro-inflammatory cytokines, C-reactive protein, reactive oxygen species, cortisol, growth hormone and FFAs which resolves within 24 hours of insulin therapy.[13] Insulin therapy, in diabetic and non-diabetic critically ill patients, has shown to improve clinical outcomes owing to its powerful anti-inflammatory effect.[14,15]

The inflammatory milieu in hyperglycaemic emergencies predisposes to a prothrombotic state. There is diffuse vascular injury and abnormalities of coagulation cascade, platelet activation, blood flow and vascular reactivity. This may result in thrombotic events like deep vein thrombosis, ischaemic stroke and other thrombotic complications.[16]

CLINICAL PRESENTATION AND DIAGNOSIS

DKA and HHS represent the two extreme metabolic complications of insulin deficiency. It should be suspected in every clinically unwell, hyperglycaemic patient presenting to the emergency department or in hospital under treatment. HHS develops insidiously over days to weeks, whereas the development of DKA is more acute with a prodrome lasting only hours to days (Table 59.1). DKA and HHS co-exist in up to 30% of cases.[10] In both DKA and HHS, polyuria, polydipsia, weakness and weight loss are experienced for variable periods prior to admission. In DKA, nausea, vomiting and abdominal pain is present in the majority of patients. Abdominal pain, more common in children, could either be the manifestation or precipitant of DKA and needs further investigations if it fails to resolve with the correction of dehydration and metabolic acidosis.[3] Dehydration presents with loss of skin turgor, dry mucous membrane, tachycardia and hypotension. Mental obtundation occurs more frequently in HHS than DKA as more patients, by definition, are hyperosmolar and the presence of stupor or coma in patients who are not hyperosmolar requires consideration of other potential causes for mental illness.[17] Despite infection being a common precipitant in both DKA and HHS, most patients are either normothermic or hypothermic. Hypothermia could be a precipitant or due to vasodilatation and lack of substrate for cellular heat production,[18] with its extent correlating with the severity of the disease. Leucocytosis is a common feature in both DKA and HHS.

Table 59.1 Comparison of diabetic ketoacidosis and hyperosmolar hyperglycaemic state

PRESENTATION	DKA	HHS
Prodromal illness	Days	Weeks
Coma	+	+++
Blood glucose	++	+++

Acidaemia	+++	0 or +
Anion gap	++	0 or +
Osmolality	++	+++

DKA, diabetic ketoacidosis; *HHS*, hyperosmolar hyperglycaemic state.

DIABETIC KETOACIDOSIS

It is a serious acute metabolic complication of type 1 diabetes and ketosis-prone type 2 diabetes. The classic triad of DKA comprises hyperglycaemia, ketonaemia and metabolic acidosis; however, the absence of hyperglycaemia or ketonaemia does not always preclude the diagnosis of DKA. Compensatory hyperventilation with deep and laboured breathing pattern (Kussmaul breathing) may be present, as may the breath odour of acetone. The biochemical diagnostic criteria for DKA are[19]:

- Ketonaemia >3.0 mmol/L **or** significant ketonuria (more than 2+ on standard urine sticks)
- Blood glucose >11 mmol/L **or** known diabetes mellitus
- Bicarbonate (HCO_3^-) <15 mmol/L **and/or** venous pH < 7.3.

Blood glucose per se is not a determinant of severity; however, deteriorating consciousness, worsening anion gap and extent of metabolic acidosis are. To aid clinical management, DKA can be classified into mild (pH 7.25–7.3), moderate (pH 7.0–7.24) and severe (pH <7.0) forms.[20] The anion gap is more than 10 in

mild DKA whereas it is more than 12 in moderate and severe forms.

Poor compliance to insulin treatment and infection are the most common precipitants in developed nations, whereas infection and poor access to healthcare are the leading precipitants in developing countries.[9] A recent UK survey identified infection as the precipitant in 44.1% followed by non-compliance in 18.7% patients, whereas as many as 7.8% patients developed DKA during their hospital stay.[21] Patients developing DKA as inpatients, otherwise called 'hospital-acquired DKA,' assume particular significance as this may reflect the quality of care, and is preventable. Underlying medical illness like myocardial infarction, pancreatitis and drugs affecting carbohydrate metabolism can also precipitate DKA. Sodium-glucose co-transport 2 (SGLT2) inhibitors, in type 1 and type 2 diabetic patients, in the presence of risk factors like intercurrent illness, reduced oral intake and reduced insulin doses, have been linked with development of serious, life-threatening DKA.[22] In addition, numerous cases of fatal and nearfatal DKA have also been reported in patients on atypical antipsychotics.[23]

EUGLYCAEMIC DIABETIC KETOACIDOSIS

Described first in 1973 by Munro, euglycaemic DKA (EuDKA) presents with severe ketoacidosis with only mildly elevated plasma glucose levels. Inhibition of gluconeogenesis in conjunction with reduced insulin facilitated by carbohydrate restriction, partially treated DKA, or alcohol and in patients with liver failure can result in EuDKA. SGLT2 inhibitors, by inducing rapid excretion of urinary glucose, can cause EuDKA in type 2 diabetics.[22]

HYPEROSMOLAR HYPERGLYCAEMIC SYNDROME

HHS is commonly seen in elderly type 2 diabetes patients; however, younger presentations, often as an initial presentation of type 2 diabetes, are observed these days.[11] Infection, in particular, pneumonia and urinary tract infections,[24] are the most common precipitants. Inadequate dose of insulin or oral anti-hyperglycaemic agents and certain drugs including diuretics, corticosteroids, β-blockers, phenytoin and diazoxide are the other common triggers.

Characteristic features of patients with HHS are[25]:

- Hypovolaemia
- Marked hyperglycaemia (>30 mmol/L) without significant hyperketonaemia (<3.0 mmol/L) or acidosis (pH >7.3, bicarbonate >15 mmol/L)
- Serum osmolality >320 mOsmol/kg.

Neurological symptoms like mental obtundation, confusion, or seizures may correlate with severity of hyperosmolality.

MANAGEMENT

DKA and HHS are severe, life-threatening complications of diabetes and these patients are at increased risk of death. Presentation with altered mental status, cardiovascular instability, acute abdominal symptoms or severe metabolic acidosis will necessitate high dependency care or intensive care unit admission for treatment (Table 59.2). The aims of treatment are fluid resuscitation, termination of ketogenesis, restoration of biochemical milieu with insulin and electrolytes, and prompt attention to an underlying precipitant. Moreover, prevention of potentially fatal thrombotic events and aspiration pneumonitis necessitates deep vein thrombosis prophylaxis and insertion of a nasogastric tube, especially in patients with reduced consciousness state.

FLUIDS

Fluid replacement followed by insulin is the most vital step in the initial management of DKA and HHS. The objectives of fluid therapy are to restore the circulatory volume, improve tissue perfusion and correct hyperosmolality. The total osmolar load on the kidney in DKA

Table 59.2 Patients who may require high-dependency unit or intensive care unit admission

DKA	HHS
Blood ketones >6 mmol/L	Osmolality >350 mOsmol/kg
Bicarbonate <5 mmol/L	Sodium >160 mmol/L
K^+ <3.5 mmol/L	K^+ <3.5.0 mmol/L or >6.0 mmol/L
Venous/arterial pH <7.0	Venous/arterial pH <7.1
GCS <12 or abnormal AVPU	GCS <12 or abnormal AVPU
Oxygen saturation <92%, SBP <90 mm Hg, heart rate <60 or >100	Oxygen saturation <92%, SBP <90 mm Hg, heart rate <60 or >100
Anion gap >16	Urine output <0.5 mL/kg/h, Serum creatinine >200 µmol/L Hypothermia Macrovascular event like myocardial infarction or stroke Other serious co-morbidities

Adapted from Joint British Diabetes Societies Inpatient Group (see references 19 and 25).

can be as much as 2000 mOsm/day.[26] Fluid loss from osmotic diuresis is worsened by poor reabsorption of salt, water and phosphate in the kidney – a direct effect attributable to lack of insulin. Water deficits in HHS are about twice as much as in DKA and can be estimated by the formula:

$$\text{Free water deficit} = 0.6 \times \text{weight (kg)} \times (\text{Current sodium} - 1)/140$$

Fluid alone will reduce levels of glucose and counter-regulatory hormones and reduce insulin peripheral resistance. Insulin therapy drives extracellular water into the intracellular space and can exacerbate hypovolaemia and hypernatraemia as true sodium in hyperglycaemia is higher than the measured sodium. Rapid fluctuations in sodium concentration could result in pontine or extrapontine myelinolysis. This is why it is critically important to initiate fluid therapy early. However, overaggressive fluid replacement, especially in children and in those with cardiac and renal dysfunction, could lead to cerebral oedema, thus worsening the outcome. Hyperosmolality should be corrected cautiously at a rate no faster than 3 mOsm/kg H_2O/h. Crystalloids, isotonic 0.9% saline[19] or balanced crystalloids like Hartmann's should be used for fluid replacement, as there is a consensus that colloids can potentially increase the risk of mortality and morbidity.[27] Use of balanced crystalloids can reduce the incidence of resuscitation-associated hyperchloraemia.[28] Hyperchloraemic metabolic acidosis with its vasoconstrictive effect on renal arterioles may delay the resolution of acidosis. Infusion of 15–20 mL/kg of crystalloids in the first hour and subsequent fluid guided by vital signs like heart rate, blood pressure, laboratory values and clinical examination should correct the fluid deficits in first 24 hours.[3] Ten per cent dextrose is added to the replacement fluid once blood sugar falls below 14 mmol/L to avoid hypoglycaemia and allow the continuation of insulin infusion to suppress ketogenesis.

INSULIN THERAPY

Low-dose, physiological insulin replacement resolves the biochemical abnormalities as quickly as higher doses without running the risk of hypoglycaemia and hypokalaemia, and gradual correction of hyperglycaemia is associated with a lower mortality.[29] In addition to correction of hyperglycaemia, insulin acts to suppress ketogenesis and lipolysis. In DKA, a bolus dose of insulin (0.1 Unit/kg) at the initiation of therapy could risk hypoglycaemia and is not routinely recommended unless there is a delay in commencing the weight-based fixed rate intravenous insulin infusion (FRIII) at 0.1 Unit/kg per hour. In HHS, FRIII at 0.05 Unit/kg per hour is recommended once the initial fluid resuscitation has taken place. Glucose decrement is the same irrespective of the route chosen; however, for critically ill patients (see Table 59.2), intravenous infusion of regular human insulin should be used. Metabolic targets like increasing bicarbonate concentration by 3 mmol/L per hour, reducing the blood glucose concentration by 3 mmol/L per hour and reducing the blood ketone concentration by 0.5 mmol/L per hour whilst maintaining normal potassium levels are essential in guiding insulin therapy. Studies have suggested that FRIII at 0.1 Unit/kg per hour will bring the blood sugar down by 50%–60% in the first 4 hours. If the glucose levels fail to reduce appropriately, it may indicate insufficient fluid resuscitation. Severe insulin resistance occurs in 10% of cases and will necessitate the use of higher doses. The insulin infusion rate should be reduced to 0.02–0.05 Unit/kg per hour when the glucose levels fall below 12 mmol/L in DKA and below 15 mmol/L in HHS. Along with insulin infusion, subcutaneous long-acting insulin analogues should be continued. This is to avoid hypoglycaemia at the cessation of insulin infusion.[30] In DKA, FRIII should be continued until the resolution of ketoacidosis as evidenced by blood ketone levels of less than 0.6 mmol/L, venous pH over 7.3 and/or venous bicarbonate over 18 mmol/L.[19] In HHS, however, insulin infusion should only cease with the correction of mental obtundation and normalisation of serum osmolality.[9]

ELECTROLYTE THERAPY

POTASSIUM

Hyperosmolality and acidosis cause a shift of potassium from intracellular to extracellular compartment. This potassium is lost as a result of osmotic diuresis. Renal losses are augmented by secondary hyperaldosteronism and ketoanion excretion as potassium salts. Despite total body deficits (Table 59.3), the measured potassium is usually normal or high and replacement should not commence until the potassium is less than 5.5 mmol/L. DKA patients may rarely present with very low potassium (less than 3.3 mmol/L). This represents profound potassium depletion (600–800 mmol) and replacement at 10–20 mmol/h should commence

Table 59.3 Typical deficits in diabetic ketoacidosis and hyperosmolar hyperglycaemic state

	DKA	HHS
Water	100 mL/kg	100–220 mL/kg
Sodium	7–10 mmol/kg	5–13 mmol/kg
Potassium	3–5 mmol/kg	4–6 mmol/kg
Chloride	3–5 mmol/kg	5–15 mmol/kg

DKA, diabetic ketoacidosis; *HHS*, hyperosmolar hyperglycaemic state.

immediately with fluid therapy. Insulin therapy is initiated only when potassium level is more than 3.3 mmol/L. In most patients, 20–30 mmol of potassium in every litre of crystalloid generally maintains serum potassium within normal range.

PHOSPHATE

In DKA, typical total body phosphate deficit is about 1 mmol/kg but serum phosphate is usually normal at presentation. Routine phosphate replacement has not been shown to be beneficial in DKA,[31] but correction of severely low levels (<0.4 mmol/L) may be necessary as this may lead to muscle weakness, impaired cardiac systolic performance and haemolytic anaemia. Excessive phosphate replacement may cause hypocalcaemia and calcium should be monitored.

MAGNESIUM

A chronic magnesium deficiency may be present in type 1 or 2 diabetes and may be exacerbated by renal impairment. The benefits of magnesium replacement have not been demonstrated in diabetic emergencies, but the principles of magnesium supplementation are similar to other critical care situations.

BICARBONATE

Use of bicarbonate for correction of acidosis in DKA is controversial and is not routinely recommended. Side effects like paradoxical intracellular acidosis, hypokalaemia, volume overload and altered tissue oxygenation may overshadow any potential benefits. In the context of DKA, sodium bicarbonate also delays the clearance of ketones and may enhance further hepatic production even when insulin and glucose are being delivered.[32] At pH >7.0 insulin will block lipolysis and ketoacidosis production; however, when pH is between 6.9 and 7.1 it remains uncertain whether bicarbonate is beneficial or otherwise. Most authorities agree to the use of bicarbonate below pH 6.9 to partially correct the pH. The threshold for correction is debatable (between pH 6.9 and 7.15), but life-threatening hyperkalaemia is an undisputed indication for bicarbonate therapy.

MONITORING

The recognition that blood glucose is only a surrogate of the metabolic derangement in DKA has shifted the focus of management to ketonaemia. Ketonuria may persist up to 2 days after the correction of acidosis due to the presence of acetone. Moreover, urine ketone strips, being semiquantitative, may not truly reflect the condition. There is a significant correlation between serum and capillary beta-hydroxybutyrate (β-OHB) and glucose.[33] This makes point of care (POC) blood tests for ketones and glucose and near bedside electrolytes, bicarbonate and pH measurement the cornerstone of management of DKA. POC meters allow for not only rapid and accurate diagnosis but monitoring as well. Accurate measurement of β-OHB, the main ketoacid in DKA, with blood ketone meters has been one of the biggest advancements in the management of DKA.

In HHS, serum osmolality can be measured with an osmometer or estimated osmolarity. Regular monitoring of neurological status includes Glasgow Coma Scale and computed tomography (CT) scans as indicated for persistent coma or worsening neurological status.

DKA is considered to be resolved when pH >7.3 units; bicarbonate greater than 15.0 mmol/L; and blood ketone level less than 0.6 mmol/L (rather than <0.3 mmol/L). This is to prevent the rebound rise of ketones upon discontinuation of insulin infusion.[19]

The resolution of HHS is indicated by return to normal plasma osmolality and recovery from mental obtundation.

COMPLICATIONS OF DIABETIC KETOACIDOSIS AND HYPEROSMOLAR HYPERGLYCAEMIC STATE

Hypoglycaemia and hypokalaemia – Hypoglycaemia and hypokalaemia are the most frequently occurring serious complications during the management of DKA, usually due to overtreatment with insulin and inadequate replacement of potassium. Recent UK data suggested that over a quarter of these patients can develop hypoglycaemia whereas the incidence of hypokalaemia was 55%.[21]

Cerebral oedema – Clinically apparent cerebral oedema is a rare (0.5%–1%) but an extremely serious complication of DKA occurring predominantly in children; the mortality is high (25%), with a quarter of survivors being left with some permanent neurological sequelae. Studies have suggested a subclinical incidence approaching 50%.[34] Risk factors for developing cerebral oedema include degree of hypocapnia and dehydration, the failure of serum sodium to rise with treatment and the use of sodium bicarbonate.[35] It also occurs in young adults and may be associated with rapid deterioration in consciousness level with or without seizures. If progressive signs of brainstem herniation are present, the mortality is high, with only 7%–14% likely to make a complete recovery. The risks of brain herniation are related to the degree of acidosis and the volume of initial fluid resuscitation. Oedema formation most likely occurs due to a vasogenic mechanism[36] and cerebral hyperaemia with loss of autoregulation evident; this can take up to 36 hours to resolve.[37,38] Some degree of brain dysfunction is apparent even in those patients who are not comatose but who have severe DKA as measured by sensory evoked potentials. This reverts to normal with correction of the ketoacidosis.

Other – Pulmonary oedema is usually iatrogenic, and myocardial infarction can occur, particularly in the elderly. In HHS various neurological complications including reversible tetraplegia, amnesia and optic atrophy have been described.

PREVENTION OF HYPERGLYCAEMIC EMERGENCIES

Patient information and education programmes on home monitoring of glucose and ketones and recognition of early signs of hyperglycaemic emergencies could prevent emergency department and hospital admissions.

HYPOGLYCAEMIA

Hypoglycaemia is the most common and frequently underreported sequel to insulin and oral hypoglycaemic agents. The self-treated form is classified as 'mild' whereas it is 'severe' if external help is required for recovery. Any blood glucose of less than 4 mmol/L should be treated. Hypoglycaemia may lead to an impaired counter-regulatory system and, hence, non-specific and relatively insensitive neuroglycopaenic symptoms[39] and hypoglycaemia unawareness. The incidence therefore is difficult to quantify; however, patients with type 1 diabetes experience about two episodes of symptomatic hypoglycaemia per week and 1.0–1.7 episodes/patient per year of severe hypoglycaemia.[40] The UK hypoglycaemia study showed that the incidence of hypoglycaemia in type 2 diabetes can be as high as 25% as the disease approaches the insulin-deficient end of the spectrum.[41] Although more frequently seen in type 1 diabetes, the incidence matched for duration of insulin therapy is similar in both type 1 and 2 diabetes.[42]

Risk factors to developing hypoglycaemia include elderly patients, alcohol, early pregnancy, renal and hepatic impairment, strict glycaemic control, previous history of severe hypoglycaemia,[43] sulfonylureas, administration of wrong insulin product, and abrupt reduction in food intake.[44]

The adverse effects of hypoglycaemia range from autonomic symptoms (sweating, palpitations, shaking) to transient impairment in the level of consciousness to permanent neurological damage and increased risk of death even at 1 year after discharge.[45] It can cause seizures, hemiparesis, coma, arrhythmias, prolonged QT interval[46] and contributes to increased cardiovascular morbidity and mortality. Much of these effects result from brain neuronal glucose deprivation and hypoglycaemia-induced sympathoadrenal activation.

IN-PATIENT HYPOGLYCAEMIA

Hypoglycaemia in hospitalised patients is seen both in diabetic and non-diabetic patients. Hypoglycaemia not triggered by glycaemic lowering agents (spontaneous hypoglycaemia) may be a manifestation of severe illness. Attempts should be made to diagnose the underlying disease, as hypoglycaemia is an independent risk factor in increased length of hospital stay and mortality. One study quoted 66% increased risk of death within 1 year and about 3 days longer stay in patients who experienced hypoglycaemia compared to those who didn't.[45] Five to thirty-two percent of in-patients treated with insulin could suffer from episodes of severe hypoglycaemia.[47] Over 29% of DKA patients treated with FRIII suffered from hypoglycaemic episodes.[21] Episodes of severe hypoglycaemia are more prevalent in type 1 diabetic patients and nocturnal episodes seemed to be the commonest ones.

Potential causes of in-patient hypoglycaemia are summarised (Box 59.1). Insulin prescription errors are one of the most common causes.

Box 59.1 Potential causes of in-patient hypoglycaemia

1. Errors in insulin and OHA administration – inappropriate use of 'stat' or 'PRN' rapid/short-acting insulin, incorrect type or inappropriately timed insulin or OHA administration, IV insulin infusion without glucose infusion, inadequate mixing of mixed insulin
2. Missed meals or inadequate carbohydrate intake
3. Acute discontinuation of long-term steroid therapy
4. Severe illness
5. Prolonged starvation times (i.e. 'nil by mouth')
6. Drug interactions – concomitant administration of hypoglycaemic agents with warfarin, quinine, salicylates, MAO inhibitors, NSAIDs
7. Endocrinal disorders (hypothyroidism, hypopituitarism, Addison's disease) leading to loss of counter-regulatory hormone production

IV, Intravenous; *MAO*, monoamine oxidase; *NSAIDs*, non-steroidal anti-inflammatory drugs; *OHA*, oral hypoglycaemic agents.

MANAGEMENT OF HYPOGLYCAEMIA

The majority of hypoglycaemic episodes are preventable. In type 1 diabetics, both avoidance of strict glycaemic targets and patient education are effective.[48] Meticulous attention to factors mentioned in Box 59.1 will help to mitigate the incidence of hypoglycaemia. For type 1 diabetic patients with frequent disabling or severe hypoglycaemia whilst being on multiple daily injections (MDI), adoption of continuous subcutaneous insulin infusion (CSII) has shown to reduce the incidence of hypoglycaemia. During treatment in DKA patients, administration of 100 mL

10% glucose solution and 100 mL 20% glucose solution at blood glucose levels less than 14 mmol/L and 6 mmol/L, respectively, can reduce the incidence of hypoglycaemia.[49]

In patients experiencing hypoglycaemia, Diabetes UK's policy to 'make four the floor' recommends 4 mmol/L as the threshold of treatment in diabetic patients. Nevertheless, adults experiencing hypoglycaemic symptoms with blood glucose levels of more than 4 mmol/L should receive prompt treatment as well. Strategies to treat hypoglycaemia vary with the level of consciousness. It is generally agreed that 15–20 g of quick-acting carbohydrate is the initial treatment of choice for patients who are alert and orientated.

For confused, disorientated or uncooperative patients, glucagon 1 mg IM is an effective option, whereas 75–100 mL 20% dextrose (or 150–200 mL 10% dextrose) intravenous (IV) is the initial treatment for unconscious patients or those having seizures due to hypoglycaemia.

The key steps following initial treatment are-

1. Repeat capillary blood glucose in 10–15 minutes
2. Repeat initial steps if blood sugar is less than 4 mmol/L. Glucagon, however, should only be administered once and non-responders should receive IV dextrose.
3. Administer long-acting carbohydrate once blood sugar is more than 4 mmol/L
4. Insulin, if due, should not be omitted. The regimen, however, may need to be reviewed.

Diabetes insipidus and other polyuric syndromes

Alaistair Craig Carr

Diabetes insipidus (DI) refers to a syndrome of pathological polyuria, excessive thirst and polydipsia. Polyuria is defined as urinary output greater than 3 L/day in an adult of normal mass and greater than 2 L/m^2 in children. The urine in DI is inappropriately dilute, having low specific gravity (<1.005) and low osmolality (<200 mOsmol/kg) in the face of high (>285 mOsmol/kg) or normal plasma osmolality.

Three subtypes of DI are recognised:

1. **nephrogenic DI** (NDI) – caused by insensitivity of the kidney to antidiuretic hormone (ADH)
2. **cranial/central/hypothalamic/neurogenic DI** (CDI) – caused by reduced or absent production of ADH
3. **gestational DI** – caused by increased placental vasopressinase production or as a variant of central or NDI developing during pregnancy.

A separate disorder is occasionally classified as a type of DI; **primary polydipsia** (also called psychogenic or neurogenic polydipsia or polydipsic DI). This is caused by excessive water ingestion secondary to psychological disturbance or rarely a hypothalamic lesion. In hospital in-patients, a similar iatrogenic condition results from overenthusiastic administration of intravenous solutions of dextrose 5% or hypotonic saline. Although water overload reduces plasma osmolality and thereby the ability of the kidney to maximally concentrate urine, the hypo-osmolar diuresis seen with water overload is physiological, as the body attempts to lose free water and restore normal plasma osmolality.

In critically ill patients, polyuria may be the sole part of the DI syndrome apparent to the clinician. Patients are seldom in control of their own fluid intake or able to report thirst. Failure to recognise and treat the syndrome appropriately may result in severe dehydration, hyperosmolality and an increased risk of morbidity and mortality. As there are many causes of polyuria in the critically ill (Box 60.1), it is important to adopt a systematic approach to its clinical assessment, investigation and diagnosis.

The classification as a solute or water diuresis is not always absolute; the table provides a convenient structure but a diuresis should be considered in terms of the individual patient together with physical and biochemical assessments. A diuresis frequently represents the clearance of both excess water and solute (e.g. following the resolution of septic shock with multiorgan failure).

BACKGROUND PHYSIOLOGY AND ANATOMY

OSMOLALITY

Osmolality is the measure of osmoles of solute per kilogram of solvent and includes both permeant (e.g. urea) and impermeant (e.g. sodium) solutes. It may change with either water or permeant solute movement. Osmolarity is the measure of osmoles per litre of solute and, unlike osmolality, is temperature dependent. Normal plasma osmolality is in the range of 275–295 mOsmol/kg. Plasma osmolality can be estimated from several equations.[2] The formula of Worthley[3] below is simple and correlates well with measured values.[4]

$$\text{Plasma osmolality (mOsmol/kg)} = 2[Na^+] + [\text{Urea}] + [\text{Glucose}]$$

All units of solute are mmol/L.

Where a patient is markedly uraemic, a value of 8 mmol/L is substituted for the actual urea. Actual osmolality may differ markedly from estimated osmolality in the presence of unmeasured, osmotically active solutes such as mannitol, ethanol, bicarbonate, lactate and amino acids. Whenever concern exists that a patient may be hyper- or hypo-osmolal, osmolality should be measured by assessing the freezing point depression of the plasma or urine. Increasing the osmolality results in depression of the freezing point.

The osmolal gap is the difference between the calculated and measured osmolality in plasma or urine. The normal osmolal gap is less than 10 mOsmol/kg. An increased osmolal gap indicates the presence of an unmeasured osmotically active solute.

TONICITY

Tonicity describes the ability of a solution of impermeant solute (such as sodium) to cause the movement of water between itself and another fluid compartment.

ABSTRACT

Polyuria is a common finding amongst critically ill patients. It may be physiological or pathological and represent a solute, a water or a combined diuresis. It is essential that the intensive care physician understands, monitors and appropriately manages pathological diureses, as untreated, in the absence of normal autonomous control of drinking, profound volume and solute disturbances can arise, leading to long-term morbidity and mortality.

This chapter presents an overview of the central, peripheral and renal physiological control mechanisms of plasma osmolality and volume before describing pathologies that upset these, resulting in a diuresis. Normal values of plasma and urine osmolality, and plasma antidiuretic hormone concentrations are offered. An investigative approach to differentiating cranial, nephrogenic, gestational and polydipsic diabetes insipidus as well as a normal physiological diuresis is outlined. Treatment strategies are suggested.

Box 60.1 Causes of polyuria

1. Water Diuresis:
   a. Pathological
      Diabetes insipidus: cranial, nephrogenic, gestational
   b. Physiological
      Psychogenic polydipsia (excess drinking is pathological but the diuresis is not)
      Iatrogenic – excessive administration of hypotonic solutions e.g.
      5% dextrose solution,
      0.45% saline,
      0.18% saline 4% dextrose solutions
2. Solute Diuresis:
   a. Pathological
      Hyperglycaemia
      Azotaemia (uraemia[1])
      Cerebral salt wasting
      Fanconi's syndrome
      Renal tubular acidosis
      Glomerulonephritis
      Hyperaldosteronism
      Addison's disease
      Anorexia nervosa
      Migraines
      Paroxysmal tachycardia (via increased atrial natriuretic peptide release)
      Poisons/drugs:
         Ethanol
         Methanol
         Ethylene glycol
         Mannitol
         Loop diuretics
         Thiazide diuretics
   b. Physiological
      Resolving sepsis (redistribution of fluid into the vascular compartment from the third space)
      Iatrogenic – excessive administration of isotonic or hypertonic solutions e.g.
         0.9% saline
         hypertonic saline

It may be considered an index of the water concentration rather than the solute concentration, as the solute is impermeant. The tonicity of plasma is largely determined by sodium, the main solute in extracellular fluid that cannot cross freely into the intracellular space. This characteristic facilitates the control of extracellular fluid volume through the regulation of sodium balance.

It is possible for a solution to be both hypotonic and iso-osmolar. An example of this is 5% dextrose solution; the solution contains no impermeant solute (assuming no absence of insulin, glucose freely enters the cell) but is iso-osmolar with the intracellular milieu.

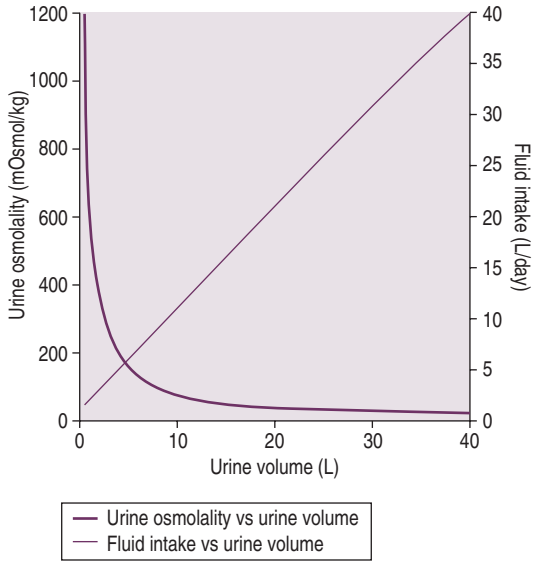

Figure 60.1 Urine output rises and urine osmolality falls in health as a function of increasing water intake. Assuming normal solute ingestion, normal solute excretion (around 800 mmol/day) is preserved between water intakes of 1.5 and 32 L/day.

SOLUTE AND WATER INTAKE AND LOSSES

In order to understand disorders of osmolality, tonicity, fluid balance and urine output, it is necessary to be aware of the physiological mechanisms which maintain normal fluid and osmolal balance in health. Assuming a normal diet, a 75 kg man has daily obligatory losses of around 800 mmol of solute, approximately 300 mmol of urea and 500 mmol of cations and anions. The maximum concentrating ability of the healthy kidney is around 1200 mOsmol/kg; consequently, minimum daily urine production of 666 mL is required to excrete osmotically active solutes. Additionally, insensible water losses approximate 10 mL/kg per day and rise markedly with fever and hot dry climates. Minimum daily obligatory water losses due to insensible losses and solute excretion therefore total around 1.5 L.

NORMAL URINARY OSMOLALITY

In health, urinary osmolality is usually maintained between 500 and 700 mOsmol/kg. As the obligatory solute load to be excreted is relatively constant, urine osmolality will fall in response to increased free water intake and rise in response to dehydration or water restriction (Fig. 60.1). The minimum urine osmolality achievable in man is around 25 mOsmol/kg. Diuresis refers to urine output greater than 1.5 mL/kg per hour and may be transient or persistent, physiological or pathological. Water diuresis occurs when total daily urinary solute excretion is within the normal range

but urine osmolality is low. Osmotic or solute diuresis occurs when the total daily solute excretion is higher than normal; the urine passed is usually iso-osmolar to plasma if the extracellular fluid volume is expanded or hyperosmolar if the patient is hypo- or euvolaemic.

PLASMA OSMOLALITY AND PLASMA VOLUME REGULATION

Changes in plasma osmolality and volume can occur in tandem or independently of one another. Whilst normal plasma osmolality lies in a population range of 275–295 mOsmol/kg (265–285 mOsmol/kg in pregnancy), individuals usually vary less than ±1% around their set value.

The body regulates osmolality and volume by separate mechanisms. Water balance and osmolality are maintained via osmoreceptors which mediate their control via control of thirst and ADH production. Control of the plasma volume is maintained via volume receptors and sodium receptors which mediate their actions through the sympathetic nervous and renin-angiotensin-aldosterone systems. Additionally, volume receptors have inputs to the hypothalamus via which they too can mediate ADH release and the sensation of thirst. Atrial natriuretic peptide (ANP) and brain natriuretic peptide (BNP), predominantly released from atrial and ventricular myocytes, respectively, inhibit the release of renin, aldosterone, vasopressin and endothelin, leading to both a natriuresis and a diuresis.[5]

THIRST

In health, fluid intake is determined by the sensation of thirst and subsequent fluid ingestion. Plasma osmolality greater than 290 mOsmol/kg, elevated angiotensin II (AII) concentrations, sympathetic nervous system activation and circulating volume depletion of 5%–10% are all associated with the onset of thirst. Fluid and solute excretion are largely regulated through the kidney, although some solutes such as ethanol and glucose are largely cleared through metabolism rather than excretion.

In the intensive care unit (ICU), patients lose control over their fluid and solute intake and frequently have impaired excretory mechanisms. Thus both volume and solute homeostasis may become dependent upon the skills of attending clinicians.

OSMORECEPTORS AND OTHER INPUTS TO THE SUPRAOPTIC AND PARAVENTRICULAR NUCLEI

Osmolality is mainly detected at osmo- (Na^+) receptors around the anterior aspect of the third ventricle of the brain. These sense both plasma osmolality and cerebrospinal fluid sodium concentration. Hypertonic saline is a more potent stimulus than equi-isotonic equi-isoosmolar solutions of other solutes.[6] These osmoreceptors link to the cells of the paraventricular nuclei (PVN) and supraoptic nuclei (SON), the sites of ADH synthesis. Axons of PVN and SON cells form part of the pituitary stalk linking the hypothalamus to the pituitary gland, where they terminate. A proportion of the axons terminate in the median eminence where they release ADH and oxytocin. These are transported to the anterior lobe of the pituitary by portal vessels and stimulate release of adrenocorticotrophic hormone (ACTH) and prolactin, respectively; the ADH acts synergistically with corticotropin releasing factor (CRF), but has ACTH secretagogue properties in its own right.[7,8]

Direct sympathetic nervous system inputs to the PVN and SON stimulate ADH release via α-adrenoreceptors. Other central osmoreceptors directly contact plasma outwith the blood–brain barrier in the subfornical organ (SFO). ANP and AII[9] are believed to act via these receptors to inhibit or elicit ADH synthesis and/or release and to modify the sensation of thirst. Osmoreceptors in the mouth, stomach and liver play roles in the anticipation of an osmolal load following ingestion of food and may preemptively stimulate hypothalamic ADH synthesis.

Baroreceptor and osmoreceptor inputs to the PVN and SON are distinct; it is therefore possible to lose the normal ADH response to hyperosmolality but maintain a normal ADH response to hypovolaemia.[10] In animal experiments, when hypotension increases the basal plasma ADH concentration, there is simultaneous resetting of the osmomolality-plasma ADH response curve to preserve osmoregulatory function from the new higher baseline.[11] Without this, the ADH response to hypotension would lead to hypo-osmolality in addition to vasoconstriction.

The normal response of osmoreceptors to changing plasma osmolality in terms of ADH is illustrated in Fig. 60.2. At plasma osmolalities of less than 275 mOsmol/kg, the osmoreceptors remain hyperpolarised and virtually no ADH release occurs via them. At osmolalities greater than 295 mOsmol/kg, the osmoreceptors are maximally depolarised and plasma concentrations of ADH of greater than 5 pg/mL are attained. Other inputs and influences upon ADH release are summarised in Fig. 60.3 and Box 60.2.

ANTIDIURETIC HORMONE/ ARGININE VASOPRESSIN

ADH (8-arginine vasopressin [AVP]) is a nine amino-acid peptide differing from oxytocin at only two residues but sharing the disulfide bond between the first and sixth ones. This similar structure and conformation results in some functional and receptor cross-reactivity.[12] It is synthesised in the SON and PVN, bound to neurophysin, transferred down axons to the posterior pituitary and stored in granules prior to release. Synthesis and replacement of released stores is

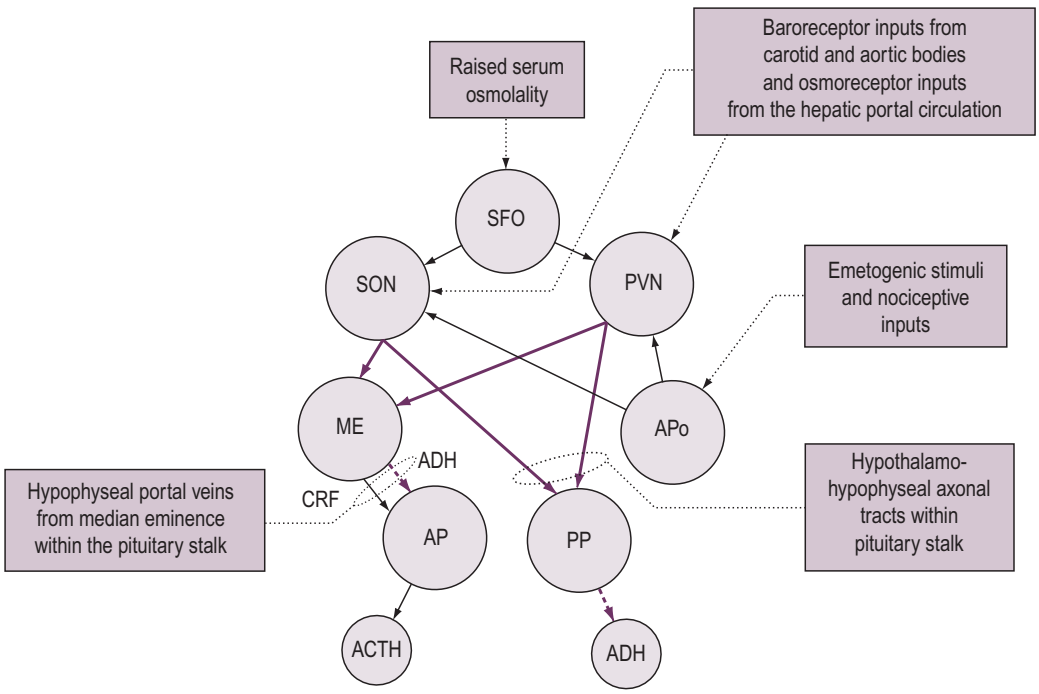

Figure 60.3 A schematic representation of anatomical and physiological connections of the supraoptic and paraventricular nuclei (SON and PVN), the principal sites of antidiuretic hormone (ADH) synthesis within the hypothalamus. *Blue arrows* represent the transport of ADH or its precursor between anatomically distinct sites. Baroreceptor inputs into these nuclei travel via the vagus nerve to reach the central nervous system. Whereas the majority of ADH produced in the SON and PVN is transported to the posterior pituitary (PP) for storage, some is transported to the median eminence (ME) then onwards to the anterior pituitary (AP), where it acts synergistically as a secretagogue for adrenocorticotropic hormone (ACTH). *APo*, Area postrema; *CRF*, corticotropin-releasing factor; *SFO*, subfornical organ.

a rapid process (1–2 hours) and patients with damage to the pituitary can achieve near normal plasma osmoregulatory concentrations (1–8 pg/mL) of ADH via release of newly synthesised ADH via axons terminating in the median eminence. However, the higher plasma concentrations associated with hypovolaemia (up to 40 pg/mL) under the influence of the sympathetic nervous system, baroreceptor responses and AII cannot be achieved.

Once released from the pituitary, ADH has a plasma half-life of around 10–35 minutes.[13] It is metabolised by hepatic, renal and placental vasopressinases with around 10% being excreted unchanged in the urine.

ACTIONS OF ANTIDIURETIC HORMONE

Through V_1, V_2 and V_3 receptors, ADH has antidiuretic, vasopressor, haemostatic and ACTH secretagogue actions. Additionally, it has roles in memory, water permeability of the blood–brain barrier, nociception, splenic contraction and thermoregulation. It also has actions on the uterus and mammary tissue mediated through oxytocin receptors. Cardiac inotropic (positive and negative) effects are reported through purinergic P_2 receptors but this remains controversial.[14,15]

Antidiuresis

ADH activates V_2 receptors on the principal cell basal membranes of the collecting duct and distal tubule. This induces cyclic adenosine monophosphate (cAMP) production which in turn activates protein kinases effecting the integration of vesicles containing aquaporin-2 highly selective water channels into the luminal membrane. Prostaglandin E_2 (PGE_2) synthesis, which inhibits cAMP production, is stimulated by the action of ADH on V_1 receptors on the luminal membrane of the collecting duct.[16] Thus, a form of autoregulatory limitation of the antidiuretic effect of ADH may exist. Hypokalaemia, lithium and hypercalcaemia also antagonise the renal actions of ADH.

ADH also increases renal urinary concentrating ability by increasing expression of urea transport proteins in the collecting duct and reducing renal medullary blood flow (V_1-mediated), thereby increasing medullary interstitial hypertonicity. Hypertonicity additionally depends upon intact ascending loop of Henle function with sodium and chloride reabsorption without simultaneous absorption of water. Dysfunction reduces the osmolal gradient between the collecting duct and the interstitium and reduces water absorption even in the presence of ADH and functioning aquaporin-2.

Exogenous ADH administration may paradoxically induce diuresis in patients with septic shock.[17] Increased renal perfusion pressure and thereby glomerular filtration rate (GFR) may be responsible.

Vasoconstriction

At higher concentrations, ADH activates V_1 as well as V_2 receptors, causing preferential vasoconstriction in muscle, skin and fat with relative sparing of coronary, cerebral and mesenteric circulations. These relative sparing effects are controversial.[18–21] Activation of V_1 receptors activates phospholipase C, increasing inositol trisphosphate and ultimately intracellular free calcium. This leads to smooth muscle constriction in the blood vessel wall.

Following brainstem death, reducing ADH may cause both hypotension and CDI with disturbances of osmolality and organ function. Treatment with α-adrenoreceptor agonists may restore organ perfusion pressure but also cause ischaemic damage. Low-dose ADH infusions (0.5–3 U/h) titrated against urine output reduces the need for catecholamine support and reduces perturbations in plasma osmolality and fluid balance. 1-deamino-8-O-arginine vasopressin (DDAVP) has similar benefits but causes less vasoconstriction. It is preferred for the treatment of CDI associated with brainstem death where hypotension is not a concomitant feature.

Coagulation

ADH increases circulating levels of tissue plasminogen activator, factor VIII and von Willebrand factor.[22] These effects are possibly mediated by V_2 receptors. At high physiological concentrations, it also acts via V_1 receptors as a platelet aggregating agent.[23–25] ADH and DDAVP are used as first-line treatments in patients with von Willebrand's disease, and may be used in bleeding associated with uraemic platelet dysfunction.

ACTH secretion

ADH transported from the median eminence to the anterior pituitary acts upon V_3 receptors to directly stimulate ACTH release and increase plasma cortisol. The ADH also increases the efficacy of CRF in releasing ACTH. In septic shock, ADH insufficiency may contribute to the relative adrenal insufficiency noted in certain patients. The relative importance and potency of ADH compared with CRF in stimulating ACTH release in humans is unclear.

Volume receptors

Volume homeostasis takes precedence over sodium homeostasis with rises and falls in sodium occurring in order to preserve correct circulating volume. In euvolaemia, sodium homeostasis is maintained. Sodium concentration is detected by SFO osmoreceptors outside the blood–brain barrier and by the juxtaglomerular apparatus which secretes renin in response to both reduced GFR and reduced tubular sodium load.[26]

High pressure baroreceptors in the pulmonary veins, left atrium, carotid sinus and aortic arch are the predominant determinants of sodium balance.[27] Reduced stretch increases sympathetic nervous system activity, activates the renin-angiotensin-aldosterone system, reduces sodium excretion (via reduced GFR)

and increases reabsorption of sodium in the proximal and distal convoluted tubules. Additionally, release of ADH is stimulated, resulting in concomitant water retention. Conversely, stretch of the baroreceptors reduces sodium retention through reduced activity of these systems and through release of ANP/BNP with reduced sodium reabsorption in the distal convoluted tubule and collecting duct. ADH release is reduced by the fall in sympathetic nervous tone from the baroreceptors and by the action of ANP on cerebral osmoreceptors lying outside the blood–brain barrier.[28]

The role of low-pressure baroreceptors in the systemic venous circulation and right atrium is less clearly defined. Venodilatation occurs in both sepsis and reduced cardiac output states. Simultaneous reduced baroreceptor signalling in the high-pressure system results in sodium and water retention. This expands the extracellular fluid compartment, potentially causing tissue oedema. As sepsis resolves, venous tone is restored, capillary leak reduces, and an increase in the loading of the high-pressure baroreceptors results and a natriuresis takes place. Patients may become transiently polyuric as they clear the excess salt and water accumulated whilst shocked. During this physiological diuresis, plasma osmolality remains tightly within the normal range provided that renal concentrating mechanisms have not been injured during the septic episode or by drug administration.

CRANIAL DIABETES INSIPIDUS

CONGENITAL CRANIAL DIABETES INSIPIDUS

Congenital cranial diabetes insipidus (CDI) is rare and usually inherited as an autosomal dominant characteristic due to mutations of the gene encoding the ADH precursor pre-provasopressin neurophysin II.[29] Onset may occur anywhere between 1 year of age and middle adult life and is associated with the eventual destruction of ADH-producing cells due to abnormal ADH precursor accumulation.[30] Until destruction of SON and PVN cells is complete, ADH secretion (facilitated by expression of the normal gene) and regulation of plasma osmolality are often unaffected.

ACQUIRED CRANIAL DIABETES INSIPIDUS

Acquired CDI may be transient or permanent with either an absolute (complete) or relative (incomplete) lack of ADH. If non-traumatic, it is usually associated with abnormality of the inferior hypophyseal arterial system[31] or autoimmune reactivity against ADH-producing cells.[32] Complete CDI is usually associated with lesions above the median eminence level in the supraoptic or paraventricular nuclei or of the neurohypophyseal stalk, whereby the production of ADH in the hypothalamus is terminated.[33] Permanent central DI tends to be associated with transecting, obliterating or chronic inflammatory lesions and transient DI with acute inflammatory or oedematous lesions with gradual recovery of ADH secretion occurring as the inflammation or oedema resolves. An exception is the transient DI seen following posterior pituitary excision or destruction; ADH produced in the hypothalamus can still be released into the systemic circulation from capillaries in the median eminence.

If normal ADH release into the circulation in response to rising plasma osmolality is reduced or absent, inappropriately high urine volumes of inappropriately low osmolality are passed. With absolute ADH deficiency, over 20 L/day of very dilute urine (25–200 mOsomol/kg) may be produced. If unable to drink freely or if thirst mechanisms are impaired, profound dehydration rapidly follows unless appropriate interventions are made.

Where ADH deficiency is relative/partial, urinary osmolalities of 500–800 mOsmol/kg and volumes as low as 3 L/day are not atypical. These osmolalities are inappropriately low relative to the plasma osmolality and the urine volumes inappropriately high when assessed in terms of the minimum required for the solute excretion. The diagnosis of partial CDI may not be obvious; there are many other causes of diuresis of this magnitude. Additionally, extrinsic stimulants of ADH release (see Box 60.2) may have an antidiuretic effect, further complicating the diagnosis.

Plasma osmolality in CDI is usually in the high normal or slightly supranormal range but remains remarkably constant in those with free access to water and intact thirst mechanisms. They will drink huge quantities of water to regulate and maintain their water balance. Hyperosmolality or hypernatraemia suggest impaired sensation of thirst or inability to access water (see water deprivation test later) and is also seen if patients are administered large quantities of isotonic saline or Hartmann's solution to replace their hypotonic urine losses. If unrecognised and untreated, hyperosmolality and hypernatraemia may result in death.

CDI is usually associated with reduced production of ADH or impaired release mechanisms of ADH. However, dysfunction of osmoreceptors or intracellular signalling pathways with normal ADH production and storage has been described. It is possible to have normal release of ADH in response to hypotensive baroreceptor activation but subnormal release in response to hyperosmolality. This has been described in association with chronic hypernatraemia.[34]

The main recognised causes of CDI are listed in Box 60.3. Traumatic or post-surgical brain injury are common causes of CDI in the ICU. Transsphenoidal surgical treatment of suprasellar tumours results in DI in 10%–70% of patients; the frequency parallels the magnitude of the tumour removed. Transcranial surgery may also cause CDI in the absence of a fall in plasma ADH; it is postulated release of a

Box 60.3 Causes of cranial diabetes insipidus

Acquired:

1. idiopathic
2. autoimmune[29]
3. tumours (especially suprasellar, lung, breast, lymphoma and leukaemia)
4. surgery (especially transsphenoidal surgery)
5. traumatic head injury (strongly associated with base of skull fracture)[35]
6. hypoxic brain injury
7. brainstem death
8. electrolyte disturbance – profound hyponatraemia
9. radiotherapy
10. drugs – amiodarone, lithium (Li more likely to cause nephrogenic DI)
11. inflammatory/infectious diseases
    - sickle cell disease
    - TB
    - abscesses
    - encephalitis
    - meningitis
    - sarcoidosis (may also cause nephrogenic DI)
    - Wegener's granulomatosis
    - histiocytosis X
12. vascular disease
    - ischaemic or haemorrhagic strokes
    - aneurysmal bleeds (especially anterior communicating artery SAH [subarachnoid haemorrhage])
    - Sheehan's syndrome
    - pituitary apoplexy

Congenital (1%–2% of all cases)

1. autosomal dominant mutations of ADH expression (despite the dominant expression of the gene, the onset of clinical DI may take up to 30 years to develop)[36]
2. Wolfram syndrome – autosomal recessive condition characterised by DI, diabetes mellitus, optic atrophy and deafness

ADH, antidiuretic hormone; *DI*, diabetes insipidus.

hypothalamic ADH precursor acting as a competitive antagonist of both ADH and synthetic analogues. The presence of a competitive antagonist creates an endocrinological picture similar to NDI with normal or high plasma ADH but an inappropriate diuresis of dilute urine.

Following surgery or traumatic brain injury, different patterns of polyuria may arise. Immediate polyuria is common and may be transient or permanent. Occasionally it is preceded by a period of oliguria due to an initial surge of ADH release. Additionally, a classical triphasic pattern of urine output may be observed with:

1. transient polyuria due to transient impairment of the release of ADH (0–5 days in duration), then
2. a phase of normal or reduced urine output; the ADH previously stored in the pituitary gland is gradually released into the circulation as the cells storing it involute (3–6 days in duration)
3. persistent polyuria as the pituitary stores exhaust and no replacement hormone from the hypothalamus is produced.

During the second phase of this pattern, administration of fluids may result in volume overload and hyponatraemia as the ADH release is not under feedback control from osmoreceptors but occurring in an uncontrolled manner as a result of pituitary degeneration. Effectively, there is a transient syndrome of inappropriate ADH (SIADH) secretion. The triphasic pattern is usually associated with sudden severe damage to the hypothalamus or pituitary from trauma, surgery or intracranial bleed. Careful, regular clinical and biochemical assessments are essential to ensure normal water balance and osmolality during this transition from DI to SIADH and back to DI again.

The exact urinary pattern seen in DI is relatively unimportant and gradual resolution may occur over several months in those with transient DI. In all instances, avoidance of unnecessary fluid and solute imbalances that worsen morbidity or mortality require meticulous, regular assessments of the patient and their plasma and urinary biochemistry and fluid inputs and outputs. Imaging the hypothalamus and pituitary with T1 magnetic resonance imaging (MRI) may provide prognostic information as to whether recovery is likely or not; hypothalamic lesions have a poorer prognosis than pituitary ones.[37]

A high level of suspicion of DI is recommended in anyone suffering from pituitary disease or with past pituitary injury; the symptoms may have gradual and insidious onset. Anterior pituitary failure can lessen the impact of CDI as deficiencies of ACTH and cortisol reduce GFR and free water loss. Additionally, loss of feedback inhibition may increase ADH release from the median eminence. Thus, in Sheehan's syndrome and pituitary apoplexy, presenting symptoms tend not to be those of DI with polyuria. However, once corticosteroid therapy is commenced, polyuria indicating DI may become apparent or exacerbated. Conversely, patients with persistent idiopathic CDI require long-term endocrine follow-up as a proportion develop tumours of the pituitary several years following initial diagnosis of DI.[38,39]

TREATMENT OF CRANIAL DIABETES INSIPIDUS

Four separate problems have to be addressed when treating CDI:

1. associated anterior pituitary dysfunction should be considered and managed if present

2. hypernatraemia must be recognised and meticulously managed
3. any deficit of total body water must be recognised and corrected
4. the underlying ADH deficiency must be addressed.

In all ICU patients with DI, hourly urine volumes, fluid losses and fluid inputs and at least twice-daily urine and plasma osmolalities are recommended. In shocked patients and those with hypernatraemia, hourly monitoring of plasma sodium is recommended to avoid worsening hyperosmolality or over-rapid correction of hypernatraemia.

ANTERIOR PITUITARY DYSFUNCTION

If present, this requires recognition and treatment. In the emergent situation with a shocked patient, hydrocortisone 100 mg can be administered as an intravenous (IV) bolus, and steroid replacement continued if required. Steroids may worsen the diuresis but will improve cardiovascular stability in patients with pituitary ablation.

HYPERNATRAEMIA

Restricted access to fluids or replacement of dilute urine with equal volumes of isotonic (to plasma) intravenous fluids in CDI with on-going water diuresis will lead to hyperosmolality/hypertonicity. In order to counteract cellular dehydration in chronic (>24 hours) hypernatraemic states, the brain accumulates intracellular organic osmolytes such as amino acids, taurine and sorbitol.[40–42] Any sudden reduction in plasma tonicity may then result in cerebral oedema, pontine myelonecrosis and permanent neurological damage as water moves into brain cells down an osmotic gradient.

When a euvolaemic state is present, AVP or DDAVP may be administered to reduce urine output. Simultaneous fluid restriction and replacement of the previous hour's urine output with an appropriate fluid to avoid falls in plasma sodium concentration greater than 0.5 mmol/h[43] is then introduced. Absolute safety data determining the ideal reduction rate of plasma sodium are unavailable. However, in hypernatraemia of greater than 48 hours duration, reductions greater than 8 mmol/L in any 24-hour period should be avoided.[44] Formulae exist to guide fluid replacement whilst controlling the rate of plasma sodium concentration reduction. Nonetheless, close monitoring with hourly plasma sodium measurement more reliably avoids sudden unexpected changes in tonicity.[45]

DEHYDRATION AND HYPOVOLAEMIA

Hypovolaemia associated with shock requires rapid resuscitation. If hypernatraemia is also present, extreme caution is required during resuscitation. Isotonic saline should be used and frequent reassessments of plasma sodium, cardiovascular and neurological states are recommended. With hypernatraemia greater than 155 mmol/L, a combination of isotonic (0.9%) and hypertonic saline should be considered to reduce the rate of sodium reduction. In the face of plasma hypertonicity, cells reduce their chloride and potassium conductance in addition to synthesising intracellular osmolytes. If 0.9% saline (effective osmolality 290 mOsmol/kg when diluted by plasma proteins) is infused rapidly into hypertonic plasma with a sodium of 160 mmol/L (effective osmolality 330 mOsmol/kg), a rapid drop in plasma osmolality may cause cerebral and other organ oedema, seizures and death. Gradual reduction of plasma osmolality facilitates downregulation of intracellular osmolyte synthesis and increased potassium and chloride conductance with reduced swelling as plasma tonicity falls.

CORRECTION OF POLYURIA AND ADH DEFICIENCY

During mild polyuria (2–3 mL/kg per hour) where resolution is expected, replacement of the previous hour's urine output with appropriate fluid (usually IV 5% dextrose, IV 0.18% saline/4% dextrose or nasogastric water in ICU) whilst closely monitoring plasma and urinary osmolality and electrolytes may suffice. Overadministration of dextrose solutions may cause hyperglycaemia, hyperosmolality and osmotic diuresis.

Severe (>3 mL/kg per hour) or persistent polyuria merits ADH/AVP or DDAVP administration. DDAVP is a selective V_2 receptor agonist and is therefore less likely to cause hypertension. Resistant to breakdown by vasopressinases, DDAVP is long-acting. Daily dose rates of 1–4 micrograms in a single or divided dose by intravenous, intramuscular or subcutaneous administration are usual. Oral and intranasal formulations also exist. ADH may be administered subcutaneously or by intravenous infusion. In the acute situation, an ADH infusion (0.1–3 U/h) can be conveniently titrated against urine output and facilitates re-establishment of the hypertonic renal medullary interstitium before conversion to longer-acting DDAVP. ADH and DDAVP dose requirements are often higher during the acute onset of CDI – this may reflect loss of medullary interstitial hypertonicity, competitive antagonism at V_2 renal receptors by biologically inactive ADH precursors released from the damaged hypothalamic-pituitary tract, or both.

The dose of ADH or DDAVP used is the minimum dose required to achieve acceptable control of urine output. Excessive administration may cause water retention and hypo-osmolal syndromes.

Other drugs may also reduce the polyuria of CDI. Provided there is some residual ADH synthesis, chlorpropamide, clofibrate and carbamazepine are all reported to both enhance ADH release and renal responsiveness to ADH. However, in modern ICU

management of CDI, DDAVP and ADH have better efficacy, better safety profiles and are more easily titrated to effect than the alternatives whose role is now largely confined to treatment of NDI (see later).

NEPHROGENIC DIABETES INSIPIDUS

Nephrogenic diabetes insipidus (NDI) may be congenital or acquired (Box 60.4). As the majority of congenital cases present in the first week of life, the majority of cases seen in the adult ICU are acquired, the commonest causes being lithium toxicity due to long-term drug treatment, hypercalcaemia and post-obstructive uropathy following relief of urinary tract obstruction.

CONGENITAL NEPHROGENIC DIABETES INSIPIDUS

Eighty to ninety percent of patients presenting with congenital NDI are male with x-linked recessive abnormalities of the *AVPR*$_2$ gene coding for the V_2-receptor.[29,46] The majority of the mutations result in intracellular trapping of the V_2-receptor, preventing integration into the collecting duct membrane. Drugs that facilitate receptor integration into the membrane, restoring some of the urine concentrating abilities of ADH, are being investigated.[47] Female children also present but usually with less severe polyuria and polydipsia due to part-expression of the recessive gene.

Approximately 10% of cases of congenital NDI have mutations of the *AQP*$_2$ (aquaporin 2) gene which codes for the AQP_2 channel and are not x-linked. Over 40 autosomal dominant and recessive mutations have been described to date.

The remaining congenital NDI cases arise from failure to generate renal medullary interstitial hypertonicity, with inability to reabsorb water even with normal V_2 receptor and AQP_2 channels.

Absence of the Kidd (blood group) antigen prevents urinary concentration greater than 800 mOsmol/kg even with water deprivation and exogenous ADH administration.[48] The antigen is also normally expressed in the collecting duct epithelium, facilitating transport of urea (urea transport B protein) from urine into the medullary interstitium contributing to the osmolal gradients required to facilitate water reabsorption. Patients with mutations in chloride channel, potassium channel or the sodium-potassium-chloride co-transporter genes resulting in the Bartter syndrome are even less able to generate medullary interstitial hypertonicity and urine can rarely be concentrated greater than 350 mOsol/kg.[49]

With congenital NDI, early diagnosis and management is essential as avoidance of hypernatraemia and dehydration facilitates the achievement of normal developmental milestones and avoids the cerebral damage once commonly accepted as an inevitable association of NDI.

Box 60.4 Causes of nephrogenic diabetes insipidus

Acquired
1. lithium toxicity
2. post-obstructive diuresis
3. hypercalcaemia
4. hypokalaemia
5. hypoproteinaemia
6. Sjogren's syndrome
7. amyloid
8. multiple myeloma
9. sickle cell disease
10. polycystic kidney disease
11. pyelonephritis
12. renal transplantation
13. other drugs: amiodarone, amphotericin B, clozapine, colchicine, demeclocycline, foscarnet, gentamicin, loop diuretics, rifampicin

Congenital
1. x-linked recessive – *AVPR*$_2$ gene mutations
2. autosomal recessive or dominant – *AQP*$_2$ gene mutations
3. Bartter's syndrome
4. Gitelman's syndrome
5. Urea Transport Protein B (Kidd Ag) deficiency/absence

ACQUIRED NEPHROGENIC DIABETES INSIPIDUS

Lithium-associated nephrotoxicity is the commonest cause of acquired NDI; greater than 20% of patients on chronic lithium therapy develop polyuria. Lithium enters collecting duct principal cells via sodium channels and inhibits intracellular adenylate cyclase antagonising the effects of ADH. It also reduces medullary interstitial hypertonicity, possibly through reducing urea transport protein B expression. Some reversal of both polyuria and lithium-mediated toxicity is possible in early lithium-related NDI following amiloride administration. Amiloride's natriuretic action occurs through closure of the collecting duct luminal sodium channels through which lithium enters the cells.[50] Indomethacin increases intracellular cAMP, counteracting the diminution of this and AQP_2 caused by lithium, markedly reducing urine output. However, care is required as non-steroidal anti-inflammatory drugs (NSAIDs) may worsen renal failure, reducing GFR and lithium excretion, and thereby worsening toxicity.

Hypercalcaemia, hypokalaemia, relief of urinary tract obstruction and hypoproteinaemia are also recognised as causing NDI and are associated with reduced expression of AQP_2 channels, urea transport proteins and a loss of interstitial hypertonicity. These defects normally cause milder polyuria than that associated with lithium toxicity. Aging also reduces urinary concentrating ability, probably due to a combination of pathophysiological changes characteristic of both NDI

and CDI with relative reductions of both AQP_2 and AVP production.[51]

TREATMENT OF NEPHROGENIC DIABETES INSIPIDUS

The treatment of NDI aims to remove the underlying cause wherever possible and to minimise the occurrence of hypernatraemia and hypovolaemia.

1. Correct reversible causes
   a. Stop any drugs suspected in the aetiology
   b. Correct hypokalaemia, hypercalcaemia and hypoproteinaemia
2. Reduce solute load. If maximum urine concentration is 250 mOsmol/kg, a solute intake of 750 mOsmol/day requires production of greater than 3 L of urine to clear the solute. If intake is reduced to 500 mOsmol/day, 2 L of urine will suffice. In the ICU, reduction of solute intake is difficult as drugs and diluents have high solute loads and catabolic patients have high protein requirements. Rather than restricting solute intake, close monitoring of fluid balance and adequate, appropriate replacement of urinary losses may be preferred.
   a. Salt intake restriction (aiming <100 mmol/day)
   b. Protein intake reduction aiming to meet minimum daily requirements including essential amino acids requires specialist dietetic advice and supervision to avoid protein malnutrition. Protein restriction in children is inappropriate as it may adversely affect normal growth and development.
3. Diuretics – thiazides and amiloride
   a. Thiazides – In DI, water losses exceed solute ones causing plasma hyperosmolality and intracellular dehydration to maintain the intravascular volume. Thiazide diuretics cause solute loss in excess of water and reduce intravascular volume. This causes activation of the sympathetic nervous and renin-angiotensin-aldosterone systems and reductions in GFR and ANP. Thiazides also increase expression of AQP_2 channels in the collecting duct.[52] These neuroendocrine changes facilitate increased proximal tubular reabsorption of sodium and water and increased ADH release. Less ultrafiltrate reaches the collecting duct and urine volumes can fall by up to 30%. Combined with a solute reduced diet, urine output may reduce up to 50%.
   b. Amiloride may prove a useful adjunct to thiazides, causing further slight reduction in urine output and combatting thiazide-associated hypokalaemia. It may have benefit in its own right in lithium-associated nephrotoxicity as noted earlier. If administered before damage becomes irreversible, it can both reduce cellular damage and reverse the antagonism of lithium on the actions of ADH.

   Loop diuretics are not effective in reducing the diuresis of NDI. Whilst they reduce intravascular volume and stimulate the sympathetic nervous system similarly to thiazides, they also reduce interstitial medullary sodium concentrations and hypertonicity, thus reducing water reabsorption by the collecting duct rather than enhancing it.
4. ADH
   In partial NDI (most acquired cases), supplementing endogenous ADH to create supraphysiological concentrations can reduce urine production by up to 25%. This may occur through greater V_2 receptor occupation or antagonism of any endogenous antagonists present. Care is required with long-term use as hypertension may result.
5. NSAIDs
   PGE_2 increases GFR and urine flow and decreases intracellular cAMP and thereby aquaporin expression. NSAIDs reduce the formation of renal PGE_2 and when used alone may reduce urine output by up to 50%.[53] Greatest efficacy is cited for indomethacin.[54] Combination with low solute diet and a thiazide diuretic may provide additional antidiuretic benefit.[55] However, the risks of NSAIDs are magnified in the ICU population who already bear increased risk of renal impairment and gastric erosions.
6. Chlorpropamide
   This enhances both ADH release and the sensitivity of the kidney to it. It is suggested to act via increasing renal medullary hypertonicity. Doses of 250 mg od or bd are prescribed but may cause hypoglycaemia[56] and use is reserved for severe refractory partial NDI.
7. Clofibrate
   This oral lipid-lowering agent is reported to enhance ADH release and increase the renal sensitivity to ADH.[57] Its use in CDI has largely been superseded by the introduction of safer, more efficacious DDAVP therapy. Its use in treatment of DI has been associated with myopathy.[58] If considered for treatment of partial NDI, biochemical markers of myopathy should be measured regularly.
8. Carbamazepine
   Although more effective in treating partial CDI, carbamazepine in doses three times those effective in epilepsy may reduce urine output in partial NDI. The high dose rate limits its utility.
9. Molecular chaperones
   Novel 'molecular chaperones' are being developed to treat NDI where functional V_2 receptors are confined intracellularly, unable to integrate into the principal cell basolateral membranes.[59] These membrane-permeable V_2 receptor antagonists cause receptor refolding into forms that allow membrane integration.[60] Animal models of congenital NDI, in vitro human V_2R mutations testing and early studies in humans report some

successes.[61] Unfortunately, a Relcovaptan (SR49059) study, whilst showing promising clinical results, had to be discontinued owing to cytochrome P450 pathway interference. Nonetheless, other chaperone molecules are currently being explored for human testing.[62,63]

GESTATIONAL DIABETES INSIPIDUS

In pregnancy, possibly under the influence of increased hCG,[64] the central osmostat resets,[65,66] thirst develops at osmolalities around 10 mOsmol/kg lower than in the non-pregnant state, the normal range of plasma osmolality falls to 265–285 mOsmol/kg and plasma sodium to 130–145 mmol/L. Reduced baroreceptor stimulation stimulates retention of water and sodium.[67]

During pregnancy, placental vasopressinases (cysteine-aminopeptidases) increase ADH metabolism up to fourfold and placental relaxin contributes to a 50% increase in GFR and venodilatation.[68] Aldosterone concentrations rise up to fivefold. Daily urinary production increases as a result of an increased solute load (including urinary proteins, glucose and amino acids), increased drinking and a raised GFR. Increased solute excretion means that small reductions in urine concentrating ability may cause unexpectedly large increases in urine volume. The diagnosis of gestational diabetes insipidus (GDI) – see Box 60.5 – requires careful differentiation from physiological polyuria and other pathological polyurias (e.g. gestational diabetes).

GDI occurs in around 1:30,000 pregnancies and can result from:

1. Increased ADH destruction by overexpressed placental vasopressinases[69] (especially gemellar pregnancies) or reduced de-activation of vasopressinases (e.g. in acute fatty liver of pregnancy),[70] pre-eclampsia or haemolysis, elevated liver enzymes, low platelets (HELLP) syndrome. Exogenous ADH is also rapidly metabolised and may prove ineffective. DDAVP, the preferred treatment, is resistant to degradation by placental vasopressinase.
2. Relative ADH insufficiency, with barely sufficient reserves in the non-pregnant state, maybe unmasked by increased vasopressinase activity in pregnancy that cannot be compensated for by increased secretion.[71] This condition responds to treatment with ADH/DDAVP and is indicative of latent, subclinical DI that pre-dated pregnancy. Investigation and follow-up following pregnancy is warranted as a proportion of patients in this category will later develop hypothalamo-pituitary axis pathologies such as tumours or autoimmune hypophysitis.
3. Central DI is associated with Sheehan's syndrome and pituitary apoplexy. Sheehan's syndrome is commonest, and is usually preceded by major bleeding or hypotension at the time of delivery. Pituitary apoplexy has been described antenatally, too.[72]
4. Gestational NDI of unknown aetiology that is resistant to both ADH and DDAVP, with resolution in the post-natal period, has also been described.[73]

Box 60.5 Causes of gestational diabetes insipidus

1. Sheehan's syndrome
2. Pituitary apoplexy
3. Hepatic dysfunction:
   a. Acute fatty liver of pregnancy
   b. Pre-eclampsia
   c. HELLP syndrome
4. Vasopressinase release by placenta
5. Idiopathic gestational nephrogenic diabetes insipidus (resolves post-partum)

HELLP, haemolysis, elevated liver enzymes, low platelets.

The treatment of GDI varies depending on the underlying cause. In all cases, it is important not to allow the patient to become hypernatraemic and hyperosmolal, as this is likely to have adverse effects on both mother and child. Where hypernatraemia and hyperosmolality do occur, careful correction is required in a closely monitored, very gradual, step-wise fashion. A lowering of sodium by as little as 10 mmol/L per day has been associated with pontine myelinolysis.[74]

The associations between acute fatty liver of pregnancy, HELLP, pre-eclampsia and DI are well recognised, if not fully understood. It has been suggested that liver dysfunction results in reduced clearance of the vasopressinases released by the placenta and thus increased clearance of maternal ADH.[75,76] It is important to bear these associations in mind, as the polyuria of DI may mask the hypertension and fluid overload of pre-eclampsia and HELLP leading to later diagnosis, delayed management and poorer outcome.[77]

POLYDIPSIA (PSYCHOGENIC/NEUROGENIC/PRIMARY)

Polydipsia may result from:

1. a psychiatric disorder or disturbance[78]
2. drugs causing xerostomia[79] or drying of airways (e.g. oxygen therapy, phenothiazines, anticholinergics)
3. hypothalamic lesions which directly disturb the thirst centre[80] (e.g. sarcoidosis)

In all three causes outlined above, excessive drinking causes production of large quantities of urine of appropriate osmolality. If ingested fluids are hypotonic, the urine will be hypo-osomolal secondary to a fall in ADH secretion. If ingested fluids are hypertonic, the urine will have high osmolality but remain of high volume because of the combination of low ADH production and high ANP production causing a solute diuresis.

Polydipsia may also result from the appropriate detection by osmoreceptors of a raised plasma osmolality due to raised glucose, alcohol or sodium. The glycosuria itself will cause an osmotic diuresis and plasma osmolality may be normal or raised, depending on the severity of the hyperglycaemia and any accompanying ketoacidosis and dehydration.

Excessive drinking of hypotonic fluids leads to hyponatraemia and may progress to water intoxication with cerebral oedema, confusion, impaired consciousness, seizures and death. It has also been postulated that long-term polydipsia may lead to the development of dysregulation of ADH secretion and cranial DI.[81] These are important considerations in patients presenting with reduced consciousness and polyuria; water intoxication (more usually associated with SIADH) and DI may co-exist.

SOLUTE DIURESIS

Failure to reabsorb water in DI results in polyuria. Failure to reabsorb solute results in an osmotic load in the tubules and collecting duct that opposes water absorption and may also cause polyuria. Common causes include glycosuria, diuretic drugs, high protein feeds (increased urea load), supra-normal sodium and other solute intake (through fluids, feeds and drugs) and tubular inability to reabsorb solute (recovering ATN or drug toxicity).

Differentiation of solute from water diuresis is best facilitated by measuring 24-hour urinary solute excretion. Normally, 600–900 mOsmol/day of solute is excreted. Values greater than 900 mOsmol/day indicate a solute diuresis. Spot urine osmolalities greater than 300 mOsmol/kg are also suggestive but not diagnostic. In critically ill patients, simultaneous impairment of both water reabsorption and increased solute elimination are common and total solute excretion greater than 900 mOsmol/day via hypo-osmolal urine may be seen.

THE DIAGNOSIS OF POLYURIC SYNDROMES

MEASURE AND CALCULATE PLASMA OSMOLALITY AND URINE OSMOLALITY

High urine osmolality in the presence of high plasma osmolality is appropriate. When plasma osmolalities are greater than 295 mOsmol/L, urine osmolalities should reach 1000–1200 mOsmol/kg. Urine osmolalities less than 1000 mOsmol/kg imply a concentrating defect. Considerations include the causes of DI and medications that might reduce renal interstitial hypertonicity (e.g. loop diuretics). Urine osmolalities of less than 150 mOsmol/kg in this circumstance are sufficient to make the diagnosis of DI.

Polyuria with high plasma osmolalities and urine osmolalities greater than 1000 mOsmol/kg indicate an osmotic diuresis. The diuresis may be inappropriate inasmuch as it leads to dehydration but appropriate in that the kidneys are maximally retaining water whilst excreting a large solute load. An osmolal gap greater than 10 mOsmol/kg should prompt testing for unmeasured solutes (e.g. ethanol, mannitol, ethylene glycol, sorbitol or methanol).

When plasma osmolalities are less than 280 mOsmol/kg, urine osmolalities should also be less than 280 mOsmol/kg as the body attempts to clear free water. This picture implies water overload. Low plasma osmolality with high urine osmolality implies SIADH and would not normally be associated with polyuria. Cerebral/renal salt wasting should be considered if plasma osmolality and sodium are low/low-normal, intravascular volume depletion is present, there is a diuresis and urinary sodium is greater than 40 mmol/L. Urine may be iso-, hyper- or hypo-osmolal to plasma.

WATER DEPRIVATION AND ANTIDIURETIC HORMONE TESTS

In health, water deprivation rapidly causes increased plasma osmolality, ADH release and increased urine osmolality to 1000–1200 mOsmol/kg to preserve water and restore normal plasma osmolality. In the absence of pre-existing dehydration, a water deprivation test may be useful to determine the cause of persistent polyuria of unknown aetiology. The test is potentially dangerous as dehydration and hyperosmolality can develop rapidly, causing permanent cerebral damage and cardiovascular collapse; it should be conducted under close, expert supervision during daylight hours.

The limitations of the test should also be appreciated:

1. in acute CDI, release of ADH precursors from injured brain tissue may cross-react with ADH assays, rendering their interpretation unreliable
2. at high concentrations of ADH, the urine concentrations achieved in partial NDI and primary polydipsia may be similar
3. patients with partial CDI occasionally become hypersensitive to small rises in ADH such as those induced by the rise in osmolality associated with water deprivation and thus maximally concentrate urine once osmolality is raised, leading to an erroneous diagnosis of primary polydipsia[82]
4. in patients with chronic hypernatraemia and CDI secondary to osmoreceptor dysfunction, hypovolaemia with water deprivation may cause sufficient baroreceptor stimulus to release ADH and suggest normal urine concentrating abilities.[83]

Conducting the water deprivation test:

Step 1. Plasma and urine osmolalities and plasma ADH are measured at time zero and access to IV/oral fluids is denied.

Step 2. Plasma and urine osmolalities are measured hourly until either three consecutive urine osmolalities are within 50 mOsmol/kg of one another

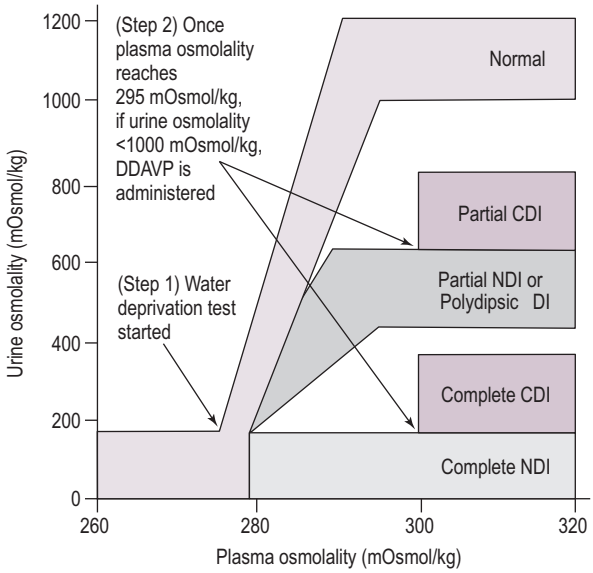

Figure 60.4 Urine versus plasma osmolality during water deprivation testing. *CDI*, Cranial diabetes insipidus; *DDAVP*, 1-deamino-8-0-arginine vasopressin; *NDI*, nephrogenic diabetes insipidus. *Adapted from Sands JM, Bichet DG. Nephrogenic diabetes insipidus.* Ann Intern Med. *2006;144:186–189.*

or plasma osmolality is greater than 295 mOsmol/kg. At this time, plasma ADH is measured again.

Step 3. If plasma osmolality is greater than 295 mOsmol/kg and urine osmolality is less than 1000 mOsmol/kg, 4 µg DDAVP s/c is administered to the patient and urine osmolality is measured hourly for three hours (this time is necessary to allow time for at least partial recovery of the medullary interstitial hypertonic gradient in patients with primary polydipsia). (DDAVP is preferred to AVP as it avoids misinterpretation of results in the presence of vasopressinases which would rapidly metabolise AVP and suggest a diagnosis of NDI rather than CDI. Although neither is the correct diagnosis if vasopressinases are present, the treatment is as for CDI [i.e. the administration of DDAVP].)

Step 4. Urine osmolality is then plotted against plasma osmolality (Fig. 60.4)

Step 5. Plasma and urine osmolalities are plotted against plasma ADH concentrations (Fig. 60.5)

INTERPRETATION OF THE TESTS (see Figs 60.4 and 60.5)

In complete DI, plasma osmolality will rise but urine osmolality will not rise above 300 mOsmol/kg. Upon administration of ADH, patients with complete CDI will raise their urine osmolality to 500 mOsmol/kg or higher, whereas there will be no rise in urine osmolality in complete NDI.

In complete CDI, the original plasma ADH measurement will be zero, whereas in complete NDI, the initial ADH measurement will be normal or high, dependent upon the corresponding plasma osmolality at the time of measurement.

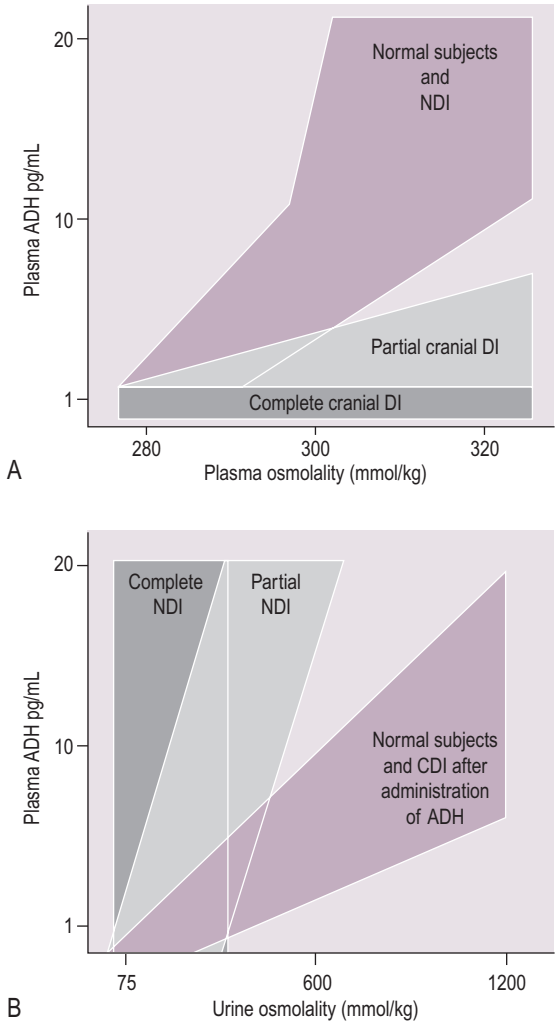

Figure 60.5 (a) As plasma osmolality increases as a result of water deprivation or hypertonic saline infusion, the measured concentration of antidiuretic hormone (ADH) should rise. Failure to do so suggests cranial diabetes insipidus. (b) At a given value of plasma ADH, whether endogenous or exogenous in origin, urine osmolality is expected to lie within a corresponding range of osmolality. However, the range of expected osmolalities is high as osmoreceptors adjust regulation around the basal level of ADH, which is also partly determined by volume receptors. In nephrogenic diabetes insipidus (NDI), the urine osmolality remains low even when high plasma ADH concentrations are measured. *CDI*, Cranial diabetes insipidus.

In partial DI, plasma osmolality will rise and urine osmolality will also increase but usually plateaus between 400 and 800 mOsmol/kg. In partial CDI, the ADH will initially be normal or low and will rise with increasing plasma osmolality but is unlikely to rise above 4–5 pg/mL. In partial NDI, the ADH will initially be normal or high and will increase with plasma osmolality to greater than 8 pg/mL but without achieving a correspondingly appropriate rise in urine concentration.

Following administration of ADH or DDAVP, urine osmolality is expected to increase greater than 100% in complete CDI, remain unchanged in complete NDI and rise by 10%–50% in partial CDI or NDI. In partial CDI, urine osmolality normally rises above plasma osmolality, whereas in partial NDI it tends to remain hypo- or iso-osmolal to plasma following ADH/DDAVP administration.

Contraindications to water deprivation tests include infancy, pre-existing hypovolaemia and hyperosmolality. Treatment of the fluid deficit and/or hyperosmolality should precede further investigations.

HYPERTONIC SALINE INFUSION

In patients with equivocal results from a water deprivation test and those at high risk of dehydration/hypovolaemia from water deprivation (e.g. infants), a hypertonic saline infusion test may be undertaken to establish the cause of a water diuresis. Interpretation of the test is as for the water deprivation test with clearer demarcation between partial CDI and primary polydipsia and the reduced risk of missing a diagnosis of CDI secondary to osmoreceptor dysfunction.[84]

Hypertonic saline is available in multiple different concentrations. Care is required in calculating the appropriate infusion rate to use for the test, as this varies with the concentration of the hypertonic preparation stocked. 0.0425 mmol/kg per minute of hypertonic sodium chloride solution is infused for up to three hours or until a plasma osmolality of 300 mOsmol/kg is achieved.

Blood samples are taken 30 minutes before and at 30-minute intervals throughout the test and plasma sodium, osmolality and ADH measured. Urine samples are collected before and where possible at 60-minute intervals throughout the test period and measurements of osmolality and sodium performed. Thirst and blood pressure are recorded at 30-minute intervals.

MAGNETIC RESONANCE IMAGING T1-WEIGHTED IMAGING OF THE NEUROHYPOPHYSEAL TRACT

Imaging may helpful in differentiating partial CDI from psychogenic polydipsia where results of a water deprivation test and the history make the differentiation uncertain. In CDI, the normal bright spot (stored ADH) seen in the posterior pituitary is usually reduced or absent, whereas in psychogenic polydipsia it is usually present or even enhanced (Fig. 60.6).

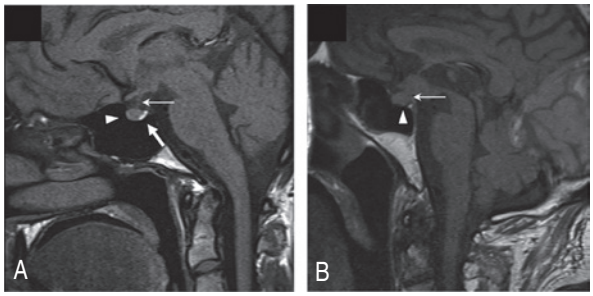

Figure 60.6 Sagittal T1-weighted magnetic resonance imaging scans of the hypothalamic-pituitary region in a patient with posterior pituitary (a) and a patient with cranial diabetes insipidus (CDI) (b). (a) A normal anterior pituitary *(arrowhead)* and pituitary stalk *(thin white arrow)* and hyperintensity of the posterior pituitary *(thick white arrow)*. (b) Sagittal T1-weighted scan obtained in a patient with CDI due to lymphoma shows a massively thickened pituitary stalk *(thin white arrow)* and an absent hyperintense signal in the posterior pituitary gland *(arrowhead)*. *Reproduced with permission from Fenske W, Allolio B. Clinical review: current state and future perspectives in the diagnosis of diabetes insipidus.* J Clin Endocrinol Metab. *2012;97(10):3426–3437.*

Although rapid and less labour-intensive than a hypertonic saline infusion test, the results of the MRI are not yet held to be entirely specific or sensitive. It is reported that the signal is often reduced in NDI (possibly due to ADH store depletion secondary to oversecretion) and in up to 30% of elderly subjects without any clinical symptoms of DI. Additionally, the signal intensity may change bi-directionally over time, even in young subjects. MRI-derived diagnostic information should be considered indicative rather than conclusive.

OTHER TESTS

Other tests have been explored for possible utility in suspected DI. Non-osmotic stimuli of ADH release such as nicotine and hypotension have been found unreliable. More promisingly, the biochemically stable C-terminal glycoprotein cleaved from the ADH-prohormone at the time of activation is relatively easy to measure and correlates well with plasma ADH concentrations; this copeptin may offer a simpler alternative to ADH measurement during water deprivation and hypertonic saline tests.

Thyroid emergencies

Jonathan M Handy, Alex Li

INTRODUCTION

Thyroid emergencies are a rare cause for admission to critical care. However, mortality is high unless specific treatment is provided in an expeditious manner. Abnormal thyroid function tests (TFTs) are commonly encountered during critical illness; numerous factors must be considered before interpreting these findings as indicating thyroid disease.

BASIC PHYSIOLOGY

Thyroid hormones affect the function of virtually every organ system and must be constantly available for these functions to continue. The two biologically active hormones are tetraiodothyronine (thyroxine or T_4) and triiodothyronine (T_3). These are synthesised by incorporating iodine into tyrosine residues, a process which occurs in thyroglobulin contained within the lumena of the thyroid gland (Fig. 61.1). Stimulation of hormone release by thyroid stimulating hormone (TSH) results in endocytosis of thyroglobulin from the lumen into the follicular cells, followed by hydrolysis to form T_4 and T_3, which is released into the circulation.[1]

Both T_4 and T_3 contain two iodine atoms on their inner (tyrosine) ring. They differ in that T_4 contains two further iodine atoms on its outer (phenol) ring, whereas T_3 contains only one, resulting in a comparatively longer plasma half-life for T_4 of 5–7 days compared with that of 10 hours for T_3. T_4 is produced solely by the thyroid gland, whereas the majority of T_3 is synthesised peripherally by the removal of one iodine atom (de-iodination) from the outer ring of T_4. If de-iodination of an inner ring iodine atom occurs, the metabolically inert reverse-T_3 (rT_3) is formed. This is produced in preference to T_3 during starvation and many non-thyroidal illnesses, and the ratio of inactive (rT_3) to active T_3 synthesis appears to play an important role in the control of metabolism.[2] Numerous factors can affect the peripheral de-iodination process (Box 61.1). Both T_4 and T_3 are highly protein bound in the serum, predominantly to thyroid binding globulin but to a lesser extent to albumin and prealbumin. Changes in concentration of these serum binding proteins have a large effect on total T_4 and T_3 serum concentrations. Such protein changes do not, however, affect the concentration of free hormone or their rates of metabolism. The serum binding proteins act as both a store and a buffer to allow an immediate supply of the metabolically active free-T_4 (fT_4) and free-T_3 (fT_3). In addition, protein binding reduces the glomerular filtration and renal excretion of the hormones.

On reaching the target organs, fT_4 and fT_3 enter the cells predominantly by diffusion. Here, microsomal enzymes de-iodinate the fT_4 to form fT_3. This varies in differing tissues, the majority occurring in the liver, kidneys and muscles. The fT_3 subsequently diffuses into the nucleus, where it binds nuclear receptors and exerts its effect through stimulation of messenger RNA with subsequent synthesis of polypeptides including hormones and enzymes. The role of thyroid hormones in development and homeostasis are widespread and profound: the most obvious effects are to stimulate basal metabolic rate and sensitivity of the cardiovascular and nervous systems to catecholamines.

The regulation of thyroid function is predominantly determined by three main mechanisms, the latter two providing physiological control. Firstly, availability of iodine is crucial for the synthesis of the thyroid hormones. Dietary iodide is absorbed and rapidly distributed in the extracellular fluid, which also contains iodide released from the thyroid gland and from peripheral de-iodination processes. This becomes trapped within thyroid follicular cells, from which it is actively transported into the lumen to be oxidised into iodine and subsequently combined with tyrosine.[3] Other ions such as perchlorate and pertechnetate share this follicular cell active transport mechanism and thus act as competitive inhibitors for the process.

Secondly, thyroid hormone release is controlled by close feedback loop with the anterior pituitary. Diminished levels of circulating hormones trigger secretion of TSH, which acts on the follicular cells of the thyroid gland causing them to release thyroglobulin-rich colloid from the lumena. This thyroglobulin is hydrolysed to form T_4 and T_3 for systemic release. Increased levels of T_4 and T_3 cause diminished TSH secretion, resulting in the follicular cells becoming flat and

ABSTRACT

This chapter will focus on the biochemistry, clinical presentation, and management of critically ill patients presenting with thyroid endocrine emergencies. An understanding of the synthesis, storage, release and conversion of thyroid hormones allows better comprehension of the pathological processes underlying thyroid disease. This is therefore reviewed in advance of the clinical aspects of care.

Clinical diagnosis of thyroid disease in critically ill patients can be challenging due to the varied presentations; biochemical assay of thyroid function is needed to provide diagnostic confirmation. Treatment is aimed at supportive care and symptom management while correcting the underlying endocrine abnormalities.

Critically ill patients can develop abnormalities in thyroid function tests for numerous reasons. Not all require treatment and the causes and interpretation of abnormal thyroid function tests are discussed.

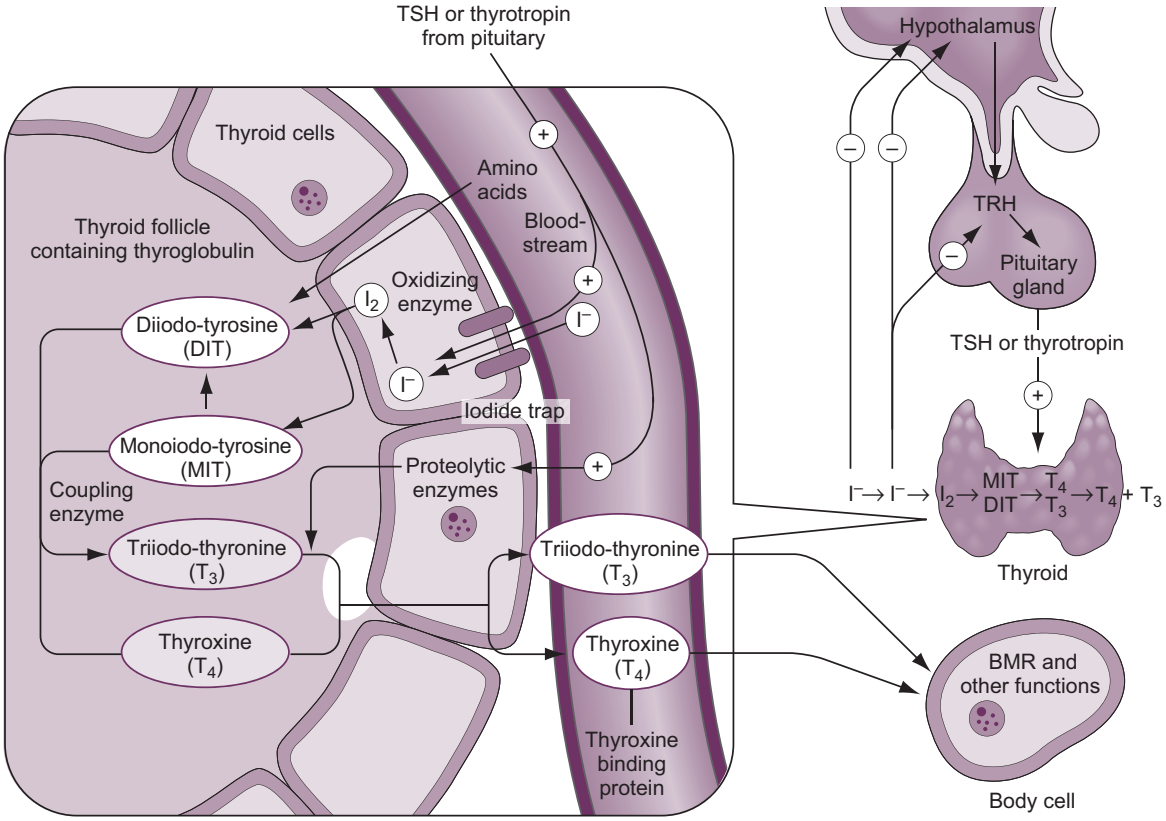

Figure 61.1 Synthesis of tetraiodothyronine (T_4) and triiodothyronine (T_3). Stimulation of hormone release by thyroid stimulating hormone (TSH) produced in the pituitary gland results in endocytosis of thyroglobulin from the lumen into the follicular cells, followed by hydrolysis to form T_4 and T_3 which is released into the circulation. *BMR*, Basal metabolic rate; *TRF*, thyrotropin-releasing factor; *TRH*, thyrotropin-releasing hormone.

Box 61.1 States associated with decreased de-iodination of T_4 to T_3

- Systemic illness
- Fasting
- Malnutrition
- Postoperative state
- Trauma
- Drugs: propylthiouracil; glucocorticoids; propranolol; amiodarone
- Radiographic contrast agents (ipodate, iopanoate)

allowing increased capacity for colloid storage. As a result, less thyroglobulin is mobilised and hydrolysed with less T_4 and T_3 release. The degree to which TSH is secreted in response to changes in circulating thyroid hormones is dependent on the hypothalamic hormone thyrotropin-releasing hormone (TRH), which is itself modulated by feedback from the thyroid hormones (see Fig. 61.1). TRH secretion is inhibited by dopamine, glucocorticoids and somatostatin.

Lastly, further regulation occurs during the enzyme-dependent peripheral conversion of fT_4 to fT_3. It is this latter stage that provides the rapid and fine control of local fT_3 availability. All of these mechanisms may be altered by drugs and in pathological states.

THYROID CRISIS (THYROID STORM)

Thyrotoxic storm is arguably the most serious complication of hyperthyroidism with reported mortality ranging from 10% to 75% in hospitalised patients.[4,5] Crisis most commonly occurs as a result of unrecognised or poorly controlled Grave's disease; however, other underlying diseases may be the cause.[6,7] Females outnumber males. Laboratory findings are inconsistent due to acute disruption of the normal steady state of the circulating hormones and there is no definitive value that separates thyrotoxicosis from thyroid storm. The latter is a clinical diagnosis and a scoring system has been proposed to guide the likelihood of the diagnosis (Table 61.1).[8] Precipitating factors are not always present, though many have been identified (Box 61.2).

Table 61.1 Severity assessment in thyroid crisis

TEMP (°C)	PULSE	CARDIAC FAILURE	CNS EFFECTS	GI SYMPTOMS	SCORE
Normal	<90	Absent	Normal	Normal	**0**
37.2–37.7	90–109	Pedal oedema	—	—	**5**
37.8–38.2	110–119	Bibasal crepitations Atrial fibrillation	Agitation	Diarrhoea Nausea Vomiting Abdominal pain	**10**
38.3–38.8	120–129	Pulmonary oedema	—	—	**15**
38.9–39.2	130–139	—	Delirium	Unexplained jaundice	**20**
39.3–39.9	>140	—	—	—	**25**
>40	—	—	Seizure Coma	—	**30**

Calculations:

- Add the scores for each of the five clinically observed parameters
- Add a further **10 points** if **atrial fibrillation** is present
- Add a further **10 points** if an identifiable **precipitating factor** is present
- Total score of **45** or greater is highly suggestive of thyroid storm
- Total score of **25–44** supports impending crisis
- Total score of less than **25** makes thyroid storm unlikely

CNS, Central nervous system; *GI*, gastrointestinal.

Box 61.2 Factors associated with precipitating thyroid storm

- Infection; sepsis
- Withdrawal of antithyroid treatment
- Surgery; trauma
- Parturition
- Diabetic ketoacidosis
- Radioactive iodine therapy
- Iodinated contrast dyes
- Hypoglycaemia
- Excessive palpation of the thyroid gland
- Emotional stress
- Burn injury
- Pulmonary thromboembolism
- Cerebrovascular accident; seizure disorder (including eclampsia)
- Thyroid hormone overdose

Box 61.3 Clinical features of hyperthyroidism/ thyroid crisis

- Fever
- Cardiovascular
  - Tachycardia, atrial fibrillation, ventricular arrhythmias
  - Heart failure
  - Hypertension (early), hypotension (late)
- Neuromuscular
  - Tremor
  - Encephalopathy, coma
  - Weakness
- Gastrointestinal
  - Diarrhoea, nausea and vomiting
- Respiratory
  - Dyspnoea
  - Increased oxygen consumption and carbon dioxide production
- Goitre (possible airway compromise)
- Laboratory abnormalities

CLINICAL PRESENTATION

The classic signs of thyroid crisis include fever, tachycardia, tremor, diarrhoea, nausea and vomiting (Box 61.3).[9] However, presentation is extremely variable and may range from apathetic hyperthyroidism (apathy, depression, hyporeflexia and myopathy)[10] to multiple organ dysfunction.[11,12] Differential diagnosis includes sepsis and other causes of hyperpyrexia such as adrenergic and anticholinergic syndromes.

FEVER

This is the most characteristic feature. Temperature may rise above 41°C. There have been suggestions that pyrexia is present in all cases of thyroid storm,[13] although normothermia has been reported.[11] Pyrexia is rare in uncomplicated thyrotoxicosis and should always raise suspicion of thyroid storm. It is not clear whether

this febrile response is due to alteration of central thermoregulation, or elevation of basal metabolic thermogenesis beyond the body's ability to lose heat.

CARDIOVASCULAR FEATURES

Dehydration with electrolyte imbalance is common and fluid requirements may be substantial in some patients; conversely, diuresis may be required in those with severe cardiac congestion. Cardiac decompensation can occur in young patients with no known antecedent cardiac disease. Systolic hypertension with widened pulse pressure is common initially; however, hypotension may supervene later. Shock with vascular collapse is a pre-terminal sign.[14]

NEUROMUSCULAR FEATURES

Tremor and hyperreflexia are common early signs, but as 'storm' progresses central nervous dysfunction evolves with progression from agitation and anxiety to encephalopathy or even coma.[15] Thyroid storm has been reported in association with status epilepticus and cerebrovascular accident.[16] Weakness may be a feature, particularly with apathetic thyrotoxicosis.[11] Thyrotoxic myopathy and rhabdomyolysis may be present[11,17]; the latter being differentiated from the former by its association with markedly elevated creatine phosphokinase levels. A number of other syndromes of neuromuscular weakness have been described including hypokalaemic periodic paralysis[18,19] and myasthaenia gravis.[20]

GASTROINTESTINAL FEATURES

Diarrhoea, nausea and vomiting are common, though the patient may present with symptoms of an acute abdomen.[21] Severe abdominal tenderness should raise the possibility of an abdominal emergency. Liver function tests may be abnormal due to congestion or necrosis and tenderness over the hepatic area may be present. Hepatosplenomegaly may be present. The presence of jaundice is a poor prognostic sign.[14]

RESPIRATORY CONSIDERATIONS

Dyspnoea at rest or on exertion may be present for a number of reasons. Oxygen consumption and carbon dioxide production are increased with subsequent increase in the respiratory burden. This may be exacerbated by pulmonary oedema, respiratory muscle weakness and tracheal obstruction from enlarged goitre (rare).

LABORATORY FINDINGS

Numerous abnormalities may be found

- fT_4 and fT_3 are usually increased, though this does not correlate with clinical severity: TSH is often undetectable
- Hyperglycaemia in non-diabetics
- Leucocytosis with a left shift, even in the absence of infection (leucopenia may be present in patients with Grave's disease)
- Abnormal liver function tests and hyperbilirubinaemia
- Hypercalcaemia due to haemoconcentration and the effect of thyroid hormones on bone resorption.
- Hypokalaemia and hypomagnesaemia (particularly in apathetic thyrotoxicosis)
- Serum cortisol should be elevated. If low values are found, adrenal insufficiency should be considered and treated. Adrenal reserve in thyrotoxic patients is often exceeded in the absence of absolute adrenal insufficiency.

MANAGEMENT

Patients with thyroid storm or an impending crisis should be treated in the intensive care or high-dependency unit. This permits close monitoring and treatment of cardiac and neurological dysfunction and correction of accompanying dehydration and electrolyte imbalances.

Treatment is aimed at:

- Control and relief of adrenergic symptoms
- Correction of thyroid hormone abnormalities
- Resolving the precipitating cause
- Investigation and treatment of the underlying thyroid disease
- Supportive measures

β-ADRENERGIC BLOCKADE

This is the mainstay of controlling adrenergic symptoms.[22] Intravenous propranolol titrated in 0.5–1 mg increments while monitoring cardiovascular response diminishes the systemic hypersensitivity to catecholamines. In addition, it inhibits peripheral conversion of T_4 to T_3.[23] Concurrent administration of enteral propranolol is the norm, with doses as high as 60–120 mg 4–6 hourly often being necessary due to enhanced elimination during thyroid crisis.[24] An alternative regimen uses intravenous esmolol with a loading dose of 250–500 μg/kg followed by infusion at 50–100 μg/kg per minute. This allows rapid titration of β-blockade while minimising adverse reactions.[25] Patients with contraindications to β-blockade or who exhibit resistance to this treatment may be successfully treated with reserpine or guanethidine though their onset of action is slow and side effects may be significant.

DIGOXIN

Control of heart rate and rhythm may result in significant improvement in cardiac performance. Electrolyte imbalance, particularly hypokalaemia and hypomagnesaemia, should be corrected prior to drug therapy. Relative resistance to digoxin may occur due to increased renal clearance[26] and increased Na/K ATPase units in

cardiac muscle.[27] Arterial thromboembolic phenomena are common (10%–40%) in thyrotoxicosis-related atrial fibrillation. This may be due to a procoagulant state or an increased incidence of mitral valve prolapse. Anticoagulation is controversial, given the increased sensitivity to warfarin and potential for bleeding; however, it should be considered in the management of these patients.

AMIODARONE

Amiodarone has theoretical benefits in thyrotoxicosis as it inhibits peripheral conversion of T_4 to T_3 and reduces the concentration of T_3-induced adrenoceptors in cardiac myocytes.[28] It does, however, cause profound (and sometimes physiologically irrelevant) changes to thyroid function tests and should not therefore be used as the first-line agent.

THIONAMIDES

These drugs block de novo synthesis of thyroid hormones within 1–2 hours of administration, but have no effect on the release of preformed glandular stores of thyroid hormones. Transient leucopenia is common (20%) and agranulocytosis can rarely occur with carbimazole use.

Propylthiouracil

This is usually considered the drug of choice in thyroid storm due to its ability to partially block peripheral conversion of T_4 to T_3. Its main mechanism of action is to block the iodination of tyrosine. Only enteral preparations are available and absorption may be unpredictable during thyroid crisis. Rectal administration has been reported. The initial dose is 200 mg every 4 hours.

Methimazole

Methimazole lacks peripheral effects, but has a long duration of action making administration easier and more reliable. It may be used in combination with drugs that block peripheral T_4-to-T_3 conversion (such as iopanoate or ipodate). Only enteral preparations are available, though rectal administration has been reported. The initial dose is 20 mg every 6 hours.

Carbimazole

This is metabolised to methimazole and is rarely associated with agranulocytosis. Only enteral preparations are available.

IODINE

The release of preformed glandular thyroid hormones is inhibited by administering either inorganic iodine or lithium. Enterally administered iodides include Lugol's solution and sodium or potassium iodide. Intravenous infusion of sterile sodium iodide may be used at a dose of 1 g 12 hourly; however, this is not always available commercially. If not, it may be prepared by the hospital pharmacy. Iodine therapy should not commence without prior thionamide administration. Used alone, it will enrich hormone stores within the thyroid gland and exacerbate thyrotoxicosis.

Iodine-containing contrast media (e.g. ipodate and iopanoate) may be used instead of the simple iodides, the former blocking T_4-to-T_3 conversion and inhibiting the cardiac effects of thyroxine. Ipodate is administered orally as a loading dose of 3 g followed by 1 g daily. As with the iodides, treatment should always be preceded by thionamide administration.

LITHIUM

Lithium carbonate has a similar, though weaker action to iodine and can be used in patients with iodine allergy. An initial dose regime of 300 mg 8-hourly has been used with subsequent dosage adjusted to maintain serum drug levels at about 1 mmol/L.[29] Renal and neurological toxicity tend to limit its use.

STEROIDS

Glucocorticoids reduce T_4-to-T_3 conversion and may modulate any autoimmune process underlying the thyroid crisis (e.g. Grave's disease). In addition, relative glucocorticoid deficiency may be a feature of the crisis. An adrenocorticotropic hormone (ACTH) stimulation test is desirable prior to administration of hydrocortisone (100 mg 6–8-hourly); alternatively, dexamethasone (4 mg 6-hourly) can be administered until the test has been performed. Combination therapy with iodides can produce rapid results. Glucocorticoids are the most effective treatment for type-2 amiodarone-induced thyrotoxicosis.[30]

OTHER THERAPIES

Plasmapheresis, charcoal haemoperfusion and dantrolene have all been used as novel therapies in thyroid storm; however, their use is not established or proven.

SUPPORTIVE THERAPY

Fluid management

Fluid management may be extremely difficult in patients suffering from thyroid storm, particularly the elderly. Fluid losses may be profound due to diarrhoea, vomiting, pyrexia and reduced intake. However, congestive cardiac failure may also develop as a result of the high cardiac demand. Echocardiography and cardiac output monitoring may be invaluable in guiding therapy for such patients.

Temperature control

Usually this can be achieved via passive cooling, but refractory hyperpyrexia has been successively treated with active measures such as endovascular cooling.[31]

Nutrition

Thyrotoxic patients have high energy expenditure and may present with a significant energy, vitamin and

nitrogen deficit. Nutritional requirements should take account of any deficit and the ongoing hypercatabolic state. Thiamine is usually supplemented.

Drug therapy

Consideration should be given to the enhanced metabolism and elimination of drugs that occurs in thyrotoxic patients. Salicylates and furosemide should be avoided, as they both displace thyroid hormones from their binding proteins and can rapidly exacerbate systemic symptoms.

Precipitating factors

Both the precipitating factors and the disease process underlying the thyroid crisis should be sought and treated aggressively. Infection is the leading precipitant of crisis; thus, early microbiological cultures and antibiotic therapy should be considered.

MYXOEDEMA COMA

Myxoedema coma is the extreme manifestation of hypothyroidism which, although rare, carries a mortality ranging from 30% to 60%. The term is a misnomer in that the majority of patients present with neither the non-pitting oedema known as myxoedema nor coma.[32] The condition should be considered in any patient presenting with reduced level of consciousness and hypothermia. The crisis occurs most commonly in elderly women with long-standing undiagnosed or undertreated hypothyroidism in whom an additional significant stress is experienced. Numerous precipitating factors have been identified (Box 61.4).

Box 61.4 Factors precipitating myxoedema coma

- Infection
- Cold environmental temperatures/hypothermia
- Burns
- Stroke
- Surgery
- Trauma
- Congestive heart failure
- Carbon dioxide retention
- Gastrointestinal haemorrhage
- Hypoglycaemia
- Medications
  - Amiodarone
  - Anaesthetic agents
  - Analgesics/narcotics
  - Beta blockers
  - Diuretics
  - Lithium
  - Phenytoin
  - Rifampicin
  - Sedatives/tranquilisers

CLINICAL PRESENTATION

Myxoedema coma can be defined when decreased mental status, hypothermia and clinical features of hypothyroidism are present (Box 61.5). When these features are present, diagnosis is straightforward; however, asymptomatic or atypical presentation (e.g. decreased mobility) may occur.[33] The presence of hypotension and bradycardia at presentation, a need for mechanical ventilation, hypothermia unresponsive to treatment, sepsis, intake of sedative drugs, lower Glasgow Coma Scale (GCS), high APACHE II score, and high SOFA score have been associated with an increased predicted mortality.[34]

NEUROMUSCULAR

Alteration of conscious or mental state is present in all patients. This can range from personality changes to coma with about 25% of patients experiencing seizures prior to the onset of coma. Electroencephalogram usually reveals non-specific changes. Weakness is common and skeletal muscle dysfunction may develop secondary to increased membrane permeability. The latter can lead to a rise in creatine phosphokinase. Hyponatraemia is present in up to 50% of patients and may contribute to alterations in conscious level. Lumbar puncture often reveals elevated protein levels and a high opening pressure.

HYPOTHERMIA

Hypothermia represents the decrease in thermogenesis that accompanies reduced metabolism and is exacerbated by low ambient temperatures. Mortality is proportional to the degree of hypothermia. A low-reading thermometer should be used during assessment.

CARDIOVASCULAR FEATURES

Diastolic hypertension is due to increased systemic vascular resistance and blood volume reduction[35]; however, myxoedema is associated with bradycardia and impaired myocardial contractility, with reduced cardiac output and hypotension a common feature. While pericardial effusions may occur, tamponade is uncommon. Creatine phosphokinase may be elevated, though this more commonly originates from skeletal rather than cardiac muscle. Acute coronary syndrome must nevertheless be excluded as a precipitant of the crisis. Electrocardiography (ECG) changes include bradycardia, decreased voltage, non-specific ST and T changes, varying types of block and prolonged QT interval. All of the cardiovascular abnormalities are reversible with thyroid hormone treatment.[36]

Box 61.5 Clinical features of myxoedema coma

- Neuromuscular
  - Abnormal conscious level
  - Psychiatric alterations
  - Weakness
  - Slow relaxing reflexes
  - Fatigue
- Hypothermia
- Cardiovascular
  - Diastolic hypertension
  - Bradycardia
  - Low cardiac output
  - Pericardial effusions
  - Electrocardiography alterations
- Respiratory
  - Diminished central response to hypoxia and hypercapnia
  - Respiratory alkalosis
  - Respiratory muscle weakness
  - Increased sensitivity to sedative drugs
  - Pleural effusions
  - Sleep apnoea
- Airway
  - Deep voice, goitre, vocal cord oedema, macroglossia
- Gastrointestinal
  - Gastric atony, distension, paralytic ileus, faecal impaction and megacolon (late)
  - Weight gain
  - Malabsorption
  - Ascites (rare)
- Bladder distension, urinary retention
- Cold intolerance
- Coarse hair
- Dry, pale, cool skin
- Laboratory abnormalities
  - Hyponatraemia
  - Hypoglycaemia

RESPIRATORY FEATURES

Hypothyroidism causes numerous respiratory alterations (see Box 61.5). There is a propensity to respiratory alkalosis, particularly during artificial ventilation. This is due to low metabolic rate which may be compounded by iatrogenic hyperventilation.[37] Diaphragmatic weakness may occur due to abnormalities of the phrenic nerve; as a result, exercise tolerance may be significantly reduced. These abnormalities improve with thyroid hormone replacement, though full recovery can take several months.

LABORATORY FINDINGS

TFTs will reveal low T_4 and T_3; TSH is raised in primary and low in secondary and tertiary hypothyroidism.

Hyponatraemia is common and usually develops due to free water retention resulting from excess vasopressin secretion or impaired renal function.[38] It may be severe and can contribute to diminished mental function. Although total body water is increased, intravascular volume is usually decreased.

Hypoglycaemia may result from hypothyroidism alone, or as a result of concurrent adrenal insufficiency (Schmidt's syndrome). The mechanism is probably reduced gluconeogenesis, but infection and starvation may contribute.

Azotaemia and hypophosphataemia are common; renal function may be severely abnormal due to low cardiac output and vasoconstriction. Mild leucopenia and normocytic anaemia are frequently present, though macrocytic and pernicious anaemia due to autoimmune dysfunction may occur.

Arterial blood gases often reveal respiratory acidosis, hypoxia and hypercapnia.

MANAGEMENT

The mainstay of therapy consists of thyroid hormone replacement, steroid replacement and supportive measures. Once clinical diagnosis has been made or is suspected, blood should be collected for thyroid function and plasma cortisol tests. This should be followed by thyroid hormone treatment, which should not be delayed to await laboratory results. Consideration should be given to identifying and treating precipitating factors and complications of the crisis.

THYROID HORMONE THERAPY

All patients with suspected myxoedema coma should receive presumptive treatment with thyroid hormone. The optimum speed, type, route and dose of thyroid hormone replacement in myxoedema coma are unknown due to the rarity of the condition and paucity of trials. The severity of clinical presentation does not correlate with the doses of replacement hormone that are required. Rapid replacement can result in life-threatening myocardial ischaemia or arrhythmias; delayed therapy exposes patients to prolonged risk of complications from the crisis. Both scenarios are associated with increased mortality.

Some experts favour administration of T_3, as it is biologically more active, has more rapid onset of action, and bypasses the impaired de-iodination of T_4 to T_3 which occurs in hypothyroidism and non-thyroidal illness. High serum T_3 concentration has, however, been associated with increased mortality[39] and T_3 is expensive and may be difficult to obtain. T_3 may be administered orally or intravenously and has been combined with T_4 therapy.[40,41] In one study of 23 successive patients suffering from myxoedema coma, those who received oral L-thyroxine had no difference in outcome from those receiving intravenous (IV) thyroxine.[34]

Most authorities recommend use of T_4 alone,[39,41,42] as the delayed conversion to T_3 allows more gradual

replacement of the deficient hormone. Bioavailability of orally administered T_4 is unpredictable given the high incidence of gastrointestinal dysfunction; therefore, intravenous administration is more frequently used. A loading dose of intravenous levothyroxine 100–500 µg is recommended,[41] as this saturates the binding proteins. This should be followed by 50–100 µg daily until conversion to the bioequivalent oral formulation is possible. The doses must be adjusted to allow for patient age, weight and their cardiovascular risk factors; the lower doses should be administered to patients who are elderly, frail or have co-morbidities (particularly cardiovascular disease).

CORTICOSTEROIDS

Corticosteroids are an important part of treatment, as relative or absolute hypoadrenalism may occur concurrently with hypothyroid disease. A random serum cortisol level should be collected prior to commencing hydrocortisone therapy at 100 mg 8-hourly. If ACTH stimulation test is warranted, dexamethasone 4 mg 6-hourly should be commenced with conversion to hydrocortisone or cessation of treatment once the results are known. If random serum cortisol levels return at normal levels, steroid treatment can be discontinued.

SUPPORTIVE THERAPY

Hypothermia should be treated by passive re-warming where possible but active measures may be required. Appropriate cardiovascular, temperature gradient, electrolyte and acid-base monitoring should be provided during the re-warming phase in order to prevent haemodynamic and metabolic compromise.

Numerous alterations in respiratory physiology occur, including hypoventilation and altered response to arterial oxygen and carbon dioxide tensions. In addition, anatomical changes to the airway, delayed gastric emptying and increased sensitivity to sedative drugs may be present. These changes should be considered when mechanical ventilation is required, particularly during intubation and the weaning process.[37]

Patients usually present with intravascular fluid depletion despite peripheral oedema. Cardiac output monitoring may help guide fluid resuscitation and therapy. Echocardiography is useful in identifying cardiac dysfunction, pericardial effusions and assisting in assessment of intravascular volume status. Cardiac monitoring should be used to alert to the presence of arrhythmias. Inotropes and vasopressors should be avoided where possible due to their potential to precipitate cardiac arrhythmias. Where inotropes are required, increased dosage may be necessary as reduction in β-adrenoceptors is common. α-Adrenoceptor function is usually preserved.

Hyponatraemia is reversible with thyroid hormone treatment, but severe abnormalities contributing to neurological dysfunction may require more expeditious correction. Free water intake should be restricted and hypertonic saline solutions may be required. Hypotonic fluid therapy should be avoided. If glucose therapy is required, hypertonic solutions (20%–50%) should be infused via a central venous catheter.

Precipitating factors must be considered. As with all critically ill patients, microbial cultures should be collected and antibiotic therapy commenced unless cultures are negative. Prophylaxis against venous thromboembolism and peptic ulceration should be considered. Enteral feeding should be attempted but may be unsuccessful if gastrointestinal dysfunction and stasis is present.

NON-THYROIDAL ILLNESS

Non-thyroidal illness describes the phenomenon of starved or systemically unwell patients with abnormal serum TFTs but with no apparent thyroidal illness. Low T_3, T_4 and TSH are commonly found, the degree of abnormality correlating with the severity of illness. Variants of these hormone levels are well described. Low serum T_3 is a frequent finding and occurs due to down-regulation of the monodeiodinase enzyme that converts T_4 to T_3, while rT_3 may increase due to increased activity of the T_4-to-rT_3 monodeiodinase.[43]

Serum T_4 is also commonly low in the critically ill. This is due to a decrease in the concentration of thyroid hormone binding proteins and the presence of inhibitors that reduce T_4 binding to these proteins. There is also suggestion that T_4 entry into cells may be impaired.[44] Free T_4 levels should be normal in less severe illness; however, in severe illness, the level may be low due to inadequate correction during the fT_4 assay.[45]

Low serum TSH levels were previously thought to be associated with the euthyroid state; however, more recent work suggests that acquired transient central hypothyroidism is present in these patients.[46] Cytokines such as tumour necrosis factor-α are known to inhibit TSH secretion. Such phenomena are probably evolutionary adaptations to conserve protein and energy during severe illness. Elevated TSH may also occur in nonthyroidal illness, but few of these patients prove to have hypothyroidism following recovery from their acute illness.

Changes in TFT are well described during starvation, sepsis, bone marrow transplantation, surgery, myocardial infarction, coronary artery bypass surgery, and probably any critical illness. However, replacement of thyroid hormone in these patients is of no benefit and may be harmful[47]; hence, thyroid function should not be assessed in critically ill patients unless there is a strong clinical indication to do so. A number of specific nonthyroidal illnesses are associated with abnormal TFTs. These include some psychiatric illnesses, hepatic disease, nephritic syndrome, acromegaly,

Table 61.2 Changes in thyroid hormone concentrations

	FT_4	T_3	TSH

Hyperthyroid	↑	↑	↓
Hypothyroid	↓	↓ N	↑
Non-thyroidal illness	↑ N ↓	↓	N ↓

↑, Increased; ↓, decreased; *FT_4*, free tetraiodothyronine; *N*, normal; *T_3*, triiodothyronine; *TSH*, thyroid-stimulating hormone.

acute intermittent porphyria and Cushing's syndrome. Where assays are performed, TSH should not be interpreted in isolation as low values will not discriminate between true thyroid versus nonthyroidal disease. If low T_4 is also present, nonthyroidal illness is likely. If T_4 is elevated, then hyperthyroidism is the likely diagnosis, though elevated T_4 has been documented in nonthyroidal illness.

Given the alterations in these hormones and difficulties with their assay during critical illness, thyroid hormone replacement should not be undertaken on the strength of TFT results alone; additional laboratory and clinical indications must also be present (Table 61.2).

Adrenocortical insufficiency in critical illness

Balasubramanian Venkatesh, Jeremy Cohen

The adrenal glands form an essential part of the organism's response to stress. Hence, in intensive care, an adequate adrenal response is considered to be of prime importance. Whilst primary adrenal insufficiency (AI) is a well-recognised but rare condition in intensive care, secondary, or relative AI is thought to be more prevalent. Adrenocortical insufficiency may present as an insidious, occult disorder, unmasked by conditions of stress, or as a catastrophic syndrome that may result in death.

PHYSIOLOGY

The adrenal glands are functionally divided into medulla and cortex; the latter is responsible for the secretion of three major classes of hormones: glucocorticoids (GCs), mineralocorticoids and sex hormones. The major pathogenic effects of disease result from cortisol and aldosterone deficiency.

Cortisol, the major GC synthesised by the adrenal cortex, plays a pivotal role in normal metabolism. It is necessary for the synthesis of adrenergic receptors, normal immune function, wound healing, and vascular tone. These actions are mediated by the GC receptor, a member of the nuclear hormone receptor superfamily. The activated receptor migrates to the nucleus and binds to specific recognition sequences within target genes, but also interacts with numerous transcription factors and cytosolic proteins. Numerous isoforms of the GCs receptor have now been described; the alpha subtype, a 777 amino acid polypeptide chain, was initially felt to be the primary mediator of GC action. In contrast, the beta isoform, a 742 amino acid chain, was felt to have no physiological activity. More recently it appears that the beta subtype has a negative effect on alpha–mediated gene transactivation, the physiological relevance of which remains controversial. Furthermore, additional isoforms have now been described, suggesting that GC receptor diversity may be an important factor in understanding the complex effects of corticosteroid action.[1]

Under normal circumstances, cortisol is secreted in pulses, and in a diurnal pattern.[2] The normal basal output of cortisol is estimated to be 15–30 mg/day, producing a peak plasma cortisol concentration of 110–520 nmol/L (4–19 μg/dL) at 8–9 a.m., and a minimal cortisol level of less than 140 nmol/L (<5 μg/dL) after midnight. The daily output of aldosterone is estimated to be 100–150 μg/day.

Secretion is under the control of the hypothalamic-pituitary axis. There are a variety of stimuli to secretion, including stress, tissue damage, cytokine release, hypoxia, hypotension and hypoglycaemia. These factors act upon the hypothalamus to favour the release of corticotropin releasing hormone (CRH) and vasopressin. CRH is synthesised in the hypothalamus and carried to the anterior pituitary in portal blood, where it stimulates the secretion of adrenocorticotropic hormone (ACTH), which in turn stimulates the release of cortisol, mineralocorticoids (principally aldosterone) and androgens from the adrenal cortex. CRH is the major (but not the only) regulator of ACTH release and is secreted in response to a normal hypothalamic circadian regulation and various forms of 'stress'. Vasopressin, oxytocin, angiotensin II and β-adrenergic agents also stimulate ACTH release while somatostatin, β-endorphin and enkephalin reduce it. Cortisol has a negative feedback on the hypothalamus and pituitary, inhibiting hypothalamic CRH release induced by stress, and pituitary ACTH release induced by CRH. During periods of stress, trauma or infection, there is an increase in CRH and ACTH secretion and a reduction in the negative feedback effect, resulting in increased cortisol levels, in amounts roughly proportional to the severity of the illness.[3–5]

Cortisol is transported in the blood to the tissues in three fractions; approximately 80% is closely bound to corticosteroid binding globulin (CBG), 10%–15% loosely bound to albumin, and 5%–8% as a free fraction. At normal levels of total plasma cortisol (e.g. 375 nmol/L or 13.5 μg/dL), less than 5% exists as free cortisol in the plasma; however, it is this free fraction that is biologically active. Circulating CBG concentrations are approximately 700 nmol/L. In normal subjects CBG can bind approximately 700 nmol/L (i.e. 25 μg/dL).[6] At levels greater than this, the increase in plasma cortisol is largely in the unbound fraction. The affinity of CBG for synthetic corticosteroids, with the exception of prednisolone, is negligible. CBG is a

ABSTRACT

Dysfunction of the hypothalamo-pituitary adrenal axis has become a central feature in descriptions of the pathophysiology of sepsis and critical illness. Changes in glucocorticoid secretion and responsiveness, protein binding, and activity have been reported. These changes have been described by the terms 'relative adrenal insufficiency', or 'critical illness related corticosteroid insufficiency', and form part of the rationale for trials of glucocorticoid treatment in septic shock. However, despite hundreds of published articles, including literature reviews and consensus statements, controversy still exists regarding the fundamental nature of the disorder and its relevance to clinical management. The role of steroid supplementation in critical illness continues to be debated. This chapter attempts to establish a critical reappraisal of the evidence for adrenal dysfunction in critical illness, and explores the indications for corticosteroid supplementation in the management of a number of critical illnesses with special emphasis on sepsis and septic shock.

critical illness related corticosteroid insufficiency (CIRCI)

substrate for elastase, a polymorphonuclear enzyme that cleaves CBG, markedly decreasing its affinity for cortisol.[7] This enzymatic cleavage results in the liberation of free cortisol at sites of inflammation. CBG levels have been documented to fall during critical illness,[8–10] and these changes are postulated to increase the amount of circulating free cortisol.

Cortisol is lipophilic and diffuses into the cell freely. However, once inside the cell the concentrations of cortisol are profoundly affected by the activity of the 11β-Hydroxysteroid dehydrogenase 1 & 2 (11β-HSD 1 & 2) enzyme system.[11–14] 11β-HSD1 acts in vivo primarily as a reductase, generating active cortisol from inactive cortisone. By contrast, 11β-HSD2 has dehydrogenase action, inactivating cortisol by conversion to cortisone. 11β-HSD2 is found primarily in mineralocorticoid target tissues such as kidney, sweat glands and colonic mucosa, where it prevents illicit activation of the mineralocorticoid receptor by cortisol. 11β-HSD1 has a wide distribution including liver, adipose and vascular tissues, and whilst its primary action is reductase, there is some evidence its directionality may be tissue specific.[15] The system is able to regulate intracellular GC concentration irrespective of circulation concentration, thus rendering circulating levels highly problematic as indicators of tissue GC activity. Altered HSD status has been reported in critical illness.[16,17]

Cortisol has a half-life of 70–120 minutes. It is eliminated primarily by hepatic metabolism and glomerular filtration. The excretion of free cortisol through the kidney represents 1% of the total secretion rate. Currently, available routine assays measure only total cortisol levels, bound and free.

The metabolic effects of cortisol are complex and varied. In the liver, cortisol stimulates glycogen deposition by increasing glycogen synthase and inhibiting the glycogen-mobilising enzyme glycogen phosphorylase.[18] Hepatic gluconeogenesis is stimulated, leading to increased blood glucose levels. Concurrently, glucose uptake by peripheral tissues is inhibited.[19] Free fatty acid release into the circulation is increased, and triglyceride levels rise.

In the circulatory system, cortisol increases blood pressure both by direct actions upon smooth muscle and via renal mechanisms. The actions of pressor agents such as catecholamines are potentiated, whilst nitric oxide-mediated vasodilation is reduced.[20,21] Renal effects include both an increase in glomerular filtration rate, sodium transport in the proximal tubule, and sodium retention and potassium loss in the distal tubule.[22]

The primary effects of cortisol upon the immune system are anti-inflammatory and immunosuppressive. Lymphocyte cell counts decrease, whilst neutrophil counts rise.[22] Accumulation of immunologically active cells at inflammatory sites is decreased. The production of cytokines is inhibited, an effect that is mediated via nuclear factor kappa B (NF-kB). This occurs both by induction of NF-kB inhibitor, or by direct binding of cortisol to NF-kB, thus preventing its translocation to the nucleus. Whilst the well-defined effects of cortisol upon the immune system are primarily inhibitory, it is also suggested that normal host defense function requires some cortisol secretion. Cortisol has been described to have a positive effect upon immunoglobulin synthesis, potentiation of the acute phase response, wound healing, and opsonisation.[23]

CLASSIFICATION

AI may be considered to be primary, secondary or relative. Primary AI, otherwise known as Addison's disease, results from hypofunction of the adrenal cortex. Secondary AI occurs when there is suppression or absence of ACTH secretion from the anterior pituitary. In the setting of critical illness, a further classification has been proposed – that of critical illness related corticosteroid insufficiency (CIRCI). CIRCI represents a situation of disturbed GC metabolism which may result in an inadequate response to the physiological stress of severe illness.

PRIMARY ADRENAL INSUFFICIENCY

Primary AI or Addison's disease is a rare disorder. In the Western world its estimated prevalence is 120 per million.[24] In adulthood, the commonest cause is autoimmune, but in the intensive care setting, consideration should be given to other causes of adrenal gland destruction (Box 62.1). These include infection, haemorrhage and infiltration. Tuberculosis is the commonest

Box 62.1 Causes of primary adrenal insufficiency

  - Metyrapone
  - Suramin
  - Rifampicin
  - Phenytoin
- Congenital
  - Adrenal dysgenesis
  - Adrenoleucodystrophy
  - Impaired steroidogenesis
- Cytokine mediated

infective cause worldwide, but rarer infections such as histoplasmosis, coccidiomycosis and cytomegalovirus (CMV) (especially in patients with human immunodeficiency virus [HIV]) have also been implicated. Haemorrhage into the glands is associated with septicaemias, particularly meningococcal (Waterhouse-Friderichsen syndrome). Asplenia and the antiphospholipid syndrome may also be associated with adrenal haemorrhage. Adrenal gland destruction may also be secondary to infiltration with tumour, or amyloid.

Drugs may impair adrenal function either by inhibiting cortisol synthesis (etomidate, ketoconazole) or by inducing hepatic cortisol metabolism (rifampicin, phenytoin). High levels of circulating cytokines are also reported to have a suppressive effect upon ACTH release.[25]

PRESENTATION (BOX 62.2)

The disease is often unrecognised in its early stages, as the presenting features are ill-defined. Symptoms include tiredness and fatigue, vomiting, weight loss, anorexia and postural hypotension. Hyperpigmentation is seen in non-exposed areas (such as palmar skin creases) and is due to the hypersecretion of melatonin, a breakdown product from the ACTH precursor pro-opiomelanocortin.

Presentation to an intensive care physician is likely to be in the form of adrenal crisis. This may be precipitated by concurrent illness or surgery, or by failure to take replacement medication. Classically adrenal crisis will present as refractory shock with a poor response to inotropic or pressor agents. Abdominal or flank pain is often present and may lead to an erroneous diagnosis of an acute surgical abdomen.

Treatment should consist of immediate supportive measures, fluid resuscitation, and high-dose intravenous GC therapy. *A standard dose would be 100 mg of hydrocortisone 6-hourly, or as an infusion.* At these doses, separate mineralocorticoid replacement is not required.[26]

Box 62.2 Clinical features of Addison's disease

Symptoms	**Signs**
Muscular weakness	Hyperpigmentation – skin creases, buccal mucosa
Fatigue	Postural hypotension
Abdominal pain	Associated vitiligo
Vomiting	Decreased axillary and pubic hair
Diarrhoea	Auricular calcification
Salt craving	Vasodilated shock (in crisis)
Weight loss	
Arthralgia and myalgia	
Mood change	
Headache	
Sweating	
Syncope	

Adrenal crisis should be suspected in cases of undifferentiated shock not responding to standard management. Suggestive features would include a history of symptomatology consistent with the diagnosis, hyperpigmentation on examination, and demonstration of hyponatraemia, hyperkalaemia, and peripheral blood eosinophilia. A random plasma total cortisol taken during a crisis will be low (below 80 nmol/L) and in the acute phase ACTH stimulation testing is not required.

SECONDARY ADRENAL INSUFFICIENCY

The commonest cause of ACTH deficiency is sudden cessation of exogenous GC treatment. Patients who have been taking more than 30 mg/day of hydrocortisone or equivalent for more than 3 weeks are at risk of adrenal suppression.[22] Other causes include pituitary surgery, pituitary infarction (Sheehan's syndrome), or pituitary tumour.

Presentation is similar to that of primary AI. The major distinguishing characteristics are a lack of hyperpigmentation, and the absence of mineralocorticoid deficiency; hence, hyperkalaemia is not a feature of secondary AI, although hyponatraemia may still be present due to increased vasopressin levels.

INVESTIGATION OF ADRENAL INSUFFICIENCY

In a stable patient, suspected AI is routinely investigated by an ACTH stimulation test. The test is performed by administering 250 µg of a synthetic ACTH molecule comprising of the first 24 amino acids: tetracosactrin (Synacthen). Plasma total cortisol is measured at 0 and 30 minutes after administration, and a normal response is defined as a peak cortisol measurement over 525 nmol/L.[27] However, it should be noted that current immunoassays exhibit a significant degree of variability, and thus local laboratory reference ranges should be used.[28] The test cannot be performed if the patient is currently being prescribed hydrocortisone as this will cross react with the assays; *an alternative replacement therapy such as dexamethasone should be used in these cases.*

Secondary AI may be differentiated from primary by a prolonged ACTH test. This is performed by the use of a depot preparation or an intravenous infusion of tetracosactrin for 24–48 hours. Patients with secondary hypoadrenalism show a greater plasma cortisol response at 24 hours than at 4 hours; alternatively, measurement of a baseline ACTH level may be used. In patients with primary AI this will be elevated.

Other biochemical tests that may be used in investigation of AI include the insulin hypoglycaemia test, the overnight metyrapone test, and the CRH stimulation test. These investigations are not normally necessary in uncomplicated cases. In addition, the use of the low-dose ACTH stimulation test has been advocated in which only 1 µg of tetracosactrin is used. This approach has not yet gained widespread acceptance.

Critical illness related corticosteroid insufficiency

Substantial alterations in GC metabolism occur in response to critical illness.

Annane et al. prospectively studied 189 patients with septic shock and detailed a three-level classification system based upon the basal cortisol level and response to ACTH.[29] Mortality was found to be highest in those patients with a basal cortisol level above 34 μg/dL (938 nmol/L) and response to ACTH of less than 9 μg/dL (248 nmol/L). Patients with a basal cortisol above 34 μg/dL but a cortisol response greater than 9 μg/dL did better, whilst the best prognosis was seen in the group with a lower basal cortisol level and high response to ACTH. A similar pattern has been observed in numerous other studies of patients with both septic and non-septic critical illness. The significance of this observation, however, is not clear. It has been suggested to either represent a partially suppressed adrenal axis, implying a role for cortisol replacement therapy, or alternatively as indicating an 'overstressed' axis, in which case steroid treatment would be inappropriate. Treatment of septic patients fulfilling CIRCI criteria with hydrocortisone has been shown to improve outcome only in one study,[30] but these results have not been widely accepted. Alternative diagnostic criteria, relying on baseline plasma cortisol levels without ACTH stimulation, have been proposed,[31] but the lack of a consistently observed relationship between cortisol levels and mortality means that the optimal diagnostic criteria for CIRCI remain controversial (Box 62.3). Possible explanations for the difficulties in assessing adrenal function in this patient group include spontaneous fluctuations in the measured cortisol values,[32] increased variability of assays,[28] and changes in CBG levels affecting free cortisol values.[10,33] Measurement of the free cortisol fraction, representing the bioavailable active hormone, has been the focus of recent research interest, with some evidence suggesting it may give a more accurate representation of adrenal function.[10,33] However, the superiority of free cortisol estimations is by no means clear[16,34,35] and the limited availability of the assay means the test is not in general clinical use.

An alternative hypothesis put forward to explain the constellation of adrenocortical changes in critical illness is a sick euadrenal syndrome analogous to the sick euthyroid state,[36] in which changes in the free cortisol fraction, intracellular cortisol:cortisone interconversion, GC receptor density and gene transcription may all act to affect adrenal function at a tissue level. The complexity of this system suggests that simple measurement of total plasma cortisol levels may only give a partial insight into the true functioning of the 'stress response' in the critically ill. Recent evidence indicates that tissue sensitivity to the action of GCs in patients with septic shock is highly variable, and cannot be accurately assessed using plasma cortisol concentrations.[37]

Box 62.3 Controversies in the diagnosis of adrenal insufficiency in the critically ill

1. Limitations of a random cortisol
   a. In the critically ill there is a marked fluctuation in plasma cortisol concentration limiting the utility of a random cortisol[32]
   b. The 'normal' range of cortisol in critical illness is not defined
   c. There is no consensus 'cut-off' value below which adrenal insufficiency is present
2. Limitations of total cortisol
   a. Free cortisol is the bio-active fraction of cortisol
   b. There is large variation in total cortisol assay results when the same specimen is tested in different laboratories and using different assays[28]
   c. Peripheral tissue-specific glucocorticoid resistance is not tested
3. Limitations of the conventional Synacthen test
   a. The HDSST results in plasma Synacthen concentrations that are supraphysiological
   b. Published data may have overestimated the incidence of adrenal insufficiency, as many studies have not excluded patients who received etomidate
   c. The low-dose SST may be a better predictor of outcome

HDSST, High dose short Synacthen test; *SST,* short Synacthen test.

Box 62.4 Proven role for steroids in critical illness

1. Addisonian crisis
2. Anaphylaxis
3. Asthma
4. Bacterial meningitis
5. Chronic obstructive pulmonary disease (COPD) with acute respiratory failure
6. Croup
7. Hypercalcaemia
8. Fulminant vasculitis
9. Idiopathic thrombocytopenic purpura
10. Myasthaenic crisis
11. Myxoedema coma
12. Organ transplantation
13. Pneumocystis carinii pneumonia
14. Thyroid storm

STEROID THERAPY IN CRITICAL ILLNESS

Steroids have an established role in the management of a number of critical illnesses as outlined in Box 62.4. However, their use in other conditions has not been without controversy.

SPINAL INJURY

High-dose methylprednisolone has been advocated in the management of patients with spinal cord injury

following the publication of the National Acute Spinal Cord Injury Study (NASCIS) II and III trials. The major criticism of these studies is the lack of a demonstrable improvement in the primary outcome measures. For a more detailed review of the use of steroids in spinal cord injury, the reader is referred to Chapter 80.

HEAD INJURY

The role of steroids in the management of cerebral oedema secondary to tumours is well documented and accepted. However, their role in the management of head injury has been the subject of intense debate. Several prospective studies have not been able to prove any benefit with steroids in head trauma. However, these studies were not adequately powered to detect a difference. The recent Corticosteroid Randomisation After Significant Head Injury (CRASH) trial with nearly 10,000 patients clearly demonstrated the lack of any benefit with steroids in head injury.[38]

However, a more recent study of multiple trauma suggested that patients fulfilling criteria for CIRCI had a lower rate of development of ventilator-associated pneumonia when treated with hydrocortisone[39]; these findings were more marked in patients with head injury. A replication study, however, failed to confirm this finding.[40]

ACUTE RESPIRATORY DISTRESS SYNDROME

The acute respiratory distress syndrome (ARDS) clinical trial network published the results of its multicentre study where corticosteroids were administered to patients with ARDS persisting beyond 7 days. Although steroid use was associated with earlier ventilatory wean, improved arterial oxygenation and increased respiratory compliance, there was a higher rate of return to assisted ventilation and neuromuscular weakness.[41] No overall mortality difference was demonstrable between steroid and placebo groups. Commencement of steroids more than 2 weeks after onset of ARDS led to almost a fourfold increase in mortality as compared to the placebo group. Consequently, steroids cannot be routinely recommended for persistent ARDS and may be harmful in late-stage ARDS. Although one randomised controlled trial demonstrated some benefit in early ARDS, trial design issues preclude widespread application of these results.[42] Steroids were also not found to be of benefit in ARDS associated with severe H1N1 pneumonia.[43]

SEPTIC SHOCK

Since the first reported use of steroids in sepsis in 1951, therapy with this drug has undergone several transformations from 'steroid success' in sepsis and malaria in the 70s and early 80s to 'steroid excess' (30 mg/kg methylprednisolone) in severe sepsis in the mid to late 80s to total abandonment in early 90s and finally a resurgence of its use in the new millennium. The results of the only prospective randomised trial of steroids in septic shock by Annane[30] which found a beneficial effect have not been widely accepted owing to problems of randomisation, change of protocol and the use of etomidate (an adrenal suppressant drug) in the study. A European multicentre randomised trial of steroids in septic shock (CORTICUS)[44] did not demonstrate a mortality difference between steroids and placebo. Neither the CORTICUS trial ($N = 499$) nor the French study ($N = 299$) had adequate statistical power to demonstrate a clinically significant reduction in mortality. A recent meta-analysis[45] of 17 trials with 2138 patients reported reduced mortality in patients with septic shock treated with hydrocortisone. These conflicting data mean that the role of GC treatment in the management of septic shock is still uncertain. The most recent iteration of the Surviving Sepsis Campaign Guidelines suggests not using intravenous hydrocortisone if fluid resuscitation and vasopressor therapy are able to restore haemodynamic stability, and advised against the use of the ACTH test.[46] Subsequent to the publication of these guidelines, other studies have provided some further information in this field. A trial comparing vasopressin and noradrenalin either with or without hydrocortisone[47] (vasopressin vs norepinephrine as initial therapy in septic shock [VANISH]) found no beneficial effect of the hydrocortisone, contradicting a subgroup finding from a previous study.[48] The hydrocortisone for prevention of septic shock (HYPRESS) study[49] found no effect of hydrocortisone on the prevention of the development of shock in unshocked patients with severe sepsis. The role of fludrocortisone in septic shock also remains controversial. The study by Annane et al., quoted above, included a dose of 50 µg of fludrocortisone administered orally.[30] It has been argued, however, that doses of cortisol above 50 mg a day provide sufficient mineralocorticoid cover, and thus separate supplementation is unnecessary.[26] Furthermore, the oral route of administration is unreliable in critically ill patients. A study comparing fludrocortisone plus hydrocortisone versus hydrocortisone alone in septic patients failed to demonstrate a difference in outcome.[50]

The results of two large trials are awaited. An ANZICS CTG (Australia and New Zealand Intensive Care Society Clinical Trials Group) driven large multicentre randomised controlled trial (adjunctive corticosteroid treatment in critically ill patients with septic shock [ADRENAL]) of hydrocortisone in septic shock is underway (NCT01448109). This 3800 patient study is due to report its findings in 2017. Additionally, the APROCCHS (activated protein C and corticosteroids for human septic shock) trial (NCT00625209,

$N = 1200$), initially designed as a randomised factorial trial comparing activated protein C with hydrocortisone and fludrocortisone or placebo and converted to a randomised controlled trial to investigate the benefit to risk ratio of corticosteroids, completed enrolment in July 2016 and is due to report its findings soon.

CARDIAC ARREST

Little data exist on the role of GCs in post cardiac arrest patients with shock. Similarities between the post arrest shock state and septic shock have led some advocacy for the use of steroid therapy in this condition. A recent blinded randomised controlled trial, however, found no effect of hydrocortisone as compared with placebo on rate of shock reversal or mortality in vasopressor-dependent patients following cardiac arrest.[51]

PNEUMONIA

Adjunctive treatment with glucocorticoids has been advocated in the management of pneumonia as a strategy to reduce systemic effects of locally produced pulmonary cytokines. Results from these studies have been conflicting. A pilot study reported an improvement in oxygenation and mortality in patients with severe pneumonia treated with 7 days of hydrocortisone.[52] A larger trial in community-acquired pneumonia reported a reduced length of stay in patients receiving a 4-day course of dexamethasone; however, only 5% of these patients required intensive care unit (ICU) care.[53] Conversely, a trial of 7 days of prednisolone treatment in patients with community-acquired pneumonia showed no evidence of efficacy in either cure rate or length of stay[54] and a recent observational study of 316 patients with ICU acquired pneumonia suggested that systemic steroid treatment was associated with an increase in mortality.[55] More recent blinded randomised trials have observed a shorter time to clinical stability in hospitalised patients with pneumonia treated for 7 days with prednisolone,[56] as well as a reduced incidence of treatment failure.[57] A 2015 systematic review and meta-analysis suggested systemic corticosteroid therapy in this group reduced mortality by 3%, and need for mechanical ventilation by 5%.[58] At present GC treatment is not routinely recommended for critically ill patients with pneumonia; an exception would be for the case of *Pneumocystis jirovecii* infection in patients suffering from HIV.[59]

MENINGITIS

Randomised controlled trials have demonstrated the benefit of early steroid therapy in paediatric meningitis, particularly with *H. influenzae* infections. There is also evidence of benefit in adult patients with meningitis, particularly with pneumococcal infections. However, in cryptococcal meningitis associated with HIV infection there is evidence of harm (for more detail refer to Chapter 54).[60]

Box 62.5 Side effects of corticosteroid therapy

Adrenal suppression	Hypertension
Hypokalaemia	Osteoporosis
Glucose intolerance	Peptic ulcer disease
Truncal obesity	Glaucoma
Myopathy	Hyperlipidaemia
Mood alterations including psychosis	Aseptic necrosis of femoral/humeral head

SIDE EFFECTS OF STEROID THERAPY

Steroid therapy is associated with numerous side effects. Those that would be of particular relevance to intensive care are discussed below. A full list is given in Box 62.5.

1. Suppression of the adrenal axis (discussed above). Patients who have been receiving steroid treatment for less than a week are unlikely to be affected.
2. Hyperglycaemia – this may be associated with adverse outcomes in critically ill patients.[61]
3. Myopathy – steroid therapy is known to be associated with muscle weakness and also shown to be an independent risk factor for developing ICU acquired muscle paresis. This has significant clinical implications for weaning patients from mechanical ventilation.
4. Hypokalaemia.
5. Leucocytosis: Corticosteroids increase the neutrophil count by a shift from the marginating to the circulating pool. This effect may lead to concerns that the patient has developed an occult infection.
6. Poor wound healing.
7. Immunosuppression.
8. Pancreatitis.

Acute calcium disorders

Balasubramanian Venkatesh, Priya Nair

Calcium is an important cation and one of the principal electrolytes of the body. A total of 1–2 kg is present in the average adult, of which 99% is found in the bone. Of the remaining 1%, nine tenths is present in the cells and only a tenth in the extracellular fluid (ECF). In the plasma, 50% of the calcium is ionised, 40% bound to plasma proteins mainly to albumin and the remaining 10% is chelated to anions such as citrate, bicarbonate, lactate, sulphate phosphate and ketones. The chelated fraction is usually of little clinical importance, but is increased in conditions where some of these anionic concentrations might be elevated, as in renal failure. Whilst most calcium inside the cell is in the form of insoluble complexes, the concentration of intracellular ionised calcium is about 0.1 mmol/L, creating a gradient of 10,000:1 between plasma and intracellular fluid (ICF) levels of ionised calcium.[1] A schematic illustration of calcium distribution within the various body compartments is shown in Fig. 63.1.

Because ionised calcium is the biologically active component of ECF calcium with respect to physiological functions (Box 63.1) and is also the reference variable for endocrine regulation of calcium homeostasis, its measurement is recognised as being one of prime importance in the management of disorders of calcium homeostasis.

HORMONAL REGULATION OF CALCIUM HOMEOSTASIS

The concentration of ionised calcium in the plasma is subject to tight hormonal control,[3,4] particularly by parathyroid hormone (PTH). A G-protein coupled calcium receptor plays a significant role in the maintenance of calcium homeostasis. This receptor, responsible for sensing extracellular calcium concentration, is present on the cell membrane of the chief cells of the parathyroid and in bone, gut and the kidney. In response to ionised hypocalcaemia, PTH secretion is stimulated, which in turns serves to restore serum calcium levels back to normal by increasing osteoclastic activity in the bone and renal reabsorption of calcium and stimulating renal synthesis of 1,25 dihydroxy D (calcitriol – the active metabolite of Vitamin D). Calcitriol production is stimulated by hypocalcaemia, and inhibited by hypercalcaemia. Calcitriol increases serum calcium by largely promoting gut absorption, and to a lesser extent renal reabsorption of calcium.

Calcitonin, a hypocalcaemic peptide hormone produced by the thyroid, acts as a physiological antagonist to PTH. Although calcitonin has been shown to reduce serum calcium levels in animals by increasing renal clearance of calcium and inhibiting bone resorption, its role in humans is less clear. Despite extreme variations in calcitonin levels, for example, total lack in patients who have undergone total thyroidectomy, or excess plasma levels as seen in patients with medullary carcinoma of the thyroid gland, no significant changes in calcium and phosphate metabolism are seen. Calcitonin is useful as a pharmacological agent in the management of hypercalcaemia.

METABOLIC FACTORS INFLUENCING CALCIUM HOMEOSTASIS

Alterations in serum protein, pH, serum phosphate and magnesium closely impact on serum calcium concentrations. Total plasma calcium levels vary with alterations in plasma protein concentration. Several equations have been put forward for the adjustment of serum calcium in the face of alterations in serum protein concentrations. The validity of these equations are dependent upon the patient population, the methodology used for assessment of serum calcium and the reference intervals.[5] Clinicians often use simple rules of thumb – a correction is made for hypoalbuminaemia by adding 0.2 mmol/L to the measured serum calcium concentration for every 10 g/L decrease in serum albumin concentration below normal (40 g/L). The corresponding correction factor for globulins is 0.04 mmol/L of serum calcium for every 10 g/L rise in serum globulin.

Changes in pH alter protein binding of calcium. As the relationship between ionised calcium and changes in pH is well defined, iCa concentrations can be predicted for a given pH using the following formula:

ABSTRACT

Calcium is an important cation and one of the principal electrolytes of the body. Calcium is essential for a wide variety of physiological functions, ranging from muscle contractility, electrical conduction, cell growth, and neurotransmitter release. Disorders of calcium homeostasis are observed in critically ill patients, hypocalcaemia more common than hypercalcaemia. Over the past decade there has been considerable research into vitamin D supplementation in the critically ill patient, although the existing data are insufficient to make an evidence-based recommendation regarding its potential benefit in the intensive care unit. Newer drugs receptor activator of nuclear factor κB ligand (RANKL) are emerging for the management of hypercalcaemia in malignancy and they may have a role to play in the management of hypercalcaemia in critically ill patients. Debate also continues about the utility of ionised calcium measurements and the significance of ionised hypocalcaemia in critically ill patients. A randomised controlled trial of ionised calcium measurement and supplementation will inform clinical practice and guide therapy.

$$\text{corrected iCa at pH 7.4} = \text{measured iCa} \times [1 - (0.53 \times (7.40 - \text{measured pH}))]^{5}$$

Another rule of thumb is that an increase in pH by 0.1 pH units results in a decrease in ionised calcium by approximately 0.1 mmol/L.[6]

Table 63.1 Daily calcium balance

GASTROINTESTINAL TRACT	
Diet	600–1200 mg/day
Absorbed	200–400 mg/day
Secreted	150–800 mg/day
RENAL	
Filtered	11 000 mg/day
Reabsorbed (97% in the proximal convoluted tubule)	10 800 mg/day
Urinary calcium	200 mg/day
BONE	
Turnover	600–800 mg/day

Calcium and phosphate are closely linked by the following reaction in the ECF: $HPO_4^{2-} + Ca^{2+} = CaHPO_4$. Increases in serum phosphate shift the reaction to the right. When the calcium phosphate solubility product exceeds the critical value of 5 mmol/L, calcium deposition occurs in the tissues, resulting in a fall in serum calcium concentration and a secondary increase in PTH secretion. Reductions in phosphate concentration lead to corresponding changes in the opposite direction.

As magnesium is required for PTH secretion and end-organ responsiveness, alterations in serum magnesium have an impact on serum calcium concentration.

Turnover of calcium in the bone is predominantly under control of PTH and calcitriol, although prostaglandins and some of the cytokines also play a role. Bone resorption is mediated by osteoclasts, while osteoblasts are involved in bone formation. The daily calcium balance is summarised in Table 63.1.

MEASUREMENT OF SERUM CALCIUM

Most hospital laboratories measure total serum calcium. The normal plasma concentration is 2.2–2.6 mmol/L. However, the ionised form (1.1–1.3 mmol/L) is the active fraction and its measurement is not routine in many laboratories, although most contemporary blood gas analysers can measure serum ionised calcium concentrations. Estimation of ionised calcium from total serum calcium concentration using mathematical algorithms is unreliable in critically ill patients.[2,7,8] Heparin forms complexes with calcium and decreases ionised calcium.[9] A heparin concentration of less than 15 units/mL of whole blood is therefore recommended for the measurement of ionised calcium.[10] Anaerobic collection of the specimen is recommended, as CO_2 loss from the specimen may result in alkalosis and reduction in ionised calcium concentration. Calcium levels are also reduced by a concomitant lactic acidosis

owing to chelation by lactate ion.[11] Free fatty acids (FFAs) increase calcium binding to albumin and may form a portion of the calcium binding site.[12] Increases in FFAs may be seen in relation to stress, use of steroids, catecholamines and heparin. The impact of pH on calcium measurements has been described above. The normal reference levels of serum calcium are reduced in pregnancy and in the early neonatal period.[13]

HYPERCALCAEMIA IN CRITICALLY ILL PATIENTS

The frequency of hypercalcaemia in critically ill patients is not well established, although it is not as common as hypocalcaemia. Depending on the patient population, the reported incidence ranges from 3% to 5% to as high as 32%.[14,15] Admission to the intensive care unit (ICU) with a primary diagnosis of a hypercalcaemic crisis is uncommon. Although a number of aetiologies have been described (Box 63.2) in the critical care setting, it is usually due to malignancy-related hypercalcaemia, immobilisation, renal failure or posthypocalcaemic hypercalcaemia.[28] Before undertaking a work up for hypercalcaemia, it is important to exclude false positive measurements. This is usually the result of inadvertent haemoconcentration during venipuncture and elevation in serum protein, although ionised calcium levels are not reported to be affected by haemoconcentration.[29] *Pseudohypercalcaemia* has also been described in the setting of essential thrombocythaemia. The erroneous result is thought to be due to in vitro release of calcium from platelets analogous to the pseudohyperkalaemia seen in the same condition.[23]

Box 63.2 Causes of hypercalcaemia

Common causes of hypercalcaemia in the critically ill patient

Complication of malignancy
- Bony metastases
- Humoral hypercalcaemia of malignancy

Posthypocalcaemic hypercalcaemia
- Recovery from pancreatitis[15]
- Recovery from acute renal failure following rhabdomyolysis[16–20]

Primary hyperparathyroidism
Adrenal insufficiency[21,22]
Prolonged immobilisation[23–26]
Disorders of magnesium metabolism
Use of total parenteral nutrition (TPN)[27]
Hypovolaemia
Iatrogenic calcium administration

Less common causes of hypercalcaemia in the critically ill patient

Granulomatous diseases – sarcoidosis, tuberculosis, berylliosis
Vitamin A & D intoxication
Multiple myeloma
Endocrine:
- Thyrotoxicosis
- Acromegaly
- Phaeochromocytoma

Lithium – chronic therapy
Tamoxifen
Thiazides
Rare association between drugs and hypercalcaemia
Theophylline, omeprazole and growth hormone therapy

MECHANISMS OF HYPERCALCAEMIA

From a pathophysiological standpoint, hypercalcaemia may be due to an elevation in PTH, in which case the homeostatic regulatory and feedback mechanisms are preserved, and this is termed *equilibrium hypercalcaemia*. Alternatively, it could be a non-parathyroid mediated hypercalcaemia with associated breakdown of homeostatic mechanisms, and this situation is termed *disequilibrium hypercalcaemia*.

Malignancy-related hypercalcaemia might arise from bony metastases or humoral hypercalcaemia of malignancy. In the latter (seen with bronchogenic carcinoma and hypernephroma), tumour osteolysis of bone resulting from the release of PTH-like substances (these cross react with PTH in the radioimmunoassay, but are not identical to PTH), calcitriol, osteoclast activating factor and prostaglandins is thought to be the major underlying mechanism. Aggravating factors include dehydration, immobilisation and renal failure.

Posthypocalcaemic hypercalcaemia is a transient phenomenon seen in patients following a period of hypocalcaemia.[28] This has been attributed to parathyroid hyperplasia which develops during the period of hypocalcaemia, which results in a rebound hypercalcaemia following resolution of the underlying hypocalcaemic disorder.

Immobilisation hypercalcaemia results from an alteration in balance between bone formation and resorption.[24–26,30] This leads to loss of bone minerals, hypercalcaemia, hypercalciuria and increased risk of renal failure. In patients with normal bone turnover, immobilisation rarely causes significant hypercalcaemia. However, in patients with rapid turnover of bone (children, post fracture patients, hyperparathyroidism, Paget disease, spinal injuries and Guillain-Barré syndrome), this may result in severe hypercalcaemia.

Intravascular volume depletion reduces renal calcium excretion by a combination of reduced glomerular filtration and increased tubular reabsorption of calcium. Hypercalcaemia further compounds this problem by causing a concentrating defect in the renal tubules, thus creating a polyuria and further aggravating the hypovolaemia.

Extrarenal production of calcitriol by lymphocytes in granulomata is thought to be the predominant

mechanism of hypercalcaemia in granulomatous diseases.[21,22]

Only 10%–20% of patients with adrenal insufficiency develop hypercalcaemia.[31,32] The aetiology of this is thought to be multifactorial: intravascular volume depletion, haemoconcentration of plasma proteins and the loss of anti-vitamin D effects of glucocorticoids.

Hypercalcaemia can be associated with the use of certain medications – vitamin D toxicity, loop diuretics, thiazide diuretics and lithium. For rarer causes of hypercalcaemia, the reader is referred to reviews by Jacobs and Kallas.[21,33]

MANIFESTATIONS OF HYPERCALCAEMIA

The clinical manifestations of hypercalcaemia (commonly encountered when total serum calcium exceeds 3 mmol/L) are outlined in Box 63.3. *Hypercalcaemic crisis* is defined as severe hypercalcaemia (total serum Ca >3.5 mmol/L) associated with acute symptoms and signs.

INVESTIGATIONS

A detailed diagnostic algorithm is outside of the scope of this chapter. The basic work up should include serum calcium, phosphorus and alkaline phosphatase estimation, PTH assay, renal function assessment and a skeletal survey.

Box 63.3 Clinical manifestations of hypercalcaemia

Cardiovascular
Hypertension
Arrhythmias
Digitalis sensitivity
Catecholamine resistance
Urinary system
Nephrocalcinosis

Pancreatitis
Neuromuscular
Weakness
Neuropsychiatric
Depression
Disorientation
Psychosis
Coma
Seizures

Ectopic calcification is usually seen with chronic hypercalcaemia.

THERAPY OF HYPERCALCAEMIA AND HYPERCALCAEMIC CRISIS

Mild asymptomatic hypercalcaemia does not require emergent treatment. Therapy is usually directed at the underlying cause.

The management of hypercalcaemic crisis consists of two principal components:

1. Increasing urinary excretion of calcium
2. Reducing bone resorption.

INCREASING URINARY EXCRETION OF CALCIUM

As almost all patients with hypercalcaemia are volume depleted, the initial therapy consists of rehydration with normal saline followed by diuresis with furosemide. Rehydration with normal saline improves intravascular volume, reduces serum calcium by extracellular dilution and saliuresis promotes calcium loss in the urine. Volume expansion should be titrated to clinical endpoints and central venous pressure (CVP) monitoring. A urine output of 4–5 L should be aimed for in these patients to promote calciuresis. In many patients, these measures would achieve a reduction in serum calcium by about 0.4–0.5 mmol/L. Hypokalaemia, hypomagnesaemia and calcium stone formation in the urine are potential side effects of this mode of treatment.

In patients with established renal failure in whom forced diuresis cannot be instituted, dialysis against a dialysate with zero or low calcium concentrations should be the treatment of choice.

REDUCTION OF BONE RESORPTION

Measures to increase urinary excretion of calcium should be followed up with administration of agents minimising bone resorption. A number of agents are available and these are listed in Table 63.2.

Disodium ethylenediaminetetraacetic acid (EDTA) at a dose of 15–50 mg/kg intravenously (IV) rapidly lowers serum calcium. However, its propensity to rapidly reduce serum calcium coupled with its nephrotoxic effects limits its usefulness to life-threatening hypercalcaemia. Other therapeutic modalities include the use of non-steroidal anti-inflammatory drugs (NSAIDs) and parathyroidectomy. Calcimimetics are agents which increase the activation of the calcium receptor, thus reducing serum PTH concentrations. Cinacalcet is a first-generation calcimimetic which has shown promise in early randomised trials for the management of hypercalcaemia. It has also been shown to be effective in the management of primary hyperparathyroidism across a wide spectrum of disease severity.[35] However, the role of calcimimetics in the management of acute hypercalcaemia[36] is limited.

At the present time, several newer and more potent bisphosphonates are under development. Their efficacy, combined with a relative lack of side effects, make them the agents of choice for the treatment of malignancy-related hypercalcaemia.

Table 63.2 Therapeutic agents for reducing bone resorption

THERAPY	INDICATIONS	DOSE	ONSET TIME/ DURATION	LIMITATIONS	MECHANISM OF ACTION	COMMENTS
Bi-phosphonates* Etidronate (first generation) Pamidronate (second generation)	Malignancy-related hypercalcaemia	5 mg/kg/day 90 mg as an infusion every 4 weeks	1–2 days, lasts 5–7 days 1–2 days, lasts 10–14 days	Hyperphosphataemia, short duration of action Hypophosphataemia, fever and hypomagnesaemia	Inhibit osteoclast activity, may have some effect on osteoblasts	High potency group. Pamidronate lowers Ca levels more rapidly than etidronate
Calcitonin	Hypercalcaemia Pagets disease	Initial IV dose 3–4 U/kg followed by 4 U/kg subcutaneously (SC) 12th hourly	Hours, lasts 2–3 days	Nausea, abdominal pain, flushing, tachyphylaxis, limited efficacy	Inhibit osteoclast activity, reduces renal tubular reabsorption of calcium	Tachyphylaxis minimised by concomitant steroid therapy
Glucocorticoids	Vit D toxicity, Myeloma, lymphoma, Granulomata	IV hydrocortisone 200–400 mg/day	Days, lasts days to weeks	Glucocorticoid side effects	Inhibit inflammatory cell production of calcitriol, reduce gut absorption of calcium	Improve the efficacy of calcitonin
Gallium nitrate	Malignancy-related hypercalcaemia	100–200 mg/m^2/day for 5–7 days	5–6 days, lasts 7–10 days	Nephrotoxic	Inhibits bone resorption and alters bone crystal structure	Recent Phase II data suggest equivalent efficacy with pamidronate[34]
Plicamycin	Malignancy-related hypercalcaemia	25 µg/kg IV	Rapid onset, lasts for a few days	Hepatotoxic, nephrotoxic and thrombocytopoenia	Inhibits cellular RNA synthesis	Side-effect profile limits the use of this drug
Intravenous phosphates	Limited clinical role	10–15 mmol as an infusion repeated at regular intervals	Hours, lasts 24–48 h after cessation	Ectopic calcification, severe hypocalcaemia	Ectopic calcification, reduce gut absorption, inhibition of bone resorption	Use superseded by the other modalities described.

*Other biphosphonates include ibandronate, risedronate and zoledronate. As compared to pamidronate, zoledronate has the advantage of simplicity of administration and better control of hypercalcaemia.

IV, Intravenous.

Other drugs that have been used in the management of hypercalcaemia include prostaglandin inhibitors for cancer-related hypercalcaemia, ketoconazole, and chloroquine (for sarcoid-induced hypercalcaemia)[22] and glucocorticoids for granulomatous disease-related hypercalcaemia.

ADJUNCT MEASURES IN THE MANAGEMENT OF HYPERCALCAEMIA

Monitoring of cardio-respiratory function and biochemical status is mandatory during therapy of hypercalcaemia. Thiazide diuretics, Vitamin D and absorbable antacids should be avoided. Hypercalcaemia potentiates digitalis effect and dosage should be adjusted accordingly. Endocrinologists should be consulted for further management.

HYPOCALCAEMIA

Hypocalcaemia is more common than hypercalcaemia in critically ill patients with an estimated incidence of around 70%–90%.[28] As the ionised calcium is the biologically active moiety, it is important to look at ionised hypocalcaemia. The frequency of this is far more varied, ranging from 15 to 70.[28,37,38] *Spurious hypocalcaemia* is seen with poor storage of specimens prior to analysis, resulting in CO_2 loss from the specimen, use of EDTA or large doses of heparin as anticoagulants in the syringe. Gadodiamide used in association with magnetic resonance imaging (MRI) as a contrast medium can interfere with the colorimetric assay and cause spurious hypocalcaemia.[39]

AETIOLOGIES

The aetiology of ionised hypocalcaemia based on the predominant pathophysiological mechanism is listed in Box 63.4. The other contributory mechanisms of hypocalcaemia in each of the conditions are shown in brackets.

Although a long list of causes exists for hypocalcaemia, calcium chelation and hypoparathyroidism constitute the common mechanisms of ionised hypocalcaemia in intensive care. The increasing prevalence of citrate anticoagulation used for renal replacement therapy, if not accompanied by appropriate metabolic monitoring, could emerge as another cause of hypocalcaemia in critically ill patients. Frequently, hypocalcaemia is accompanied by a number of other biochemical abnormalities, thus a pattern recognition approach towards the cause of hypocalcaemia will point to its aetiology and save a considerable amount of investigations for the patient. Common diagnostic patterns are listed in Table 63.3.

Whilst alkalosis is frequently associated with ionised hypocalcaemia, the presence of a metabolic acidosis in the face of low serum ionised calcium narrows the differential diagnosis even further (Box 63.5).

Box 63.4 Aetiology of ionised hypocalcaemia

Calcium chelation
Alkalosis (increased binding of calcium by albumin)
Citrate toxicity (calcium chelation)
Massive blood transfusion (citrate leading to calcium chelation)
Hyperphosphataemia (calcium chelation, ectopic calcification, reduced vitamin D3 activity)
Pancreatitis (calcium soap formation, reduced parathyroid secretion)
Tumour lysis syndrome (hyperphosphataemia)
Rhabdomyolysis (hyperphosphataemia and reduced levels of calcitriol)
Hypoparathyroidism
Hypo- and hypermagnesaemia
Sepsis (decreased parathyroid hormone [PTH] secretion, end-organ resistance to PTH, reduced calcitriol production, intracellular shift of calcium, hypomagnesaemia and actions of inflammatory cytokines on the parathyroid glands, kidneys and bone)
Burns (decrease in PTH secretion)
Neck surgery (removal of parathyroid gland, calcitonin release during thyroid surgery and hungry bone syndrome post-parathyroidectomy)
Hypovitaminosis D
Inadequate sun exposure
Inadequate intake
Malabsorption
Liver disease (impaired 25-hydroxylation of cholecalciferol)
Renal failure (impaired 1-hydroxylation of cholecalciferol, hyperphosphataemia)
Medications-phenytoin (inhibition of active calcium transport by intestinal epithelial cells), steroids (increased 24-hydroxylase activity)
Reduced bone turnover
Osteoporosis
Elderly
Cachexia
Drug induced
Bisphosphonates (see under hypercalcaemia)
Propofol
EDTA (calcium chelation)
Ethylene glycol (formation of calcium oxalate crystals in the urine)
Cis-platinum (renal tubular damage leading to hypermagnesuria)
Foscarnet (calcium chelation)
Protamine
Gentamicin (hypermagnesuria leading to hypomagnesaemia and therefore hypocalcaemia)

EDTA, ethylenediaminetetraacetic acid.

CLINICAL MANIFESTATIONS OF HYPOCALCAEMIA

Mild degrees of hypocalcaemia are usually asymptomatic. Ionised calcium levels less than 0.8 mmol/L may cause neuromuscular irritability and result in

Table 63.3 Pattern recognition in the diagnosis of common causes of hypocalcaemia

AETIOLOGY OF HYPOCALCAEMIA	CLINICAL/BIOCHEMICAL PATTERNS
Low serum albumin	Reduced total calcium, normal ionised calcium
Alkalosis	Normal total calcium, reduced ionised calcium
Hypomagnesaemia	Reduced ionised calcium and hypokalaemia
Pancreatitis	Hypocalcaemia, elevated serum lipase and glucose
Renal failure	Elevated blood urea nitrogen, elevated phosphate
Rhabdomyolysis	Hypocalcaemia, elevated phosphate, creatine kinase (CK) and urinary myoglobin
Tumour lysis syndrome	Hypocalcaemia, elevated phosphate, potassium and urate
Citrate toxicity	Low ionised calcium with high total calcium

Box 63.5 Hypocalcaemia with metabolic acidosis

Acute renal failure
Tumour lysis
Rhabdomyolysis
Pancreatitis
Ethylene glycol poisoning
Hydrofluoric acid intoxication

clinical symptoms. The clinical manifestations of hypocalcaemia are summarised in Box 63.6. The manifestations listed in the table below are by no means a comprehensive list of all the clinical features, but include the ones most commonly seen in the critical care setting.

When eliciting tetany, Trousseau's sign (carpopedal spasm) is more specific for hypocalcaemia than Chvostek's sign (facial twitch in response to facial nerve stimulus – present in 10%–30% of the normal population). Electrocardiographic (ECG) changes do not correlate well with the degree of hypocalcaemia. The symptoms of hypocalcaemia are exacerbated by a co-existing hypokalaemia and a hypomagnesaemia.

The laboratory work up should include serum calcium, phosphorus, magnesium and alkaline phosphatase, PTH and vitamin D assays and renal function assessment.

Box 63.6 Clinical manifestations of hypocalcaemia

Central nervous system
Circumoral and peripheral paraesthesia

Hypotension, inotrope unresponsiveness
Prolonged QT intervals, T-wave inversion
Loss of digitalis effect
Respiratory
Apnoea
Laryngospasm
Bronchospasm

APPROACH TO THE TREATMENT OF ASYMPTOMATIC AND SYMPTOMATIC HYPOCALCAEMIA

ARGUMENTS FOR AND AGAINST CORRECTION OF ASYMPTOMATIC HYPOCALCAEMIA

As stated before, it is not clear if asymptomatic hypocalcaemia needs correction. Based on published data which suggest that critical care hypocalcaemia is associated with a higher mortality and increased length of stay in intensive care,[40–42] it is advocated that ionised hypocalcaemia be corrected routinely irrespective of the level. However, arguments exist against the routine correction of asymptomatic ionised hypocalcaemia. Increases in cytosolic calcium lead to disruption of intracellular processes, activation of proteases and can lead to ischaemia and reperfusion injury.[43] Also, there are data suggesting that ionised calcium is an important participant in the pathogenesis of coronary and cerebral vasospasm.[16] In rodent models of endotoxic shock, there are also data demonstrating an increased mortality when these rats were administered intravenous calcium.[17] Most clinicians agree that an ionised calcium level of less than 0.8 mmol/L needs correction even if asymptomatic.

MANAGEMENT OF ACUTE SYMPTOMATIC HYPOCALCAEMIA

Acute symptomatic hypocalcaemia is a medical emergency that requires immediate therapy. In addition to treatment of underlying cause and support of airway, breathing and circulation, the definitive treatment includes administration of intravenous calcium. Intravenous calcium is available as a calcium salt of chloride or gluconate or acetate. The main difference between these formulations is the amount of elemental

Table 63.4 Commonly used intravenous calcium preparations

PREPARATION	DOSAGE	ELEMENTAL CALCIUM/GRAM
Calcium gluconate	10 mL	93 mg (2.3 mmol)
Calcium chloride	10 mL	272 mg (6.8 mmol)
Calcium acetate		253 mg (6.35 mmol)

Box 63.7 Indications for calcium administration

Absolute
Symptomatic hypocalcaemia
Ionised Ca <0.8 mmol/L

Relative
Beta-blocker overdose
Hypermagnesaemia
Hypocalcaemia in the face of high inotrope requirement
Massive blood transfusion post cardiopulmonary bypass to augment cardiac contractility

calcium available at equivalent volumes of drug (Table 63.4). The dose of calcium required should be based on the elemental calcium.[18] Intravenous calcium can be administered as a bolus or as an infusion. Rapid administration of calcium may cause nausea, flushing, headache and arrhythmias. Digitalis toxicity may be precipitated. Extravasation of calcium may lead to tissue irritation, particularly with the chloride salt. Calcium chloride may be better than calcium gluconate for the management of hypocalcaemia, if there is concomitant alkalosis. Following an initial bolus, an infusion may be commenced at a rate of 1–2 mg/kg/h of elemental calcium to maintain target levels of ionised calcium. With correction of the underlying disorder and restoration of calcium to normal levels, the infusion can be tapered and stopped. Adequacy of calcium therapy can be monitored clinically and by performing serial determinations of ionised calcium. Failure of ionised calcium to increase after commencement of IV calcium may indicate an underlying magnesium deficiency. This can be corrected by administration of 10 mmol of intravenous magnesium over 20 minutes. Administration of calcium in the setting of hyperphosphataemia may result in calcium precipitation in the tissues. In these situations, a phosphate binder may be administered. Calcium salts should not be administered with bicarbonate since the two precipitate. The other indications for calcium administration are listed in Box 63.7. Other therapy for hypocalcaemia consists of oral calcium supplements and calcitriol administration, although these are usually used in the management of chronic hypocalcaemia.

ASSOCIATION BETWEEN IONISED CALCIUM CONCENTRATION AND OUTCOME IN CRITICAL ILLNESS

A recent retrospective study examined the association between serum ionised calcium and mortality in a heterogeneous cohort of critically ill patients.[19] Data from greater than 7000 patients generating greater than 175,000 iCa measurements were analysed. The investigators concluded that within a broad range of values, ionised calcium concentration has no independent association with hospital or ICU mortality. However, from multivariate logistic regression analysis, an ionised calcium less than 0.8 mmol/L or an ionised calcium greater than 1.4 mmol/L were independently associated with ICU and hospital mortality. In patients requiring massive blood transfusion, another study reported a concentration dependent effect of hypocalcaemia on mortality.[20]

DIRECTIONS FOR FUTURE RESEARCH

VITAMIN D SUPPLEMENTATION IN CRITICAL ILLNESS

The traditional role of vitamin D has been thought to be the maintenance of adequate serum calcium and phosphate levels, for bone mineralisation and optimal cardiac and skeletal muscle function. Over the past decade, data from biochemical and molecular genetic studies indicate that vitamin D has a much wider range of effects than this traditional role. This is due to the activation to 1,25-dihydroxy-vitamin D in many tissues (in addition to the known activation in the kidneys) by tissue 1-alpha-hydroxylase and the action of this activated form on target tissue mediated by binding to vitamin D binding receptors, which are now known to exist on a myriad of tissues. These non-skeletal effects, termed pleiotropic, include potentiation of antimicrobial action, modification of inflammation, cardioprotective effects and immunomodulatory effects. Several large observational studies have demonstrated an association between increased morbidity and mortality and lower vitamin D levels as measured by serum 25-hydroxy-vitamin D in critically ill patients. On the other hand, there are data to suggest that a single measurement of vitamin D may not be reflective of the 24 hours profile in critically ill patients owing to the marked variability.[27,44] Moreover, there are also data to suggest that 1,25 dihydroxy-vitamin D levels may be increased during the inflammatory response. Both enteral and parenteral supplementation in critically ill patients are feasible and safe.[45] Currently, the existing data are insufficient to make an evidence-based recommendation regarding its potential benefit in the ICU.[34] A single-centre randomised trial of supplementation vitamin D deficient patients did not show a difference in the primary end point (hospital length of stay) but did report a significantly reduced mortality in severely

deficient patients.[46] Results from large prospective randomised controlled trials are lacking.

NEWER DRUGS FOR THE MANAGEMENT OF HYPERCALCAEMIA

Denosumab, a monoclonal antibody that binds to the receptor activator of nuclear factor κB ligand (RANKL), is used to prevent bone resorption in patients with skeletal metastases. Early studies show promise in the management of malignancy-related hypercalcaemia, refractory to bisphosphonates.[47] These agents may have utility in the management of hypercalcaemia in critically ill patients.

ELUCIDATING THE ROLE OF IONISED CALCIUM MEASUREMENTS IN THE INTENSIVE CARE UNIT

Perturbations of ionised calcium are common in critically ill patients. These are often thought to be an adaptive response to critical illness. Although measurement is routine on most contemporary blood gas analysers, utility is unproven. A randomised controlled trial of ionised calcium measurement and supplementation will inform clinical practice and guide therapy.

Pre-eclampsia and eclampsia

Joey Ka Ming Wai, Tony Gin

Pre-eclampsia was defined previously as new onset of hypertension after 20 weeks' gestation, associated with proteinuria. However, the diagnosis can now be made without proteinuria, if there is evidence of maternal organ dysfunction, or uteroplacental dysfunction resulting in foetal growth restriction (Table 64.1).[1] Eclampsia describes the occurrence of seizures in a pre-eclamptic woman not attributable to other causes.

Pre-eclampsia presents with a spectrum of signs and symptoms, and it can quickly progress to a serious disease (now termed pre-eclampsia with severe features). Patients may be referred to the intensive care unit (ICU) for poorly controlled hypertension, management of complications such as convulsions, stroke, pulmonary oedema, hepatic failure, haemorrhage and coagulopathy, and for postpartum monitoring and care.

The worldwide estimates for pre-eclampsia and eclampsia are 4.6% and 1.4% respectively, with wide variation across regions, and highest in less resourced countries.[2] Although maternal mortality from pre-eclampsia is low and considered avoidable in developed countries, hypertensive diseases are still often one of the leading causes of maternal death. Mothers have nearly four times the odds of dying and eight times the odds of severe outcomes if they have pre-eclampsia, and over 40 times the odds of dying if they have eclampsia.[3] This translates to worldwide estimates of 50,000 maternal deaths per year from pre-eclampsia and eclampsia, as well as substantial foetal growth restriction, and perinatal morbidity and mortality.[4,5] Although pre-eclampsia resolves after delivery of the placenta, women will subsequently have approximately two to four times the risk for ischaemic heart disease and stroke, as well as renal disease, metabolic disorders and death.[6–8]

Many organisations have issued guidelines for the prevention, diagnosis and treatment of pre-eclampsia and other hypertensive disorders in pregnancy.[9–13]

AETIOLOGY

The exact cause of pre-eclampsia is unknown, although the placenta is necessary for the disease, and delivery of the placenta is curative. There are many risk factors for pre-eclampsia, including previous or family history of pre-eclampsia, primigravidae, multiple gestation, advanced maternal age, and pre-existing medical conditions (e.g. diabetes, obesity, renal disease, hypertension and autoimmune disorders).[14]

Although there is a genetic predisposition, no single gene has been implicated in the majority of women. Pre-eclampsia may be a result of cumulative effects of variants at multiple genes, both foetal and maternal.[15,16] Some investigators differentiate early onset (before 34 weeks' gestation) and late onset pre-eclampsia (at or after 34 weeks) because of differences in clinical features, biomarkers and outcomes.[17]

There have been many attempts to predict pre-eclampsia from risk factors, symptoms, signs and investigations, but none of the prediction models have been very accurate or widely validated.[18] Low-dose aspirin therapy is often given to slightly reduce the risk of developing the disease and other adverse pregnancy outcomes in those with one or two risk factors. Biomarkers may have some diagnostic or predictive value but this is still debated.[19,20] In the United States and United Kingdom, regular blood pressure monitoring is still the standard screening test for pre-eclampsia.

PATHOGENESIS

Pre-eclampsia is a systemic disease that affects most organ systems. Many theories of pathogenesis have been proposed, and the current predominant concept is that of a two-stage disease with an initial stage of abnormal placentation and placental ischaemia, followed by a second stage of clinical disease.[8] Initially, the normal endovascular invasion of foetal trophoblast into the maternal uterine spiral arteries is inadequate, with reduced remodelling and dilatation of the arteries, leading to placental hypoperfusion and hypoxia that becomes more severe as pregnancy progresses. This acts as a precipitating factor that leads to an imbalance of angiogenic and antiangiogenic factors and a generalised inflammatory response. The exact link between placental triggering and the systemic response is unknown, but there is placental release of inflammatory cytokines and circulating antiangiogenic factors such as soluble Fms-like tyrosine kinase-1 (sFlt1) and soluble endoglin (sEng), along with reduced concentrations of angiogenic factors such as vascular endothelial growth factor (VEGF) and placental

ABSTRACT

Pre-eclampsia is now defined as new onset hypertension after 20 weeks' gestation with either proteinuria, maternal organ dysfunction, or foetal growth restriction. Pre-eclampsia with severe features requires rapid control of hypertension, prophylaxis against seizures with magnesium, and organ support as required before urgent delivery. Major complications include eclampsia, intracranial haemorrhage, stroke, pulmonary oedema, hepatic failure and coagulation abnormalities. Echocardiography is useful for cardiovascular and fluid management. If premature delivery is necessary, corticosteroids are given to promote foetal lung maturation. Complications may still occur after delivery and patients should be actively monitored and managed for at least another 24 hours. Although pre-eclampsia resolves after delivery of the placenta, women will subsequently have approximately two to four times the risk for ischaemic heart disease and stroke, as well as diabetes and death.

Table 64.1 Basic diagnostic criteria for pre-eclampsia

Hypertension (after 20 weeks' gestation)	Systolic arterial pressure >140 mm Hg *or* Diastolic arterial pressure >90 mm Hg
And one or more of the following new-onset conditions	
1. Proteinuria	Protein ≥300 mg in a 24-hour collection Protein/creatinine ratio ≥30 mg/mmol spot urine or positive dipstick 1+
2. Any maternal organ dysfunction	
Renal	Creatinine ≥0.09 mmol/L
Hepatic	Severe epigastric or right-upper-quadrant pain Elevated transaminases
Neurological	Convulsions (eclampsia) Altered mental state Persistent severe headaches Visual disturbances, blindness, papilloedema Hyperreflexia and clonus
Haematological	Thrombocytopenia Disseminated intravascular coagulation Haemolysis
Cardiorespiratory	Pulmonary oedema
3. Uteroplacental dysfunction	Fetal growth restriction

growth factor (PIGF). All this leads to diffuse endothelial dysfunction with an increase in sensitivity to vasoactive substances, a decrease in endothelial synthesis of vasodilator substances such as prostaglandin and nitric oxide, activation of platelets and coagulation, and an increase in capillary permeability. This then causes widespread vasoconstriction, fluid extravasation, proteinuria, decreased intravascular volume, haemoconcentration and decreased organ perfusion. PIGF and sFlt are being evaluated as diagnostic and prognostic biomarkers, and one experimental therapeutic strategy is to restore the balance of these angiogenic and antiangiogenic factors.

CLINICAL PRESENTATION

Pre-eclampsia is a syndrome with a spectrum of presentations. Although hypertension is the cardinal sign, some women present with convulsions, headache or abdominal pain, and there may be severe features without a marked increase in blood pressure. Rarely, cocaine intoxication and phaeochromocytoma may be confused with pre-eclampsia.

Haemodynamic changes of pre-eclampsia are hypertension, increased systemic vascular resistance and decreased intravascular volume. Cardiac output is often decreased, usually secondary to changes in preload and afterload rather than contractility.[21] Sympathetic activation occurs, and this may account for observations of increased cardiac output in the early stage.[22] Early onset and late onset pre-eclampsia appear to have different patterns of cardiovascular change.[23] Common echocardiographic findings are increased left ventricular mass, increased peripheral resistance, diastolic dysfunction and variable change in cardiac output.[24]

Pulmonary oedema may occur, especially after delivery, because of iatrogenic fluid overload, decreased left ventricular function, increased capillary permeability and narrowing of the colloid osmotic–pulmonary capillary wedge pressure (PCWP) gradient. Sudden ventricular tachycardia may occur during hypertensive crises.

Neurological symptoms include headache, visual changes, hyperreflexia, eclamptic convulsions, cerebral oedema and stroke. Intracranial haemorrhage is an important cause of death. Posterior reversible encephalopathy syndrome has been recognized as a primary event in eclampsia.[25]

Renal changes include reduced glomerular filtration rate due to reduced renal plasma flow and filtration coefficient. These features, together with proteinuria, are associated with the characteristic lesion of glomeruloendotheliosis. Hyperuricaemia is associated with increased prenatal risk, particularly if serum uric acid concentration rises rapidly.

Haemostatic abnormalities include thrombocytopenia, which may be associated with decreased platelet function. Associated coagulation abnormalities may occur but are unlikely unless the platelet count is less than $100{,}000 \times 10^9$/L.[26,27]

Hepatic complications include liver oedema, hepatocellular necrosis, periportal and subcapsular haemorrhage, hepatic infarcts and rupture. Patients with HELLP syndrome (see later in the chapter) are particularly at risk.

The leading causes of maternal death in pre-eclampsia/eclampsia are intracranial haemorrhage, pulmonary oedema and hepatic complications. Foetal morbidity results from placental insufficiency, prematurity and abruptio placentae.

MANAGEMENT OF PRE-ECLAMPSIA

The definitive curative treatment of pre-eclampsia is delivery of the placenta and foetus.

Table 64.2 Management in pre-eclampsia

General measures	Keep patient in lateral position Stress ulcer prophylaxis Deep vein thrombosis (DVT) prophylaxis
Maternal monitoring	Intra-arterial blood pressure monitoring in severe cases Sp_{O_2}, urine output, intake-output chart Consider central venous catheter or cardiac output monitoring
Investigations	Complete blood count, renal function and electrolytes Urate Liver function test Clotting profile Blood group matching Urinalysis
Foetal monitoring	Continuous foetal heart monitoring Other options as assessed by obstetricians: ultrasound, amniotic fluid index (AFI), umbilical artery Doppler
Magnesium sulphate	
Prophylaxis and treatment of eclampsia	Intravenous: Loading dose 4–6 g over 10–15 min Maintenance 1–2 g/h Intramuscular: 4 g every 4 h
For recurrent eclampsia	A further intravenous loading dose of 2–4 g over 10 min May increase maintenance up to 2 g/h
Antihypertensive therapy	Acute treatment if systolic blood pressure (SBP) > 160 mm Hg or diastolic blood pressure (DBP) > 110 mm Hg Control of blood pressure should be gradual and sustained while preserving maternal organ perfusion and placental perfusion
Liaison with obstetricians regarding timing of delivery	Antenatal steroid if gestation <34 weeks

The principles of management include:

- Timely delivery of the placenta and foetus.
- Supportive care before delivery, and during the immediate postpartum period, focusing on:
  - control of blood pressure,
  - prevention of seizures with magnesium sulphate,
  - maintenance of placental perfusion,
  - prevention of complications
  - monitoring of foetal well-being.

The management for pre-eclampsia is summarized in Table 64.2.

The main factors affecting timing of delivery are gestational age and severity of disease at time of diagnosis. In general, delivery is indicated when pre-eclampsia with severe features is diagnosed after 34 weeks of gestation. Before 34 weeks' gestation, prematurity is a major cause of neonatal morbidity, and expectant management with corticosteroid to promote foetal lung maturation may be decided. After delivery, severe cases should preferably be managed in an ICU for 24–72 hours.

ANTIHYPERTENSIVE THERAPY

The aim of antihypertensive therapy is to prevent maternal complications (intracerebral haemorrhage, cardiac failure and abruptio placentae) while maintaining placental blood flow. Hypertension is a marker and not a causal factor in pre-eclampsia. Controlling hypertension reduces the risk of complications, but it does not ameliorate the underlying pathological process. Acute treatment is indicated when blood pressure is greater than 160 mm Hg systolic or 105–110 mm Hg diastolic.[28] Reduction of systolic pressure is important for the prevention of stroke.[29] Initially, systolic blood pressure should be reduced by about 20–30 mm Hg and diastolic pressure by 10–15 mm Hg while monitoring the foetus, with the goal of achieving an initial range of 140–150/90–100 mm Hg. Concomitant plasma expansion reduces the risk of sudden hypotension when vasodilators are used. Recommended antihypertensive drugs for acute treatment are summarised in Table 64.3. The most commonly used drugs are labetalol intravenous (IV), hydralazine IV and oral nifedipine; insufficient data are available to show which of these is superior.[30]

If hypertension is refractory to conventional treatment, sodium nitroprusside (initial dose 0.25 µg/kg per minute, maximum dose 5 µg/kg per minute) can be used to reduce blood pressure rapidly in a hypertensive emergency but care should be taken in patients with depleted intravascular volume and duration

Table 64.3 Emergency drug treatment of hypertension in pre-eclampsia

DRUG	DOSAGE GUIDE	MECHANISM OF ACTION	NOTES
Labetalol	Bolus 20–40 mg IV every 10–15 min to maximum dose of 300 mg Infusion 1–2 mg/min, reducing to 0.5 mg/min or less after blood pressure is controlled	Non selective beta-adrenergic receptor block with alpha$_1$-blocking effect	Reduces blood pressure without decrease in uteroplacental flow[29] Crosses placenta, but neonatal hypoglycaemia and bradycardia is rarely seen Need foetal heart monitoring Should not be given to patients with asthma or myocardial dysfunction
Hydralazine	Bolus 5 mg IV followed with 5–10 mg every 20 min to maximum of 20 mg	Direct arteriolar vasodilator	Slow onset of action of 10–20 min but may cause sudden hypotension Consider concomitant fluid bolus (<250 mL) Adverse effects include headache, tachycardia, tremor, nausea, rarely neonatal thrombocytopenia
Nifedipine	Oral route is preferred, 10 mg, repeat after 20 min as required (sublingual route may cause sudden hypotension)	Calcium channel blocker	Cause uterine muscle relaxation that may increase risk of postpartum haemorrhage Potentiation of neuromuscular block in patient receiving magnesium sulphate

should be limited to less than 4 hours to avoid foetal cyanide poisoning. Nitroglycerine infusion (initial dose 5 µg/min, maximum dose 100 µg/min) may be useful in cases complicated by pulmonary oedema.

ANTICONVULSANT THERAPY

Anticonvulsants are used to prevent recurrent convulsions in eclampsia or to prevent initial convulsions in pre-eclampsia. Magnesium sulphate should be used as first-line treatment for prophylaxis and treatment of eclamptic seizures, and for prophylaxis of seizures in severe pre-eclampsia. The Magpie trial conducted in 33 countries showed that women in the magnesium group had a 58% (95% confidence interval [CI], 40%–71%) lower risk of eclampsia and probably lower maternal mortality.[31] Magnesium was more cost-effective in developing countries where pre-eclampsia is a more significant problem.[32] However, the benefits of using magnesium in mild pre-eclampsia are still debated, especially in developed countries.

The mechanism of action of magnesium for preventing eclamptic seizures is uncertain. Although abnormal electroencephalograms are frequent in pre-eclampsia and eclampsia, they are not altered by magnesium sulphate. Magnesium may reduce cerebral vasospasm via antagonism of calcium at membrane channels or intracellular sites. Magnesium amplifies release of prostacyclin by vascular endothelium, and this may inhibit platelet aggregation and vasoconstriction. Doppler ultrasonography suggests that magnesium vasodilates smaller-diameter intracranial blood vessels, and some of its effects may be from relieving cerebral ischaemia. The anticonvulsant activity of magnesium may be mediated by blockade or suppression of *N*-methyl-D-aspartate (NMDA) receptors. Magnesium has tocolytic effects, mild general vasodilator and antihypertensive actions, and increases renal and uterine blood flow.

Guidelines for administration of magnesium sulphate are summarised in Table 64.2. The kidney rapidly excretes magnesium. The half-life in patients with normal renal function is 4 hours and 90% of the dose is excreted by 24 hours after the infusion.[33] When there is renal impairment or oliguria, the dose should be reduced and serum concentration should be monitored. Suggested target serum concentration for severe pre-eclampsia is 2–3.5 mmol/L (4–7 mEq/L or 4.8–8.4 mg/dL). Magnesium toxicity is associated with muscle weakness and may lead to respiratory paralysis (>7.5 mmol/L). Increased conduction time with increased PR and QT intervals and QRS duration can lead to sinoatrial and atrioventricular block (>7.5 mmol/L) and cardiac arrest in diastole (>12.5 mmol/L). Toxicity is unlikely when deep tendon reflexes are present (the upper limb should be used during epidural analgesia). Magnesium toxicity can be treated with small IV doses of calcium gluconate and enhanced clearance with renal replacement therapy when it is associated with renal failure. Other reported adverse effects of magnesium include death from overdose, increased bleeding, slowed cervical dilatation and increased risk of pulmonary oedema. Magnesium crosses the placenta and can cause neonatal flaccidity and respiratory depression.

If repeated seizures occur despite therapeutic levels of magnesium, conventional anticonvulsants can be considered, but it is important to exclude other causes of convulsions. Although benzodiazepines and phenytoin are inferior to magnesium for preventing eclamptic seizures, these agents may be considered when magnesium

sulphate is contraindicated (e.g. renal failure, muscle weakness, allergy). Diazepam 5–10 mg IV, lorazepam 2–4 mg IV, and midazolam 1–2 mg IV have all been used depending on the desired duration of effect. Phenytoin is given as an initial IV loading dose of 10 mg/kg followed 2 hours later by 5 mg/kg. Doses are diluted in normal saline and given no faster than 50 mg/min. Electrocardiogram and arterial pressure should be monitored. Maintenance doses of 200 mg orally or intravenously are started 12 hours after the second bolus and given 8-hourly. However, there is no consensus on the optimal dosing regimen. Monitoring of phenytoin level is necessary to avoid toxicity.

ECLAMPSIA

With modern obstetric care, eclampsia may present without marked preceding hypertension or proteinuria, and up to 40% of cases occur postpartum, often more than 48 hours after delivery.[34,35] Priorities in the management of eclamptic seizures are airway protection, oxygenation, and termination and prevention of seizures. Delivery of the foetus should be arranged after maternal stabilisation. Patients should be placed in the left lateral position and given oxygen. Magnesium should be given if not already started. A further loading dose of $MgSO_4$ 2 g can be given if patient is already on magnesium therapy (see Table 64.2). Approximately 10% of eclamptic patients will have a recurrent seizure despite receiving magnesium. Prolonged seizures can be terminated by diazepam 5–10 mg intravenously. If seizures are refractory, thiopental and suxamethonium should be given and the airway secured. Eclampsia is not the only cause of seizure during pregnancy. Recurrent convulsions or prolonged unconsciousness may indicate additional cerebral pathology (e.g. cerebral oedema, intracerebral haemorrhage, cerebral venous thrombosis) and an urgent computed tomographic (CT) scan should be done whenever possible.

FLUID BALANCE

Pre-eclamptic patients usually have reduced circulating intravascular volume. There may also be a significant decrease in blood pressure upon initiation of antihypertensive therapy, particularly with hydralazine. However, the effectiveness of fluid loading is uncertain,[36] and there is a risk of pulmonary oedema so restrictive management is recommended. Oliguria is common in patients with pre-eclampsia, but this does not necessarily imply volume depletion. Fluid challenge should be considered for treatment of oliguria only when there are other signs of hypovolaemia. Renal failure in pre-eclampsia is uncommon. Some patients may require a period of continuous renal replacement therapy but the majority of cases recover. The risk of irreversible renal damage is greater when there is associated abruptio placentae, disseminated intravascular coagulation (DIC), hypotensive shock or sepsis.

Low-dose dopamine (3 μg/kg per minute) infusions have not been shown to improve renal outcome and are no longer recommended.[37] Furosemide should not be used to treat oliguria without pulmonary oedema because this may exacerbate the fluid-depleted state.

Pulmonary oedema is managed with oxygen therapy, positive end-expiratory pressure with or without ventilation, inotropes, vasodilators, morphine or diuretics as required.

CARDIOVASCULAR MONITORING

There is controversy over the effectiveness of central venous pressure (CVP) and PCWP for assisting fluid management. Optimal CVP and PCWP values are unknown, but the response to fluid challenge may be useful. Pulmonary artery catheterisation placement carries inherent risks and should only be considered when there are clear indications (e.g. refractory hypertension, pulmonary oedema, severe cardiac disease and refractory oliguria), and the obtained data will be used to guide decision making.[38]

Echocardiography has been increasingly recognised as a non-invasive tool to assess ventricular function and fluid responsiveness. Pregnant women already have an increased cardiac output, reduced peripheral vascular resistance and increased heart rate. In women with untreated pre-eclampsia, diastolic dysfunction with preserved ventricular systolic function is a common finding.[24] Although doctors may not feel confident about interpreting findings in pregnant and pre-eclamptic women, the usual focused assessments of ventricular dilatation, ejection fraction, and left-ventricular end-diastolic pressure can still be used to assist in the diagnosis and management of pulmonary oedema, heart failure and chest pain.[39] The response to straight leg raising may also be used to guide fluid responsiveness.

POSTPARTUM CARE

Patients are frequently referred to an ICU for postpartum care, particularly after caesarean delivery. Pre-eclampsia may persist or even develop postpartum.[40] The risk of pulmonary oedema is greatest after delivery. After delivery, there may be an initial improvement with a relapse in the first 24 hours. Magnesium should be continued for 24 hours after delivery or the last seizure. Antihypertensive drugs may be reduced according to the blood pressure. Psychological support is important, especially if there has been an adverse neonatal outcome. Full recovery from the organ dysfunction of pre-eclampsia is normally expected within 6 weeks. However, patients are more likely to develop pre-eclampsia in subsequent pregnancies, and have double the risk of early cardiovascular disease and mortality.[6–8]

HELLP SYNDROME AND HEPATIC COMPLICATIONS

HELLP is a syndrome characterised by *h*aemolysis (microangiopathic haemolytic anaemia), *e*levated *l*iver enzymes and *l*ow *p*latelets, although exact criteria vary and there is debate over whether it is a severe form of pre-eclampsia or a separate disorder.[41] The pathogenesis of HELLP is similar to that of early onset pre-eclampsia, but biomarker derangements are more severe.[42] Typically, HELLP syndrome presents at early gestational ages and is more common in white and multiparous women. In about 30% of cases, it first presents in the postpartum period, sometimes with no evidence of pre-eclampsia before delivery.

Many patients have non-specific signs such as right-upper-quadrant or epigastric pain, nausea, malaise or headache. Although most patients will have hypertension and proteinuria, these can be mild or absent. Important differential diagnoses include idiopathic thrombocytopenic purpura, systemic lupus erythematosus, thrombotic thrombocytopenic purpura, haemolytic–uraemic syndrome, and acute fatty liver of pregnancy. Complications of HELLP syndrome include DIC, abruptio placentae, acute renal failure, pulmonary oedema, severe ascites, pleural effusion, acute respiratory distress syndrome (ARDS), sepsis and stroke. Hepatic complications include segmental hepatic infarction, parenchymal haemorrhage, and subcapsular haematoma with or without rupture. If these are suspected, urgent CT scan should be performed. Hepatic artery embolisation has been successful in stable patients, but hepatic rupture is a surgical emergency requiring operative treatment ranging from packing to transplantation.

Patients with HELLP are treated aggressively, similarly to pre-eclampsia, with an emphasis on stabilisation and rapid delivery.[43] Dexamethasone is not usually given for maternal reasons because there is no difference in maternal or perinatal death, and no evidence of significant maternal benefit.[44] Platelet transfusions may be required for active bleeding or before caesarean delivery.

After delivery, patients usually show a continuing deterioration in platelet count and liver enzymes, with a peak in severity 24–48 hours after delivery followed by gradual resolution and complete recovery if complications are avoided.

ANAESTHESIA AND ANALGESIA

Platelet count and coagulation tests should be checked before regional anaesthesia. Epidural analgesia in labour reduces fluctuations in arterial pressure and improves placental blood flow.[45] For caesarean delivery, regional anaesthesia avoids the risks of aspiration, difficult intubation from airway oedema, exaggerated hypertensive response to intubation and magnesium-induced sensitivity to muscle relaxants associated with general anaesthesia.

If general anaesthesia is required, smaller-size endotracheal tubes may be required. The hypertensive response to intubation should be attenuated with drugs such as fentanyl (2.5 µg/kg), alfentanil (10 µg/kg), magnesium sulphate (40 mg/kg), a combination of alfentanil (7.5 µg/kg) with magnesium sulphate (30 mg/kg), or remifentanil (1 µg/kg). Occasionally, awake intubation under topical anaesthesia may be necessary when there is airway obstruction.

Obstetric emergencies

Winnie TP Wan, Tony Gin

The intensive care unit (ICU) will receive obstetric patients with the usual range of medical and surgical emergencies, and provide supportive care for patients who suffer specific obstetric complications. The pattern of admission varies widely among countries with different standards of obstetric care. A prospective cohort study in the Netherlands reported the incidence of ICU admission to be 2.4 per 1000 deliveries.[1] The most common reasons for admission were major obstetric haemorrhage, hypertensive disorders of pregnancy and sepsis. In Maryland in the United States, from 1999 to 2009 the ICU utilisation was 4.2 per 1000 deliveries, with hypertensive disorders, haemorrhage and cardiac diseases being the most common.[2] The recent Confidential Enquiries report from 2009 to 2014 in the United Kingdom reported an overall maternal mortality rate of 8.5 per 100,000 maternities, with the commonest cause of direct death being thrombosis and thromboembolism, and of indirect death being cardiovascular disease.[3] Over half of the mothers that die will spend some time in an ICU, and many die there. Overall, however, maternal outcomes are better than expected, and severity of illness scoring systems such as Acute Physiology and Chronic Health Evaluation (APACHE) II and Simplified Acute Physiology Score (SAPS) II overestimate mortality. The Mortality Prediction Model (MPM) II may be useful as it relies less on physiological and laboratory variables that are altered by pregnancy.[4]

The Confidential Enquiries report highlighted the need for early consultation by obstetricians to intensivists. Several obstetric early warning scores are in development to improve patient management and triage.[5] As serious emergencies are rare, and management can be different from non-pregnant patients, it is also useful to conduct simulation training for obstetric, emergency room, resuscitation, operating theatre, anaesthetic and critical care staff with a special focus on emergencies in pregnant patients.

PATHOPHYSIOLOGY[6]

Two important points to recognise in treating obstetric patients are:

1. During pregnancy, the normal ranges for physiological variables change (Table 65.1). This may modify the presentation of the problem, variables used to guide treatment, and the response to treatment. The majority of physiological changes revert to normal several days after delivery.
2. Both mother and foetus are affected by the pathology and subsequent treatment.

AIRWAY AND VENTILATION[7,8]

Several factors may complicate tracheal intubation in pregnancy:

- altered anatomy in pregnancy predisposes to a potentially difficult airway
- oedematous tissues
- delayed gastric emptying
- increased oxygen consumption.

Intensivists must be familiar with the difficult airway algorithm in obstetrics and the use of the laryngeal mask airway. Avoidance of intubation and the use of non-invasive ventilation may be a good option. Lung protective ventilation with low tidal volumes, and positive end-expiratory pressure are applicable in pregnant patients, but airway pressures may need to be higher because of decreased compliance, and permissive hypercapnia more limited ($PaCO_2$ <45 mm Hg) to prevent foetal acidosis.

CIRCULATION

Tachycardia, low blood pressure, increased cardiac output and warm peripheries are normal in late pregnancy. After 20 weeks' gestation, aortocaval compression by the gravid uterus can decrease uterine perfusion and venous return to the heart. This is best prevented by using the full left-lateral position, but a left-lateral tilt or manual displacement of the uterus may be more practicable.

Haemodynamic support should start with good hydration, and assessment should take into account the altered cardiovascular variables in pregnancy. Transthoracic echocardiography is especially useful for diagnosis and monitoring.[9] The uterine vascular

ABSTRACT

The management of obstetric emergencies is influenced by the need to consider that both the mother and foetus are affected by the emergency and the subsequent treatment. During pregnancy, maternal physiological variables change, and this can affect endpoints used to guide therapy. Transthoracic echocardiography is often very useful for diagnosis and monitoring of cardiac function and fluid status. Cardiopulmonary resuscitation should prioritize adequate chest compression, and preparation for emergency caesarean delivery if there is no return of circulation within 4 minutes. In acute respiratory failure, lung protective ventilation strategies are modified because hypercapnia is detrimental to the foetus. In severe postpartum haemorrhage, tranexamic acid should be given as early as possible and a Massive Transfusion Protocol in place to guide therapy. All staff involved in obstetric emergencies should have simulation training to prepare them for these diverse but infrequent emergencies where timely appropriate management is essential.

bed is considered maximally dilated but is still responsive to stimuli that cause vasoconstriction, such as circulating catecholamines. Ephedrine has traditionally been the vasoconstrictor used in obstetrics because it was thought to preserve uterine blood flow better than pure alpha agonists. However, alpha agonists, such as phenylephrine, are more effective and not associated with foetal acidosis when used to manage hypotension during caesarean delivery.[10] There is no evidence favouring any particular inotrope.

COAGULATION

Pregnancy is associated with at least a fivefold increase in thromboembolism, and patients should be given thromboembolic prophylaxis, typically with unfractionated heparin or low-molecular-weight heparin (LMWH) and elastic compression stockings.

MOTHER AND FOETUS

In the critically ill it is important to monitor the foetus because of the problems associated with:

- premature labour
- the placental transfer of drugs
- maintenance of placental perfusion and oxygenation.

An obstetric opinion should be sought as soon as possible regarding cardiotocography, ultrasound examination and timing of delivery. Foetal heart rate is usually a good indicator of placental perfusion. Nutrition is very important for the foetus and adequate maternal feeding should be started as soon as possible. Perineal and breast nursing care should not be neglected.

CARDIOPULMONARY RESUSCITATION[11,12]

Despite being younger than the usual cardiac arrest patients, pregnant patients have a poor survival rate. The obstetrician and neonatologist should be notified when the cardiac arrest call is activated, and preparations be made for perimortem caesarean delivery.

MODIFICATION OF CARDIOPULMONARY RESUSCITATION

Updated guidelines emphasise the importance of good-quality chest compression, and suggest rescuers consider starting cardiopulmonary resuscitation (CPR) with chest compression rather than ventilations (the sequence changes from 'ABC' to 'CAB').

After about 20 weeks' gestation, the gravid uterus can compress the inferior vena cava and impede venous return and cardiac output from CPR. Positioning for obstetric CPR should aim at relieving aortocaval compression and optimising the quality of chest compression. It can be done by manual left uterine displacement in the supine position first, either at the patient's left side with a two-handed technique, or at the patient's right side with a one-handed technique. Chest compression should be performed with a slightly higher hand position (slightly above the centre of the sternum). Airway management in pregnant patients is more difficult. Bag-mask ventilation with high-flow oxygen before intubation is especially important. Early tracheal intubation after cricoid pressure will facilitate ventilation and decrease the risk of acid aspiration. During advanced life support (ALS), drugs are given and defibrillation performed according to the normal protocols. Apical placement of the paddle may be difficult because of the position and breast enlargement, and adhesive defibrillation pads are preferred. Foetal or uterine monitors should be removed before defibrillation.

Both maternal and foetal survival from cardiac arrest depend on prompt caesarean delivery to relieve the effects of aortocaval compression. Resuscitation team leaders should activate the protocol for an emergency caesarean delivery as soon as cardiac arrest is identified in a pregnant woman with an obviously gravid uterus. Emergency caesarean section may be considered at 4 minutes after onset of maternal cardiac arrest if there is no return of spontaneous circulation.

POST-RESUSCITATION CARE

Therapeutic hypothermia has been shown to improve outcome in post-arrest adult patients. According to the ACLS 2015 guideline, targeted temperature management (32°C–34°C) should be considered in pregnant patients. The targeted temperature should follow the protocol for non-pregnant patients. Foetal monitoring should be continued during targeted temperature management.

TRAUMA[13,14]

The epidemiology of trauma in pregnant women varies considerably among countries.[15,16] Trauma complicates approximately 7% of pregnancies, but maternal morbidity and mortality are higher than similar injuries in non-pregnant women. Most injuries occur as the result of motor vehicle accidents, and other common causes are interpersonal violence, falls and suicide (usually postpartum). Fifty per cent of foetal loss occurs after what is usually considered 'minor' trauma.

Special considerations of trauma in obstetric patients include the potential for miscarriage, preterm rupture of membrane, placenta abruptio, inadequate uteroplacental blood flow, preterm labour, and foetal distress and demise. The gravid uterus displaces the bowel cephalad so visceral injuries are less common after lower abdominal injuries. The dilated pelvic vasculature increases the risk of retroperitoneal haemorrhage following pelvic injuries. Head injuries and haemorrhagic shock account for most maternal deaths, whereas placental abruption and maternal death are the most frequent causes of foetal death.

PRIMARY AND SECONDARY SURVEY

Initial resuscitation should follow the normal plan of attention to airway, breathing and circulation. Unless a spinal injury is suspected, the pregnant patient should be transported and examined in the left-lateral tilt position or with manual left uterine displacement. Blood volume is increased during pregnancy and

hypotension may not be evident until 35% or more of total blood volume is lost. Uterine blood flow is not autoregulated and may be decreased despite normal maternal haemodynamics, so that slight overhydration may be preferred to underhydration. Excessive resuscitation with crystalloids or non-blood colloids may increase the mortality from severe haemorrhage. Continuous foetal heart rate monitoring should be used.

In trauma assessment the increased significance of pelvic fractures in terms of uterine injury and retroperitoneal haemorrhage should be considered.

- Ultrasound is the investigation of choice.
- Diagnostic peritoneal lavage, if performed, should be through an open surgical incision above the fundus.
- Chest drains are placed slightly higher than normal, in the third or fourth intercostal space.
- It is important to exclude herniation of abdominal contents through a ruptured diaphragm.
- Vaginal examination to look for either leak of amniotic fluid and/or vaginal bleeding is vital.

Necessary radiological investigations should be performed as indicated as the radiation hazard to the foetus is very small, except in the early first trimester when exposure to more than 50–100 mGy is a cause for concern. A chest X-ray delivers less than 5 mGy to the lungs and very little to the shielded abdomen. The foetal radiation dose from abdominal examinations can range from 1 mGy for a plain film up to 20–50 mGy for an abdominal pelvic computed tomography (CT) with fluoroscopy.[17]

DEFINITIVE CARE

Cardiotocographic monitoring is essential, but there is wide variation in practice and recommended duration of monitoring. Premature labour and placental abruption may not be diagnosed unless regular monitoring is continued for at least 6 hours and even 24 hours if indicated. Rh immune globulin 300 µg should be considered for all Rh D-negative within 72 hours of injury to prevent future Rh alloimmunisation of the newborn. The Kleihauer–Betke test can be used to detect foetal blood in the maternal circulation and give an estimate of the volume of foeto-maternal haemorrhage.

BURNS[18,19]

Approximately 7% of women of reproductive age are seen for treatment for major burns. Although the women are usually young and healthy, pregnancy is already a hypermetabolic state and the foetus is at great risk from many complications. Factors influencing morbidity and mortality include the depth and size of burn wound, the underlying health and age of the pregnant women, the estimated gestational age of the foetus, associated inhalational injury, and significant secondary complications. Preterm labour and stillbirth are more likely in the first few days after the burn injury. The presumed pathogenesis is due to the high levels of prostaglandins and maternal acidosis.

SPECIAL CONSIDERATIONS IN PREGNANT BURN PATIENTS

FLUID RESUSCITATION

Replacement of fluid loss from burns must keep in mind the normally increased circulating volume of pregnancy. Pregnant burn patients usually require significantly more fluid to maintain haemodynamic stability. Pregnancy affects the total body surface area as the abdomen increases in size. The Lund–Browder chart is still the commonly used method for burn area estimation.

DEFINITIVE BURN CARE

Topical povidone-iodine solution should be avoided because the iodine may be absorbed and affect foetal thyroid function. Inhalational injuries with hypoxia and carbon monoxide are especially detrimental to the foetus because carbon monoxide has a greater affinity and longer half-life when it is bound to foetal haemoglobin.

SEVERE OBSTETRIC HAEMORRHAGE

Obstetric haemorrhage accounts for 27% of all maternal deaths.[20] The aim of management is rapid restoration of circulating volume, correct coagulopathy and remedy of the underlying cause of haemorrhage. There should be a Massive Transfusion Protocol activated at the appropriate time to aid timely and optimal transfusion of blood products.

Antepartum haemorrhage is defined as bleeding from the genital tract after 24 weeks of gestation. Its incidence is 2%–5% of all pregnancies. The common causes are placenta praevia and placental abruption; both are ultimately managed by delivery. In placenta praevia, the placenta implants in advance of the presenting part and classically presents as painless bleeding during the second or third trimester. Placenta praevia is relatively common (1 in 200 pregnancies) but severe haemorrhage is relatively rare. In placental abruption, a normally implanted placenta separates from the uterine wall. The incidence of placental abruption is low (0.5%–2%) but perinatal mortality may be as high as 50%. In concealed abruption, vaginal bleeding can be absent and several litres of blood may be concealed in the uterus.

Postpartum haemorrhage is most commonly due to uterine atony and abnormal placentation, with retained tissues, trauma to the genital tract and coagulopathy as other causes. In an emergency, the aorta can

be compressed against the vertebral column by a fist pressed on the abdomen above the umbilicus.

Uterine atony is managed initially with bimanual compression, uterine massage and drugs that include[21]:

- *oxytocin:* 5 units slow intravenous injection, or infusion (40 units in 500 mL Ringer lactate solution at 125 mL/h)
- *ergonovine (ergometrine):* 0.5 mg slow intravenous or intramuscular injection (contraindicated in patients with hypertension)
- *carboprost:* 250 µg intramuscular injection, repeated at intervals of not less than 15 minutes to a maximum of 8 doses (contraindicated in patients with asthma) or 500 µg direct intramyometrial injection
- *misoprostol:* 1000 µg rectally.

If bleeding persists, tamponade techniques using gauze packs or balloons can be useful.

In severe postpartum haemorrhage, as well as activating the Massive Transfusion Protocol, tranexamic acid should be given as early as possible. The large WOMAN trial of over 20,000 women found that tranexamic acid 1 g reduced death due to bleeding with no adverse effects, and it should be given as soon as possible after the onset of bleeding.[22]

Specific invasive management – such as angiographic arterial embolisation, laparotomy for uterine haemostatic suturing techniques such as B-lynch and multiple square sutures, surgical bilateral uterine artery ligation, or definitive hysterectomy – may be required. Recombinant factor VIIa has been used but should be given as part of a research protocol. The initial dose is 90 µg/kg, and a second dose can be given 20–60 minutes later if there is no response.

For patients with known and suspected risk factors for postpartum haemorrhage, prophylactic interventional radiology can be employed. Balloons are placed in the internal iliac or uterine arteries before delivery, and are inflated to occlude the vessels in the event of postpartum haemorrhage.[23]

Disseminated intravascular coagulation still develops in 10%–30% of cases, partly because tissue thromboplastin is released during abruption.

SEPSIS AND SEPTIC SHOCK[24,25]

Maternal sepsis and septic shock are relatively uncommon but increasing, with rates of approximately 10 cases per 10,000 deliveries. Sepsis should always be considered because the underlying physiological changes in pregnancy and the response to labour can confound the presentation of sepsis and make its diagnosis difficult. Delays in recognition and management have been noted in 70% of cases. The total Sequential Organ Failure Assessment (SOFA) score performs well in obstetric patients.[26]

The most common sources of infection are chorioamnionitis, postpartum endometritis, urinary tract infections, pyelonephritis and septic abortion. Animal studies suggest that pregnancy increases the susceptibility to endotoxin, and that metabolic acidosis and cardiovascular collapse occur earlier.

Management of septic shock follows the same guidelines as for the non-pregnant population, with initial resuscitation, source control and prompt antibiotics. Vasopressors may reduce placental perfusion so the foetal heart rate should be monitored. Norepinephrine is still the first-line drug of choice. It has been used to maintain blood pressure during caesarean delivery without foetal effects.[27] Gram-negative organisms are the frequent causative organisms, but streptococci and *Bacteroides* may also be present. Antimicrobial therapy is dependent on hospital prevalence and susceptibility patterns; empirical broad-spectrum therapy should be started early. Typical combinations are ampicillin, gentamicin and clindamycin, or carbapenem and vancomycin. Tetracyclines and quinolones should not be used in pregnancy.

VENOUS THROMBOEMBOLISM[28,29]

The incidence of venous thromboembolism (VTE) ranges from 0.5 to 2 episodes per 1000 deliveries, which is a 5- to 10-fold increase in risk compared with those reported in non-pregnant women of comparable age. Pulmonary thromboembolism is a common cause of maternal death, accounting for 15%–25% of maternal mortality. Major international guidelines for the management of VTE in pregnancy have slight differences.[29]

Pregnancy is associated with increased risk of VTE because of:

- venous stasis
- hypercoagulable state
- vascular injury associated with delivery.

Accurate diagnosis of VTE is crucial because of the long-term implications for therapy. Symptoms of dyspnoea or pain in the leg or chest require accurate diagnosis, especially in the immediate postpartum period. Although contrast venography is the gold-standard test for diagnosing deep-vein thrombosis, the radiation exposure and invasive nature of the test mean that compression ultrasonography is the usual first choice. D-dimer testing is not recommended in some guidelines because D-dimer values normally increase throughout pregnancy. Venography, perfusion lung scanning, pulmonary angiography and helical CT scan should not be avoided if indicated.

TREATMENT OF VTE DURING PREGNANCY[29]

Treatment is either subcutaneous LMWH or intravenous unfractionated heparin. LMWH has gradually

replaced unfractionated heparin, based on the results of large trials in non-pregnant patients showing that LMWHs are at least as safe and effective as unfractionated heparin. In addition, the risk of heparin-induced thrombocytopenia and osteoporosis appears lower with LMWH than unfractionated heparin. The need for dose adjustments in proportion to change in weight over the course of pregnancy remains controversial. Full-dose anticoagulation should be continued during pregnancy. Subcutaneous LMWH can be discontinued 24–36 hours before, and intravenous unfractionated heparin 4–6 hours before elective induction of labour or caesarean section. A temporary retrievable venous filter can be inserted and removed postpartum. LMWH or unfractionated heparin should be restarted in the postpartum patient for at least 6–12 weeks. Neuraxial anaesthesia should not be used on patients with full anticoagulation.

With life-threatening massive pulmonary embolus, surgical treatment or thrombolysis must be considered. Thrombolysis obviously carries the risk of maternal and foetal haemorrhagic complications. No controlled trials are feasible and outcome data must be extracted from case reports. A review found that thrombolytic therapy was associated with a low maternal mortality rate of 1%, with a 6% rate of foetal loss and a 6% rate of premature delivery.[30] The foetal risks appear to be lower than that obtained with surgical intervention in pregnant patients, and maternal risks lower than reported risks for surgery, thrombolysis or transvenous filters in non-pregnant patients. Although heparin remains the treatment of choice, guidelines suggest that thrombolysis may be considered when there is limb- or life-threatening thromboembolism.

AMNIOTIC FLUID EMBOLISM[31]

Amniotic fluid embolism (AFE) has signs and symptoms in common with other obstetric emergencies and it is a diagnosis of exclusion, so the true incidence and mortality rates are uncertain. The incidence of AFE has been reported as 1 in 13,000 deliveries in the United States, and 1 in 50,000 deliveries in the United Kingdom. The maternal mortality rate in developed countries ranges from 20% to 60%.

PATHOPHYSIOLOGY

The pathophysiology of AFE remains uncertain. Traditionally, it was thought that amniotic fluid and foetal debris entered the maternal circulation by forceful uterine contraction and caused embolic effects. However, recent studies show that foetal cells are commonly found in the maternal circulation, and that AFE has more in common with anaphylaxis and septic shock than other embolic diseases. The term 'anaphylactoid syndrome of pregnancy' has been proposed but the condition is still commonly referred to as AFE. The exact trigger is unknown. There is an abnormal maternal immune response to foetal antigen exposure, and inflammatory mediators cause pulmonary vasoconstriction, complement activation and coagulopathy.

CLINICAL PRESENTATION

AFE is a clinical diagnosis. Classically, patients present with severe hypoxia, hypotension or sudden cardiovascular collapse, and coagulopathy during labour, but AFE may occur earlier during pregnancy, during delivery or in the early puerperium. There is no gold standard test for diagnosis, although biomarkers, such as the insulin-like growth factor-binding protein-1, have been proposed.

Animal studies indicate that AFE causes a biphasic haemodynamic response. The early phase probably lasts less than half an hour and is characterised by severe hypoxia and right heart failure as a result of pulmonary hypertension from vasoconstriction or vessel damage. Patients who survive this first phase develop left ventricular failure with the return of normal right ventricular function. Left ventricular failure may be a result of the initial hypoxia or the depressant effects of mediators. Disseminated intravascular coagulation is present in most patients. It could be caused by a specific activator of factor X, tissue factor or other substances, such as trophoblasts, in the amniotic fluid.

TREATMENT

Treatment is supportive. Invasive monitoring and echocardiography are useful to evaluate the effects of haemodynamic support. Survivors of AFE regain normal cardiorespiratory function but may have neurological sequelae.

ACUTE RESPIRATORY FAILURE[32]

Pregnant women should receive medication for optimal asthma control. There is no evidence that appropriate use of inhaled glucocorticosteroids, beta agonists and leukotriene modifiers is associated with increased incidence of foetal abnormalities. In contrast, there is a substantial risk of preterm delivery posed by poorly controlled maternal asthma.[33] Acute exacerbation should also be treated aggressively with systemic glucocorticosteroids when necessary.

Pulmonary oedema is more likely in the pregnant patient (1:1000 pregnancies) because of the increased cardiac output and blood volume, and the decreased plasma oncotic pressure. The principles of treatment are relatively straightforward in terms of determining the cause of the oedema and improving oxygenation, although it can be difficult to distinguish between hydrostatic and permeability oedema.

The prevalence of acute respiratory distress syndrome (ARDS) during pregnancy has been estimated at 16–70 cases per 100,000 pregnancies, with mortality rates from 23% to 50%.[34] Important causes of ARDS in pregnancy are sepsis, aspiration and pre-eclampsia. Non-invasive positive-pressure ventilation has not been evaluated for treatment of hypoxaemic respiratory failure in pregnancy. Clinical criteria for intubation are similar to those in non-pregnant patients, but arterial blood gases must be interpreted carefully because of the underlying respiratory alkalosis in pregnancy. The ARDS Network lung protective strategy can be adopted in pregnant patients by using the non-pregnant predicted body weight and gestational age-appropriate blood gas targets. Permissive hypercapnia may cause foetal respiratory acidosis that will reduce the ability of foetal haemoglobin to bind oxygen. Furthermore, the transfer of CO_2 across the placenta requires a gradient of 10 mm Hg (1.33 kPa). Therefore, $PaCO_2$ should probably be kept below 45 mm Hg (6.0 kPa) and Pa_{O_2} above 70 mm Hg (9.3 kPa). If conventional ventilation fails, the effectiveness of alternative strategies, such as prone ventilation and extracorporeal membrane oxygenation (ECMO), have only been reported in case studies. Although ECMO has been effective in pregnant patients with severe ARDS from influenza H1N1, a review of the topic was more cautious in its overall recommendation.[35]

ACID ASPIRATION (MENDELSON SYNDROME)

Obstetric patients are at increased risk of acid aspiration because of decreased gastric emptying, increased gastric acidity and volume, and increased intra-abdominal pressure. Aspiration of acidic material will cause acute lung injury, the severity being related to the amount, content and acidity of the aspirate.

The initial presentation is hypoxaemia and bronchospasm. Chemical pneumonitis and increased permeability pulmonary oedema develop over several hours.

Treatment includes standard respiratory support. Rigid bronchoscopy may be required to remove large food particles. Bronchoalveolar lavage and steroids are not useful and antibiotics should only be given for proven infection.

TOCOLYTIC THERAPY AND PULMONARY OEDEMA[36]

Pulmonary oedema is an uncommon (1 in 400 pregnancies) but serious complication of tocolytic therapy, especially with beta-adrenergic agonists. The underlying mechanism for pulmonary oedema is unclear, but it is probably related to fluid overload and the cardiovascular effects of beta-adrenergic agonists leading to increased pulmonary capillary hydrostatic pressure. The initial management of pulmonary oedema is discontinuation of the tocolytic and oxygen therapy, with further monitoring, diuretics and respiratory support as necessary. Pulmonary oedema is less common but can occur with other tocolytics such as nifedipine and nicardipine.

PERIPARTUM CARDIOMYOPATHY[37]

Peripartum cardiomyopathy (PPCM) is characterised by a new onset of heart failure between the late third trimester of pregnancy and 6 months postpartum in previously healthy women. Diagnosis requires echocardiographic evidence of left ventricular dysfunction (ejection fraction <45%). The incidence varies from 1:1000 to 1:10,000 pregnancies and is significantly higher in Afro-Caribbean women. PPCM often presents as acute heart failure. The echocardiogram usually shows features of dilated cardiomyopathy.

The exact aetiology of PPCM remains controversial with possible causes including angiogenic imbalance, genetic factors, volume overload, inflammatory, autoimmune and hormonal imbalance. Treatment is largely supportive with diuretics, inotropes and non-invasive positive-pressure ventilation. Intra-aortic balloon pump and left ventricular assist device may be used in severe cases. Bromocriptine therapy is used but is controversial and based on animal studies where the prolactin blockade prevented PPCM.

OVARIAN HYPERSTIMULATION SYNDROME[38,39]

Ovarian hyperstimulation syndrome (OHSS) is a rare iatrogenic complication of ovarian stimulation, which usually occurs during the luteal phase or early part of pregnancy. The prevalence of severe OHSS is low, at 0.5%–5% of stimulated ovarian cycles, but it has become more recognised owing to the increasing number of women undergoing assisted reproductive techniques.

The exact aetiology and pathogenesis of OHSS remain uncertain. It appears that exogenous or endogenous human chorionic gonadotropin (hCG) is the central triggering factor. The stimulated ovaries become markedly enlarged with the overproduction of ovarian hormones and vasoactive substances, including cytokines, angiotensin and vascular endothelial growth factor (VEGF). As a result, the capillary permeability increases leading to hypovolaemia with haemoconcentration, oedema and accumulation of fluid in the abdomen and pleural spaces.

OHSS can be classified as mild, moderate, severe or critical. Critical OHSS patients may have oliguria, renal failure, tense ascites, hydrothorax, thromboembolism, pericardial effusion, liver derangement, ovarian torsion, cerebral oedema and ARDS.

The treatment of OHSS is supportive until the condition resolves. In most cases, the syndrome follows a self-limiting course that parallels the decline in serum

hCG level. Abdominal and pleural tapping is needed to release the accumulated fluid. Albumin can be used as a plasma expander. Prophylaxis for thromboembolism with an anticoagulant should be given, and surgical intervention may be necessary for ovarian torsion.

Severe cardiac disease in pregnancy

Alice Green, Steve M Yentis, Jeremy P Campbell

INTRODUCTION

Cardiac disease is now the leading cause of maternal mortality in the developed world. It is estimated to be present in 0.2%–4% of pregnancies,[1–4] and this figure is increasing as more women with congenital heart disease (CHD) reach childbearing age.[5] In addition, advancing maternal age and co-morbidities such as diabetes, obesity and hypertension all increase the risk of acquired cardiovascular disease in pregnancy.[1,6]

With early diagnosis and management, many women with cardiac conditions can deliver safely; however, some conditions are associated with significant morbidity and mortality. Cardiac disease remains the largest single cause of maternal death in the United Kingdom.[7] Of the women who died from a cardiac condition in the period 2009–2014, 47 (31%) were classified as sudden adult death syndrome (SADS), 34 (22%) were classed as ischaemic deaths, 27 (18%) had myocardial disease/cardiomyopathy, 21 (14%) had an aortic dissection, 11 (7%) had valvular heart disease, 6 (4%) had essential hypertension, and 7 (5%) had other cardiac conditions.[7]

Most cardiac mortality occurs in women with structurally normal hearts who were not known to have heart disease before pregnancy; only 17% of women who died between 2009–2014 were known to have pre-existing cardiac problems.[2,7] It is therefore important to identify women at risk of heart disease and to be aware of the presentation and management of cardiac disease in pregnancy.[2,6]

PHYSIOLOGY AND PATHOPHYSIOLOGY

Pregnancy places a high physiological demand on the cardiovascular system. Blood volume increases by 50%, starting as early as the sixth week, rising rapidly to mid-pregnancy, then rising at a slower rate.[1] Red cell mass increases at a slower rate, resulting in a physiological anaemia. Cardiac output increases by 50%, as a combination of early increased stroke volume and increased heart rate in the third trimester. Pregnancy may therefore be poorly tolerated if this increase is limited by disease.[2] There is a reduction in systemic vascular resistance (SVR) and blood pressure falls during the first trimester, returning to pre-gestational levels before term.

Anxiety, pain and contractions during labour and delivery increase cardiac output, oxygen consumption (threefold) and blood pressure.[1] After delivery, there is a temporary increase in intracardiac pressures due to relief of caval compression and autotransfusion from the contracting uterus. This may cause a deterioration in susceptible patients and the risk can remain for several weeks after delivery.[2]

PRECONCEPTION

Preconception counselling should be offered to all women known to have heart disease and efforts should be made to prevent unwanted pregnancies.

The most common complications in those with pre-existing disease are arrhythmias, heart failure and thromboembolic events.[1] Patients with stenotic valvular lesions, pulmonary hypertension, mechanical heart valves, Eisenmenger syndrome and severe cardiomyopathies have the poorest outcomes and tolerate the haemodynamic changes of pregnancy, delivery, anaesthesia and surgery less than women with other cardiac disorders.[3,8] These are the women most likely to need critical care support pre- or postnatally. Women with impaired ventricular function should be made aware that this may deteriorate with pregnancy and may not fully recover.[2]

The World Health Organization (WHO) risk classification categorises cardiac lesions as low-risk (WHO I), medium-risk (WHO II), high-risk (WHO III) and lesions where pregnancy is contraindicated (WHO IV). The European Society of Cardiology (ESC) guidelines include minor modifications to this classification (Table 66.1).[2,4]

ANTEPARTUM MANAGEMENT

Pregnant women with cardiac disease should be seen early in a joint cardiac, obstetric and anaesthetic clinic to perform a risk assessment, including any further investigations, and formulate a management plan.[8,9]

ABSTRACT

Cardiac disease in pregnancy is a leading cause of maternal morbidity and as more women with congenital heart disease are reaching childbearing age, and with risk factors for acquired heart disease increasing, it is important that critical care physicians are aware of the presentation and management of these women. It is also necessary to understand the physiological changes that occur during pregnancy, how they can alter the presentation of cardiac disease and how they influence peri-partum management.

KEYWORDS

Pregnancy
cardiac disease
peripartum
cardiomyopathy
valve disease

Table 66.1 ESC-modified World Health Organization risk classification of cardiac lesions

CONDITIONS IN WHICH PREGNANCY IS WHO I	
No detectable increase in maternal mortality and no or mild increase in morbidity	Uncomplicated small or mild • Pulmonary stenosis • Patent ductus arteriosus • Mitral valve prolapse Successfully repaired simple lesions (atrial or ventricular septal defects, patent ductus arteriosus, anomalous pulmonary venous drainage) Atrial or ventricular ectopic beats, isolated
CONDITIONS IN WHICH PREGNANCY RISK IS WHO II OR III	
WHO II (if otherwise well and uncomplicated)	
Small increase in maternal mortality and moderate increase in morbidity	Operated atrial or ventricular septal defect Repaired tetralogy of Fallot Most arrhythmias
WHO II–III (depending on individual)	
	Mild left ventricular impairment Hypertrophic cardiomyopathy Native or tissue valvular heart disease not considered WHO I or IV Marfan syndrome without aortic dilatation Aorta <45 mm in aortic disease associated with bicuspid aortic valve Repaired coarctation
WHO III	
Significantly increased risk of maternal mortality or severe morbidity. Expert counselling required if pregnancy is decided upon. Intensive specialist cardiac and obstetric monitoring needed throughout pregnancy, childbirth and puerperium.	Mechanical valve Systemic right ventricle Fontan circulation Cyanotic heart disease (unrepaired) Other complex congenital heart disease Aortic dilatation 40–45 mm in Marfan syndrome Aortic dilatation 45–50 mm in aortic disease associated with bicuspid aortic valve
CONDITIONS IN WHICH PREGNANCY IS WHO IV (PREGNANCY CONTRAINDICATED)	
Extremely high risk of maternal mortality or severe morbidity, pregnancy is contraindicated. If pregnancy occurs, termination should be discussed. If pregnancy continues, care as for class III.	Pulmonary arterial hypertension of any cause Severe systemic ventricular dysfunction (LVEF <30%, NYHA III–IV) Previous peripartum cardiomyopathy with any residual impairment of left ventricular function Severe mitral stenosis, severe symptomatic aortic stenosis Marfan syndrome with aorta dilated >45 mm Aortic dilatation >50 mm in aortic disease associated with bicuspid aortic valve Native severe coarctation

High-risk women should be seen regularly in the clinic during pregnancy and a plan for delivery should be made at approximately 32–34 weeks, including the mode of delivery, length of the second stage, appropriate prophylaxis against postpartum haemorrhage, length of hospital stay and the possible need for critical care support (both planned and unplanned). Such support may not necessarily require admission to a critical care unit, depending on what resources/facilities can be provided within the maternity unit, but it is important that intensivists are involved at this planning stage. Appropriate antithrombotic prophylaxis must also be discussed and planned, with the risks from maternal thrombosis weighed against the maternal and foetal risks from anticoagulation.[2]

INTRAPARTUM MANAGEMENT

Women with high-risk conditions should deliver at centres that are able both to accommodate pregnant/postpartum women requiring high-dependency or intensive care, and to provide appropriate specialist cardiac support.[6,9] Vaginal delivery is usually the delivery of choice, as it is associated with less blood loss, smaller fluid shifts, and lower rates of thrombosis and infection.[4,8,9] Caesarean section is generally done for obstetric indications, although planned operative delivery may be appropriate in women with worsening and/or severe conditions. Women with severe or life-threatening structural abnormalities may benefit from delivery in a cardiothoracic centre.

The general principle of management during labour is to reduce cardiovascular stress, in most cases with early epidural analgesia, a limited second stage and assisted delivery. Monitoring of electrocardiography (ECG), invasive arterial blood pressure and central venous pressure is done according to the risk factors and complexity of each case.

Regional anaesthesia is usually preferred for caesarean section, as for women without cardiac disease, unless there are concerns over coagulation. In women with severe cardiac disease, both regional and general anaesthesia have advantages and disadvantages that must be weighed up for each case, the general rule being that extreme care and attention to detail are probably more important than the choice of technique itself.

POSTPARTUM MANAGEMENT

It is important to appreciate that maternal deaths from cardiac disease may commonly occur after delivery. Arrhythmias, heart failure and thrombotic events are particular hazards, and introduction (or re-introduction) of appropriate medication, including thromboprophylaxis, must be considered.[2]

SPECIFIC CONDITIONS

STRUCTURAL HEART DISEASE

VALVULAR DISEASE

Valvular disease may present for the first time during pregnancy.[2] Careful cardiovascular assessment is required early in pregnancy in all women born in a country without effective medical screening for rheumatic heart disease (25% of women giving birth in the United Kingdom were born elsewhere).[6] Pregnant women can usually tolerate valvular incompetence better than stenosis, as a reduced SVR improves forward flow and reduces the regurgitation.[9] The use of antibiotic prophylaxis to reduce the risk of endocarditis in these patients remains controversial.[4,9]

Because of the physiological changes of pregnancy, measurements of flow across valves may be misleading, and valve areas are often preferred.[10]

Mitral disease

Mitral stenosis is poorly tolerated and women are at an increased risk of pulmonary oedema and atrial fibrillation due to left atrial enlargement. Drug treatment includes anticoagulation because of the increased risk of an intracardiac thrombus, diuretics to relieve congestion, and beta-blockers to preserve sinus rhythm.[2] Management around delivery should include invasive arterial monitoring and any sudden drops in SVR treated with vasoconstrictors or cautious volume expansion.[9]

Aortic disease

Those with severe stenosis will not tolerate blood loss, tachycardia or caval compression; therefore, fluid depletion and hypotension should be avoided.[9] Women with severe disease have traditionally undergone operative delivery in a tertiary centre under general anaesthesia, with invasive cardiovascular monitoring, although regional anaesthesia has also been described and there are increasing reports of successful vaginal delivery in women with severe aortic stenosis.[2] These women will require postpartum monitoring in a high-dependency area.

Aortic dissection is associated with unrepaired coarctation of the aorta, Marfan syndrome and other connective tissue disorders.[2] Hormonal, haemodynamic and thromboembolic changes during pregnancy contribute to the elevated risk, which is highest in the third trimester and early postpartum period.[9,11] Systolic hypertension is a risk factor and strict blood pressure control is advised (e.g. with methyldopa and beta-blockers), with invasive arterial pressure monitoring in severe cases.[4,11] Serial echocardiograms during pregnancy are useful for monitoring ventricular function and aortic root diameter.

Vaginal delivery with epidural analgesia, as above, is usually aimed for, although for patients on oral anticoagulants and in vascular Ehlers-Danlos syndrome, ascending aortic aneurysms greater than 45 mm, or acute or chronic aortic dissection, caesarean section is sometimes preferred.[11]

Mechanical heart valves

Pregnant women with a mechanical heart valve are at increased risk of infection, thrombotic events and – through the need for anticoagulation – bleeding and possible foetal toxicity.[2,9,12] Valve thrombosis has been reported in 4.7% of women with mechanical valves during pregnancy, with a 20% mortality and haemorrhagic complications in 23%.[12]

PULMONARY HYPERTENSION

Pulmonary hypertension (defined as mean pulmonary artery pressure >25 mm Hg) has a reported

maternal mortality of 25%–56% and is classified by the modified WHO criteria as Class IV; therefore, women should be advised to avoid pregnancy.[13] Targeted pulmonary vasodilator therapies (e.g. inhaled iloprost or intravenous prostacyclin) have gained some improvement, but mortality remains up to 33%.[2] Pregnancy outcome is also poor, with high rates of preterm delivery, foetal growth restriction and foetal/neonatal loss.[13]

Women who proceed with pregnancy should be seen at regular intervals and a plan is often made for elective caesarean section at ~34 weeks of gestation.[2,14] In severe cases, this should be in a tertiary centre with close monitoring in the ICU pre- and post-delivery, as sudden death a few days postpartum, due to intractable right heart failure, is well reported.[2,9,13–14]

FONTAN CIRCULATION

The Fontan procedure is used to palliate any single ventricle circulation that is not suitable for surgical repair into a two-ventricle circulation. Decompensation may cause arrhythmias, heart failure, chest pain and hypoxia, and therefore may present antenatally to ICU.[5] Maintenance of preload and forward flow through the pulmonary vessels is essential in these patients and dehydration and caval compression should be avoided. Reduced venous return caused by positive-pressure ventilation is particularly hazardous.

ISCHAEMIC HEART DISEASE

Pregnancy increases the risk of acute myocardial infarction (MI) three- to fourfold and if MI occurs within 2 weeks of delivery, mortality is up to 45%.[2,9] The incidence of ischaemic heart disease in pregnancy is increasing along with maternal age, obesity, diabetes, smoking, hyperlipidaemia and hypertension; many of these women will be asymptomatic.[6]

A high index of suspicion is required for any pregnant woman presenting with chest pain.[6] Aortic dissection and pulmonary embolism should also be ruled out. Treatment of MI is as for the non-pregnant population, with urgent angiography +/– primary percutaneous coronary intervention. Aspirin, clopidogrel and beta-blockers appear relatively safe during pregnancy, except for an increased risk of bleeding at delivery with antiplatelet drugs.[2]

The most common cause of MI immediately postpartum is spontaneous coronary artery dissection, 78% of whose sufferers will have no risk factors for coronary artery disease.[9] The use of ergometrine to induce uterine contraction after delivery is associated with MI secondary to coronary artery spasm in patients at risk. Patients should be treated with sublingual or intravenous glyceryl trinitrate and may require immediate coronary angiography.[9]

FUNCTIONAL HEART DISEASE

VENTRICULAR DYSFUNCTION

Ventricular impairment may present during pregnancy due to unmasking of an undiagnosed condition or precipitating peripartum cardiomyopathy.[2] In overt failure, admission, bed rest, diuretics and anticoagulation should be considered and early delivery planned. Inotropic support may be required and may be a bridge to transplantation in some patients.[2,15]

Peripartum cardiomyopathy

Peripartum cardiomyopathy (PPCM) is a rare idiopathic form of heart failure that presents in the last month of pregnancy or within 5 months of delivery.[16,17] It is a diagnosis of exclusion and left ventricular ejection fraction is nearly always less than 45%.[15,16] Risk factors include multiparity, twin pregnancy and extremes of age, and mortality is ~15%–30%.[2,9,16] The presentation can be challenging, as symptoms can mimic those experienced during normal pregnancy and it may be confused with pre-eclampsia.[6,17] Symptoms include increasing shortness of breath, peripheral oedema and fatigue.[16]

Treatment, timing and mode of delivery depend on disease severity, with vaginal delivery acceptable for most stable patients and caesarean preferred for those who are unstable.[16,17] Treatment is similar to that of patients with systolic heart failure and includes salt restriction, diuretics, beta-blockers and peripheral vasodilators.[9] The choice of agents is limited during pregnancy and breastfeeding but can be changed to standard therapy postpartum. Patients with PPCM are at high risk of thrombotic complications during and for several months after pregnancy. In those presenting with cardiogenic shock, an intra-aortic balloon pump or extracorporeal membrane oxygenation may be required. Studies have found that bromocriptine may be useful in those with acute onset PPCM.[15,16]

The clinical course varies between complete recovery within 6 months in most patients, and rapid progression to heart failure and death. Those with a history of PPCM have a 20%–30% risk of relapse and worsening heart failure in subsequent pregnancies, with those whose cardiac function has not returned to normal having a 45%–50% risk of recurrence.[2,17]

Hypertrophic cardiomyopathy

If ventricular function is preserved, then pregnancy is generally well tolerated; however, those with significant outflow obstruction, ventricular arrhythmias and severe hypertrophy are at increased risk of decompensation.[2] The highest risk period is around delivery and the first 48 hours postpartum, due to rapid fluid shifts that can precipitate heart failure and arrhythmias.[2]

ARRHYTHMIAS AND IMPLANTABLE CARDIOVERTER DEFIBRILLATORS

Palpitations are relatively common in pregnancy; however, if they are sustained or women become symptomatic, they should be investigated further.[2] A high number of ventricular ectopics on ambulatory ECG monitoring may be an early sign of ventricular dysfunction. Beta-blockers are the first line of drug treatment for supraventricular and ventricular tachycardias in pregnancy.[2]

Patients with implantable cardioverter defibrillators (ICDs) may undergo pregnancy with no increase in ICD discharge.[2] Delivery should be planned in a centre with the resources to manage ICDs, as it may be appropriate to turn off the device and have continuous ECG monitoring with a manual defibrillator available if proceeding to surgery, as diathermy may cause interference.[2]

Anaphylaxis

Peter R Platt, Paul HM Sadleir

First I feel I must explain and indeed justify the use of the word itself, for it may seem somewhat barbarous at first glance. This neologism I invented twelve years ago on the assumption, which I think is still valid, that a new idea calls for a new word in the name of scientific precision of language. Phylaxis, a word seldom used, stands in the Greek for protection. Anaphylaxis will thus stand for the opposite. Anaphylaxis, from its Greek etymological source, therefore means that state of an organism in which it is rendered hypersensitive, instead of being protected.

Charles Richet, Nobel Lecture, 11 December 1913.[1]

DEFINITION AND CRITERIA FOR DIAGNOSIS

Anaphylaxis is an acute multisystem disorder with a variable presentation secondary to the release of multiple mediators from mast cells and/or basophils. Since its original description and later the recognition of a new immunoglobulin, IgE in 1968, the term anaphylaxis has been generally used specifically for an acute hypersensitivity reaction to a foreign substance mediated by IgE. With the recognition that the mast cell could be triggered to release mediators via other mechanisms producing an identical pathophysiological syndrome, the collective term '*anaphylactoid*' was coined to distinguish these reactions from those mediated by IgE. To some extent this term and the ICD9/10 coding limited to 'anaphylactic shock' resulted in failure to capture accurate epidemiological data resulting in calls for a change of diagnostic criteria. Using anaphylaxis guidelines published from 2010 by major allergy/immunology organisations,[2–4] the World Allergy Organization (WAO) aligned these guidelines.[5] Importantly, it was agreed that a diagnosis of anaphylaxis should be based upon symptoms and signs as defined by Sampson et al.[6] in 2006 (Table 67.1). These clinical criteria may be limited to signs in the sedated or anaesthetised patient in the critical care environment; hypotension that is relatively unresponsive to vasopressors may be the only warning sign of anaphylaxis in these settings. The WAO recommended abandonment of the terms *anaphylactoid* and *pseudo-allergy* to describe non-IgE mediated reactions. They redefined *anaphylaxis* as 'a serious, life-threatening generalized or systemic hypersensitivity reaction' that may be *immune mediated* (IgE or non IgE) or *non-immune mediated*, although this has not met with universal agreement. The pathophysiological mechanisms of anaphylaxis are discussed in detail below, with particular emphasis on the most prevalent immunological, IgE-dependent mechanism. Immunological non-IgE mechanisms including complement activation and activation of the kallikrein-kinin contact system are discussed in the section detailing representative agents. Non-immunological mechanisms include direct activation of the only recently identified MrgprX2 mast cell receptor[7] responsible for histamine release caused by drugs such as opioids. Physical factors such as exercise, cold and heat can co-contribute as causes of anaphylaxis and those that are unexplained are classified as idiopathic.

EPIDEMIOLOGY

For decades the prevalence of allergic diseases worldwide has been dramatically increasing with as many as 20% of the population of developed countries being affected. Estimates of incidence rates of anaphylaxis are widely variable around 10–20 per 100,000 population. Less than one-third of these patients will require hospital admission. In the United Kingdom between 1992 and 2012, hospital admissions[8] increased by 615% and critical care admissions between 2005 and 2009 almost doubled[9] but annual fatality rates remained stable at 0.047 cases per 100,000 population. In contrast, Australian total hospital admissions for anaphylaxis increased almost fourfold and fatal anaphylaxis almost doubled in the period 1997–2013.[10] Although anaphylaxis is a potentially lethal condition, it only accounts for a small proportion of the workload of critical care units being responsible for as few as 0.1% of childhood and 0.3% of adult admissions; greater than 90% of these cases can be expected to survive.

RISK FACTORS

Anaphylaxis may be associated with a number of risk factors that can increase the severity, risk of fatality and decreased response to treatment. The largest number of incident cases of anaphylaxis is in children but it is teenagers with food allergy and poorly controlled asthma that are at risk of critical bronchospasm

ABSTRACT

Anaphylaxis is an acute, life-threatening disorder that requires rapid recognition and immediate treatment. Its prevalence is increasing in line with the overall allergic disease problem affecting the developed world. Most cases are treated successfully in the community or hospital emergency department. Severe cases with critical airway obstruction, from angioedema or bronchospasm, or cardiovascular collapse require expert management in a critical care environment. All age groups are susceptible but the causes differ, with food allergy being the main cause in the young and medications in the older. Although recognition is straightforward in most cases, cryptogenic anaphylaxis is not uncommon in the perioperative or intensive care setting. Treatment continues to evolve; epinephrine and volume replacement remain critically important but the use of transoesophageal echocardiography and extracorporeal membrane oxygenation are increasingly utilised in those unresponsive to first-line therapy. Deaths continue to occur both in the community and hospital; anaphylaxis is one of the few unpredictable and non-discriminatory causes of death during surgery and anaesthesia.

Table 67.1 Clinical criteria for diagnosing anaphylaxis

Anaphylaxis is highly likely when any one of the following three criteria are fulfilled:

1. Acute onset of an illness (minutes to several hours) with involvement of the skin, mucosal tissue, or both (e.g. generalised hives, pruritus or flushing, swollen lips-tongue-uvula)
   AND AT LEAST ONE OF THE FOLLOWING:
   a. Respiratory compromise (e.g. dyspnoea, wheeze-bronchospasm, stridor, reduced PEF, hypoxaemia)
   b. Reduced BP or associated symptoms of end-organ dysfunction (e.g. hypotonia [collapse], syncope, incontinence)
2. Two or more of the following that occur rapidly after exposure *to a likely allergen for that patient* (minutes to several hours):
   a. Involvement of the skin-mucosal tissue (e.g. generalised hives, itch-flush, swollen lips-tongue-uvula)
   b. Respiratory compromise (e.g. dyspnoea, wheeze-bronchospasm, stridor, reduced PEF, hypoxaemia)
   c. Reduced BP or associated symptoms (e.g. hypotonia [collapse], syncope, incontinence)
   d. Persistent gastrointestinal symptoms (e.g. crampy abdominal pain, vomiting)
3. Reduced BP after exposure *to known allergen for that patient* (minutes to several hours):
   a. Infants and children: low systolic BP (age specific) or greater than 30% decrease in systolic BP*
   b. Adults: systolic BP of less than 90 mm Hg or greater than 30% decrease from that person's baseline

*Low systolic blood pressure for children is defined as less than 70 mm Hg from 1 month to 1 year, less than (70 mm Hg + (2 × age)) from 1 to 10 years, and less than 90 mm Hg from 11 to 17 years.
BP, Blood pressure; *PEF*, peak expiratory flow.
Modified from Sampson HA, Muñoz-Furlong A, Campbell RL, et al. Second symposium on the definition and management of anaphylaxis: summary report – second National Institute of Allergy and Infectious Disease/Food Allergy and Anaphylaxis Network symposium. *J Allergy Clin Immunol*. 2006;117:391–397.

that can be rapidly fatal. Increasing age and co-morbidities such as coronary artery disease or hypertension, particularly if treated with beta-blockers and/or angiotensin-converting enzyme (ACE) inhibitors, are associated with unresponsiveness to treatment, hospitalisation and increased fatality. Systemic mastocytosis (SM) and other variants of mast cell activation disorders are often only recognised after unexpectedly severe reactions to insect stings or drugs.

PATHOPHYSIOLOGY OF ANAPHYLAXIS

Mast cells and basophils release mediators such as histamine that are responsible for the physiological changes seen during anaphylaxis. Although there are a number of mechanisms of release, the focus of this section is IgE-mediated anaphylaxis. Mast cells are found in the tissues and basophils in the circulation. Both have high affinity receptors (FcεRI) on their surfaces. The number of FcεRI varies between 29,000 and 680,000 per cell in different individuals.[11] A correspondingly variable amount of IgE is bound with a very high affinity to the FcεRI. Binding of an allergen to adjacent FcεRI/antibody complexes, 'cross-linking', will lead to a sequence of signalling events resulting in mediator release from the mast cell or basophil; however, this is not all or none – maximal stimulation will only release 10%–20% of stored mediators. A minimum number of cross-linking events, between 100 and 1000, are required for any degree of release.[12]

MEDIATOR RELEASE

After full activation of the FcεRI and maintenance of the receptor complex for as little as 100 seconds, there is transduction of intracellular signals that lead to the release of pre-synthesised mediators such as histamine, serotonin, various proteases such as tryptase, carboxypeptidases and other enzymes contained in granular stores.[13] These, particularly histamine, are responsible for the immediate cardiovascular, respiratory and skin changes that are seen at the onset of anaphylaxis. Phospholipid metabolites are the second group of mediators, generated as a consequence of the release of phospholipaseA_2, such as platelet activating factor (PAF) and the eicosanoids PGD_2, LTC_4, and LTB_4 that individually can have physiological consequences such as bronchospasm and local or generalised angioedema. Enhanced gene expression leads to the generation of the third group of mediators, the cytokines and chemokines that are responsible for cell signalling and chemotaxis.[14] The physiological response results from the complex interaction of these multiple mediators with their individual receptors and thus may be variable in duration, intensity and clinical features.

FcεRI engagement also generates negative intracellular signals that limit the duration and intensity of the release process and also triggers endocytosis of the activated complexes, thus removing them from the cell surface and terminating the response. This results in acute desensitisation of the mast cell to the triggering allergen.

THE PHYSIOLOGICAL RESPONSE TO MEDIATOR RELEASE

In a setting of patient heterogeneity, complex mediator release mechanisms and different triggers, the physiological response is unpredictable in both the individual organ and in overall severity.

SKIN CHANGES DURING ANAPHYLAXIS

Skin eruptions are the most consistent feature of anaphylaxis, although their absence does not exclude the

condition and generalised erythema may frequently not manifest until after resolution of haemodynamic instability. Urticarial lesions (hives) develop rapidly and are pruritic, raised, patchy erythema. Angioedema describes swelling of the deeper dermis and subcutaneous tissues (non-pitting, non-pruritic, oedematous swelling), and may also involve mucosal surfaces. In anaphylaxis, both urticaria and angioedema are frequent, and usually the consequence of IgE-dependent activation of cutaneous mast cells resulting in increased vascular permeability which is predominantly a consequence of activation of H1 histamine receptors. Nervous system stimulation, axonal reflexes and other mediators, such as tryptase, cytokines and chemokines may play a role in amplifying the reaction.

RESPIRATORY CHANGES DURING ANAPHYLAXIS

Respiratory manifestations of anaphylaxis may involve the lower airway (dyspnoea, bronchospasm, hypoxaemia) or upper airway (stridor or upper airway obstruction, tongue swelling, dysphonia or dysphagia, rhinitis). Mast cell-derived mediators cause vasodilatation, smooth muscle contraction and mucus secretion in the nasal and bronchial mucosa. Autopsy findings in cases of fatal anaphylaxis include pulmonary oedema, laryngeal and/or pharyngeal oedema, lung hyperinflation and mucous plugging (suggesting bronchospasm and air-trapping), and evidence of asphyxiation (petechial haemorrhages). Upper airway oedema or obstruction is more common in food allergies compared to medication-triggered anaphylaxis.

Anaphylaxis during surgery and anaesthesia is most commonly associated with mild increases in airway pressure and severe bronchospasm is rare except in patients with a history of increased airway responsiveness such as in asthma, smoking and other conditions associated with chronic airflow limitation. There are rare reports of bronchospasm being the only presenting feature.

CARDIOVASCULAR CHANGES DURING ANAPHYLAXIS

Fisher[15] from clinical observations of anaphylaxis under anaesthesia found the most common manifestation was cardiovascular depression characterised by profound hypotension, sinus tachycardia, loss into the interstitial space of up to 35% of blood volume and low cardiac filling pressures. Although simplistic, it is not unreasonable to regard histamine as the principal mediator that is responsible for the initial cardiovascular effects.[16,17]

PERIPHERAL VASCULATURE

Hypotension occurs not only as a result of a fall in systemic vascular resistance but also because of failure of venous return due to both interstitial loss and sequestration of blood in the peripheral venous systems. Vasopressors, essential to increase systemic vascular resistance, will be ineffectual on their own unless cardiac output is maintained by volume repletion. Having studied details of 214 deaths associated with anaphylaxis, Pumphrey in 2003 reported a striking pattern of sudden death after a change to an upright posture in 10 of 38 anaphylactic shock deaths that occurred outside hospital.[18] He described a mechanism based on lack of venous return to explain this phenomenon. He went on to express the importance of the recumbent position with legs raised in first aid of shocked patients and explained why epinephrine can be ineffective in these patients. The benefit of posture has also been echoed by Brown[19] in the emergency medicine setting, as has the benefit of the pneumatic antishock garment or MAST suit.[20] The importance of venous capacitance has largely been forgotten or ignored in discussions of the circulatory changes during anaphylactic shock, although the relationship between venous capacitance and cardiac output are well described.[21,22]

THE HEART

The use of echocardiography during anaphylaxis characteristically shows a hyperdynamic but empty heart.[23,24] Rarely, Takotsubo cardiomyopathy[25] may occur that is characterised by apical ballooning and systolic dysfunction of apical and mid segments of the left ventricle with compensatory hyperkinesis of the basal segments. The electrocardiogram may show changes consistent with ischaemia and cardiac enzymes may be elevated but angiography reveals normal coronary arteries. Endogenous and exogenous epinephrine in large doses may lead to catecholamine cardiotoxicity or coronary microvascular dysfunction.

Allergic events may be associated with angina and angiographic evidence of coronary spasm in both adults and rarely children and also with atheromatous plaque erosion or rupture, causing myocardial infarction. This association between acute allergic reactions and coronary events is known as Kounis syndrome.[26]

CAUSES OF ANAPHYLAXIS

FOOD

Almost 10% of the population of developed countries have a food allergy with one-third being severe.[27] Almost any food may be responsible for allergy, but only eight food groups account for 90% of food-related allergy; peanuts, tree nuts, fish and crustacea often persist into adulthood, whereas milk, egg, wheat and soy often resolve before the teens. Food allergy is responsible for almost all allergic hospital admissions

in under 4-year-old age group and most fatalities in teenagers, particularly when associated with asthma. By middle age food-related allergy is relatively uncommon as a cause of hospital admissions and fatalities compared to those due to drug and insect stings. Latex allergy can be associated with cross-reactivity to fruits including avocado, banana, chestnut, kiwifruit and papaya. Food-associated, exercise-induced anaphylaxis can occur when an otherwise harmless food is consumed 2–4 hours before exercise.

DRUGS

Cephalosporins. Historically, penicillin has been the most common antibiotic causing anaphylaxis and fatalities but with changing patterns of antibiotic prescribing, cephalosporins[28] have become a greater issue. In the hospital setting antibiotics are often administered intravenously, which increases the risk compared to the oral route and cephalosporins are widely used as prophylaxis during surgery. Although cephalosporins share a common beta-lactam ring with penicillins, it is becoming clearer that the classic, beta-lactam derived determinants of penicillin allergy are less important than the side chains in cephalosporin allergy. The amino-penicillins may cross-react with early generation cephalosporins that share identical side chains. Although cross reactivity occurs between cephalosporins, it is not determined by the 'generation' of the drug but the side chains.

Vancomycin will cause the 'red man syndrome' if administered rapidly. Very rarely anaphylaxis to vancomycin may be IgE mediated but most commonly histamine release results from direct activation of the mast cell, possibly via the MrgprX2 G-protein coupled receptor in the surface membrane of the mast cell. Temporary discontinuation of the infusion and administration of low-dose epinephrine will lead to rapid resolution of the symptoms except in the rare instances that the reaction is IgE mediated.

Sulphonamides. Patients often express an allergy to sulpha or sulphur[29] drugs because of an adverse reaction to sulphonamide antibiotics. It is still common practice to avoid other drugs containing a sulphur-containing moiety such as frusemide, acetazolamide and parecoxib even though there is no convincing evidence of cross-reactivity. There is no contraindication, as has been suggested, to use epinephrine that contains metabisulphite as a preservative for the treatment of individuals having an anaphylactic reaction who claim to have a sulphite or 'sulfa' allergy.

Neuromuscular blocking drugs (NMBDs)[30] are the commonest cause of anaphylaxis in the perioperative period with as many as 4% of cases being fatal. Although NMBD reactions are universally IgE mediated, they depart in several ways from those seen with most other causes. Prior exposure is seen in less than half the cases caused by NMBD, suggesting exposure to other sensitisers in the environment. There is convincing evidence that pholcodine in cough suppressants is the responsible agent.[31] Although a relatively small molecule, there is no evidence that haptenisation is required to generate an allergic response to NMBD. The ability of these drugs to cross-link adjacent receptor bound antibody is the result of the bivalency of the NMBD that has two substituted ammonia groups in its structure. Suxamethonium and rocuronium have the greatest potential for inducing anaphylaxis, whereas atracurium[32] and particularly cis-atracurium less so.

Non-steroidal anti-inflammatory drugs (NSAIDs) and *aspirin*[33] are both associated with hypersensitivity reactions such as aspirin-exacerbated respiratory disease (AERD) and urticaria-angioedema without respiratory involvement that are mediated via cyclooxygenase 1 (COX-1) inhibition and the leucotriene shunt. Bronchospasm is precipitated in around 10% of asthmatics via this pathway. Specific IgE has been identified in over 50% of patients with a history of anaphylaxis to propyphenazone but only rarely to diclofenac that in some causes an immediate hypersensitivity reaction indistinguishable from an IgE-mediated reaction. It is possible that the testing methods are not sensitive enough to identify the NSAID-specific IgE.

Iodinated contrast media (ICM). There is a widely held belief that hypersensitivity to ICM is related to iodine and thus the misconception that there is cross-sensitivity with other iodine-rich foods such as fish or shellfish and iodine-containing surgical antiseptics.[34] Fish allergy is caused by sensitivity to specific proteins and antiseptic allergy to povidone. Mild immediate reactions to ICM[35] are common and are related to the physical properties of the media such as high osmolality and ionic preparations. Modern non-ionic, low-osmolality formulations have reduced this problem and radiology departments have pre-treatment protocols[36] for susceptible individuals. Less commonly, severe anaphylaxis may occur with an individual contrast agent associated with a positive skin test suggesting an IgE-mediated mechanism.[37] Referral to an Immunologist for cross sensitivity testing with other agents can identify a suitable alternative; pre-treatment will clearly be of no benefit in this group.

Protamine[38] is used for the neutralisation of heparin in cardiac and vascular surgery, dialysis and cardiac catheterisation. It has also been incorporated in intermediate and long-acting insulin preparations, resulting in a cohort of exposed patients with a significant risk of sensitisation.

Its use is associated with IgE-mediated anaphylaxis in this group of patients but also has a direct histamine-releasing effect on mast cells, the magnitude of which is dose and rate related and may be of critical significance in the unstable patient. Rarely, heparin/protamine complexes are responsible for complement activation and release of thromboxane in the pulmonary arterial circulation, causing severe

right-sided heart failure that should be distinguished from anaphylaxis.

Chlorhexidine[39] exposure is common in both hospital and the community, leading to widespread sensitisation. In the hospital setting skin application may rarely cause anaphylaxis but is unlikely unless the epidermis is breached by vascular cannulation or surgical incision, particularly if the antiseptic is not allowed to dry. Anaphylaxis after application in the mouth during dental surgery or urethra during catheterisation using chlorhexidine-containing gel lubricants is more likely due to rapid absorption into the circulation from mucous membranes. Of particular importance in the critical care environment is the risk of chlorhexidine-coated central venous lines that can present as cryptogenic or recurrent anaphylaxis.

Angiotensin-converting enzyme inhibitors (ACEIs) and angiotensin receptor blockers (ARBs). Although not responsible for inducing anaphylaxis, this group of drugs may exacerbate hypotension by blocking the compensatory response and reduce the effectiveness of treatment, particularly when prescribed with a beta-blocker.

ACEIs are associated with the spontaneous onset of laryngopharyngeal angioedema that can cause critical airway obstruction.[40] It may occur shortly after onset of treatment of the drug but also after months or years of uneventful use. The initial episode can occur at the time of anaesthesia and surgery and may be triggered by the minor trauma of laryngeal mask or endotracheal tube insertion; if associated with hypotension, anaphylaxis may be erroneously suspected. Bradykinin is thought to be the mediator responsible and thus ARBs are suitable alternatives when ACEIs are ceased after an episode of oedema. Occasionally, angioedema can occur weeks or months after cessation of ACEIs. If an ARB has been prescribed in the place of the ACEI, the oedema may be incorrectly ascribed to the ARB.

GELATIN-BASED COLLOIDS, MEAT AND CETUXIMAB

Although seemingly unrelated, these three causes of anaphylaxis have the oligosaccharide galactose-alpha-1,3-galactose (alpha-gal) in common. This sugar is common to all mammals except the higher primates, including human. With both gelatin-based colloid and Cetuximab (Erbitux, Bristol-Myers Squibb and ImClone Systems), acute hypersensitivity reactions occurred on first exposure, raising speculation as to the sensitisation process. In the late 2000s reports from the United States, Sweden and Australia clarified the association between ticks, delayed anaphylaxis after the ingestion of red meat[41] and anaphylaxis after initial exposure to Cetuximab,[42] a chimeric mouse-human IgG1 monoclonal antibody used in the treatment of colorectal cancer and squamous-cell cancers of the head and neck. In these patients, pre-existing antibodies to alpha-gal were identified in the serum, the generation of which was sensitisation by exposure to tick bites. The alpha-gal is transferred from host mammal to human with resultant production of antibodies that are specific for the alpha-gal present in gelatin, cetuximab and meat.

With the recognition of complications associated with the use of starch-based colloids in critically ill patients, gelatin-[43]based colloids have had a resurgence but also an increased risk of anaphylaxis. This should be considered as a greater risk in patients allergic to red meat and in tick-prone areas, although the pathogenic relationship, as yet, is not fully elucidated.

Intraoperative anaphylaxis may be caused by Floseal Haemostatic Matrix (Baxter Healthcare Co., Hayward, California), a topical haemostatic agent containing bovine-derived gelatin. Other gelatin-containing haemostatic agents such as Gelfoam (Pfizer, New York) and SurgiFlo (Ethicon, Somerville, New Jersey) have also been implicated.

BLOOD PRODUCTS

Anaphylaxis occurs in 1:20,000–1:50,000 whole blood transfusions. The mechanisms implicated include (1) IgA-deficient recipients who have anti-IgA antibodies, (2) transfusing an allergen in the donor blood such as penicillin or nuts to a sensitised recipient, (3) recipient with antibodies to plasma proteins such as transferrin or IgG and less commonly (4) transfusion of IgE antibody from the donor that reacts with an allergen in the recipient. A haemolytic transfusion reaction should be considered in the differential diagnosis.

LATEX

In the 1980s, coincident with, and in part due to, the human immunodeficiency virus epidemic, latex allergy became a major health issue. Massive demand for latex gloves resulted in the production of a low quality, highly allergenic product leading to widespread sensitisation, particularly of workers in the health care setting. The use of cornstarch in powdered gloves resulted in an effective means of dispersion of airborne latex particles into the hospital environment, particularly the operating room. Of the greater than 200 polypeptides occurring in natural rubber latex (NRL), 13 are the primary allergens (Hevea braziliensis [Hev b] 1–13), which induce antibody formation detectable by specific IgE testing. In the late 90s Mertes[44] reported latex as the second most common cause of perioperative anaphylaxis in France (16.7%); this incidence has not fallen but has not been reported as being so common elsewhere. Surgery in infancy, particularly spina bifida that often requires multiple surgeries and catheterisations, was responsible for greater than 75% of anaphylaxis cases in children. With the introduction of better quality control in the manufacture of low allergenic gloves, the discontinuation of powder and the adoption of latex-free

policies in the health care environment, both sensitisation and anaphylaxis rates have fallen significantly.

ANAPHYLATOXINS

The anaphylatoxins C3a, C4a and C5a are produced on activation of the complement system and act on a group of G-protein coupled anaphylatoxin receptors. This pathway is an alternative to the IgE pathway of mast cell activation with resultant mediator release and clinical syndrome of anaphylaxis.

In early 2008 many severe adverse events were reported worldwide associated with heparin therapy, including over 100 deaths in North America. Subsequent investigation identified a highly sulphated heparin-like contaminant – oversulphated chondroitin sulphate (OSCS) as the cause.[45] The associated activation of the kinin-kallikrein system with formation of bradykinin enhanced the hypotensive response.

Polyethoxylated castor oil has been used widely in the formulation of poorly water-soluble drugs such as the anticancer agent paclitaxel, intravenous multivitamin preparations, early formulations of propofol and diazepam and the obsolete anaesthetic induction agents Althesin and Propanidid. There have been several mechanisms of activation of anaphylaxis linked to this agent, including direct histamine release, IgE, IgG and complement.

MAST CELL DISORDERS

The descriptions above relate to normal populations of mast cells. There are a number of disorders of mast cells associated with abnormal proliferation or increased susceptibility to activation.[46]

SM is a condition associated with a mutation of the tyrosine kinase receptor c-KIT that results in both increased numbers and aberrant activation of mast cells. Such patients may have variable symptoms attributable to mast cell activation or may present with particularly severe anaphylaxis to hymenoptera stings. Skin lesions, typically urticaria pigmentosa, are present in most cases. A baseline mast cell tryptase (MCT) over 20 ng/mL is consistent with a diagnosis of SM. The primary diagnostic feature is the finding of multifocal mast cell clusters of atypical morphology in bone marrow.

Monoclonal mast cell activation syndrome (MMAS) presents with the same symptoms as SM and is associated with a KIT mutation and abnormal mast cell clones but the baseline tryptase is normal. There are no skin changes and atypical cell clusters in the bone marrow are sparse or absent.

Non-clonal mast cell activation syndrome (nc-MCAS) has a similar clinical presentation to MMAS but no atypical clonal mast cells or evidence of KIT mutation. It is possible, but not proven, that the increased susceptibility to activation is due to an intrinsic defect in the mast cell causing increased sensitivity to activation.

Surgery, anaesthesia and the critical care environment are associated with anxiety, stress, pain and exposure to innumerable drugs that may trigger the susceptible mast cells in these conditions. Perioperative management[47] of patients can be achieved successfully with mast cell stabilising drugs and the avoidance of opioids and muscle relaxants that have histamine-releasing properties.

LABORATORY TESTS

MAST CELL TRYPTASE

The principal effector cell of anaphylaxis from whatever cause is the mast cell with, as yet, incompletely defined contributions from the basophil. There are assays of many of the mediators released from the mast cell on degranulation but most of these are only available in research laboratories. The only useful widely available laboratory test to aid in the clinical diagnosis of anaphylaxis is MCT.[48] Immature forms of tryptase, alpha- and beta-protryptase, that are secreted in small amounts from the unstimulated mast cell account for a baseline level in plasma with a range of 1–11.4 ng/mL. This level is determined genetically and in any one individual varies little over time. Mature tryptase in significant amounts is only detected in the plasma after degranulation. In disorders in which there is an increase in the mast cell population such as the various forms of mastocytosis, baseline levels of protryptase may be elevated. ImmunoCAP tryptase (Thermo Fisher Scientific, Uppsala, Sweden) is widely available in commercial laboratories and measures both immature and mature forms. Any elevation over the upper limit of the reference range in the clinical setting of suspected anaphylaxis is considered diagnostic if the baseline level (measured either prior or 24 hours post event) is in the normal range. Peak levels of tryptase are seen 15–120 minutes after the onset of the reaction with a decline determined by the biological half-life of about 2 hours. If tryptase is still elevated after 24 hours, it should be repeated weeks later; if still elevated, mastocytosis or a haematological neoplasm should be suspected. In severe anaphylactic events, MCT levels greater than 300 ng/mL are not uncommon. In as many as one-third of perioperative, food or insect sting anaphylaxis, MCT may not be elevated above 11.4 ng/mL. Baseline tryptase varies little and if the peak level after a suspected episode of mast cell degranulation is greater than 20% above baseline plus 2 ng/mL, it would be suspicious. Thus, a relatively small rise of MCT from 5–8 ng/mL may be of significance. Optimal timing of the recommended three blood samples for MCT is 1, 4 and 24 hours after the initiation of the event. Activation limited to basophils may be rarely responsible for anaphylaxis, in which case

Table 67.2 Grading of anaphylaxis

Grade I Skin symptoms and/or mild fever reaction
Grade II Measurable but not life-threatening CVS, GI or respiratory disturbance
Grade III Life-threatening hypotension (shock) and/or bronchospasm
Grade IV Cardiac and/or respiratory arrest

CVS, Cardiovascular system; *GI*, gastrointestinal.
Modified from Ring J, Messmer K. Incidence and severity of anaphylactoid reactions to colloid volume substitutes. *Lancet*. 1977;1:466–469.

the tryptase level would not rise. When anaphylaxis is suspected as a cause of death, a postmortem blood sample may aid in the diagnosis, although significant elevations have been reported with other causes such as cardiac or trauma.

GRADING OF ANAPHYLAXIS

Ring and Messmer[49] classified hypersensitivity reactions to colloid volume substitutes into four grades based on the severity of symptoms and signs in 1977 (see Table 67.2). This classification system has been used with only minor modifications to describe the severity of immediate hypersensitivity reactions to all food-, environmental- and drug-induced allergens since. Its great success has been the ability to classify both IgE- and non-IgE-mediated reactions and reactions that do not meet the 'life-threatening' criterion required for anaphylaxis. In 2004, Brown[50] proposed a classification system (see Table 67.3) in which the discriminating features of the two grades representing anaphylaxis were identified by retrospective analysis of cases to determine which were highly correlated with hypotension and hypoxia (grade 3) or only less closely associated (grade 2). The majority of cases that will require review by intensive care staff are likely to fall into Brown's grade 3. Additional classification systems have been developed for the signs of intraoperative anaphylaxis; however, none have been demonstrated to be more effective in guiding management or predicting outcome than Ring and Messmer, and some omit cases of immediate hypersensitivity in which early intervention has prevented progression to anaphylaxis (see Table 67.3).

TREATMENT OF ANAPHYLAXIS

Anaphylaxis is a hyperacute syndrome that may rapidly progress to respiratory or cardiac arrest and death. Early signs and symptoms may have a wide differential diagnosis, and indeed anaphylaxis may be a retrospective diagnosis (indicated by the MCT). Simultaneous assessment and resuscitation should begin immediately. The natural history of anaphylaxis

Table 67.3 Grading system after Brown SG

GRADE	DEFINED BY
1. Mild (skin and subcutaneous tissues only)*	Generalised erythema, urticaria, periorbital oedema or angioedema
2—Moderate (features suggesting respiratory, cardiovascular, or gastrointestinal involvement)	Dyspnoea, stridor, wheeze, nausea, vomiting, dizziness (presyncope), diaphoresis, chest or throat tightness, or abdominal pain
3—Severe (hypoxia, hypotension, or neurological compromise)	Cyanosis or Sp_{O_2} ≤92% at any stage, hypotension (SBP <90 mm Hg in adults), confusion, collapse, LOC or incontinence

*Mild reactions can be further subclassified into those with and without angioedema (see text).
LOC, Loss of consciousness; *SBP*, systolic blood pressure.
Modified from Brown SG. Clinical features and severity grading of anaphylaxis. *J Allergy Clin Immunol*. 2004;114(2):371–376.

is that it is a temporary condition that will resolve if the patient can be sustained for the period required to allow it do to so. Overall, life-threatening respiratory symptoms are more common than lethal cardiovascular derangement, although cardiovascular collapse is more common in iatrogenic medication reactions.[51] Priorities in the initial management are the early administration of epinephrine, rapid administration of intravenous fluids to correct hypovolaemic/maldistributive shock, and aggressive management of threatened or established respiratory failure from reduced airway compliance (bronchospasm) or upper airway obstruction (Table 67.4).

GENERAL MEASURES

Management of a patient with a syndrome that may be anaphylaxis should include the mobilisation of a resuscitation team, application of supplemental oxygen, and establishment of intravenous access (14–16 g). The patient should be placed supine or in the Trendelenburg position with the legs above the level of the heart. Sudden death has been described on adoption of an erect posture in anaphylaxis, of importance when considering elevation of the torso if respiratory distress is present. Pregnant patients should be placed in the left lateral position or with partial left uterine tilt. Electrocardiography monitoring, pulse oximetry and non-invasive blood pressure monitoring should be applied to all patients. In the presence of cardiovascular shock, intra-arterial blood pressure monitoring allows rapid detection of deterioration and titration of therapy as well as the ability to take blood samples for gas and

Table 67.4 Drug doses for life-threatening anaphylaxis

DRUG	ADULT	CHILD (20 KG)
Epinephrine (IM;1 : 1000)	500 µg	0.01 mg/kg (200 µg)
Epinephrine (IV)	50–100 µg initial dose; 0.1–1 µg/kg per minute infusion	Bolus not recommended 0.1–1 µg/kg per minute infusion
Norepinephrine	0.1–1 µg/kg per minute infusion	0.1–1 µg/kg per minute infusion
Vasopressin	2-unit bolus, infusion 0.03–0.06 U/min	0.0001–0.0003 UI/kg per minute[55]
Methylene Blue	2 mg/kg over 20 min	2 mg/kg over 20 min
Glucagon	1–5 mg IV; 5–15 µg/min infusion	20–30 µg/kg up to 1 mg; 5–15 µg/min
Aminophylline	5.6 mg/kg over 20 min	5.6 mg/kg over 20 min
Methylprednisolone	1–2 mg/kg	1–2 mg/kg
Diphenhydramine	25–50 mg IV	1 mg/kg IV
Ranitidine	50 mg IV	1 mg/kg IV
Icatibant	30 µg sc injection (max 90 µg/d)	N/A

IM, Intramuscular; *IV*, intravenous.

acid-base analysis. Central venous access is also useful for administering vasopressor and inotropic agents and grossly assessing response to volume expansion. Neither should delay the immediate management of presumed anaphylaxis.

AIRWAY AND BREATHING

A rapid assessment of the patency of the airway should include an examination of the upper airway for evidence of oedema. Early intubation should be considered in patients who develop stridor, hoarseness, difficulty swallowing or significant facial or tongue oedema. Interim measures may include the use of inhaled epinephrine (adult dose 5 mg of 1:1000 epinephrine) and inhaled heliox to reduce the work of breathing; however, the first-line treatment for both upper airway obstruction and bronchospasm in anaphylaxis is systemic epinephrine. Therapeutic effects include bronchodilatation, reduced upper airway mucosal oedema and reduced mast cell and basophil mediator release. Upper airway or external neck landmarks may be distorted due to oedema. Endotracheal intubation and induction of anaesthesia in this situation is likely to be difficult and requires the availability of – and familiarity with – difficult intubation adjuncts including flexible fibreoptic bronchoscope, videolaryngoscopy or surgical cricothyroidotomy.

Severe bronchospasm not responsive to intravenous epinephrine should be treated according to guidelines for the management of acute asthma.

CIRCULATION

Epinephrine is the first-line treatment. Sinus tachycardia is a common feature of anaphylaxis, and should not discourage its use. In the absence of significant cardiovascular derangement, intramuscular epinephrine is commonly administered. The adult dose is 500 µg repeated at 5 minute intervals based on response. An epinephrine autoinjector for intramuscular use contains 0.15 mg (for children over 10 kg) or 0.3 mg (for children over 30 kg) to administer the paediatric dose of approximately 0.01 mg/kg. Intravenous epinephrine is preferred in the presence of severe hypotension as the intramuscular route has unpredictable absorption.[52] An initial dose of 50–100 µg IV, followed by incremental increases in the bolus dose or infusion titrated to response, is recommended. Human epidemiological and therapeutic animal studies suggest that delayed or inadequate administration of epinephrine increases the likelihood of fatal anaphylaxis. Therapeutic effects include vasoconstriction and increased peripheral vascular resistance, decreased venous capacitance, and increased myocardial contractility (as well as increased coronary blood flow due to an increased diastolic:systolic time ratio and coronary vasodilatation).

Intravenous fluids should be administered with an initial rapid bolus of 20 mL/kg of crystalloid. Effective resuscitation of anaphylactic shock may require up to 50 mL/kg in the first 15 minutes in order to maintain cardiac preload.[53] Positive-pressure ventilation with a high mean intrathoracic pressure or inadequate expiration resulting in the development of significant auto-positive-end-expiratory-pressure may also impede venous return.

If cardiovascular shock has not responded to intravenous fluids (50 mL/kg in the first 15 minutes) and epinephrine boluses (total 2 mg) and subsequent infusion (e.g. up to 40 µg/min), further management is best guided by immediate transthoracic or

transoesophageal echocardiography. This will distinguish insufficient fluid resuscitation (low left ventricular [LV] end-diastolic diameter) from vasoplegia (low LV end-systolic diameter with reasonable LV end-diastolic diameter), pump failure (poor cardiac contractility) or acute pulmonary hypertension (with right ventricular failure). It is also useful in the assessment of Kounis syndrome (acute ST-elevation during anaphylaxis). Regional wall motion abnormalities with ST segment changes may require angiography with coronary intervention to exclude or treat plaque rupture or coronary vasospasm.

Typical echocardiography findings in anaphylactic shock are the finding of a left ventricle that is hyperdynamic with a low end-systolic diameter, with or without reduced end-diastolic diameter depending on the adequacy of volume resuscitation. If nonresponsive to epinephrine, consideration should be given to a norepinephrine infusion, followed by nonadrenergic vasopressors such as vasopressin (initial adult dose 2–4 units IV, followed by infusion).[54] Other agents used in nonresponsive shock include methylene blue (2 mg/kg over 20 minutes followed by infusion) or glucagon (1–5 mg IV).

Pulseless electrical activity or asystole occurs in up to 20% of cases of intraoperative anaphylaxis. Contrary to expectations, external chest compressions have been observed to produce an effective arterial waveform during anaphylaxis, and the neurological-deficit-free survival from grade 4 intraoperative anaphylaxis is over 95%. Good outcomes have been observed in patients after prolonged resuscitations (over 60 minutes) and resuscitative attempts should proceed for longer than is usual for cardiac arrest as a result of other pathophysiological conditions.

EXTRACORPOREAL MEMBRANE OXYGENATION

The presence of significant pump failure (poor cardiac contractility) in resuscitated anaphylactic shock is an indication for veno-arterial extracorporeal membrane oxygenation (VA ECMO) support. This has been described as an effective therapy in multiple case reports. Effective circuit flows may be difficult to achieve in the presence of maldistributive-hypovolaemic shock due to poor venous drainage, although echocardiography-guided resuscitation should allow this to be rapidly corrected. Successful use of VA ECMO will allow time for the resolution of anaphylaxis or reversal of the conditions that caused secondary cardiac decompensation.

ECMO does have a significant iatrogenic complication rate, and side effects of ECMO therapy may be synergistic with the features of anaphylaxis (low venous pressures, oedema, bleeding diathesis), increasing the complication rate from cannulation or circuit operation. VA ECMO in refractory anaphylactic shock in the absence of intrinsic cardiac pump failure is also likely to be problematic. If the cause of refractory shock is low afterload, then it may be that peripheral VA ECMO circuit flows are still insufficient to produce an adequate systemic arterial pressure. Significant cardiac ejection may also occur in this situation and result in upper-body hypoxaemia in the presence of pulmonary dysfunction or underventilation and the use of peripheral arterial (return) cannulation ECMO configurations.

The use of veno-venous ECMO support in bronchospasm secondary to anaphylaxis has the same indications and considerations as that which apply to the use of ECMO in severe acute asthma.

SUPPLEMENTAL MANAGEMENT

ANTIHISTAMINES

Patients with immediate hypersensitivity who do not have life-threatening signs may be administered antihistamines, which are an effective treatment for skin (urticarial and pruritic), gastrointestinal and mild respiratory symptoms (rhinorrhea). A combination of H1 (diphenhydramine) and H2 (ranitidine) antagonists are most effective; however, neither are recommended in severe reactions due to the exacerbation of hypotension, sedation or QT-interval prolongation associated with intravenous administration. Antihistamines should not delay or replace the use of epinephrine in anaphylaxis, and are generally omitted in guidelines for the management of life-threatening anaphylaxis.

CORTICOSTEROIDS

Corticosteroids will not alter the course of the acute reaction in anaphylaxis. Their administration is thought to possibly prevent prolonged anaphylaxis or biphasic reactions. It is also a reasonable intervention in patients with bronchospasm or a history of asthma. Methylprednisolone 1–2 mg/kg should be administered after agents effective for acute anaphylaxis have been administered.

GLUCAGON

As patients who are currently taking beta-adrenergic blocking agents have been observed to have a poorer outcome in anaphylaxis, the traditional treatment for beta-blocker overdose is suggested. However, it is unclear if excess mortality is a consequence of beta-blocker therapy or the comorbidities associated with its prescription.

NON-URTICARIAL ANGIOEDEMA

Angioedema without urticaria can occur in patients taking ACEIs or in patients with inherited or acquired C1-esterase inhibitor deficiency. Although the first-line therapy for acute angioedema involving the airways is antihistamines, corticosteroids and epinephrine, this is likely to be ineffective in these patients in which the

angioedema may be at least partly mediated by excess bradykinin. Specific treatments for non-histaminergic angioedema include a bradykinin receptor antagonist (icatibant), a plasma kallikrein inhibitor (ecallantide) or an antifibrinolytic agent (tranexamic acid). For suspected hereditary or acquired C1-esterase deficiency, a purified C1-esterase inhibitor may be indicated.

REMOVING THE TRIGGER

Anaphylaxis results from interaction between the patient and the environment; however, the dose-response curve of IgE-mediated phenomena is such that more allergen exposures causing anaphylaxis are supramaximal doses. Anaphylaxis also represents the consequences of activation of an amplification-cascade sequence of neurological and hormonal events. As such, once the response to a supramaximal dose of allergen is detected (anaphylaxis), the process is now possibly independent of the initial mast-cell degranulation trigger. It is therefore rare that removal of the triggering allergen is an important part of managing anaphylaxis. An exception to this may be food allergens, which may be absorbed slowly and result in a dose-response-sensitive syndrome. Of particular concern is the presence of chlorhexidine and antibiotic-impregnated inserted devices (central venous catheters) and potential for ongoing or prolonged anaphylaxis.

OBSERVATION AFTER ANAPHYLAXIS

Mild cases of anaphylaxis should be observed for 4 hours, while cases that have been administered epinephrine should be observed for 6 hours after the last dose. Severe cases including those that have suffered cardiovascular collapse should be observed at least overnight. Patients with food anaphylaxis or a history of recurrent anaphylaxis are at increased risk of late complications.

Of cases admitted to intensive care for positive pressure ventilation after intraoperative anaphylaxis, 30% are extubated within 6 hours of admissions and 70% within 24 hours.[56] Extubation over an airway exchange catheter after confirmation of sufficient airway patency to allow a leak around a deflated endotracheal tube cuff appears to have a low complication rate.

FOLLOW-UP MANAGEMENT

After recovery from the acute event, it is essential that the patient, family and all health care personnel involved in the patient's care are aware of the trigger and risk of future exposure. Discharge must be with a letter with copies to all concerned detailing the event and advice should be given regarding procurement of an alert bracelet. Follow-up should be arranged with an allergy specialist for further investigations such as allergen skin tests and specific IgE tests if the trigger is unknown. Also a risk reduction strategy should be planned including avoidance of specific triggers and training in the use of self-injectable epinephrine or desensitisation. Anaphylaxis caused by a drug or therapeutic agent should be reported to the appropriate State or National agency.

Host defence and immunodeficiency

Alexander A Padiglione, Steve McGloughlin

Diverse host defence mechanisms protect the body from a great variety of microorganisms, and also play a role in protecting us from cancer. There is a coordinated immunological response to infection, involving both cellular and humoral components. The immune system can be defective in many ways, leading to an increased propensity to infections, and sometimes cancer. However, the response also needs to be controlled to avoid inappropriate and excessive activation, such as when excessive systemic activation results in disseminated intravascular coagulation (DIC).

INNATE IMMUNITY

The innate immune system is the first line of defence against many microorganisms, providing immediate but non-specific responses that do not require prior exposure to antigens from those microorganisms. This system consists of plasma proteins (including components of the complement system, via the alternative pathway or mannose-binding lectin [MBL] pathway), some lymphocytes with cytotoxic activity (natural killer or NK cells) and some macrophage functions. It also has an important role in antigen presentation to stimulate the longer-lasting adaptive immune response.

ACUTE-PHASE REACTION

The acute-phase reaction is a response of the haematopoietic and hepatic systems, involving many plasma proteins and cellular components of the blood. It occurs within hours of acute physical stress or infection. Most of the proteins are inflammatory mediators or inhibitors of transport proteins. Fibrinogen, the bulk protein of the coagulation system, is one of the plasma proteins to show the greatest rise in the acute-phase reaction, and is responsible for the elevation in the erythrocyte sedimentation rate. Decreases in haemoglobin, serum iron and albumin can all occur. The fall in albumin is due to redistribution and decreased synthesis and generally does not require supplementation. The function of many acute-phase proteins remains unclear, but may be beneficial to the patient.

THE ADAPTIVE IMMUNE SYSTEM

Adaptive immune responses exhibit specificity, memory, amplification and diversity. This specificity (immune response against a particular antigen) and memory (prompt response on subsequent exposures) is mediated by antigen receptors on the surface of lymphocytes. Amplification and diversity of immune responses are regulated by cytokines, which are secreted by lymphocytes and other cells, and through the effects of various lymphocyte surface molecules, including adhesion molecules and co-stimulatory molecules. Cytokines have various activities, the most important of which are cell activation (e.g. interferon gamma [IFN-γ]), regulation of immune responses (e.g. interleukin [IL]-10) and pro-inflammatory effects (e.g. tumour necrosis factor [TNF] and lymphotoxins).

ANTIGEN PRESENTATION AND THE ROLE OF T AND B LYMPHOCYTES

The adaptive immune response is initiated by the processing and presentation of fragments of a microorganism in a form that makes them antigenic to lymphocytes. Major histocompatibility complex (MHC) class I (human leucocyte antigen [HLA]-A, B, C) and class II (HLA-DR, DP, DQ) molecules are the major cell-surface antigen presentation molecules, and determine the nature of the subsequent response against the antigen.

Class I MHC molecules are present on most nucleated cells, and present processed *endogenous* peptides (such as fragments of viruses) to the T-cell receptor (TcR) of CD8+ (cytotoxic) T lymphocytes. Activated CD8+ T cells have a cytotoxic effect on the presenting cell, resulting in the death of the cell and inhibition of viral replication.

Class II MHC molecules are found on macrophages and monocytes (where they present fragments of phagocytosed microorganisms to TcRs on CD4+ [helper] T cells) and B cells (where antigen is bound to specific surface immunoglobulins, the B-cell antigen receptor).

Activation of CD4+ T cells by these *exogenous* antigens results in the expression of cell-surface molecules

ABSTRACT

The innate immune system provides immediate but non-specific responses to infection. The adaptive immune response is delayed and relies on antigen presentation to lymphocytes, but exhibits specificity, memory, amplification and diversity. Immunodeficiency disorders can be classified functionally into five groups: antibody deficiency, complement deficiency, cellular immunodeficiency, phagocyte dysfunction and combined immunodeficiency (T cells, B cells and NK cells). Aetiologically, they may be primary (which are rarer, usually more severe and manifest at a younger age) or acquired.

Critical illness itself can be immunosuppressive. Asplenic/hyposplenic patients are at lifelong risk of overwhelming sepsis, and require education, vaccination and appropriate use of antibiotics.

Table 68.1 Immunoglobulin isotypes

IMMUNOGLOBULIN	TYPES	CHARACTERISTICS
IgM	1	Large pentamer Major effect within circulation early in the immune response – presence may indicate recent infection Important opsonin Activates complement and works as a bacterial agglutinator
IgA	2	IgA_1 & IgA_2 Produced at secretory surfaces, such as the mucosa of the gut and respiratory tract, and also in the breast, where it is a major constituent of colostrum and provides secretory antibody to the gut of the neonate
IgE	1	Produced at mucosal surfaces Important part of the immune response against parasitic infections
IgD	1	Mainly acts as a B-cell receptor
IgG	4	Only antibody able to cross the placenta IgG_1 & IgG_3: Important opsonin, particularly effective at activating complement and binding to Fc receptors on phagocytic cells IgG_2: mainly active against polysaccharide antigens, such as those present in bacterial cell walls IgG_4: functions remain uncertain

and secretion of cytokines with immunoregulatory effects. These immunoregulatory molecules augment the functions of many other cells, including B cells, T cells and macrophages (T-cell help). CD4+ T-cell activation may also elicit macrophage activation (critically dependent on the production of IFN-γ) to assist in killing of the microorganism.

Proliferating B cells differentiate into plasma cells, which secrete immunoglobulins with antibody activity against the initiating antigen, or into memory B cells, which live for a long time and rapidly respond on re-exposure to an antigen.

IMMUNOGLOBULINS

Nine isotypes of immunoglobulin (also known as antibodies) can be produced, each of which has a different function (see Table 68.1).

SECONDARY ANTIBODY FUNCTION

Antibodies act through one of several secondary effector mechanisms. Antibodies complexed with antigens can activate the complement system through the classical pathway, resulting in the generation of biologically active molecules, such as C3b, which is an important opsonin, and the activation of the membrane attack complex (MAC), which directly lyses bacterial cell walls.

Antibodies of the IgM, IgG_1 and IgG_3 isotypes are also important opsonins. These molecules, when bound to the surface of a microorganism, enhance binding to immune cells and facilitate their phagocytosis. These effects of complement and antibody are mediated through complement receptors (CRs) and receptors for the Fc portion of the immunoglobulin molecules (Fc receptors) on the surface of phagocytic cells such as neutrophils and macrophages.

DIVERSITY OF IMMUNE RESPONSES

Different microorganisms elicit different types of immune response. Virus-infected cells elicit a cytotoxic CD8+ T-cell response; intracellular pathogens such as mycobacteria and protozoa elicit a CD4+ T-cell response, which results in macrophage activation; encapsulated bacteria elicit an opsonising antibody response; other bacteria such as *Neisseria* spp. elicit a complement-activating antibody response, which lyses the cell wall of the bacterium. The nature of the immune response is regulated by cytokines, which provide T-cell help (Th) in the course of an immune response. Thus IL-2, IL-12 and IFN-γ production induces a predominantly cellular immune response (Th1), whereas the production of IL-4 and IL-13 induces a predominantly antibody-mediated immune response (Th2).

IMMUNODEFICIENCY DISORDERS

Immunodeficiency can be classified functionally into five groups: antibody deficiency, complement deficiency, cellular immunodeficiency, phagocyte dysfunction and combined immunodeficiency (T cells, B cells and NK cells).

Immunodeficiency can also be classified aetiologically as either primary or acquired.

Primary immunodeficiency disorders are the result of a developmental anomaly or a genetically determined defect of the immune system. Primary immunodeficiency due to an absent or non-functional gene product critical for normal function is more severe, so it tends to present early in life. Primary immunodeficiency due to aberrant regulation of lymphocyte differentiation, which is probably determined by the products of several genes and may be influenced by environmental factors, tends to be less severe so it presents later. Our understanding of the genetic basis of many of these conditions is improving, including a number of specific gene defects that lead to selective susceptibility to single pathogens.

Acquired immunodeficiency disorders are more common than primary immunodeficiency disorders and may present at any time after early childhood. Most result from an immune defect that is a consequence of a disease process, infection (e.g. human immunodeficiency virus [HIV]) or complication of a therapeutic procedure such as splenectomy, immunosuppressant therapy or haemopoietic stem cell transplantation (HSCT).

An immunodeficiency disorder may be considered in an adult patient with an unexplained abnormal propensity to infections, such as recurrent or multiple serious infections (e.g. deep abscess, meningitis, osteomyelitis, sepsis, pneumonia), persistent thrush, opportunistic infections or poor response to antimicrobial therapy, and requires the demonstration of a specific immune defect (Table 68.2).

ANTIBODY DEFICIENCY

A poor systemic antibody response most commonly results in a lack of opsonising antibody, and a propensity to infections with encapsulated bacteria such as *Streptococcus pneumoniae* or *Haemophilus influenzae*, often manifesting as recurrent respiratory tract infections including sinusitis. Chronic enterovirus infections of the nervous system and infection with some mycoplasmas may also occur in children with severe primary immunoglobulin deficiency (agammaglobulinaemia).

PRIMARY ANTIBODY DEFICIENCY DISORDERS

Failure of B-cell production or differentiation is the cause of most primary antibody deficiency disorders.[1]

X-linked agammaglobulinaemia (XLA) is a rare disorder due to mutations of the *Btk* gene on the X-chromosome that results in the absence of a B-cell tyrosine kinase necessary for the maturation of B cells, and hence absent mature B cells in blood and secondary lymphoid tissues and consequent immunoglobulin deficiency. In the hyper-IgM immunodeficiency syndrome, B cells are able to differentiate into plasma cells secreting IgM at elevated levels, but not IgG, IgA or IgE.

Common variable immunodeficiency (CVID) is a group of disorders that appear to be the consequence of immunoregulatory defects that result in impaired B-cell differentiation, leading to hypogammaglobulinaemia. It may manifest as recurrent respiratory tract infections, enteropathy and malignancies.

IgA deficiency also results from impaired B-cell differentiation. Deficient secretory antibody responses are common in patients with IgA deficiency, but most affected individuals are able to produce compensatory secretory IgM or IgG antibody responses and are asymptomatic. Some may also have a defect of systemic antibody responses, such as an IgG subclass deficiency and/or impairment of antibody responses to polysaccharide antigens, and hence suffer from recurrent respiratory tract infections.[2]

The immunoregulatory defect underlying CVID and IgA deficiency sometimes results in an increased propensity to autoimmunity. This can include the production of anti-IgA antibodies, which may result in anaphylactoid reactions to blood products containing IgA.

ACQUIRED ANTIBODY DEFICIENCY DISORDERS

B-cell chronic lymphocytic leukaemia or lymphoma and myeloma are commonly associated with reduced synthesis of normal immunoglobulins, which may result in bacterial infections.[3] A thymoma is a rare cause of immunoglobulin deficiency, and should be considered in a patient presenting with primary immunoglobulin deficiency after the age of 40.[4]

Asplenic patients have impaired production of antibodies against polysaccharide antigens, leading to infection with encapsulated bacteria, such as pneumococcus, *H. influenzae* type B and meningococcus.[5]

Drugs occasionally affect B-cell differentiation and cause immunoglobulin deficiency, particularly IgA deficiency. The most common offender is phenytoin. Most patients do not have antibody deficiency severe enough to cause infections. Intensive plasmapheresis may also cause severe immunoglobulin deficiency if immunoglobulin replacement is not used.

TREATMENT OF ANTIBODY DEFICIENCY DISORDERS

Infections can be prevented by regular monthly infusions of intravenous immunoglobulin (IVIg) in patients with primary or acquired antibody deficiency. Acute infections should be treated with appropriate antibiotics. The routine use of IVIg as an adjunct in the management of sepsis in adults cannot be recommended, as higher-quality studies have failed to confirm earlier suggestions of benefit.

CELLULAR IMMUNODEFICIENCY

Impairment of cell-mediated immune responses leads to an increased propensity to infections normally controlled by cellular immune responses (see Table 68.2). These pathogens typically replicate intracellularly

Table 68.2 Tests of immunocompetence

IMMUNE DEFICIENCY SYNDROME	CLINICAL MANIFESTATION	TESTS
Antibody-mediated	Recurrent bacterial infection, especially with encapsulated bacteria, e.g.: *Streptococcus pneumoniae* *Neisseria meningitidis* *Haemophilus influenzae*	Immunoglobulin G, A and M levels IgG subclasses Peripheral blood B-cell count (CD 19) *Consider:* Immunisation response to: Polysaccharide antigens (e.g. pneumococcal, pre and post vaccination) Protein antigens (e.g. tetanus and diphtheria antibodies)
Cell-mediated immunity	Predominantly intracellular pathogens: Viruses Herpes simplex viruses Cytomegalovirus Varicella-zoster virus Epstein–Barr virus Molluscum contagiosum virus JC virus (cause of progressive multifocal leucoencephalopathy) Mycobacteria *Mycobacterium tuberculosis* *Non-tuberculous mycobacteria* Bacterial *Salmonella* spp. *Shigella* spp. *Listeria monocytogenes* Fungi and yeasts *Candida* spp. (mucosal infections) Cryptococci *Aspergillus* spp. Protozoa *Toxoplasma gondii* Cryptosporidia *Pneumocystis jiroveci*	Peripheral blood T-cell subsets (CD3+, CD4+ and CD8+) Serology for HIV (+/– HTLV) *Consider:* T-cell response to antigens Cytokine assays Delayed-type hypersensitivity (DTH) skin test responses to antigens (rarely done now)
Phagocyte function	Recurrent severe bacterial infection, esp. *N. meningitidis*	Neutrophil count *Consider:* Tests of oxidative killing mechanisms, e.g. nitroblue tetrazolium reduction test (NBT) *or* dihydrorhodamine oxidation Neutrophil migration assays Bacteria *or Candida* killing assays
Complement system	*S. pneumoniae* *N. meningitidis* *Moraxella* spp. *Acinetobacter* spp.	Immunochemical quantitation of C3 and C4 Functional assay of the classical pathway (CH50) *Consider:* Functional assay of the alternative pathway (AH50) Immunochemical quantification of other individual components

and cause persistent (latent) infections that reactivate when the cellular immune response against them becomes ineffective.

PRIMARY CELLULAR IMMUNODEFICIENCY

Children with the DiGeorge syndrome have a complete or partial absence of the thymus, resulting in depletion of T cells from blood and lymphoid tissue.[6]

Chronic mucocutaneous candidiasis describes a heterogeneous, and often a less severe, group of cellular immune deficiencies. In some populations it has been associated with specific mutations in the autoimmune regulator (AIRE) gene and be an early manifestation of the autoimmune polyendocrinopathy–candidiasis–ectodermal dystrophy (APECED) syndrome, together with adrenal insufficiency and autoimmune hypoparathyroidism.[7]

ACQUIRED CELLULAR IMMUNODEFICIENCY

HIV infection is the most common cause of acquired cellular immunodeficiency (see Chapter 69). Less common causes include Hodgkin disease, T-cell lymphomas and sarcoidosis, which may also be complicated by opportunistic infections. A thymoma is a rare cause of chronic mucocutaneous candidiasis that occurs later in life.[4]

Suppression of cellular immune responses is an intended effect of many immunosuppressant drugs used to treat allograft rejection, graft-versus-host disease (GvHD), autoimmune diseases and vasculitis. Opportunistic infections may complicate this type of immunodeficiency.

TREATMENT OF CELLULAR IMMUNODEFICIENCY DISORDERS

Most infections complicating cellular immunodeficiency are reactivated latent infections. The degree and duration of cellular immunodeficiency determines the risk and type of infection. Use of prophylactic antimicrobials is important, and best defined in HIV-induced immunodeficiency.[8]

Acquired cellular immunodeficiency may be corrected by removing its cause (e.g. treating HIV, or ceasing immunosuppressives). Thymus transplantation may be effective in children with thymus aplasia.

COMPLEMENT COMPONENT DEFICIENCY

Deficiency of complement components is an uncommon but often overlooked cause of recurrent bacterial infections. Complement-mediated lysis of bacterial cell walls is a critical defence against certain bacteria, especially *Neisseria* spp. and related bacteria such as *Moraxella* spp. and *Acinetobacter* spp. Deficiency of classical pathway components may also result in impaired antibody responses.

PRIMARY COMPLEMENT DEFICIENCY

Congenital deficiency of C3 is extremely rare. C3b is an important opsonin and C3 deficiency will often impair phagocytosis of bacteria, causing a propensity to severe pyogenic infections. Deficiency of MAC components is more common, and should be considered in patients with recurrent meningococcal infections.[9] Deficiency of classical pathway components (C1, C2, C4) may also result in an increased propensity to infection with meningococci and other bacteria, but most affected individuals do not experience recurrent infections.

ACQUIRED COMPLEMENT DEFICIENCY

Disease processes that cause persistent activation of the complement system may cause depletion of complement components, particularly classical pathway components. This can result in infections with *Neisseria* spp. or related bacteria, and sometimes overwhelming septicaemia when the complement deficiency is severe. Systemic lupus erythematosus, myeloma and chronic atrioventricular shunt infections are rare causes of complement component deficiency.

MANAGEMENT OF PATIENTS WITH COMPLEMENT DEFICIENCY

An awareness of the possibility of complement deficiency is the most important aspect of management. Replacement therapy is not available. If a complement component deficiency is identified, screening of family members should be considered.

PHAGOCYTE DISORDERS

Phagocytosis of a bacterium or fungus by a neutrophil, leucocyte or macrophage is dependent on chemotaxis (attraction of phagocytes to the site of infection), adhesion (to endothelial cells via molecules such as integrins), binding (to opsonins on the microorganism), ingestion and intracellular killing (which involves both oxidative and non-oxidative mechanisms).

Depletion or functional impairment of phagocytes results in an increased propensity to bacterial and fungal infections, particularly infection with *Staphylococcus aureus*, Gram-negative enteric bacteria, *Candida* spp. and *Aspergillus* spp. Primary or acquired defects of phagocytes may result in localised pyogenic infections or pneumonia. Patients with severe neutropenia, however, may have little inflammatory reaction and overwhelming systemic infections, including systemic fungal and yeast infections, are common.

PRIMARY DISORDERS OF PHAGOCYTOSIS

Congenital neutropenias are rare. Defects of phagocyte function usually affect chemotaxis, adhesion or intracellular killing, either alone or in combination. The best-characterised defect of phagocyte adherence results from a congenital absence of the β-subunit of CD18 integrins in patients with leucocyte adhesion deficiency syndrome type 1.[10]

Defects of intracellular killing are usually caused by a deficiency of microbicidal enzymes. Chronic granulomatous disease (CGD) results from a deficiency of a phagosome enzyme (NADPH oxidase) leading to ineffective oxidative killing.[11] CGD usually presents in childhood but may present in adults. It should be considered in patients with recurrent abscesses or suppurative lymphadenitis, and in patients with pneumonia caused by *S. aureus* or *Aspergillus* spp. infection.

ACQUIRED DISORDERS OF PHAGOCYTOSIS

Severe neutropenia may be complicated by bacterial or fungal infections. There are many causes of neutropenia, including autoimmune neutropenia, drug therapy and haematological diseases such as cyclic neutropenia, myelodysplastic syndromes and aplastic anaemia. Cytotoxic chemotherapy commonly causes

neutropenia, and is often complicated by severe bacterial and fungal infections.

MANAGEMENT OF PHAGOCYTE DISORDERS

Acquired neutropenia may be corrected by removing the underlying cause and/or use of granulocyte colony-stimulating factor (G-CSF). Febrile neutropenia requires investigation for the source of sepsis and empirical antibiotics. If fever persists, then antifungals should be added. IFN-γ therapy may be effective in patients with CGD.

COMBINED IMMUNODEFICIENCY DISORDERS

Several immunodeficiency disorders result from a combination of immune defects, some of which are so severe that death is common unless the defect can be corrected. Such conditions are classified as severe combined immune deficiency (SCID) syndromes.

PRIMARY COMBINED IMMUNODEFICIENCY

There are many primary combined immunodeficiency syndromes, which present in early childhood.[12] Specific molecular defects have now been demonstrated for many of them. For example, defective expression of MHC class II molecules, adenosine deaminase (ADA) deficiency, and deficiency of the common γ-chain of the receptor for several interleukins (IL-2, 4, 7, 9, 15, 21) all result in a deficiency and/or functional impairment of B cells, T cells and sometimes NK cells. Deficiency of the IL receptor common γ-chain results from mutations of its gene on the X-chromosome and is the underlying defect of X-linked SCID.

Treatment of primary combined immunodeficiency

HSCT is the main treatment for many types of primary SCID, though enzyme replacement therapy can be effective in ADA deficiency and gene replacement therapy has been used to treat X-linked SCID. Antibody replacement with IVIg therapy and prophylaxis for opportunistic infections are also important in primary SCID.

ACQUIRED COMBINED IMMUNODEFICIENCY

Combined immune defects may also be acquired from disease or its treatment.

Haemopoietic stem cell transplantation

Combined immune defects may result in severe infections in patients who have received HSCT.[13] Following transplantation, an immunodeficient state exists until the recipient's immune system is reconstituted with donor cells. Consequently, both antibody-mediated and cell-mediated immunity are deficient in the first 3–4 months after transplantation and may remain deficient for a longer period of time in patients with GvHD. This immune defect is often compounded by neutropenia and/or the effects of corticosteroid or immunosuppressant therapy for GvHD. Defective antibody responses may persist for several years after transplantation, particularly antibody responses against polysaccharide antigens.

Critical illness

Many patients who are critically ill as a result of surgery, trauma, burns or overwhelming sepsis also have acquired immune defects. These defects include abnormalities of cellular immunity, immunoglobulin deficiency and impaired neutrophil function and appear to be associated with an increased risk of infection. Impairment of cell-mediated immune responses usually manifests as decreased T-cell proliferation and impaired delayed-type hypersensitivity responses, and probably results from a combination of factors, including the effects of anaesthetic drugs, blood transfusion, negative nitrogen balance and serum suppressor factors, including cytokines such as TNF. Phagocyte defects are mostly due to impairment of neutrophil chemotaxis by serum factors, and impaired intracellular killing. Deficiency of serum immunoglobulins also occurs, especially IgG deficiency, and may be associated with antibody deficiency. Serum leakage is a factor in patients with burns, and reduced synthesis and increased catabolism of immunoglobulins occur in many critically ill patients.

There is no specific treatment for immune defects in critically ill patients. General measures such as adequate nutrition, achieving a positive nitrogen balance and excision of burns appear helpful. Biological response modifiers, cytokine and mediator inhibitors, and IVIg therapy have all been evaluated. IVIg therapy reduces the number of acute infections, particularly pneumonia, but patient survival is not increased. Administration of G-CSF is safe in intensive care patients, but does not improve outcomes and cannot be routinely recommended.

Asplenia and hyposplenism

The spleen is an important part of the immune system's response to infections, particularly bloodstream infections. Splenic macrophages remove opsonised microorganisms from the blood, and IgM memory B cells produce an early antibody response to the polysaccharide antigens of encapsulated bacteria. The risk of overwhelming post-splenectomy infection (OPSI) is around 1 in 500 per annum, with 50% mortality. OPSI is most commonly caused by encapsulated bacteria, such as *Pneumococcus, Meningococcus* and *H. influenzae*, for which vaccines are available. Other important infections may include group A *Streptococcus, Capnocytophaga canimorsus* (following dog bites), *Salmonella, Enterococcus* and *Bacteroides*.

Asplenic/hyposplenic patients require education, vaccination and appropriate use of antibiotics. Pneumococcal, meningococcal and *H. influenzae* vaccines, including regular boosters, and annual influenza vaccine are

recommended, preferably 14 days before removal of the spleen if performed electively, or at least 14 days after if not.[14] Antibiotic prophylaxis (penicillin, or if allergic, macrolides) should be given in accordance with national guidelines. Enrolment of patients in spleen registries, where available, can offer ongoing patient education, vaccination reminders and access to updated recommendations (e.g. https://spleen.org.au/VSR/index.html).

Biological immune response modulators

Anti-TNF agents such as infliximab have been associated with increased rates of bacterial infection,[15] tuberculosis and some opportunistic infections.

Antibodies targeting various B- and T-cell antigens are increasingly used for rheumatological and haematological diseases. Not unexpectedly, these agents are associated with infections. For example, the anti-CD20 antibody rituximab specifically targets B cells for its therapeutic action, but is associated with infectious complications such as recurrent bacterial infection, reactivation of hepatitis B, cytomegalovirus (CMV) infection and progressive multifocal leukoencephalopathy (PML).

Human immunodeficiency virus and acquired immunodeficiency syndrome

Alexander A Padiglione, Steve McGloughlin

HUMAN IMMUNODEFICIENCY VIRUS/ ACQUIRED IMMUNODEFICIENCY SYNDROME AND THE INTENSIVE CARE UNIT

Modern antiretroviral therapy (ART) is so effective that the mortality of patients with treated human immunodeficiency virus (HIV) approaches that for the general population. Correspondingly, in developed countries the mortality risk for patients with treated HIV in intensive care unit (ICU) is now more closely related to their acute illness severity than to their degree of immunosuppression.[1]

Patients with HIV may be admitted to intensive care because of:

- *direct complications of immune deficiency:* classically, infections such as *Pneumocystis jiroveci* pneumonia (PJP) or cryptococcal meningitis, or tumours, especially lymphoma
- *indirect complications of HIV or its treatment not due to immune deficiency:* examples include sepsis or myocardial infarction, or treatment side effects
- *problems unrelated to HIV infection:* e.g. major surgery, self-poisoning or trauma; these represent an increasing proportion of the HIV infected patients in intensive care.[2]

Respiratory failure remains the commonest cause for admission; an HIV test is indicated in any critically ill patient with unexplained respiratory failure. PJP was the predominant cause, but bacterial pneumonia and non–HIV-related respiratory illnesses (e.g. chronic obstructive pulmonary disease, asthma) are increasing in prevalence. Immune reconstitution disease can also cause respiratory failure in patients with opportunistic infections recently commenced on ART.

Sepsis is an important cause of admission to ICUs amongst HIV patients; bloodstream and lower respiratory tract infections are most common. Whilst some studies suggest that HIV is an independent risk factor for sepsis and sepsis mortality, others suggest mortality is the same as in the HIV-negative population; local epidemiology (e.g. access to combination ART [cART], socioeconomic status, drug use) and co-morbidities, especially hepatitis C co-infection, may explain these differences. Early recognition of bacterial sepsis as a cause for an acute illness in HIV patients is vital. HIV patients in the ICU may also be at an increased risk of severe nosocomial infections.[1]

HUMAN IMMUNODEFICIENCY VIRUS REPLICATION

Human immunodeficiency viruses 1 and 2 are retroviruses that infect cells of the immune system with subsequent immune disturbance, especially immunodeficiency. The major cell surface receptor for HIV is the CD4 molecule, but chemokine receptors (CCR5 or CXCR4) act as a co-receptor. Inside the cell, the viral RNA is reverse-transcribed into DNA by a viral reverse transcriptase enzyme. This proviral DNA is integrated into the host DNA by a viral integrase enzyme. The proviral DNA remains in the nucleus until the cell is activated, when it is transcribed into RNA, which provides the template for assembly of new HIVs under the control of viral enzymes such as proteases. Budding of new virus from the cell leads to infection of new cells and a repeat of the replication cycle.

PRIMARY HUMAN IMMUNODEFICIENCY VIRUS INFECTION

Primary HIV infection ('seroconversion illness') occurs in 50%–75% of infected patients, typically 1–4 weeks after exposure to HIV. This infectious mononucleosis-like syndrome is characterised by fever, lymphadenopathy, headache, photophobia, fatigue and myalgia. However, mucocutaneous lesions, neurological disease and even transient immunodeficiency with secondary infections may occur.[3]

CHRONIC HUMAN IMMUNODEFICIENCY VIRUS INFECTION

The viraemia in primary HIV infection is partially controlled by cellular and antibody-mediated immune responses, which corresponds with resolution of symptoms. However, HIV replication continues to take place even though most patients are

ABSTRACT

The widespread uptake of effective antiretroviral therapy has seen a shift from intensive care unit (ICU) admissions directly related to human immunodeficiency virus or its treatment, to admissions for unrelated problems. Similarly, prognosis is now more closely related to severity of the acute illness than degree of immunosuppression. Antiretrovirals rarely need to be started urgently, but patients already on treatment should continue it during their ICU admission if possible; this can be challenging, as most antiretrovirals are oral. Serious interactions between antiretrovirals and common ICU drugs are frequent. Patients on effective antiretrovirals pose little risk to staff; needlestick injuries on undiagnosed and untreated patients pose a more significant risk but can be minimised by good infection control and protocols that enable access to post-exposure prophylaxis with antiretrovirals.

asymptomatic. This results in activation of the immune system, immune dysregulation, and eventually cellular immunodeficiency, in particular depletion of CD4+ T cells. These abnormalities develop at different rates in different individuals, depending on both host and viral factors. The median from acquiring HIV infection to developing the acquired immunodeficiency syndrome (AIDS) in the pre-ART era was around 9 years. However, about 5% of HIV-infected individuals have no evidence of CD4 loss even after 15 years and are referred to as long-term non-progressors.

There is a persistent immune response against the virus, but this usually slowly fails owing to CD4 cell depletion, immune dysregulation and viral mutation; viral replication increases and other cells become infected, including macrophages and microglial cells of the nervous system.

Chronic HIV infection may cause weight loss, fevers, lymphadenopathy and diarrhoea, though such symptoms are more likely to be caused by an opportunistic infection. Worsening HIV infection leads to a T-cell immunodeficiency syndrome, manifesting as opportunistic infections (e.g. PJP) and tumours (classically, Kaposi sarcoma [KS] and T-cell lymphoma). Neurological disease may also develop. Very severe T-cell deficiency (<100 cells/mL) presents with diseases such as cryptococcal meningitis, CMV retinitis, disseminated *Mycobacterium avium* complex (MAC) and cerebral toxoplasmosis. Globally, tuberculosis (TB) is the most common opportunistic infection; at higher CD4 counts, pulmonary disease predominates, whilst unusual extrapulmonary manifestations (including meningitis and miliary disease) are increasingly likely at lower CD4 counts.

DIAGNOSIS

HIV infection is diagnosed by demonstrating anti-HIV antibodies in the patient's serum. It may take a number of weeks for HIV antibody to become positive during seroconversion. Current testing is with combination antigen/antibody tests, which dramatically reduce any window period.[4] Most patients with HIV have positive antibodies by 3 months; after this time, absence of antibodies excludes HIV infection in almost all cases.

HUMAN IMMUNODEFICIENCY VIRUS VIRAL LOAD MONITORING/GENOTYPE TESTING

Polymerase chain reaction (PCR) testing allows the quantification of viral nucleic acid. The serum HIV viral load is usually tested every 3–4 months, and is useful in monitoring response to treatment.[5] Specific mutations in the viral RNA confer resistance to specific antiretroviral drugs. These mutations can be detected by PCR and sequencing; this genotyping is done at first diagnosis, or when a treatment regimen is failing, to guide subsequent therapy.[6]

IMMUNOLOGICAL MONITORING

Immunodeficiency and neurological disease caused by HIV infection usually develop gradually over years. The blood CD4+ T-cell count/percentage is the best indicator of the severity of HIV-induced immunodeficiency, and therefore of the patient's susceptibility to opportunistic infections. Whilst significant AIDS-related illnesses tend to occur at a CD4+ count of less than 200, there is clear benefit of starting therapy in any patient with HIV irrespective of CD4+ count, both to decrease AIDS-related morbidity/mortality, and to minimise risk of HIV transmission to others ('treatment as prevention').[7]

MANAGEMENT OF THE HUMAN IMMUNODEFICIENCY VIRUS-INFECTED PATIENT

cART has had a dramatic impact on the morbidity and mortality associated with HIV infection. Patients on effective treatment can expect a near-normal lifespan. Six classes of antiretroviral drugs are available, and function at various points in the HIV replication cycle (Table 69.1).

Antiretroviral drugs should not be used individually. Triple combination therapy against a sensitive virus usually leads to sustained virological control without the development of resistance. Adherence to ART is critical. The choice of drug therapy should be based on national guidelines and individualised for patient characteristics and genotyping results.[8]

The potency of some newer integrase inhibitors has led to renewed interest in using fewer than 3 agents to maintain virological control while minimising long-term toxicity.

DRUG TOXICITY

Improvements in ART have seen reductions in serious side effects. Older agents previously associated with lipodystrophy, lactic acidosis, peripheral neuropathy and pancreatitis are now rarely used in the developed world.[9] Severe allergic reactions to abacavir are prevented by HLA-B*5701 screening to exclude those with a predisposition.

Long-term toxicities including liver, kidney and bone disease remain significant concerns. Other factors may play a role in toxicity; for example, co-infection with hepatitis C virus is a significant risk factor for hepatotoxicity and at least some cases are probably a type of immune restoration syndrome.[10]

IMMUNE RECONSTITUTION INFLAMMATORY SYNDROME

Immune reconstitution inflammatory syndrome (IRIS) is a complication related to the commencement of

Table 69.1 Antiretroviral drugs used to treat human immunodeficiency virus infection

ANTIRETROVIRAL CLASS AND EXAMPLES	MECHANISM
NUCLEOSIDE/NUCLEOTIDE ANALOGUE REVERSE TRANSCRIPTASE INHIBITORS	Substitute natural nucleoside or nucleotide analogues during HIV replication, thereby inhibiting DNA chain elongation and the effects of the reverse transcriptase enzyme
NUCLEOSIDE ANALOGUES	
Abacavir (ABV) Didanosine (ddI) Emtricitabine (FTC) Lamivudine (3TC) Stavudine (d4T) Zidovudine (AZT)	
NUCLEOTIDE ANALOGUES	
Tenofovir (TDF), Tenofovir Alafenamide (TAF)	
NON-NUCLEOSIDE REVERSE TRANSCRIPTASE INHIBITORS	Inhibit the reverse transcriptase enzyme preventing the formation of HIV DNA
Efavirenz Etravirine (ETR) Nevirapine Rilpivirine	
INTEGRASE INHIBITORS	Block integration of viral DNA into host DNA
Dolutegravir Elvitegravir Raltegravir	
PROTEASE INHIBITORS	Inhibit the viral protease
Atazanavir Darunavir Fosamprenavir Indinavir Lopinavir Nelfinavir Saquinavir Tipranavir	
FUSION/ENTRY INHIBITORS	Block binding/fusion of the virus with the cell membrane
Enfuvirtide (T20) Maraviroc	
BOOSTER MEDICATIONS Ritonavir Cobicistat	Used in conjunction with other drugs to increase serum levels/permit less frequent dosing

DNA, Deoxyribonucleic acid; *HIV*, human immunodeficiency virus.

ART and the subsequent reconstitution of the immune system. The syndrome can lead to a worsening of treated opportunistic infections or unmask untreated infections. IRIS is more common in those patients with a history of cytomegalovirus (CMV) retinitis, cryptococcal meningitis and TB, and in those with low CD4 counts. However, it can occur with virtually any opportunistic infection. ART is usually continued if mild IRIS develops. Corticosteroids, other immunosuppressive agents and even cessation of ART may be considered for the management of severe IRIS.[11-13]

HUMAN IMMUNODEFICIENCY VIRUS TREATMENT IN THE INTENSIVE CARE UNIT

ART is a lifelong therapy that should be started in consultation with an HIV specialist. Patients already on ART should continue their therapy during an acute ICU admission, if possible, though a single short interruption (1–2 days) of therapy in patients who have been compliant and have long-term virologic control is unlikely to be harmful. Maintenance of adequate drug delivery and absorption of ART is a particular challenge in the ICU, and should be managed in consultation with a pharmacist with specialist HIV knowledge. Options include syrup formulations, crushing tablets and the use of intravenous preparations; drug levels of some medications can also be monitored.

ART also has the potential for serious drug interactions, particularly when ART includes 'booster' medications (ritonavir or cobicistat), protease inhibitors or efavirenz (metabolised via the P450 hepatic enzyme system). Certain antimicrobials, antiemetics, anticonvulsants, anticoagulants, cardiac drugs, and statins are all commonly used drugs that may be contraindicated with ART. For example, protease inhibitors can significantly potentiate the effect of midazolam. Acid-reducing drugs decrease absorption of some antiretrovirals. Web-based tools are available to check potential interactions (e.g. http://www.HIV-druginteractions.org). Renal or hepatic failure may also affect the dosing of ART.

A patient not on ART admitted to the ICU for a problem unrelated to immunosuppression can delay commencement of ART until after they recover. In patients admitted for an AIDS-related illness, the timing of therapy is more controversial. The earlier improvements in immune function need to be balanced against potential side effects from the introduction of new drugs and increased risk of complications from immune reconstitution. In most opportunistic infections, early ART therapy is associated with improved survival.[14] Our practice is to initiate ART within 2–4 weeks after diagnosis of most AIDS-related infections, as by this time the patient's clinical status has stabilised, and tolerability of treatment for the infection has been established. Specific exceptions to early treatment are cryptococcal meningitis and probably TB meningitis, where early therapy may be associated with life-threatening IRIS reactions, and drug interactions and side effects are problematic. In these conditions, we delay ART for at least 4–6 weeks.

HUMAN IMMUNODEFICIENCY VIRUS-INDUCED IMMUNODEFICIENCY

The degree of immunodeficiency, as indicated by CD4+ count/percentage, is strongly related to susceptibility to opportunistic infections, and guides the need for prophylaxis (Fig. 69.1). Some patients also have impaired antibody responses and phagocyte dysfunction, predisposing them to bacterial sepsis.

MAJOR OPPORTUNISTIC INFECTIONS

PNEUMOCYSTIS JIROVECI *PNEUMONITIS*

Interstitial pneumonitis due to *P. jiroveci* presents as subacute progressive dyspnoea, non-productive cough and fever. Respiratory examination reveals fever and tachypnoea, but focal signs are uncommon. The critical finding is hypoxia. The chest X-ray or computed tomography (CT) scan classically demonstrates interstitial 'ground glass' infiltrates but can be normal. Diagnosis is made by demonstrating *Pneumocystis* cysts in an induced sputum specimen, bronchoalveolar lavage fluid or a transbronchial biopsy.

Severe PJP is best treated with high-dose intravenous co-trimoxazole (trimethoprim-sulfamethoxazole). Many patients develop a hypersensitivity reaction to co-trimoxazole; only severe reactions necessitate changing to intravenous pentamidine. Steroid therapy must be used if the Pa_{O_2} is less than 70 mm Hg (9.3 kPa)[15] with an Fi_{O_2} of 0.21 or if the A-a gradient is greater than 35 mm Hg. These patients are at high risk of a pneumothorax; this needs to be considered if there is a sudden deterioration in respiratory status. Non-invasive ventilation can be effective for severe hypoxaemia; however, if mechanical ventilation is required, then lung protective strategies such as low tidal volumes and plateau pressures must be implemented.

Patients with a CD4 T-cell count of less than 200/mL should receive PJP prophylaxis; co-trimoxazole is most effective, which also protects against cerebral toxoplasmosis.[16]

OESOPHAGEAL CANDIDIASIS

Oesophageal candidiasis is a common presentation of HIV infection, and typically presents with odynophagia and dysphagia. These symptoms in association with oral candidiasis are usually sufficient to start treatment with fluconazole. Definitive diagnosis is by endoscopy. Patients with prior azole exposure may have azole resistance and require an intravenous echinocandin or amphotericin.

CRYPTOCOCCAL MENINGITIS

Meningitis is the most common manifestation of *Cryptococcus neoformans* infection. Subacute headache and fever are typical, but confusion or behavioural abnormalities may predominate. Neck stiffness is often minimal or absent, as the immune response needed to produce this sign is minimal. Cerebrospinal fluid examination (performed after CT imaging has excluded a space-occupying lesion) may also reveal little evidence of inflammation, particularly in the most severe cases. Cryptococcal antigen is virtually always present in both serum and cerebrospinal fluid, and cultures for

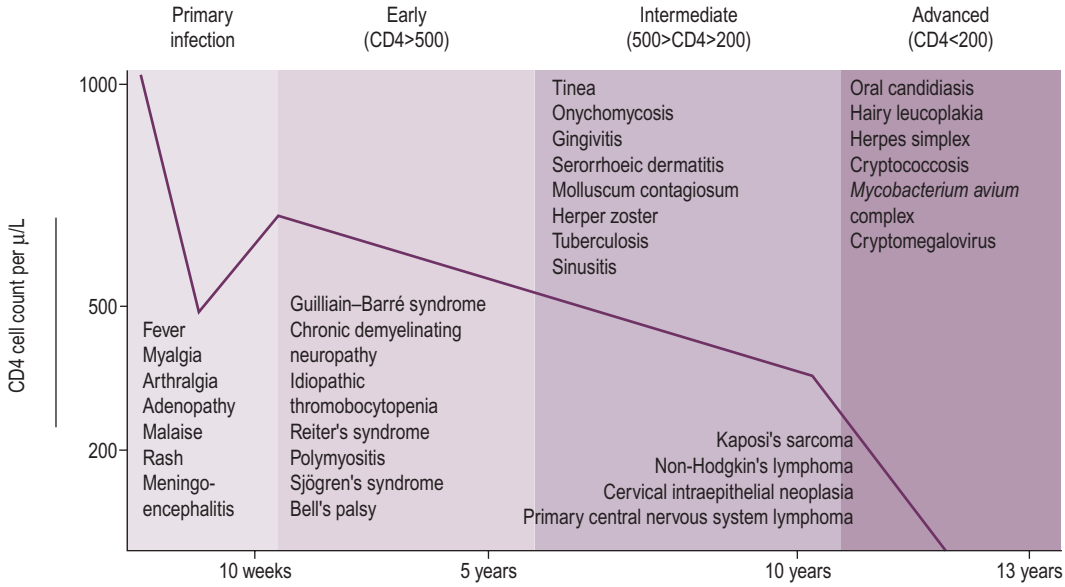

Figure 69.1 Chronological framework for understanding human immunodeficiency virus disease and its management.

cryptococci are positive.[17] Intravenous amphotericin is the treatment of choice, usually given in combination with flucytosine; it is followed by suppressive therapy with oral fluconazole until immune reconstitution is achieved with ART.[18]

TOXOPLASMA *ENCEPHALITIS*

Reactivation of *Toxoplasma gondii* infection most commonly presents as focal encephalitis, causing headaches, fever, focal neurological deficits, convulsions and coma. Contrast CT brain scan typically shows multiple ring-enhancing lesions with surrounding oedema, classically with a predilection for the basal ganglia. Serum *Toxoplasma* antibody is present in most patients; its absence strongly favours an alternative diagnosis. Treatment is oral pyrimethamine, together with either intravenous sulfadiazine or clindamycin. Hypersensitivity reactions to sulfadiazine and clindamycin are common. A brain CT scan after 2–3 weeks of therapy should show improvement; if not, consider an alternative diagnosis. Cerebral lymphoma can produce similar lesions to *Toxoplasma* encephalitis. A brain biopsy is often necessary to make the diagnosis.[19]

CYTOMEGALOVIRUS DISEASE

CMV reactivation usually occurs in patients with severe immunodeficiency (CD4 T-cell count <50/mL). The most common site is the retina. CMV retinitis usually presents with unilateral blurred vision, visual field loss or 'floaters'. Diagnosis is by fundoscopy and should be confirmed by an ophthalmologist. Treatment is usually with oral valganciclovir; intravenous ganciclovir or foscarnet are alternatives, and rarely intravitreal treatment is given. Induction is followed by suppressive therapy to prevent relapses until there is immune reconstitution following the use of ART.

CMV can reactivate in other organs, particularly the oesophagus, bile ducts or colon. It is diagnosed on biopsy of affected tissue. High or increasing CMV viral load in blood should prompt a search for end-organ CMV disease. CMV PCR can be used to monitor the response to therapy and detect antiviral resistance.

CRYPTOSPORIDIOSIS

Infection of the gastrointestinal tract by *Cryptosporidium parvum* causes a severe, intractable diarrhoea, often associated with a malabsorption syndrome. It can also cause cholangitis. Diagnosis is by demonstrating *Cryptosporidium* oocysts in faeces and/or a rectal or duodenal biopsy. The best treatment is ART to raise the CD4 count.

MYCOBACTERIUM AVIUM *COMPLEX INFECTION*

Infection with MAC is usually disseminated and affects blood leucocytes, liver, spleen and lymph nodes, and the gastrointestinal tract. It presents as nonspecific symptoms such as weight loss, fatigue, fevers, anaemia and diarrhoea. The diagnosis is usually made by culturing MAC from blood, but sometimes stool microscopy and culture or biopsy of affected tissues are necessary. Multidrug therapy (e.g. clarithromycin, rifabutin and ethambutol) is required. Suppressive therapy is continued until there is immune reconstitution following the use of ART.[20]

ACQUIRED IMMUNODEFICIENCY SYNDROME-RELATED NEOPLASMS

Certain neoplasms with a viral pathogenesis characteristically occur in HIV-induced immunodeficiency. KS is an angioproliferative tumour originating from vascular endothelium, and is a complication of human herpesvirus-8 (HHV-8) infection. It usually presents as skin lesions that have a reddish-purple colour. They vary in extent from one or two small papules to numerous bulbous lesions. The gastrointestinal tract, lymph nodes and internal organs can be involved in the severely immunosuppressed. KS is confirmed on biopsy of a lesion. KS may present at any time, but occurs most often, and is more severe, in patients with moderate to severe immunodeficiency. New antimitotic agents plus ART have resulted in KS essentially disappearing as a clinical problem in treated individuals.

Lymphomas can also complicate HIV-induced immunodeficiency. Most are B-cell lymphomas (non-Hodgkin), and reactivation of Epstein–Barr virus infection is implicated in the pathogenesis. Primary cerebral lymphoma or extracerebral lymphoma, which often has extranodal involvement, is common and usually high grade in patients with severe immunodeficiency. Treatment consists of whole brain radiation, steroids and ART.[21]

Cervical intraepithelial neoplasia and cancer are more common and aggressive in women with HIV infection, as are anal neoplasia and cancer in males.

HUMAN IMMUNODEFICIENCY VIRUS-RELATED NEUROLOGICAL DISEASE

HIV infection of macrophages and microglial cells in the nervous system often results in neurological disease. In a small number of patients, neurological disease is more problematic than immunodeficiency. Encephalopathy, myelopathy and peripheral neuropathy are all possible; an HIV test is indicated in any unexplained neurological disease. The encephalopathy usually develops insidiously in individuals with advanced immunodeficiency and eventually results in cognitive, motor and behavioural abnormalities. Myelopathy, now rare, results in an ataxic spastic paraparesis.[22]

Investigation of HIV patients with space-occupying cerebral lesions requires analysis of serology, cerebrospinal fluid and neuroimaging investigations. Analysis of cerebrospinal fluid includes PCR for Epstein–Barr virus (indicative of lymphoma), herpes simplex virus,

CMV, varicella–zoster virus (viral encephalitis), JC virus (indicative of progressive multifocal leucoencephalopathy), toxoplasmosis and *Mycobacterium tuberculosis*.

NEEDLESTICK INJURIES AND POST-EXPOSURE PROPHYLAXIS

Patients on effective ART with undetectable viral load pose minimal risk to staff. However, known patients with HIV in an ICU may be outnumbered by undiagnosed patients with HIV. ICU staff must therefore practice stringent infection control procedures on all patients at all times; this will also protect against other bloodborne viruses.

Risk of HIV transmission from needlestick injury from a patient not on ART is approximately 0.3%, and from mucosal exposure approximately 0.009%. There are no reported seroconversions after skin exposure. The major risk factors for infection after a needlestick injury are: (1) deep injury; (2) visible blood on device; (3) needle placement in a vein or artery; and (4) high viral load.

Post-exposure antiretroviral prophylaxis dramatically reduces transmission rates.[23] A protocol for dealing with blood and body fluid exposure should be in place for every health care institution.

Sepsis and septic shock

A Raffaele De Gaudio, Stefano Romagnoli

INTRODUCTION

Sepsis remains a major challenge for intensive care clinicians, researchers and health care systems worldwide due to its high mortality rate, and ongoing challenges in early identification. A recent epidemiological study involving high-income country data estimated that there are 31.5 million sepsis cases, 19.4 million severe sepsis cases, and potentially 5.3 million sepsis-related deaths annually.[1] Increased awareness of the problem of sepsis and compliance with Surviving Sepsis Campaign (SSC) bundles (see later) have led to improvements in diagnostic procedures, the early administration of broad-spectrum antibiotics and more aggressive supportive therapy, with a resultant decrease in sepsis-related mortality in recent years.[2–4] According to a recent study by Levy et al. on compliance with bundles, crude mortality rates differed between Europe and the United States (41.1% vs. 28.3%).[3] However, when adjusted for disease severity, there was little difference between the two (32.3% vs. 31.3%) – a statistic that is probably due to the effect of intensive care unit (ICU) bed availability. Sepsis-related mortality varies depending on organ dysfunction: in patients without organ dysfunction, mortality is less than 20%[5]; for severe sepsis, according to an old definition, mortality ranges between 20% and 50%[2,6]; and in case of septic shock (see below) mortality is frequently over 50%.[7] Despite this reduction in mortality, the absolute number of patients dying from sepsis is increasing due to greater prevalence.[5] The present chapter addresses current insights regarding the definitions, aetiopathogenesis, clinical presentation and treatment of sepsis and septic shock.

OLD AND NEW DEFINITIONS

The first consensus definition of sepsis by the Society of Critical Care Medicine (SCCM) and the American College of Chest Physicians (ACCP)[8] dates back to 1992 (Table 70.1). The clinical criteria for systemic inflammatory response syndrome (SIRS), sepsis (SIRS in the presence of known or suspected infection) and severe sepsis and septic shock, as well as the progression to organ dysfunction, were similarly defined. In order to clarify and simplify the identification of septic patients, an international task force recently modified the old definitions – the 'Third International Consensus Definitions for Sepsis and Septic Shock' (Table 70.2).[9] As SIRS criteria (temperature, heart rate, respiratory rate, white cell count) obtained from a large electronic database totalling approximately 1 million patients,[10] may reflect a normal/appropriate host response to infection, sepsis is now defined as a 'life-threatening organ dysfunction caused by a dysregulated host response to infection'. In this new version, the terms 'dysfunction' and 'dysregulated' are key aspects of the definition. The alteration of metabolic pathways (e.g. pro- and anti-inflammatory host reaction, neural, hormonal, metabolic, coagulation activation, and macro- and microvascular dysfunction) eventually lead to organ dysfunction, which is now described by a rise in the Sepsis-related Organ Failure Assessment (SOFA) score ≥2 (Tables 70.2 and 70.3)[11] with an associated mortality risk exceeding 10%.[9] As such, what was formerly termed 'severe sepsis' has become the new 'sepsis'. The task force has recommended a change in baseline of the total SOFA score of two points or more, as patients with chronic comorbidities may already have known elevated levels of indices, particularly renal (creatinine) and hepatic (bilirubin). 'Septic shock' is denoted by hypotension and hyperlactatemia that persist after adequate volume resuscitation (see Table 70.2). Definitively, the terms SIRS and severe sepsis have been eliminated.

THE PREDISPOSITION, INFECTION, RESPONSE AND ORGAN DYSFUNCTION SYSTEM

In the past, a staging system was used to identify and stage septic patients. Known as predisposition, infection, response and organ dysfunction (PIRO), designed to deal with the inherent heterogeneity of septic patients (Table 70.4),[12] this stratification tool included domains for predisposition (pre-morbid illness), insult/infection (site, microbiology of infection and severity of other insults, such as trauma), response (hypotension)

ABSTRACT

Increased awareness of sepsis and higher compliance with Surviving Sepsis Campaign bundles have led to decreased sepsis-related mortality. Nevertheless, sepsis remains a major challenge for intensive care clinicians, and mortality is still high. In order to clarify and simplify the identification of these patients, a new definition has recently replaced the old ones. Organ dysfunction and dysregulated host response are leading aspects of this new definition. Recent research has focused on the pro- and anti-inflammatory phases now considered intercurrent and overlapped in time rather than a continuum of events. Unbalanced progression and resolution of the septic process may lead to a state of immune paralysis that exposes many survived patients to secondary infections and late mortality. Most of the research is now focused on immune status and immune therapies. Until more personalised therapies become available, infection source control, broad-spectrum antibiotics, and organ support remain core therapies for sepsis.

and organ dysfunction (SOFA). The PIRO system has recently re-emerged as a potential means to predict multiple organ dysfunction, ICU admission, and 28-day mortality in emergency department septic patients.[13,14]

THE QUICK SEPSIS-RELATED ORGAN FAILURE ASSESSMENT FOR SEPSIS OUTSIDE THE INTENSIVE CARE UNIT

Evaluating all six components of the SOFA score can be time consuming, and some of them require laboratory measurements. A new rapid bedside score – the quick SOFA (qSOFA) – identifies patients at risk of sepsis outside the ICU (emergency departments and wards). Patients showing two or more of systolic blood pressure ≤100 mm Hg, altered mentation and/or respiratory rate ≥22 breaths/min must be screened for sepsis (see Table 70.2). The predictive validity and role of qSOFA in such patients has yet to be defined. Indeed, sepsis can be present without a qSOFA score ≥2 when different forms of organ dysfunction occur (e.g. hypoxemia, renal failure, coagulopathy) – a factor that has led to much discussion and controversy in recent times. Equally, patients may have a qSOFA ≥2 without infection (e.g. hypovolemia, cardiogenic shock or pulmonary embolism).[15]

AETIOPATHOGENESIS

In terms of organs and tissues, sepsis is a progression from a localised infection to systemic involvement of all the systems. Significant variations may be observed, depending on the initial site of infection, the causative pathogen, the pattern and degree of organ injury and dysfunction, the chronic clinical state of the patient, their genetic characteristics, and the timing and type of intervention.

Data for more than 14,000 adult patients across 1265 ICUs were reported in the 2007 Extended Prevalence of Infection in Intensive Care (EPIC II) study.[16] The sites of infection were lung (64% of cases), abdomen (20%), bloodstream (15%) and renal or genitourinary tract (14%).[16] Among the infected patients with positive cultures (70%), the isolated causes were Gram-negative (62%; 20% *Pseudomonas* spp. and 16% *Escherichia coli*), Gram positive (47%; 20% *Staphylococcus aureus*) and fungi (19%).[16]

Sepsis Prevalence, Outcomes, and Therapies (SPROUT) Study Investigators and Pediatric Acute Lung Injury and Sepsis Investigators (PALISI) Network[17] is a point prevalence study of paediatric sepsis published in 2015. Of 569 children with severe sepsis (8.2% prevalence), the sites of infection were lung (40% of cases), bloodstream (29%), abdomen (8%), central nervous system (4%) and genitourinary system (4%). The isolated causes were Gram-negative bacteria (28%), Gram-positive bacteria (27%), viruses (21%) and fungi (13%).[17]

INFLAMMATION AND IMMUNE SUPPRESSION

Pathogens activate immune cells through an interaction with pattern recognition receptors (PRRs). Four main

classes (toll-like receptors [TLRs], C-type lectin receptors, retinoic acid inducible gene-1-like receptors and nucleotide-binding oligomerisation domain-like receptors) have been identified to date.[18,19] These receptors recognise structures called pathogen-associated molecular patterns (PAMPS), which are molecules associated with groups of pathogens resulting in the activation of inflammatory gene transcription.[19,20] Interestingly, the same receptors are recognised and linked by a different group of molecules (high-mobility group protein B1, S100 proteins and extracellular RNA, DNA). Known as alarmins or damaged-associated molecular patterns (DAMPs), these are released by sterile injured cells (e.g. trauma) and share most of the pathophysiological features of sepsis in the absence of infection.[21,22]

The activation of PRRs results in several effects aimed at stimulating the host immune response to the newly identified pathogen. For instance, TLRs activate cytosolic nuclear factor-κB (NF-κB), which induces the release of several cytokines (CKs) with predominantly pro-inflammatory activities, for example tumour necrosis factor-α (TNF-α), interleukins (IL-1β, IL-2, IL-6, IL-8) and interferon-γ (IFN-γ).[23] CKs, in turn, have local and systemic effects including fever, capillary leak and the activation of both the coagulation system and neutrophils. Increased gluconeogenesis and lipolysis, and the generation of acute phase proteins, have also been observed.[23] Chemokines are locally released (e.g. intercellular adhesion molecule-1, vascular cell adhesion molecule-1, nitric oxide), promoting chemotaxis of polymorphonuclear leucocytes, which aggregate and marginate at the vascular endothelium.[23]

Traditionally, two different phases were considered sequential and biphasic: the pro-inflammatory phase, driven by CK and inflammatory mediators released by the innate immune system; and the anti-inflammatory phase, characterised by a period of immune suppression. Nowadays, the pro- and anti-inflammatory phases are considered intercurrent and overlapped in time.[24] In view of this, the resolution of inflammation is not simply a passive process; rather, it involves a complex interaction between cells and molecular signals.[25] The pro-inflammatory reaction triggered by the host-pathogen interaction is counterbalanced by an anti-inflammatory response aimed at attenuating the potentially harmful effects of inflammation.[20] Cellular

Table 70.4 The predisposition, infection, response and organ dysfunction system for staging sepsis

DOMAIN	PRESENT	FUTURE	RATIONALE
Predisposition	Pre-morbid illness with reduced probability of short-term survival. Cultural or religious beliefs, age, sex	Genetic polymorphisms in components of inflammatory response (e.g. TLR, TNF, IL-1, CD14); enhanced understanding of specific interactions between pathogens and host diseases	In the present, pre-morbid factors impact on the potential attributable morbidity and mortality of an acute insult; deleterious consequences of insult heavily dependent on genetic predisposition (future)
Insult infection	Culture and sensitivity of infecting pathogens; detection of disease amenable to source control	Assay of microbial products (LPS, mannan, bacterial DNA); gene transcript profiles	Specific therapies directed against inciting insult require demonstration and characterisation of that insult
Response	SIRS, other signs of sepsis, shock, CRP	Non-specific markers of activated inflammation (e.g. PCT or IL-6) or impaired host responsiveness (e.g. HLA-DR); specific detection of target of therapy (e.g. protein C, TNF, PAF)	Both mortality risk and potential to respond to therapy vary with non-specific measures of disease severity (e.g. shock); specific mediator-targeted therapy is predicated on presence and activity of mediator
Organ dysfunction	Organ dysfunction as number of failing organs or composite score (e.g. MODS, SOFA, LODS, PEMOD, PELOD)	Dynamic measures of cellular response to insult – apoptosis, cytopathic hypoxia, cell stress	Response to pre-emptive therapy (e.g. targeting microorganism or early mediator) not possible if damage already present; therapies targeting the injurious cellular process require that it be present

CRP, C-reactive protein; *HLA-DR*, human leucocyte antigen-DR; *IL*, interleukin; *LODS*, logistic organ dysfunction system; *LPS*, lipopolysaccharide; *MODS*, multiple organ dysfunction syndrome; *PAF*, platelet-activating factor; *PCT*, procalcitonin; *PELOD*, paediatric logistic organ dysfunction; *PEMOD*, paediatric multiple organ dysfunction; *SIRS*, systemic inflammatory response syndrome; *SOFA*, sepsis-related organ failure assessment; *TLR*, toll-like receptor; *TNF*, tumour necrosis factor.

phenotype may change into an anti-inflammatory type; phagocytes may promote tissue repair; while regulatory T cells and myeloid-derived suppressor cells further reduce inflammation.[19] IL-10, released by many types of leucocytes, inhibits the production of IL-6 and IFN-γ, and activates the production of a soluble TNF receptor and IL-1 receptor antagonist, helping to neutralise the potent TNF-α and IL-1.[26] Autophagy is a mechanism that helps to clear DAMPs and PAMPs by wrapping pathogens and damaged organelles and proteins in vesicles that undergo lysosomal degradation.[27]

FROM IMMUNE SUPPRESSION TO IMMUNE PARALYSIS

There is evidence that many patients who survive sepsis develop viral reactivation and/or secondary nosocomial infections, frequently by organisms that would not typically cause disease in immunocompetent hosts (e.g. *Candida* sp., *Acinetobacter* sp., or *Stenotrophomonas*). This has led to the conclusion that some patients enter a phase of 'immune paralysis'.[28,29] During the last 10–15 years, mortality in sepsis has substantially decreased.[2] This improvement in outcomes is due to the wider and more timely application of the SSC bundles (Table 70.5), entailing greater expertise in managing organ failure, earlier and more aggressive fluid management, timely administration of broad-spectrum antimicrobial therapy and increased attention to infectious source control (e.g. abdominal abscesses, cholangitis).[3] Most of these interventions limit the organ damage that occurs during the pro-inflammatory phase of sepsis (CK storm and shock state). As more patients survive this phase, questions of impaired immunity and secondary infections become pertinent to longer-term outcomes (Fig. 70.1).[21] Studies of patients who have died following sepsis have shown biochemical, flow cytometric and immunohistochemical findings consistent with immunosuppression.[30] Apoptosis of T- and B-lymphocytes phenomena resulting in lymphopenia and tissue lymphocyte depletion have been demonstrated.[31] In an interesting study performed for patients who have died of sepsis (40 patients and 49 controls), a sort of

Table 70.5 Surviving sepsis campaign bundles

BUNDLES	DOCUMENT REASSESSMENT OF VOLUME STATUS AND TISSUE PERFUSION
To be completed within 3 h: • Measure lactate level • Obtain blood cultures prior to administration of antibiotics • Administer broad-spectrum antibiotics • Administer 30 mL/kg crystalloid for hypotension or lactate ≥4 mmol/L	Either: • Repeat focused exam (after initial fluid resuscitation) including vital signs, cardiopulmonary, capillary refill, pulse, and skin findings. Or two of the following: • Measure CVP • Measure Scv_{O_2} • Perform bedside cardiovascular ultrasound • Perform dynamic assessment of fluid responsiveness with passive leg raise or fluid challenge
To be completed within 6 h: • Apply vasopressors (for hypotension that does not respond to initial fluid resuscitation) to maintain a mean arterial pressure (MAP) ≥65 mm Hg • In the event of persistent hypotension after initial fluid administration (MAP <65 mm Hg) or if initial lactate was ≥4 mmol/L, re-assess volume status and tissue perfusion and document findings according to 'Document reassessment of volume status and tissue perfusion' (column 2) • Re-measure lactate if initial lactate elevated	

CVP, Central venous pressure; Scv_{O_2}, central venous oxygen saturation.

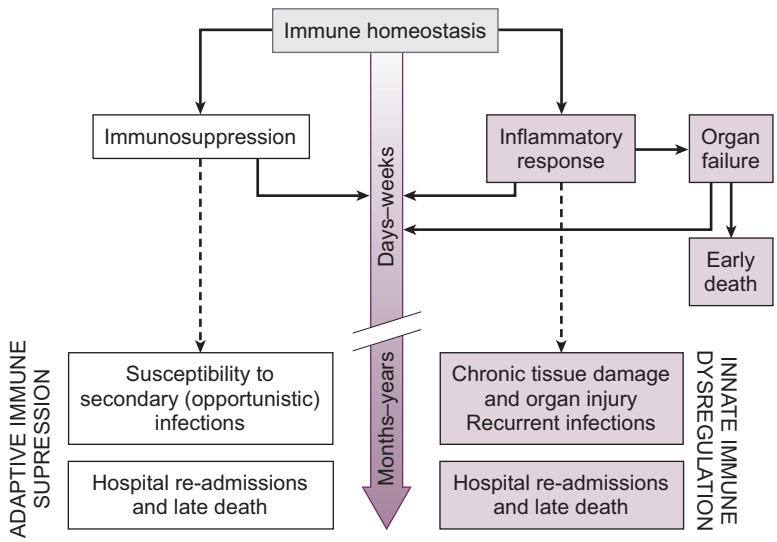

Figure 70.1 Immune system in sepsis. *Modified from Delano MJ, Ward PA. Sepsis-induced immune dysfunction: can immune therapies reduce mortality?* J Clin Invest. *2016;126:23–31.*

'immune exhaustion' was observed within 3 hours of death.[30] CKs secretion assays and the immunophenotyping of cell surface receptor-ligand expression profiles were performed and tested in harvested tissues (lung and spleen) to identify potential immune dysfunction mechanisms. Immunohistochemical staining was performed to evaluate the loss of immune effector cells. Following the administration of lipopolysaccharides (LPS; also known as 'endotoxin') – a component of the outer membrane of Gram-negative bacteria – patients with sepsis had significantly reduced levels (less than 10% compared with non-septic controls)

of splenic pro-inflammatory CKs (e.g. TNF-α, IFN-γ, IL-6 and IL-10). By inference, patients with 'immune exhaustion' or immunoparalysis may thus be prone to secondary infections and/or viral reactivation.

ENDOTHELIUM AND COAGULATION SYSTEM

The endothelium has various important roles, including regulating vascular tone, immunological function, haemostasis, vascular permeability, solute transport and osmotic balance. The transfer of fluids and nutrients into and out of tissues, the coagulation system and the inflammatory/anti-inflammatory equilibrium can be profoundly altered in sepsis.[32] Failure of the endothelium structure and function is central to the progression towards organ failure during sepsis. The integrity of the endothelium in the regulation of solutes transport and fluid leakage is largely determined by the endothelial glycocalyx (EG) – a 0.2–0.5 μm thick gel-like layer of proteoglycans, glycoproteins and glycosaminoglycans. The EG regulates the vascular barrier function, haemostasis, leucocyte and platelet adhesion, transmission of shear stress to the endothelium, and anti-inflammatory and antioxidant defences.[33]

Vascular tone and endothelium/EG alteration eventually lead to global microcirculation dysfunction. Impaired response to local stimulation (release in nitric oxide and/or endothelin is common in sepsis),[32] and obstruction of capillary lumen by thrombi and plugs of white and red blood cells frequently worsen tissue perfusion.[32] In addition, loss-of-barrier function mediated by EG is associated with tissue oedema – another key contributor to sepsis-induced organ failure.

Sepsis is also almost invariably associated with altered coagulation.[34] Haemostasis – a complex interaction between endothelium, soluble plasma molecules, platelets and leucocytes – is commonly deregulated during sepsis. Indeed, sepsis-mediated inflammation drives haemostasis towards a prothrombotic and antifibrinolytic state, which can lead to microvascular thrombosis, tissue hypoxia and organ dysfunction.[32] Tissue factor exposure and impaired anticoagulant mechanisms (including activated protein C and antithrombin) can lead to disseminated intravascular coagulation syndrome, with associated organ injury, bleeding (consumption of platelets and clotting factors) and high mortality rate.[35] In sepsis, glycocalyx shedding exposes adhesion molecules that promote leucocyte link and transmigration to the tissues, where they can release inflammatory mediators and molecules that are reactive against pathogens but which can potentially cause tissue damage.

CLINICAL PRESENTATION

Profound derangements in cellular and humoral homeostasis eventually lead to organ injury and dysfunction.

The cardiovascular system is primarily involved; intravascular volume must be promptly restored to maintain an adequate cardiac output (CO) and perfusion pressure in the presence of low systemic vascular resistance due to altered vascular tone and impedance.[36] Acute biventricular dysfunction frequently occurs in sepsis[37] with hyperlactatemia, commonly used as an indicator of oxygen delivery (DO_2)/oxygen consumption (VO_2) imbalance, a central factor in diagnosis, prognosis and therapeutic response in septic patients. Increased lactate and lactate trend/clearance is a mortality indicator.[38] Although hyperlactatemia has traditionally been related to tissue hypoxia and anaerobic metabolism subsequent to DO_2/VO_2 imbalance, the adjunctive parallel mechanisms of sepsis-induced hyperlactatemia (e.g. enhanced adrenergic tone) are recognised as relatively common phenomena.[39]

The lungs are frequently the first organ to be compromised, either as the primary infection site or, in case of extrapulmonary infection, in a subsequent phase of the disease, resulting in mild, moderate or severe acute respiratory distress syndrome (ARDS).[40]

Sepsis-associated acute kidney injury (AKI) is an independent predictor of increased mortality and morbidity.[41] Traditionally considered the result of macro haemodynamic alterations (hypotension, hypoperfusion), AKI can also occur in the absence of these conditions. Sepsis-induced AKI, however, can occur in conditions of normal or even increased renal blood flow. Functionally, sepsis-induced AKI is characterised by a dramatic decline in glomerular filtration rate and variable tubular dysfunction. Recent evidence suggests that AKI originates from a combination of co-acting factors, including inflammation, microvascular flow alteration and cell cycle arrest. The interaction between DAMPs and PAMPs is a primary function, with PRRs at the epithelial and parenchymal cell levels.[42]

The liver – a mechanical and immunological filter for portal blood – may be a major source of CKs. It is involved in the host response, and participates in the clearance of the infectious agents/products. Liver damage can occur in sepsis via haemodynamic alterations (hypotension/hypoperfusion) and through a direct assault on the hepatocytes. It has been suggested that microcirculatory changes in the liver sinusoids, neutrophil sequestration, and platelet activation and adhesion are the main contributors to known hepatic dysfunction parameters. Cholestasis, steatosis, hepatocellular injury, impaired cellular regeneration and impaired hepatic mitochondrial respiration are factors implicated in clinical septic hepatic dysfunction. An increase in aminotransferase and bilirubin levels is therefore common. However, severe hepatic failure is uncommon.[43] Subclinical liver injury has been recently identified in critically ill patients.

Cerebral dysfunction is often present in sepsis, and may precede the signs of other organ failure. It is better defined as 'sepsis-associated encephalopathy'

(SAE), to stress the absence of direct infection of the central nervous system. The main sign of SAE is altered mental status. Electroencephalography, the most sensitive diagnostic test, allows the severity of cerebral dysfunction to be graded. SAE is potentially reversible, but always worsens the prognosis. The pathophysiology of SAE is still not completely understood, and it is most likely multifactorial. Indeed, brain dysfunction in sepsis may be related to microorganism toxin activity, the effects of inflammatory mediators, metabolic alterations and abnormalities in cerebral circulation. Experimental studies have shown that microcirculatory dysfunction – a consequence of endothelial activation – is an early pathogenic step.[44]

PRINCIPLES OF TREATMENT

ANTIBIOTICS AND SEPSIS SOURCE CONTROL

Prompt identification of bacteria is fundamental to the management of septic patients. Unfortunately, the gold standard for aetiologic identification is based on outdated techniques that require a delay of 48 hours or more between samples (e.g. haemoculture) and isolation. New systems (i.e. matrix assisted laser desorption ionisation time-of-flight [MALDI-TOF] and polymerase chain reaction–electrospray ionisation mass spectrometry [PCR-ESI/MS]) significantly shorten this timeframe.[45,46] The recommended approach is based on the administration of empiric broad-spectrum antibiotic therapy as soon as sepsis is diagnosed, to be switched or de-escalated once identification and sensitivities have been obtained.[47] The timely administration of antibiotics, together with the appropriate control of the source of infection, is crucial to limit sepsis and prevent organ injury progression.[48] The current SSC guidelines recommend administering broad-spectrum intravenous (IV) antibiotics within an hour of severe sepsis (old definition) or septic shock being diagnosed.[47] However, a retrospective review of 2700 patients with septic shock showed that only 50% received antibiotics within 6 hours of the onset of hypotension.[49] A 12% reduction in survival was associated with each hour of delay in the administration of antibiotics following the onset of septic shock.[49] A recent retrospective analysis of 18,000 ICU patients with septic shock or severe sepsis (old definition) found that adjusted hospital mortality steadily increased as the delay in antibiotic administration increased (1 hour: 25.9%; >6 hours: 33.1%).[50]

The balance between the advantages and potential damages of broad-spectrum antibiotics should be regularly evaluated, as these may entail the overgrowth of potentially pathogenic bowel flora and the selection of resistant bugs.[51] The use of appropriate infectious biomarkers may help physicians avoid inappropriate or excessive antibiotic therapy. While not perfect, procalcitonin (PCT) may be helpful for this purpose; however, new specific and sensitive biomarkers are warranted to optimise an antibiotic sparing strategy that preserves the efficacy of new classes of antibiotics (ceftalozane–tazobactam, ceftazidime–avibactam, ceftaroline–avibactam, plazomicin).[52] Imaging studies aimed at identifying potential sources of infection are a key component of SSC. In the first 12 hours following diagnosis, a specific anatomical diagnosis of the infection should be carried out as rapidly as possible, and intervention undertaken to establish source control (e.g. infected peripancreatic necrosis, infected intravascular devices).[47]

RESUSCITATION TARGETS WITH FLUID AND VASOACTIVE DRUGS

Although many aspects of the mechanisms involved in the development of tissue damage are yet to be elucidated, impaired tissue oxygenation is a central issue in septic patients. A major part of early resuscitation is directed towards the correction of DO_2/VO_2 imbalance.[47,53] Hypotension, microvascular thrombosis, tissue oedema and reduced red-cell deformability contribute to microvascular derangement and obstruct DO_2 to cells. In addition, oxygen utilisation is impaired by mitochondrial damage caused by oxidative stress and other mechanisms.[54] To help clinicians apply the package of diagnostic–therapeutic interventions in a timely manner, the SSC guidelines set out a series of intervention bundles. Aimed at simplifying the care process, these bundles lie at the core of efforts to improve the treatment of sepsis (see Table 70.5).[3,47]

The swift re-establishment of an optimal DO_2/VO_2 ratio is a crucial goal for the resuscitation of septic patients. The focus here is on mean arterial pressure (MAP), central venous O_2 saturation ($Scv_{O_2} > 70\%$) and lactate level (see Table 70.5). The maintenance of adequate arterial pressure is a key factor for organ perfusion, and the MAP target is hence used as an indicator of tissue perfusion pressure. While the optimal pressure target is yet to be defined,[55] and an individualised therapy based on pre-existing hypertension and response to therapy seems the more appropriate approach, a MAP ≥65 mm Hg is currently recommended.[47] Increased lactate levels are associated with poor outcomes, and rapid lactate decreases are associated with higher survival. The value of lactate kinetics seems valid regardless of the initial value.[56] Microcirculation is frequently impaired during sepsis. However, while it is attractive, using microcirculation as a resuscitation target is premature as indicators of microvessels perfusion and reactivity are still some way from being employed in clinical practice.[57] Fluids are the principal drugs for haemodynamic resuscitation in septic patients.[3] However, there is increased awareness that these must be used with the same caution as any other IV drug in terms of both amount and type. Following the publication of randomised controlled trials (RCTs) on fluid therapy in septic patients, there is

convincing evidence that colloids containing hydroxyethyl starch (HES) are associated with a higher incidences of AKI and mortality.[58–60] Recent international studies have shown significant reductions in HES administration in critically ill patients; medical regulatory authorities and clinical practice guidelines recommend against the use of HES.[61] To date, there is no clear evidence to support the use of colloids over crystalloids in sepsis.[62] On the contrary, there is evidence that 0.9 % sodium chloride (so-called 'normal saline') causes hyperchloremic acidosis (or strong ion difference [SID]-acidosis), particularly when administered in higher doses.[63,64] This may result in AKI and increased mortality in critically ill patients, compared to balanced crystalloid solutions.[65] Apart from quality, it is an established fact that a net positive fluid balance due to the over-administration of fluid is associated with adverse outcomes in patients with sepsis.[66] Strategies based on early fluid resuscitation followed by the removal of excess fluid are therefore strongly recommended.[35,66,67] Most critical care physicians give at least 2–3 L crystalloids before starting a vasopressor to maintain the MAP target, as is commonly required in patients with sepsis. Norepinephrine is the recommended first-line vasopressor, with epinephrine (adrenaline) or low-dose vasopressin as second-line agents.[3] New vasopressors that could limit the occurrence of capillary leak are currently being investigated (e.g. selepressin, angiotensin-II, methylene blue).[68–70] As the use of vasopressors is associated with untoward side effects including organ dysfunction and atrial fibrillation, it is also important that the administration of such drugs be limited.[71] To re-establish haemodynamic stability, IV hydrocortisone is recommended (grade of recommendation 2C) in conditions where fluid resuscitation and vasopressor therapy are insufficient.[3] Myocardial dysfunction is very common in sepsis. While recent multicentre studies have questioned the merits of the protocolised early goal-directed therapy,[72] maintaining optimal CO is an important aim of septic shock resuscitation. A complete and accurate understanding of haemodynamic instability in patients with septic shock can be provided by a detailed echocardiography.[73,74] Cardiac dysfunction is clearly deleterious. High-dose dobutamine to increase CO is equally dangerous, however, as excessive catecholamine stimulation may cause tachycardia, arrhythmias, myocardial injury and direct toxic effects.[75] An interesting alternative to catecholamines currently under evaluation is the calcium sensitiser, levosimendan, which increases the affinity of the myocardium to calcium by binding to troponin C. The net effect is an increase in myocardial contractility with no accompanying increase in VO_2. In addition, this opens vascular smooth muscle potassium channels, leading to vasodilation and ameliorating ventricular–arterial coupling.[76] Finally, the use of short-term beta blockers has been investigated in a single-centre trial, the encouraging results of which are yet to be confirmed by larger RCTs.[77] Other frequently discussed topics include transfusion practices and haemoglobin thresholds. Three RCTs have concluded that a strategy of increasing DO_2 with red blood cell transfusions as part of haemodynamic goal-directed therapy did not influence survival. Equally, a recent Transfusion Requirements in Septic Shock (TRISS) study that randomised nearly 1000 patients with septic shock to a transfusion threshold of 70 or 90 g/L haemoglobin found no difference in 90-day mortality or the rate of ischemic events.[78]

ADJUVANT SUPPORTIVE CARE

Sepsis is a highly complex, heterogeneous condition. Different pathogens affect various sites in patients of all ages with multiple and varied comorbidities and immune statuses. As such, it is unlikely that any single therapy will be adequate to treat all patients with sepsis. Heterogeneity is probably one of the main reasons behind the failure of many RCTs to demonstrate the efficacy of one specific treatment (e.g. activated protein C, endotoxin adsorption, corticosteroids, antithrombin III, etc.).[79] Nevertheless, adjuvant or adjunctive therapeutic approaches (mainly adjuvant directed towards immunomodulation) have been advocated for over 10 years[80]; currently, approaches under clinical evaluation include immunoglobulins and corticosteroids.

The role of *immunoglobulins* as adjuvant therapy for sepsis still unclarified, and these are not recommended in adults or paediatric populations (grade 2B in the SSC).[47,81] Pathogen recognition and clearance, scavenging of toxins, and non-apoptotic and antiapoptotic immune cell effects are the main advocated potential beneficial effects of immunoglobulin in sepsis.[82,83] A Cochrane review found that polyclonal IgG reduced short-term mortality in adults with sepsis; however, a sensitivity analysis including only trials with a low risk of bias did not show any impact of IVIg (either polyclonal or IgM enriched) on mortality, concluding that 'adjunctive therapy with monoclonal IVIgs remains experimental'.[84] Nonetheless, some positive and encouraging data on the beneficial effects of IVIg in septic shock can be found in the literature, and there remains a need for further trials. A recent retrospective evaluation involving a large prospective multicentre cohort of patients with septic shock and multidrug-resistant Gram-negative bacteria infection showed reduced 28-day mortality in patients treated with IgM-enriched immunoglobulin preparation, compared with a matched control group.[85] Similarly, a previous retrospective cohort study of 168 patients with septic shock found that IV IgM administered for 3 consecutive days, and initiated during the first 24 hours of septic shock management, was independently associated with a decrease in 30-day mortality.[86] Finally, many questions remain unanswered regarding the potential

role of adjuvant therapy, including its optimal composition. IgM-enriched solutions perhaps offer the most promising effects on outcomes – more so than IgG solutions alone.[81]

According the SSC, IV *corticosteroids* in septic shock patients are only recommended if adequate fluid resuscitation and vasopressor therapy are not able to restore haemodynamic stability; IV hydrocortisone at a dose of 200 mg per day is suggested (grade 2C).[47] Steroids have a long history in sepsis treatment, from high doses as anti-inflammatory agents to more moderate doses to correct impaired cortisol metabolism. However, RCTs have reported no clear benefits, and the topic remains under discussion.[81] It seems probable that certain patients require steroid supplements, while others do not. Identifying the former remains a challenge, however, without a reliable biomarker of glucocorticoid-receptor activation.[87]

EXTRACORPOREAL THERAPIES

The complex interplay and imbalance of host pro-inflammatory and anti-inflammatory processes are among the principal obstacles to further reductions in sepsis-related morbidity and mortality. In recent years, most research has focused on re-establishing an equilibrium in the CK-mediated inflammation by clearing CKs from the blood using continuous renal replacement (CRRT) techniques.[88] Various forms of extracorporeal blood purification techniques, from apheresis to hemofiltration, are commonly used for the worldwide management of sepsis and sepsis-associated AKI. Nevertheless, their efficacy remains unknown, and there is currently no consensus on how extracorporeal blood purification therapies (BPTs) should be applied or studied in patients with sepsis.[89] Again, the huge heterogeneity in sepsis phenotypes may represent the principal obstacle to identifying those patients able to benefit from BPT. Most of the immune mediators in sepsis are water-soluble middle molecular-weight molecules (e.g. eicosanoids, leukotrienes, complement, CKs, chemokines), which can theoretically be removed by extracorporeal treatments including convection, diffusion, and adsorption. However, existing renal replacement technology is rather limited in its ability to achieve biologically relevant reductions in inflammation mediations, and dedicated techniques and/or materials have been developed.[89] Beyond correcting specific uremic toxins, CRRT seems to restore other physiological homeostatic mechanisms. At higher doses – or 'overdoses' – it may play a role in ridding the blood of water-soluble CKs produced during systemic inflammatory and septic states. This concept has led to speculation that high-volume hemofiltration (HVHF) may have benefits in septic patients beyond the removal of classic markers. HVHF – identified as continuous treatment with a convective (prescribed) target dose greater than 35 mL/kg per hour[90] – has been applied in septic patients to enhance the purge of middle-molecular-weight molecules, such as CKs. While encouraging results from experimental studies have been reported in the literature, large clinical trials have failed to demonstrate the benefits of HVHF as an extracorporeal treatment of sepsis.[91]

Haemoperfusion/plasmaperfusion is a technique based on blood or plasma circulation through a column containing specific sorbents, with adsorption as the only removal mechanism.[92] These techniques have been shown to increase the removal of inflammatory mediators and increase survival via hydrophobic interactions, electrostatic attraction, hydrogen bonding and van der Waals forces.[93] Hybrid techniques combining the advantages of different purification methods have been designed to increase the clearance of inflammatory mediators. Coupled plasma filtration and adsorption (CPFA), for instance, is a technique that has shown positive, if inconsistent results. Here, plasma is first extracted from the blood using a plasma filter, then slowly directed across an adsorbent material. Following this, the purified plasma is mixed with the blood from which it was previously separated, and is directed towards a second hemofilter.[94] In a larger study, the COMbining Plasma-filtration and Adsorption Clinical Trial (COMPACT)-1 trial, CPFA was combined with standard septic shock care for 5 days. Unfortunately, circuit coagulation and related issues limited the volume of plasma treated, leading to numerous protocol violations. Nevertheless, the subgroup of patients who received the higher 'dose' of CPFA had a lower mortality rate compared with controls.[95] The ongoing COMPACT-2 trial (NCT 01639664) was designed to address this question by preventing problems with regional citrate coagulation. Another haemoperfusion technique is polymyxin B haemoperfusion (PMX-HP) – a blood purification technique based on the application of polymyxin B, an old antibiotic with high affinity for endotoxin (a component of the outer membrane of Gram-negative bacteria), to polystyrene fibres used for haemoperfusion. Circulating endotoxin is bound and retained by the filter. Following the encouraging results of the randomised Early Use of Polymyxin B Hemoperfusion in Abdominal Sepsis (EUPHAS) trial, which showed a survival benefit for patients receiving PMX-HP in intra-abdominal infection-related severe sepsis,[96] a large multicentre randomised control study including 232 patients with septic shock were treated with PMX-HP (119 vs. 113 controls) within 12 hours of the surgical control of the sepsis source (perforation). The latter recently published study did not reveal any beneficial effects in patients treated versus controls.[97] The Evaluating the Use of Polymyxin B Hemoperfusion in a Randomised controlled trial of Adults Treated for Endotoxemia and Septic Shock (EUPHRATES) trial, which is currently ongoing (NCT 01046669), will provide additional information regarding the potential usefulness of polymyxin B haemoperfusion in sepsis.

High cut-off haemofiltration (HCO-HF) uses membranes with a cut-off value that approximates the molecular weight of albumin,[92] facilitating the removal of middle-molecular weight, including pro- and anti-inflammatory CKs. Clinical and experimental studies have shown that HCO-HF techniques remove CKs effectively, with a safety profile for albumin clearance.[98,99] In addition, studies have shown the clearance of CKs from the bloodstream to be associated with significant improvements in haemodynamics, oxygenation, and organ dysfunction.[99] Nonetheless, mortality reduction in septic patients undergoing HCO-HF remains undemonstrated. Finally, a number of confounding factors prevent the published studies on blood purification from being fully comparable. Over the last decade, significant new insights have been made regarding sepsis pathophysiology, and it is probably time for us to re-evaluate blood purification techniques in light of these new findings. Careful stratification based on the microbiological source of sepsis, ways of finding a more precise biological rationale and identifying the optimal timing for specific interventions are possible starting points for future trials in this complex category of patients. Coupling the right patient (at the right moment) with the appropriate technology is a new challenge in the management of sepsis and septic AKI.

IMMUNOSTIMULATION

The immune status of a patient with sepsis varies during the course of the disease according to a number of co-acting factors. This may entail the transition from a predominantly pro-inflammatory response to a largely immunosuppressed phase.[21] Depending on the patient's specific immune status, immunostimulatory therapy may be preferable to an immunosuppressive approach.[100] IL-7, which is essential for lymphocyte survival and is involved in many leucocyte functions, is a potential adjuvant therapy in sepsis. In experimental models, recombinant human IL-7 has been shown to limit the apoptosis phenomena of CD4+ and CD8+ T cells, restore IFN-γ production, and improve leucocyte recruitment to the infected nidus.[101] In a small clinical trial for patients with sepsis-induced immunosuppression (defined by a decreased expression of monocyte human leucocyte antigen-DR [HLA-DR]), granulocyte macrophage-colony stimulating factor (GM-CSF) was shown to restore HLA-DR expression. Moreover, TLR-induced pro-inflammatory monocytic CK production was restored ex vivo. Clinical outcomes (duration of mechanical ventilation, organ dysfunctions and length of ICU and hospital stay) were also improved in the GM-CSF group.[102] Similar to GM-CSF, ex vivo IFN-γ can restore the immune functions of stimulated leucocytes in septic patients. In healthy volunteers receiving IV LPS, IFN-γ limited the reduction of the LPS-induced TNF response, compared with the placebo. IFN-γ also increased monocyte HLA-DR expression.[103] In addition, IFN-γ seems to accelerate recovery from invasive fungal infections by restoring immune function, when added to standard care.[104]

CONCLUSIONS

The past two decades have seen a remarkable growth in our understanding of the complex interconnection of the multiple biological pathways involved in the sepsis pathogenesis. Significant progress on sepsis-related mortality and morbidity has been achieved in the past decade thanks to clinicians' increased awareness regarding sepsis, and the timely application of SSC-recommended diagnostic and therapeutic bundles.[3] Enhanced understanding of sepsis-induced immunosuppression has led to the development and application of potential adjunctive therapies aimed at modulating the pathologic inflammatory response and limiting its deleterious consequences. Since heterogeneity is one of the major determinant aspects in sepsis, most of the adjuvant treatments still lack a well-defined application, and research is needed to further reduce mortality. Until such time as more tailored therapies become available, infection source control, the timely application of broad-spectrum antibiotics and organ support will remain core topics in the treatment of septic patients.

Nosocomial infections

James Hatcher, Rishi H-P Dhillon

Nosocomial or health care-associated infections (HCAIs) are a major problem in hospitals, affecting up to 9% of inpatients at any one time. Intensive care units (ICUs) represent 2%–10% of hospital beds, but are responsible for 25% of all nosocomial bloodstream and pulmonary infections. In the European Prevalence of Infection in Intensive Care (EPIC) and EPIC II studies' snapshot of prevalence, the infection rate in ICU was 44.8% and 51%, respectively, with ICU-associated infection 20.6% in the EPIC study.[1,2] Nosocomial infection is, at least in theory, a preventable cause of morbidity and mortality (Box 71.1).

EPIDEMIOLOGY

The prevalence of nosocomial infection is reported as being between 3% and 12% in most institutions, but varies considerably between different sites within each institution.[3] The vulnerability of the patient population, the nature of interventions and cross-infection are but three of many factors. This is seen clearly if one compares the range between ophthalmology and critical care: 0%–23%.[4]

Ventilator-associated pneumonia (VAP) is common, has significant morbidity with increased length of stay, associated costs and a twofold increase in mortality.[5] It has been suggested that bloodstream infections, surgical wound infections and nosocomial pneumonia result in 14, 12 and 13 attributable extra hospital days, respectively.[6] Catheter-related bloodstream infection (CR-BSI) was also associated with major morbidity, although, curiously, not necessarily mortality.[7] The mortality rates directly due to these infections are hard to separate from the mortality attributed to the presenting severity of illness, which, in its own right, may have predisposed to infection. It is clear that nosocomial infection is associated with increased mortality, and huge financial and resource costs.[2]

INTERACTION BETWEEN PATIENT, ORGANISM AND ENVIRONMENT

A number of factors come together to enable nosocomial infection to occur. Some may be risk factors in their own right, whereas others may simply represent an identifier of a sicker and therefore more vulnerable population (Box 71.2).

The host usually lives in symbiotic tranquillity with a huge range of organisms (Table 71.1). Antibiotics suppress commensal organisms and allow the overgrowth of a usually insignificant organism or a resistant organism of the same type. An organism such as *Candida* will flourish in the presence of broad-spectrum antibiotics, and this overgrowth may result in symptomatic or even invasive candidiasis; cephalosporin use may encourage the intrinsically resistant but quiescent enterococci to emerge as a problematic organism.

Extrinsic organisms may be introduced from the environment, patients, staff or from surfaces. These may be organisms that are thriving in that environment because of local pressures (e.g. antibiotics), or from poor hygiene. Examples include *Acinetobacter baumanii* and methicillin-resistant *Staphylococcus aureus* (MRSA). On admission, patients will be carrying a range of organisms that have the potential to cause problems, but during their stay they are likely to acquire a new ecology from their surroundings.

The great debate remains as to the interpretation of microbiology results in the context of a non-septic patient; is this infection or colonisation? This challenge needs a multidisciplinary approach, taking into account clinical evidence together with diagnostic results.

A vast range of organisms can cause nosocomial infection but a smaller number of particular organisms cause the majority of infections (Box 71.3). It must be emphasised that each hospital and each ICU will have its own local ecology. Regional, national and international surveys give indications of general trends, but this does not supplant local knowledge.

The individual characteristics of the organism are important. These include their resilience in the local environment, the ease of transmission and the individual pathogenicity. This clearly interacts with the vulnerability of the host, as some usually innocuous organisms, such as *Candida* spp. or *Serratia marcescens*, will cause problems only in vulnerable hosts, whereas some strains of *S. aureus, Pseudomonas aeruginosa* or *Clostridium difficile* may be intrinsically more virulent.

ABSTRACT

Intensive care units are particularly vulnerable to nosocomial infections, which are associated with increased morbidity, mortality and economic cost. Endogenous microbes have a symbiotic relationship with their human host, but critical illness in the vulnerable patient leads to the breakdown of the normal human defence mechanisms resulting in health care-associated infection. Increasing population age with complex co-morbidities (coupled with the bewildering array of iatrogenic immunosuppressive treatment regimens) makes nosocomial infection a dynamic challenge. The regional, national and international spread of multidrug-resistant bacteria alongside declining therapeutic options is of particular concern for the future management of these infections. This chapter will focus on the relationship between pathogen and host, organisms causing disease including the role of multidrug resistance, routes of infection and methods to prevent and treat these challenging infections.

KEYWORDS

Nosocomial
health care-associated infection
bacteria
resistance
carbapenemase
antibiotic
colonisation
infection control

Box 71.1 Principles of diagnosis of nosocomial infections

- Diagnosis of infection usually requires the combination of clinical findings and the results of diagnostic tests
- Diagnosis of infection from direct observation at surgery, endoscopy or other diagnostic procedure is an acceptable criterion
- It must be hospital-acquired with no evidence that the infection was present or incubating at the time of hospital admission. Infection acquired in hospital, but only evident after hospital discharge, also fulfils the criteria
- Usually no specific time during or after hospitalisation is given to determine whether an infection is nosocomial or community-acquired. Each infection is examined for evidence that links it to hospitalisation (this is a matter of controversy)

Box 71.2 Risk factors for nosocomial infection

Patient
- Severity of illness
- Significant co-morbidities
- Nutritional state
- Immunosuppression
- Open wounds
- Invasive devices
- Multiple procedures
- Prolonged stay
- Ventilation
- Multiple or prolonged antibiotics
- Blood transfusion

Environment
- Changes in procedures or protocols
- Multiple changes in staff; new and locum staff
- Poor aseptic practice – poor hand washing
- Patient-to-patient – busy, crowded unit, staff shortages

The organism
- Resistance
- Resilience in terms of survival
- Formation of slime or ability to adhere – biofilm formation
- Pathogenicity
- Prevalence

Box 71.3 Organisms responsible for the majority of nosocomial infections

Methicillin-resistant *Staphylococcus aureus* (MRSA)
Coagulase-negative *Staphylococcus* (CNS)
Enterococcus spp. (*E. faecalis, E. faecium*)
Pseudomonas aeruginosa
Acinetobacter baumanii
Stenotrophomonas maltophilia
Enterobacter spp.
Klebsiella spp.
Escherichia coli
Serratia marcescens
Proteus spp.
Candida spp. (*C. albicans, C. glabrata, C. krusei*)

Other organisms may be a problem in the severely immunocompromised, such as those with acquired immunodeficiency syndrome (AIDS; see Chapter 69).

Table 71.1 Common commensals that may cause infection in a vulnerable host

SITE	COMMON COMMENSAL ORGANISMS
Skin	*Staphylococcus epidermidis*, streptococci, *Corynebacterium* (diphtheroids), *Candida* spp.
Throat	*Viridans group streptococci*, diphtheroids
Mouth	*Viridans group streptococci, Moraxella catarrhalis, Actinomyces*, spirochaetes
Respiratory tract	*Viridans group streptococci, Moraxella*, diphtheroids
Vagina	Lactobacilli, diphtheroids, streptococci, yeast
Intestines	*Bacteroides* spp., anaerobic streptococci, *Clostridium perfringens, Escherichia coli, Klebsiella* spp., *Proteus* spp., enterococci

The combination of sick patients and widespread use of potent antibiotics selects out problematic organisms and, as this epitomises intensive care practice, it is in the ICU where multiresistance is common.

RESISTANT ORGANISMS

There are several mechanisms involved in resistance and in its spread. Generally speaking, there are four main mechanisms of antibiotic resistance[8]:

1. Enzymatic inactivation of drug
2. Altered drug-binding site
3. Decreased uptake of drug, either by decreased penetration or by up-regulated efflux pumps
4. Bypass pathways.
