Preface

Oh's Intensive Care Manual first edition was in published 1979, when Intensive Care may not have been in its infancy but it certainly wasn't far beyond. Teik Oh, with tremendous foresight, brought together the fundamental elements of managing the critically ill in a particularly pragmatic manner, which could be considered a guideline for the development of the speciality. Thirty-nine years on, the eighth edition reflects both the maturation of that speciality and the phenomenal progress medically, technically, scientifically, ethically and educationally in all areas of management of the critically ill.

As with previous editions, each and every chapter has been updated, and there are many areas where new sections reflect the changing nature of the speciality and the subtle shifts in emphasis in the work place. A number of new authors have joined the contributor list, bringing their own expertise and a fresh look at previous chapters. We particularly want to thank 'retired' authors for their hard work and contributions; sometimes it's hard to say it much better than before, and their work has often been a firm base for the revision. New areas include chapters on fungal disease, genetics and sepsis, with the previous chapter on lung and heart transplantation now growing to two separate chapters – again reflecting the dynamic nature of the specialty.

As before, we hope that this edition will achieve several goals. It will update the previous edition in terms of the changing knowledge base; it will address emerging issues in Intensive Care; it will be of use to medical, nursing and allied health staff and students; but most importantly, it will adhere to the pragmatic and clinically useful style so effectively promulgated by Teik Oh. If a clinician can reach for it in the early hours of the morning, and can easily locate the information they require and feel ether guided or reassured, it will have served its purpose. If those passing examinations can say it helped, that will be gilding the lily.

ACKNOWLEDGEMENTS

It is a fitting time to use this opportunity to acknowledge the tremendous achievement of Teik Oh in the creation of this book back in 1979 and for the many editions that followed. It has been a massive asset in the development of the speciality, and there are hundreds – indeed thousands – of Intensivists across much of the world, including both of us, who have been the benefactors of the enthusiasm, energy and sheer work that Teik put into this book. The real beneficiaries have been the countless patients whose management was enhanced by the medical staff's access to this book, either during training or when it has been reached for on the Unit.

We also wish to acknowledge the major contribution Neil Soni made as a co-editor for the previous three editions. Neil's enthusiasm, energy, insights and breadth of vision were vital in maintaining the direction of the text. He recruited numerous leading international authors, many of whom continue to contribute, and led the development of many of the new chapters. His contributions continue in the current edition, and set a high bar for Jonathan Handy who has joined the team.

1

Design and organisation of intensive care units

Vineet V Sarode, Felicity H Hawker

The intensive care unit (ICU) is a distinct organisational and geographic entity for clinical activity and care, operating in cooperation with other departments integrated in a hospital. The ICU is used to monitor and support threatened or failing vital functions in critically ill patients, who have illnesses with the potential to endanger life, so that adequate diagnostic measures and medical or surgical therapies can be performed to improve their outcome.[1] Hence intensive care patients may be:

1. Patients requiring monitoring and treatment because one or more organ functions are threatened by an acute (or an acute-on-chronic) disease (e.g. sepsis, myocardial infarction, gastrointestinal haemorrhage) or by the sequelae of surgical or other intensive treatment (e.g. percutaneous interventions) with the potential for developing life-threatening conditions.
2. Patients with existing failure of one or more organ functions such as cardiovascular, respiratory, renal, metabolic, or cerebral function but with a reasonable chance of a meaningful functional recovery. In principle, patients in known end-stages of untreatable terminal diseases should not admitted.

ICUs developed from the postoperative recovery rooms and respiratory units of the mid-20th century, when it became clear that concentrating the sickest patients in one area was beneficial. Intermittent positive-pressure ventilation (IPPV) was pioneered in the treatment of respiratory failure in the 1948–1949 poliomyelitis epidemics and particularly in the 1952 Copenhagen poliomyelitis epidemic when IPPV was delivered using an endotracheal tube and a manual bag, before the development of mechanical ventilators.[2]

As outlined later, the ICU is a department with dedicated medical, nursing and allied health staff that operates with defined policies and procedures and has its own quality improvement, continuing education and research programmes. Through its care of critically ill patients in the ICU and its outreach activities (see Chapter 2), the intensive care department provides an integrated service to the hospital, without which many programmes (e.g. cardiac surgery, trauma, emergency and transplantation) could not function.

CLASSIFICATION AND ROLE DELINEATION OF AN INTENSIVE CARE UNIT

The delineation of roles of hospitals in a region or area is necessary to rationalise services and optimise resources. Each ICU should similarly have its role in the region defined and should support the defined duties of its hospital. In general, small hospitals require ICUs that provide basic intensive care services. Critically ill patients who need complex management and sophisticated investigative back-up should be managed in an ICU located in a large tertiary referral hospital. Three levels of adult ICUs are classified as follows by the College of Intensive Care Medicine (Australia and New Zealand).[3] The European Society of Intensive Care Medicine[1] has a similar classification. The American College of Critical Care Medicine also has a similar classification but uses a reversed-numbering system.[4] Nurse staffing should be in line with accepted standards that are outlined in Chapter 6.

1. *Level I ICU*: A level I ICU has a role in small district hospitals. It should be able to provide resuscitation and short-term cardiorespiratory support of critically ill patients. It will have a major role in monitoring and preventing complications in 'at-risk' medical and surgical patients. It must be capable of providing mechanical ventilation and simple invasive cardiovascular monitoring for a period of several hours. A level I ICU should have an established relationship with a level II or a level III unit that should include mutual transfer and back transfer policies and an established joint review process. The medical director should be a certified intensive care specialist. Some training and experience in managing critically ill children, preferably with Advanced Paediatric Life Support (APLS) provider status or equivalent, is desirable for medical and nursing staff in rural ICUs.
2. *Level II ICU*: A level II ICU is located in larger general hospitals. It should be capable of providing a high standard of general intensive care, including multisystem life support, in accordance with the role

ABSTRACT

This chapter outlines the accepted standards for the design and organisation of intensive care units (ICUs) and further describes how optimising these can lead to improved well-being for patients, staff and visitors.

Examples include the effect of ICU design on spread of infection and noise levels that affect sleep for patients, and how organisational aspects can alter patient outcomes and stress levels and burnout for medical and nursing staff. It is particularly important to consider these factors when planning and resourcing the very large ICUs, often with several outreach programs, that are becoming more commonplace today.

of its hospital (e.g. regional centre for acute medicine, general surgery and trauma). It should have a medical officer on site and access to pharmacy, pathology and radiology facilities at all times, but it may not have all forms of complex therapy and investigations (e.g. interventional radiology, cardiac surgical service). The medical director and the majority of the other specialists should be certified intensive care specialists. Patients admitted must be referred to the attending intensive care specialist for management. Referral and transport policies should be in place with a level III unit to enable escalation of care.

3. *Level III ICU*: A level III ICU is located in a major tertiary referral hospital. It should provide all aspects of intensive care management required by its referral role for indefinite periods. These units should have a demonstrated commitment to education and research. Large ICUs should be divided into smaller 'pods' of 8–15 patients for the purpose of clinical management. A recent study in the United Kingdom showed that an increased patient to intensivist ratio of more than 7.5 was associated with increased hospital mortality.[5] The unit should be staffed by intensive care specialists with trainees, other junior medical staff, critical care nurses, allied health professionals and clerical and scientific staff. Complex investigations and imaging and support by specialists of all disciplines required by the referral role of the hospital must be available at all times. All patients admitted to the unit must be referred to the attending intensive care specialist for management.

The classification of types of ICU must not be confused with the description of intensive care beds within a hospital, as with the UK classification focused on the level of dependency that individual patients need, regardless of location.[6]

TYPE AND SIZE OF AN INTENSIVE CARE UNIT[3]

An institution may organise its intensive care beds into multiple units under separate management by single-discipline specialists (e.g. medical ICU, surgical ICU, burns ICU). Although this may be functional in some hospitals, the experience in Australia and New Zealand has favoured the development of general multidisciplinary ICUs. Thus, with the exception of dialysis units, coronary care units and neonatal ICUs, critically ill patients are admitted to the hospital's multidisciplinary ICU and are managed by intensive care specialists (or paediatric intensive care specialists in paediatric hospitals). There are good economic and operational arguments for a multidisciplinary ICU as against separate, single-discipline ICUs. Duplication of equipment and services is avoided. Critically ill patients develop the same pathophysiological processes no matter whether they are classified as medical or surgical and they require the same approaches to support of vital organs.

The ICU may constitute up to 10% of total hospital beds. This varies significantly even in developed countries, partly due to different definitions of acute care beds.[7] The number of beds required depends on the role and type of ICU. Multidisciplinary ICUs require more beds than single-specialty ICUs, especially if high-dependency beds are integrated into the unit. ICUs with fewer than four beds are considered not to be cost-effective and are too small to provide adequate clinical experience for skills maintenance for medical and nursing staff. On the other hand, the emerging trend of very large ICUs[8] can create major management problems. Consequently, as detailed previously, these units should be divided into 'pods'. Cohorting of patients in these subunits may be based on specific processes of care or the underlying clinical problem.

HIGH-DEPENDENCY UNIT[9–11]

A high-dependency unit (HDU) is a specially staffed and equipped area of a hospital that provides a level of care intermediate between intensive care and general ward care. Although HDUs may be located in or near specialty wards, increasingly they are located within or immediately adjacent to an ICU complex and are often staffed by the ICU.

The HDU provides invasive monitoring and support for patients with or at risk of developing acute (or acute-on-chronic) single-organ failure, particularly where the predicted risk of clinical deterioration is high or unknown. It may act as a 'step-up' or 'step-down' unit between the level of care delivered on a general ward and that in an ICU. Equipment should be available to manage short-term emergencies (e.g. need for mechanical ventilation). Although early studies showed conflicting results about benefits to outcome associated with the introduction of HDUs, a more recent survey in which HDU care was based on a 'single-organ failure and support model' showed that HDUs play a crucial role in management of patients and acute care beds.[11,12]

DESIGN OF AN INTENSIVE CARE UNIT[1,3,13]

The goal of design is to create a healing environment—a design that produces a measurable improvement in the physical and/or psychological states of patients, staff and visitors. Optimal ICU design helps to reduce medical errors, improve patient outcomes, reduce length of stay, increase social support for patients and can play a role in reducing costs.[13]

The layout of the ICU should allow rapid access to relevant acute areas, including operating theatres and postoperative areas, the emergency department and interventional areas such as cardiac catheterisation laboratory, endoscopy and the medical imaging department. Lines of communication in the departments and between the other departments must be available around the clock.

Safe transport of critically ill patients to and from the ICU should be facilitated by centrally located, keyed, oversized lifts and doors, and corridors should allow easy passage of beds and equipment. There should be a single entry and exit point, attended by the unit receptionist. Through-traffic of goods or people to other hospital areas must never be allowed. An ICU should have areas and rooms for public reception, patient management and support services. The total area of the unit should be 2.5–3 times the area devoted to patient care.

PATIENT CARE ZONE

An ideal patient room should incorporate three zones: a patient zone, family zone and caregiver zone.[13] Each patient bed area in an adult ICU requires a minimum floor space of 20 m^2, with single rooms being larger (at least 25 m^2), to accommodate patient, staff and equipment. There should be at least a 2.5-m traffic area beyond the bed area. Single rooms should have an optimal clearance of not less than 1.2 m at the head and the foot of the bed and not less than 1.8 m on each side. The ratio of single-room beds to open-ward beds will depend on the role and type of the ICU. Single rooms are essential for isolation; with the emergence of resistant bacterial strains in ICUs around the world, allocation of more single rooms is recommended. They have been shown to decrease acquisition of resistant bacteria and antibiotic use.[14] Isolation rooms should be equipped with an anteroom of at least 3 m^2 for hand washing, gowning and storage of isolation material. Some of those isolation rooms should be negative-pressure ventilated for contagious respiratory infections. A nonsplash hand wash basin with elbow- or foot-operated taps and a hand disinfection facility should be available for each bed.

Bedside service outlets should conform to local standards and requirements (including electrical safety and emergency supply, such as to the Australian Standard, Cardiac Protected Status AS3003).

Utilities per bed space as recommended for a level III ICU are:

- 4 oxygen
- 3 air outlets
- 3 suction inlets
- 16–20 power outlets
- A bedside light
- 4 data outlets.

Adequate and appropriate lighting for clinical observation must be available. Patients should be able to be seen at all times to allow detection of changes in status. All patient rooms should have access to natural light. Patients exposed to sunlight have been shown to experience less stress, require fewer analgesics and have improved sleep quality and quantity. Lack of natural light or outside view increases the incidence of disorientation in patients and stress levels in staff.[15,16]

Efforts should be made to reduce sound transmission and therefore noise levels. Walls and ceilings should be constructed of materials with high sound-absorbing capability; there should be acoustic baffling in the walls, soundproofing of windows and sound attenuators in the 'heating, ventilation and air conditioning' (HVAC) system.

Suitable and safe air quality should be maintained at all times. Isolation rooms (as per Australian Standard 1668.2) should have 99.99% 'high-efficiency particulate arrestance' (HEPA) filtration, along with negative pressure compared to the surrounding environment and at least 15 air changes per hour.[17] Air conditioning and heating should be provided with an emphasis on patient comfort. A clock and a calendar at each bed space are useful for patient orientation. It is widely held that transporting long-stay ICU patients outdoors is good for their morale, and access to an outside area should be considered in the design process.

The medical utility distribution systems configuration (e.g. floor column, wall mounted or ceiling pendant) depends on individual preference. There should be room to place or attach additional portable monitoring equipment, and, as far as possible, equipment should be kept off the floor. Space for charts, syringes, sampling tubes, pillows, suction catheters and patient's personal belongings should be available, often in one or more moveable bedside trolleys.

A rigorous fire safety and evacuation plan should be in place. This should include not just the basic fire safety device such as smoke detectors, automated sprinklers and fire extinguishers but also should look at design elements to minimise fire and its spread. These include selection of products and furnishing with low fire load, construction of compartments that are fire and smoke rated and protective technologies within the HVAC system to prevent the spread of smoke. It is very important to have an experienced fire safety officer involved in the ICU design process.[18]

Efficient signage is important for visitors and non–ICU staff, especially in large multi-pod ICUs.[18]

CLINICAL SUPPORT ZONE

Because critical care nursing is primarily at the bedside, staffing of a central nurse station is less important and emphasis should be on 'decentralised' stations just inside the room or patient care area or immediately outside the room, often paired to permit observation of two adjacent rooms. Nevertheless, the central station and other work areas should have adequate space for staff to allow centralised clinical management, staff interaction, mentoring and socialisation. This central station usually houses a central monitor, satellite pharmacy and drug preparation area, satellite storage of sterile and nonsterile items, telephones, computers with Internet connections, patient records, reference books and policy and procedure manuals. A dedicated computer for the

picture archive and communication system (PACS) or a multidisplay x-ray viewer should be located within the patient care area.

UNIT SUPPORT ZONE

Storage areas should take up a total floor space of at least 10 m^2 per bed.[13] They should have separate access remote from the patient area for deliveries and be no farther than 30 m from the patient area. Frequently used items (e.g. intravenous fluids and giving sets, sheets and dressing trays) should be located closer to patients than infrequently used or nonpatient items. There should be an area for storing emergency and transport equipment within the patient area with easy access to all beds.

Two separate spaces for clean (15 m^2) and dirty (25 m^2) utility rooms with separate access are necessary. Facilities for estimating blood gases, glucose, electrolytes, haemoglobin, lactate and sometimes clotting status are usually sufficient for the unit's laboratory. There should be a pneumatic tube or equivalent system to transfer specimens to pathology. Adequate arrangements for offices (receptionist, medical and nursing), doctor-on-call rooms (15 m^2), a staff lounge (with food/drinks facilities) (40 m^2 per eight beds), wash rooms and a seminar room (40 m^2) should be available and an interview room is recommended.

EQUIPMENT

The type and quantity of equipment will vary with the type, size and function of the ICU and must be appropriate to the workload of the unit. There must be a regular programme in place for checking its safety. Protocols and in-service training for medical and nursing staff must be available for the use of all equipment, including steps to be taken in the event of malfunction. There should also be a system in place for regular maintenance and service. The intensive care budget should include provision to replace old or obsolete equipment at appropriate times. A system of stock control should be in place to ensure consumables are always in adequate supply. The ICU director should have a major role in the purchase of new equipment to ensure it is appropriate for the activities of the unit. Level II and III ICUs should have an equipment officer to coordinate these activities.

FAMILY SUPPORT ZONE

For relatives, there should be a separate area of at least 10 m^2 per eight beds (two chairs per bed), and an additional facility with bed and shower as sleep or rest cubicles can be considered. There should be facilities for tea/coffee making and a water dispenser, and toilets should be located close by. Television and/or music should be provided. It is desirable to have separate entrances to the ICU for visitors and health care professionals. One or more separate areas for distressed relatives should be available.

INTENSIVE CARE UNIT ORGANISATION

STAFFING[1,3,8,13,14,16,19]

The level of staffing depends on the type of hospital, and tertiary hospital ICUs require large teams. Whatever the size of the team, it is crucial that there is clear and proper communication and collaboration among team members and a true multidisciplinary approach. Knaus et al. in a classic study[20] first showed the importance of the relationship between the degree of coordination in an ICU and the effectiveness of its care. Other studies have shown relationships between collaboration and teamwork and better outcomes for patients and staff.[21,22] Inadequate communication is the most frequent root cause of sentinel events.[23]

MEDICAL STAFF[24]

An intensive care department should have a medical director who is qualified in intensive care medicine and who coordinates the clinical, administrative and educational activities of the department. The duties of the director should involve patient care, supervision of trainees/other junior doctors, the drafting of diagnostic and therapeutic protocols, responsibility for the quality, safety and appropriateness of care provided and education, training and research. It is recommended that the director be full time in the department.

The director should be supported by a group of other specialists trained in intensive care medicine who provide patient care and contribute to nonclinical activities. In an ICU of level II or III there must be at least one specialist exclusively rostered to the unit at all times. Specialists should have a significant or full-time commitment to the ICU ahead of clinical commitments elsewhere. There should be sufficient numbers to allow reasonable working hours, protected clinical support time and leave of all types. Participation in ICU outreach activities (rapid response calls, outpatient review; see Chapter 2) has increased the workload of intensive care specialists, as well as junior staff in many hospitals, resulting in the need to increase the size of the medical team.

There should also be at least one junior doctor with an appropriate level of experience rostered exclusively to level II and III units at all times. Junior medical staff in the ICU may be intensive care medicine trainees but should ideally also include trainees of other acute disciplines (e.g. anaesthesia, medicine, surgery and emergency medicine). It is imperative that junior doctors are adequately supervised, with specialists being readily available at all times.

Medical work patterns are important for quality of treatment and should be supervised by the director. These patterns include rosters, structure of handover and daily rounds. Appropriate rostering influences satisfaction and avoids burnout syndrome in staff.[25,26] It reduces tiredness after night shifts or long shifts and consequently

improves attention and reduces errors. It also improves the quality of information transfer during handovers and daily rounds.[27]

This physician-staffing model has been used in Australia and New Zealand for many years but has not been common in the United States. A systematic review[28] has shown that when there has been mandatory intensive care specialist consultation (or closed ICU), compared with no or elective intensive care specialist consultation or open ICU, both ICU and hospital survival were improved and there was a reduced length of stay in ICU and in hospital.[29]

NURSING STAFF

Critical care nursing is covered in Chapter 6. The bedside nurse conducts the majority of patient assessment, evaluation and care in an ICU. When leave of all kinds is factored in, long-term 24-hour cover of a single bed requires a staff complement of six nurses. Nurse shortages have been shown to be associated with increased patient mortality and nurse burnout and adversely affect outcome and job satisfaction in the ICU.[30,31]

There should be a nurse manager who is appointed with authority and responsibility for the appropriateness of nursing care and who has extensive experience in intensive care nursing, as well as managerial experience. In tertiary units the nurse manager should participate in teaching, continuing education and research. Ideally, all nurses working in an ICU should have training and certification in critical care nursing.

ALLIED HEALTH

Access to physiotherapists, dietitians, speech pathologists, social workers and other therapists should also be available. A dedicated ward clinical pharmacist is invaluable and participation of a pharmacist on ward rounds has been associated with a reduction in adverse drug events. Respiratory therapists are allied health personnel trained in and responsible for the equipment and clinical aspects of respiratory therapy, a concept well established in North America but not the UK, continental Europe and Australasia. Technical support team members, either members of the ICU staff or seconded from biomedical departments, are necessary to service, repair and develop equipment.

SUPPORT STAFF

Provision should be made for adequate secretarial support.[16] Transport and 'lifting' orderly teams will reduce physical stress and possible injuries to nurses and doctors. If no mechanical system is available to transport specimens to the laboratories (e.g. air-pressurised chutes), sufficient and reliable couriers must be provided to do this day and night. The cleaning personnel should be familiar with the ICU environment and infection control protocols. There should also be a point of contact for local interpreters, chaplains, priests or officials of all beliefs when there is need for their services.

CLINICAL ACTIVITIES

OPERATIONAL POLICIES[3]

Well-defined administrative policies are vital to the functioning of an ICU. An *open* ICU has unrestricted access to multiple doctors who are allowed to admit and manage their patients. A *closed* ICU has admission, discharge and referral policies under the control of intensive care specialists. Improved cost benefits are likely with a closed ICU and patient outcomes are better, especially if the intensive care specialists have full clinical responsibilities. Consequently, ICUs should be *closed* under the charge of a medical specialist director. All patients admitted to the ICU are referred to the director and his/her specialist staff for management, although it is important for the ICU team to communicate regularly with the parent or admitting unit and to make referrals to other specialty units when appropriate.

There must be clearly defined policies for admission, discharge, management and referral of patients. Lines of responsibilities must be clearly defined for all staff members and their job descriptions defined. The director must have final overall authority for all staff and their actions, although in other respects each group may be responsible to respective hospital heads (e.g. the Director of Nursing).

Policies for the care of patients should be formulated and standardised. They should be unambiguous, periodically reviewed and familiarised by all staff. Examples include infection control and isolation policies, policies for intrafacility and interfacility transport, end-of-life policies (e.g. do not resuscitate [DNR] procedure) and sedation and restraint protocols. However, it should be noted that when protocols involve complex issues (such as weaning from mechanical ventilation), they might be less efficient than the judgment of experienced clinicians. Clinical management protocols (e.g. for feeding and bowel care) can be laminated and placed in a folder at each bed or loaded on to the intranet.

PATIENT CARE

ICU patient management should be multidisciplinary, with medical, nursing and other staff working together to provide the best care for each patient. The critical care nurse is the primary carer at the bedside and monitors, manages and supports the critically ill patient (see Chapter 6). The medical team consists of one or more registrars, residents or fellows who direct medical care with an intensive care specialist. The patient should be assessed by a formal ward round of the multidisciplinary team twice daily, usually at a time when the junior medical staff members are handing over. The nurse coordinating the floor, pharmacists and dietitians should also take part in daily rounds. Each patient should be assessed clinically (examination, observations and pathology, radiological and other investigation results), the medication chart reviewed, progress determined and a management plan developed for the immediate and longer term. The ward

round is also an opportunity to assess compliance with checklists such as the FAST HUG (Feeding, Analgesia, Sedation, Thromboembolic prophylaxis, Head of bed elevation, stress Ulcer prophylaxis, Glycaemic control). Clearly, unstable patients will require much more frequent assessment and intervention.

It is crucial that all observations, examination findings, investigations, medical orders, management plans (including treatment limitations) and important communications with other medical teams and patients' families are clearly documented in the appropriate chart or part of the medical record either electronically or in writing.

Wherever possible, clinical management should be evidence based and derived through consensus of the members of the ICU team, accepting, however, that evidence-based medicine has limitations when applied to intensive care medicine.

Well-structured collaboration among physicians, nurses and the other professionals is essential for best possible patient care, which includes presence of interprofessional clinical rounds, standardised and structured processes of handover of interdisciplinary and interprofessional information and use of clinical information systems.[1]

CARE OF FAMILIES[32]

ICU care includes sensitive handling of relatives. It is important that there are early and repeated discussions with patients' families to reduce family stress and improve consistency in communication. Ideally one senior doctor should be identified as the ICU representative to liaise with a particular family. Discussions should be interactive and honest and an attempt made to predict the likely course, especially with respect to outcome, potential complications and the duration of intensive care management required. The time, date and discussion of each interview should be recorded. Cultural factors should be acknowledged and spiritual support available, especially before, during and after a death. Open visiting hours allow families maximum contact with their loved one and promote an atmosphere of openness and transparency.

OUTREACH

ICU outreach activities are described in Chapter 2.

NONCLINICAL ACTIVITIES[2]

Nonclinical activities are very important in the ICU because they enhance the safety, quality and currency of patient care. The College of Intensive Care Medicine recommends that full-time intensive care specialists should have as protected nonclinical time three sessions per fortnight.[24] Nursing and allied health staff should also seek protected time for these activities.

QUALITY IMPROVEMENT[33,34]

It is essential that staff members promote a culture of quality improvement (QI) within the ICU, whatever its size and role. Every ICU should maintain a database that is sufficiently well structured to allow easy extraction of benchmarking, quality control and research data. All ICUs should have demonstrable and documented formal audit and review of its processes and outcomes in a regular multidisciplinary forum. Staff members who collect and process the data should have dedicated QI time.

There are three types of quality indicators:

1. *Structure*: structural indicators assess whether the ICU functions according to its operational guidelines and conforms to the policies of training and specialist bodies (e.g. clinical workload and case mix, staffing establishment and levels of supervision).
2. *Clinical processes*: clinical process indicators assess the way care is delivered. Examples include whether deep vein thrombosis prophylaxis is given, time to administration of antibiotics and glycaemic control.
3. *Outcomes*: examples of outcome measures include survival rate, quality of life of survivors and patient satisfaction.

The QI process involves *identification* of the indicator to be improved (e.g. high ventilator-associated pneumonia [VAP] rate), *development* of a method to improve it (e.g. checklist such as the FAST HUG[35]), *implementation* of the method to improve it (e.g. requirement to tick off the checklist on the morning ward round) and reevaluation of the indicator (e.g. VAP rate) to ensure the intervention has improved the outcome and finally to *ensure sustainability* (e.g. print checklist on ICU chart).

Activities that assess processes include clinical audit, compliance with protocols, guidelines and checklists and critical incident reporting. Activities that assess outcomes are calculating risk-adjusted mortality using a scoring system such as the Acute Physiology and Chronic Health Evaluation III (APACHE III) and calculation of standardised mortality ratios (see Chapter 3), measurement of rates of adverse events, and surveys.

Risk management is a closely related field. In the ICU, risks can be identified from critical incident reports, morbidity and mortality reviews and complaints from staff, patients or family members. Using similar methodology to the QI process, risks must be identified, assessed and analysed, managed and reevaluated. A major patient safety incident should result in a root cause analysis.

EDUCATION

All ICUs should have a documented orientation programme for new staff. There should be educational programmes for medical staff and a formal nursing education programme. Educational activities for intensive care trainees include lectures, tutorials, bedside teaching and trial examinations. Clinical reviews and meetings to review journals and new developments should be held regularly. Regular assessments for advanced life support and sometimes other assessments (e.g. medication safety) are often required. Increasingly, simulation centres are used to teach and assess skills and teamwork in crisis scenarios. A number of ICUs are also involved

in undergraduate medical teaching. All staff should also participate in continuing education activities outside the hospital (e.g. local, national or international meetings) and specialists should be involved in College Continuing Professional Development (CPD) activities.

RESEARCH

Level III ICUs should have an active research programme, preferably with dedicated research staff, but all units should attempt to undertake some research projects whether these are unit-based or contributions to multicentre trials.

THE FUTURE

Intensive care medicine is increasingly facing major challenges such as the aging population, increasing complexity of case mix, changing community health care and outcome expectations, increasing antibiotic resistance and also increasing stress and burnout in staff.[36] As ICUs become larger along with ICU staff numbers, it is crucial that the basic principles and standards of ICU design, staffing and clinical and nonclinical activities outlined in this chapter are maintained, but also innovative strategies to prevent multiorgan failure, antibiotic resistance in ICU patients and staff burnout need to be explored. Better screening tools for admission to ICU and tools for predicting outcomes will be essential.

Critical care outreach and rapid response systems

John R Welch, Christian P Subbe

KEY PRINCIPLES INCLUDE

- Deteriorating patients can be identified by careful monitoring of physiological signs – understanding that many hospital patients are in the last year of life.
- Timely escalation to critical care should improve outcomes.
- Effective responses to acute deterioration are often hindered by human factors.
- Rapid response systems standardise the response to at-risk and deteriorating patients, and improve process and clinical outcomes for such patients.
- Better outcomes result from multiprofessional working and effective communication, education, data collection/audit, learning from errors, and planned improvement of whole systems of care.

Outreach, rapid response or medical emergency teams providing '*critical care without walls*'[1] originated in Australia, spread to the United Kingdom, have become a standard of care across North America and many European countries, and are now deployed in the Middle East[2] and Far East,[3] and Central and South America.[4] The aim is '*equity of care for all critically ill patients irrespective of their location*'.[5]

BACKGROUND

Hospital admission criteria have become more rigorous and lengths of stay have decreased in recent years. Intensive care units (ICUs) contain relatively few beds and have high rates of occupancy. The result is that many ward patients have serious medical problems but only the most unstable are admitted to an ICU. Consequently, many high-risk patients remain in areas with staff inexpert in managing critical illness. Key tasks, such as measuring physiological signs, are often delegated to untrained personnel who may not understand the significance of abnormal values. Junior doctors are reported to be unprepared for emergency management, multidisciplinary team-working, handover and other critical roles.[6] Their training is shorter and more specialised than before, so even senior doctors may be relatively inexperienced.[7] In addition, many hospitals use temporary staff less likely to provide the continuity and team-working essential for effective care.

Comparisons of outcomes of patients admitted to an ICU from either the emergency department, operating theatre/recovery area or the wards show that those coming from wards have the highest mortality.[8] Suboptimal treatment is common before transfer to the ICU,[9–11] and is associated with worse outcomes.[9,10,12] An analysis of hospital deaths in a national database found that '*the most common incident types were failure to act on or recognise deterioration*'.[13] Crucially, differences in mortality are caused by variations in care rather than differences between the patients themselves.[12] Patients experiencing long periods of instability before there is an effective medical response are said to have suffered 'failure to rescue'. Such failures are common: in a national review of patients subsequently transferred to the ICU, many had sustained up to 72 hours physiological instability.[9] Indeed, a review of 1000 deaths in 10 hospitals concluded that 52 deaths would have had a 50% or greater chance of being prevented; although it is noteworthy that most of these were in elderly, frail patients judged to have a life expectancy of less than a year.[14] Other patients at-risk are those recently discharged from the operating theatre after major surgery or from the ICU: about one-quarter of all 'intensive care deaths' occur after transfer back to the ward.

OUTREACH, MEDICAL EMERGENCY AND RAPID RESPONSE TEAMS

Medical emergency teams (METs) were introduced in Australia in the 1990s, usually comprising critical care residents and medical registrars. These teams could be directly activated by any member of staff bypassing traditional hospital hierarchies. METs expanded the role of the cardiac arrest team to include the pre-arrest period, generally using call-out criteria based on deranged physiological values or staff concern.[15] In the United Kingdom, a review of critical care services in 2000[16] led to increased funding and the creation of critical care outreach teams largely staffed by critical care nurses. Similar services then appeared in the United States, driven by the Institute for Healthcare Improvement[17] with an

ABSTRACT

There are many ward patients with potential or actual critical illness whose care should and could be improved. The rapid response system (RRS) represents one method of addressing these issues, at the very least by highlighting defects in current ways of working and by applying what has been learned from RRS initiatives to the whole hospital.

KEYWORDS

Deterioration

rapid response

emphasis on a complete 'rapid response system' (RRS). This highlighted the principle that whole, coordinated systems are needed to reliably avoid failure to rescue.

The RRS can be divided into:

- an afferent component designed to ensure timely escalation of the deteriorating patient – usually using agreed physiological values as a trigger
- an efferent component comprising an individual or team of clinicians who can rapidly respond to deterioration
- governance and administrative structures to oversee and organise the service and its ways of working
- mechanisms to improve hospital processes.[18]

Another approach is to think of the RRS as being based on a 'chain of prevention' made up of education, monitoring, recognition, call and response.[19]

Various models and terms are used. METs are usually physician led. Critical care outreach (CCO) and rapid response teams (RRTs) are typically nurse led, but may include other allied health professionals as well as doctors. Most teams respond to defined physiological triggers, although some also work proactively with known at-risk patients, such as those discharged from the ICU. The objectives are to prevent (unnecessary) critical care admissions, to ensure timely transfer to the ICU when needed, to facilitate safe return to the ward, to share critical care skills[16] and to improve care throughout the hospital. Also, there may be a role supporting patients and their families after hospital discharge (Box 2.1).

Box 2.1 Functions of critical care outreach

- Identification of at-risk patients.
- Support for ward staff caring for at-risk patients and those recovering from critical illness.
- Referral pathways for obtaining timely, effective critical care treatments.
- Immediate availability of expert critical care and resuscitation skills when required.
- Facilitation of timely transfer to a critical care facility when needed.
- Education for ward staff in recognition of fundamental signs of deterioration, and in understanding how to obtain appropriate help promptly.
- Outpatient support to patients and their families following discharge from hospital.
- Development of systems of coordinated, collaborative, continuous care of critically ill and recovering patients across the hospital and in the community.
- Audit and improvement of basic standards of acute and critical care – and of the outreach team itself – to minimise risk and optimise treatment of the critically ill throughout the hospital.

Together, these elements comprise a system to deliver safe, quality care with proactive management of risk and timely treatment of critical illness.

RECOGNISING CRITICAL ILLNESS

Patients with potential or actual critical illness can be identified by review of the history, by examination and by investigations. Higher risks are associated with extremes of age, significant co-morbidities or serious presenting conditions.

A consensus conference on the afferent limb of the RRS reported that (1) vital sign aberrations predict risk; (2) monitoring patients more effectively may improve outcome, although some risk is random; (3) the workload implications of monitoring on the clinical workforce have not been explored, but should be investigated; and (4) the characteristics of an ideal monitoring system are identifiable, and it is possible to categorise monitoring modalities. It may also be possible to describe monitoring levels, and a system.[20]

ABNORMAL PHYSIOLOGY AND ADVERSE OUTCOME

There is a known association between abnormal physiology and adverse outcomes[21,22]: critical care scoring systems, such as APACHE II,[23] are based upon this relationship. Patients who suffer cardiac arrest or who die in hospital generally have abnormal physiological values recorded in the preceding period, as do patients requiring transfer to the ICU.[9,21,24] These findings have led to key vital signs being incorporated into early warning scoring (EWS) systems. Different systems use various combinations of parameters including respirations, oxygen saturation, pulse, blood pressure, temperature and level of consciousness as well as other indicators, such as urine output and pain.[25] The patient's measured vital signs are compared with a set of reference values, with measurements above or below designated points used as triggers for escalation. Formats vary but many use similar approaches, awarding points for varying degrees of derangement of different functions. Improvement or further deterioration can then be tracked by changes in EWS recorded over time, so that an EWS used in this way is described as a 'track and trigger system'. Many different track and trigger systems have been developed,[26,27] broadly categorised as single- or multi-parameter systems, aggregate weighted scoring systems or combinations (Box 2.2).[5] This variance has led to calls for standardisation to improve training and reliability of response, with the National Early Warning Score (NEWS) published in 2012[28] and revised in 2017 (Table 2.1) now widely used in the United Kingdom and elsewhere. It is based on the analysis of a large database of patients' vital signs recorded in different acute hospitals.[29] A different approach has been taken by Australian METs, where the escalation criteria are usually based upon single, markedly deranged physiological values, although ward staff concern is also a trigger (Box 2.3).[30]

Table 2.1 National early warning score (NEWS)[28]

	SCORE						
PHYSIOLOGICAL PARAMETERS	*3*	*2*	*1*	*0*	*1*	*2*	*3*
Respiratory rate (breaths/min)	≤8		9–11	12–20		21–24	≥25
Oxygen saturation (%)	≤91	92–93	94–95	≥96			
Any supplemental oxygen		Yes		No			
Heart rate (beats/min)	≤40		41–50	51–90	91–110	111–130	≥131
Systolic blood pressure (mmHg)	≤90	91–100	101–110	111–219			≥220
Level of consciousness (AVPU scale)				A			V, P, U
Temperature (°C)	≤35.0		35.1–36.0	36.1–38.0	38.1–39.0	≥39.1	

AVPU, Alert, Voice, Pain, Unresponsive.

Box 2.2 Classification of track and trigger warning systems[5]

Single-parameter systems
- Tracking: periodic observation of selected basic signs
- Trigger: one or more extreme observational values

Multiple-parameter systems
- Tracking: periodic observation of selected basic vital signs
- Trigger: two or more extreme observational values

Aggregate weighted scoring systems
- Tracking: periodic observation of selected basic vital signs and the assignment of weighted scores to physiological values with the calculation of a total score
- Trigger: achieving a previously agreed trigger threshold with the total score

Combination systems
- Elements of single- or multiple-parameter systems in combination with aggregate weighted scoring

Box 2.3 Medical emergency team call-out criteria as used in the MERIT study[30]

Airway	Threatened
Breathing	Respiratory rate <5 or >36 per min
	Respiratory arrest
Circulation	Pulse rate <40 or >140 per min
	Systolic blood pressure <90 mm Hg
Neurology	Sudden fall in level of consciousness (fall in GCS of >2 points)
	Repeated or extended seizures
Other	Any patient you are seriously worried about

GCS, Glasgow Coma Scale.

As well as EWS systems based simply on acute physiology, there are methods using other data to risk-stratify patients. Systems based on laboratory parameters alone,[31] laboratory parameters in conjunction with vital sign observations,[32] or indicators of acute physiology, chronic illness and functional status[33] have all been validated. Another method is to promote the reporting of less objective but nonetheless important indicators, such as noisy breathing or changes in colour; for example, with the Dutch-Early-Nurse-Worry-Indicator-Score[34]; or to enable patients themselves – or their relatives – to activate the RRS. This method was first used in paediatric settings but also may be useful for adults.[35]

MEASURING OUTCOME

The use of RRSs is based on the premise that early detection and treatment of critical illness should improve patient outcomes. The quality of these services may be evaluated against not only such outcomes but also other indicators, including process measures (e.g. numbers of staff trained, completeness of bedside observations, timeliness of escalation and rapidity of response). The time from patient trigger to transfer to an ICU – or initiation of critical care treatment on the ward – may be a useful indicator too (i.e. the 'Score-to-Door time'[36]).

Table 2.2 shows one method that can be used to evaluate outcomes of RRS interventions 24 hours after the initial event, with outcomes classified as either positive or negative. The proportion of positive interventions provides a measure of the quality of the service. This approach has now been used in two multinational multicentre studies of RRS, enabling benchmarking and learning from others to occur. The first report – from 51 hospitals in five countries – found that, on average, urgent transfer to the ICU occurred in 24% of patient referrals, while new treatment limitations were instigated in 28% of patients not transferring to the ICU. Mortality just 24 hours after referral was 10.1%.[37]

RRSs have highlighted shortcomings in the care of ward patients, and contributed to a significant change in attitude to patients at risk. They have been instrumental in improving ward monitoring and in disseminating

Table 2.2 Matrix of possible outcomes of rapid response system intervention: the 'Multi-disciplinary Audit EvaLuating Outcomes of Rapid response' (MAELOR) tool

OUTCOMES	POSITIVE	NEGATIVE
Transfer to critical care area or operating theatre	1. Timely transfer, e.g. <4 hours after the first trigger	2. Delayed transfer, e.g. >4 hours after the first trigger
Alive on ward	3. No longer triggering	4. Still triggering
Deceased	5. On terminal care pathway/with DNACPR order	6. Following cardiopulmonary arrest
Others	7. Alive with documented treatment limitations and DNACPR order in place 8. a. Trigger from new pathology unrelated to previous call out b. Chronic condition leading to continuous trigger (e.g. tachypnoea in advanced pulmonary fibrosis) c. Discharged from hospital	9. Outcome not known/lost to follow-up

DNACPR, Do Not Attempt Cardiopulmonary Resuscitation.

From Morris A, Owen HM, Jones K, et al. Objective patient-related outcomes of rapid-response systems—a pilot study to demonstrate feasibility in two hospitals. *Crit Care Resusc.* 2013;15(1):33–39.

critical care skills. There are anecdotal reports of benefit to individuals,[38] and growing evidence of improved recognition of at-risk patients; with reduced length of stay, cardiac arrests, unplanned admissions to critical care, and morbidity and mortality.[39–42] Unfortunately, there are still relatively few high-quality studies. Positive reports include a randomised trial of phased introduction of a 24-hour outreach service to 16 wards in a general acute hospital.[43,44] The outreach team routinely followed up patients discharged from intensive care to wards and saw referrals generated by ward staff concern or the use of an EWS system. There was a statistically significant reduction in mortality in wards where the service was operational. In contrast, a large prospective, randomised trial of METs in Australia found no improvements in cardiac arrests, unplanned admissions to ICU or unexpected deaths in comparison to control hospitals in the primary analysis.[30] However, a secondary analysis showed improved outcomes in most hospitals in both the intervention and control groups, with dramatic improvements in those with the weakest baseline performance.[45] This study revealed many shortcomings in identification and care of critically ill patients, with one possible conclusion being that it is essential to take a whole systems approach to achieve timely recognition and response, and that it takes time to affect significant change across the entire hospital. An interrupted time series study of nearly 10 million patients in 232 hospitals described a progressive reduction in failure to rescue, cardiac arrests and mortality from early on, but better outcomes for the low mortality diagnostic-related group of patients only in the later years.[46,47]

Several studies have shown an inverse relation between the number of calls to the RRS and cardiac arrests.[48] This may reflect better patient assessment, more timely implementation of Do-Not-Attempt-Resuscitation orders and involvement of palliative care specialists in patients with terminal illness. This is not a negative: delivery of good palliative care can be seen as a positive outcome reinforced by an RRS.[49]

There has been less investigation of the follow-up of patients discharged from ICU, although this group is known to be at significant risk. A matched-cohort analysis of 5924 patients found follow-up by an outreach team reduced length of stay and mortality compared to historical controls and matched patients from hospitals with no outreach.[50]

SETTING UP AN OUTREACH SERVICE

Patients with potential or actual critical illness are found in every area of the hospital, so systems to identify and treat those patients need to be planned at an organisational level. Involvement of managerial and clinical staff is essential, especially from the wards. It is particularly important that there is agreement and clarity about how the outreach team or equivalent interacts with the parent/primary medical team.

KEY STEPS IN PLANNING A RAPID RESPONSE SYSTEM

- Appoint senior clinical and managerial leads to develop the service.
- Institute organisational needs analysis, audit and evaluation, asking:
  - Which patients are at risk of deterioration and where are they located?

  - Where do cardiac arrests and unexpected deaths occur?
  - What are the sources of unplanned admissions to the ICU?
  - What is the pattern of adverse events where harm can be attributed to processes of care?
  - What are the other relevant clinical governance/risk management issues or morbidity and mortality data?
- Point prevalence studies can give a snapshot view of the location of patients at risk.
- Reviewing unplanned admissions to the ICU can identify systems failings, including quality of patient management and the appropriateness and timeliness of escalation.
- Analyses should also highlight staff training needs.

Other factors to consider include:

- the patient case mix
- existing skills of ward staff
- proposed hours of service
- size of hospital – and likely demand
- existing services, such as tracheostomy specialists, respiratory specialists, renal specialists, pain teams, night teams, etc.
- training facilities
- outreach service location and equipment needs including information technology
- funding.

The Australian Commission on Safety and Quality has published a useful guide to setting up and developing an RRS, available online.[51]

THE OUTREACH TEAM

The composition and skills of the team should be designed to meet the particular needs identified by the organisation. At a minimum, the team should be capable of assessment, diagnosis, initiation of resuscitation and rapid triage of critically ill patients to higher levels of care. Such clinical competencies as airway management, venepuncture and cannulation are essential, as are skills in education, audit and research. Leadership, coordination and communication skills are also crucial. The UK Department of Health have detailed the ways of working and competencies required for care of at-risk and deteriorating patients, specifying what should be expected of junior, middle-grade and senior staff.[52]

A pragmatic, staged implementation could include:

1. Establishing an education programme in care of the deteriorating patient for ward staff so that they can recognise signs of deterioration and know how to obtain timely help.
2. Introducing a physiological track and trigger warning system with defined referral/response protocols.
3. Developing clinical bedside support – incrementally if necessary – increasing the number of clinical areas covered by the team, and the hours of work. This might include follow-up of patients discharged from critical care and responding to patients identified through the track and trigger system or by other means.[5]

It is essential that robust data are collected and used for audit and evaluation – and for feedback to ward managers and clinical staff. Successes should be highlighted and areas for improvement identified. Data may include:

- numbers of referrals and patient follow-ups
- date and time of each episode
- patient details (e.g. age, sex, date of hospital admission, location, emergency/elective admission, medical/surgical, resuscitation status)
- trigger event (e.g. early warning score, cardiac arrest call)
- significant problems identified
- interventions performed
- patient outcomes.

THE FUTURE – AND TECHNOLOGY TO MITIGATE HUMAN FACTORS

Mature RRSs experience challenges from rising demand and the charge that they deskill ward staff. One possible solution is a two-tier response system where the patient's parent team is equipped to provide a defined initial response in the first instance,[53] with the MET only activated if more severe illness is identified.[54]

It is clear that many errors causing 'failure to rescue' are due to human factors and flaws in the design of hospital systems,[55,56] as illustrated by the MERIT study finding that of patients needing escalation to the ICU – with signs that should have been reported to the MET – only 30% were actually referred.[30] Hierarchical thinking, inflexible mental modelling, unreliable performance and uncoordinated, inefficient organisation are all factors.[55,56] Even relatively simple matters, such as the documentation of vital sign recording have a role: attention to the design of charts may promote more reliable detection of deterioration.[57]

Automation has great potential to improve the reliability of some important processes. Technologies that provide continuous or semi-continuous monitoring of vital signs, automatically calculate EWS and communicate critical values, are available[58]; while checklist-based interventions might help standardise the response to deterioration.[59] The development of increasingly sophisticated expert systems will enable the analysis of patterns of physiological data that can produce specific alerts as well as prompts and advice about individual patients.

CONCLUSION

There are many ward patients with potential or actual critical illness whose care should and could be improved.

The RRS represents one method of addressing these issues, at the very least by highlighting defects in current ways of working and by applying what has been learned from RRS initiatives to the whole hospital.

Severity scoring and outcome prediction

Christopher Jake Barlow, David Pilcher

INTRODUCTION

Accurate prediction of patient outcomes is a cornerstone of clinical medicine. Outcome prediction involves identifying and measuring markers of illness severity and correlating them to relevant outcomes. The discipline of intensive care medicine is concerned particularly with mortality prediction. This chapter aims to provide an introduction to severity scores, which are the family of predictive tools used to estimate risk of death. It will discuss the application of severity scoring systems in intensive care, where they are regularly used to inform clinical trials, conduct risk stratification and in benchmarking.

Many scoring systems are in current use, and this chapter does not contain an exhaustive description of each. Rather, it focuses on:

- application of severity scoring systems
- understanding the terms used to discuss severity scoring
- an overview of the principles of mortality prediction including:
  - Development of severity scores
  - Evaluation of a scoring system
  - Limitations of scoring systems
- standardised mortality ratios (SMRs) and control charts
- common mortality scores in current use
- scores used for special populations.

Many of the examples used in this chapter are derived from the Australian and New Zealand Intensive Care Society (ANZICS) Adult Patient Database. However, the principles illustrated may be applied throughout the world of critical care medicine.

APPLICATION OF SEVERITY SCORES

WHY USE THEM?

Many severity scoring systems have been developed in intensive care medicine. Most predict mortality in the general intensive care unit (ICU) population, including the Acute Physiology and Chronic Health Evaluation (APACHE)[1–4] series of scores, the Australia and New Zealand Risk of Death (ANZROD) model,[5] the Intensive Care National Audit and Research Centre (ICNARC) models,[6] the Simplified Acute Physiology Score (SAPS)[7–9] series, the Mortality Prediction Model (MPM)[10–12] series, and the Paediatric Index of Mortality (PIM)[13–15] series. Others have been developed for use in specific patient populations in the ICU, such as the survival after venoarterial-extracorporeal membrane oxygenation (ECMO) (SAVE)[16] and respiratory ECMO survival prediction (RESP)[17] scores for patients requiring ECMO, or for other large diagnostic categories such as trauma (Injury Severity Score[18] [ISS]), and sepsis (quick-Sepsis Organ Failure Assessment [qSOFA])[19] who commonly present to ICU.

You, a senior intensivist, arrive back at work following your holiday. On your desk, you find a letter from the Health Department. Your ICU is in the spot light!

Looking through the document, the words 'high mortality', 'outlier', 'Standardised Mortality Ratio' and 'confidence interval' leap out at you.

You stretch your mind back, trying to recall the specifics of severity scores and mortality monitoring. Surely this can't be right?

Severity scores which predict mortality are often used for:

- **Quality of care evaluation and audit**
  Severity scoring allows comparison of unit performance. Risk-adjusted scoring systems are used by many clinical quality registry organisations, including The ANZICS Centre for Outcome and Resource Evaluation (CORE), ICNARC and The Dutch National Intensive Care Evaluation registry, allowing identification of units with higher than expected mortality.
- **Resource allocation and management**
  Severity scoring systems can be used to compare predicted mortality to resource use[20] and length of stay and to potentially estimate efficiency.[21]

ABSTRACT

Accurate prediction of patient outcomes is a cornerstone of clinical medicine. Outcome prediction involves identifying and measuring markers of illness severity and correlating them to relevant outcomes. The discipline of intensive care medicine is concerned particularly with mortality prediction. This chapter provides an introduction to severity scores, which are the family of predictive tools used to estimate risk of death. It will discuss the application of severity scoring systems in intensive care, where they are regularly used to inform clinical trials, conduct risk stratification and in benchmarking.

MORTALITY PREDICTION MODELS, SEVERITY SCORES, RISK OF DEATH AND SCORING SYSTEMS: WHAT'S THE DIFFERENCE?

These terms are often used interchangeably, but each is a distinct entity and they should not be confused with one another.

Prediction models use statistical techniques to estimate the chance of a particular outcome. For example, if we identify that patients admitted to the ICU with pneumonia who are aged between 65 and 70 years have a mortality of 25%, we can use this information to predict the outcome in comparable future patients.

A severity score is often a key component of MPMs.[22] A score is an arbitrary number, in which a high value typically represents a greater severity of illness and therefore chance of death. Such scores are created by weighting physiological variables and other factors, such as diagnosis or location prior to admission, and combining these to produce a total score. It is important to note that, for example, although a patient with an APACHE II score of 35 is sicker than a patient with a score of 25, neither number quantifies the actual chance of death.

The predicted mortality or 'risk of death' for a patient is the quantitative assessment of the likelihood of death. This is derived from an equation which incorporates the severity score or its components and also other factors, such as disease category, admission type, or location prior to admission. Two patients with the same severity score may have a different predicted risk of death, depending on the impact of these other factors.[23]

A scoring system refers to the combination of severity score, and the predictive equations used to derive the risk of death. For example, the APACHE III scoring system produces both the APACHE III score (incorporating age, chronic disease and physiological variables), and the APACHE III risk of death. That latter is calculated by combining weighted components of the APACHE III score, with other factors such as ICU admission diagnosis, location and time in hospital prior to ICU admission and emergency surgical status.

PRINCIPLES OF MORTALITY PREDICTION AND SEVERITY SCORES

HOW IS A SCORE OR PREDICTED RISK OF DEATH CREATED?

The first step is to identify measurable variables which have a relationship with mortality. For instance, elderly patients and those who have a particularly high or low level of serum sodium are more likely to die (Fig. 3.1). Secondly, a mathematical equation is derived which connects the measured variable to the outcome. The process of finding the best equation is known as regression analysis. The equation produced can then be used to predict the outcomes for future patients. The most common regression technique used in developing severity scores is logistic regression[24] because it is the ideal technique for 'binary' outcomes (where there are only two possible outcomes, such as 'alive or dead').

In Fig. 3.1 the relationship between age and mortality appears to be a relatively straight line. However, serum sodium, in common with many physiological variables, has a 'U'-shaped relationship with mortality, which can be divided into several sections. Many ICU scoring systems use this approach, with each section given a weighting or score based on its relationship with mortality.

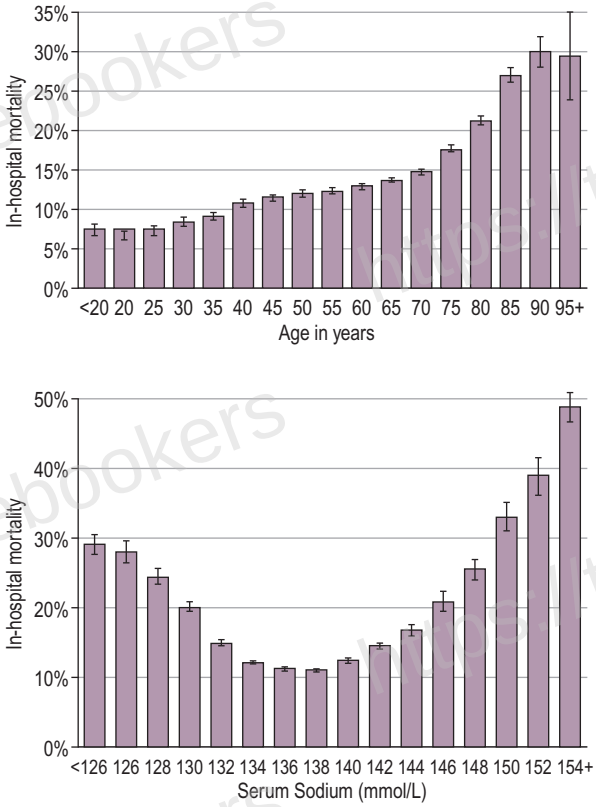

Figure 3.1 In-hospital mortality at different ages and serum sodium levels. Top pane shows the relationship between in-hospital mortality and age in years; bottom pane shows the relationship between in-hospital mortality and day 1 serum sodium level (mmol/L) for 332,409 ventilated patients admitted to 175 Australian and New Zealand Intensive Care Units (2010–2016). *ANZICS Adult Patient Database*.

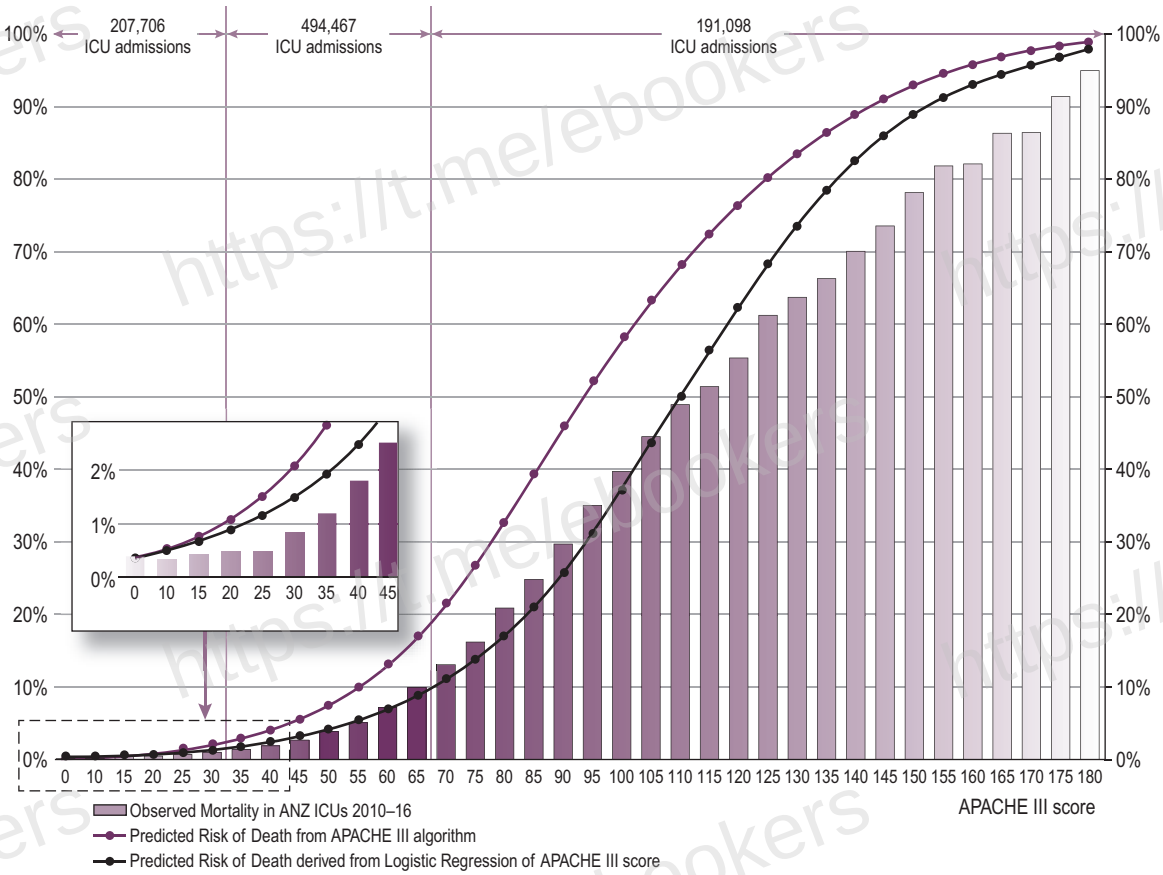

Figure 3.2 Mortality predictions derived by logistic regression. Observed and predicted mortality of 893,271 patients admitted to 176 Australian and New Zealand Intensive Care Units (ANZ ICUs) between 2010 and 2016 are plotted against Acute Physiology and Chronic Health Evaluation (APACHE) III scores. Shading of the columns represents the relative number of patients at each APACHE III score. *Purple dots/line* represent the predicted risk of death derived from the APACHE III-j algorithm at each APACHE III score. *Black dots/line* represent the predicted risk of death derived directly from logistic regression of the APACHE III score in this patient cohort. *ANZICS Adult Patient Database*.

In logistic regression the *probability* of death is calculated for each predictive variable. When the raw data are plotted on a graph, it produces an S-shaped curve. The shape of this curve means that for any given change in the predictor variable, much smaller differences in predicted mortality are found at the extreme left or right of the x-axis than in the centre of the curve. In practical terms, this means that even when overall predictions are accurate and discriminatory (see later for explanatory notes), relatively inaccurate predictions may occur for very-low-risk and very-high-risk patients (Fig. 3.2).

All common ICU MPMs incorporate multiple variables. The process of developing these models is known as multivariate regression, and the severity score is derived from the relative contribution of each of the predictor variables. Although increasing the number of variables improves predictive power, it also increases the complexity of the model and so it may be difficult to decide which variables to include. Key considerations when evaluating a variable for inclusion are the strength of the relationship with mortality, the size of the dataset used and practical aspects such as the burden of data collection. For example, the SOFA[25,26] score is relatively simple and can be 'added up by hand', whereas the predicted risk of death from APACHE IV,[4] the ICNARC model[6] or ANZROD[27] require a computer-based calculation.

EVALUATION OF A SCORING SYSTEM

It is important to know how well a scoring system relates to observed mortality and how well it performs in the specific patient groups in order to compare the outcomes of different groups of patients, in different ICUs, and across different time periods. A common statistical adage states that *'all models are wrong; the practical question is how wrong do they have to be in order to not be useful'*.[28]

Table 3.1 Comparison of published and locally assessed performance of different severity scoring systems in Australia and New Zealand

PUBLISHED PERFORMANCE		LOCAL PERFORMANCE IN ANZICS ADULT PATIENT DATABASE IN 2013			
SCORING SYSTEM	*DISCRIMINATION (AUROC)*	*DISCRIMINATION (AUROC)*	*NUMBER OF OBSERVATIONS**	*OBSERVED MORTALITY (%)*	*PREDICTED MORTALITY (%)*
APACHE II[2]	0.85	0.852 (0.848–0.856)	91,768	9.5	20.2

*Number of observations based on application of specific exclusions for each scoring system to dataset.

ANZICS, Australian and New Zealand Intensive Care Society; *AUROC*, Area under Receiver Operator Characteristic; *APACHE*, Acute Physiology and Chronic Health Evaluation; *ICNARC*, Intensive Care National Audit and Research Centre model; *SAPS*, Simplified Acute Physiology Score; *MPM*, Mortality Prediction Model; *ANZROD*, Australian and New Zealand Risk of Death model.

Understanding how well an MPM works has three components:

- Discrimination
- Calibration
- Validity

DISCRIMINATION

Discrimination describes how well the prediction model distinguishes those who will die from those who will survive.[29] Discrimination can be displayed graphically and is represented by the area under the receiver operating characteristic curve (AUROC). Models with perfect discrimination have an AUROC of 1, whereas those where prediction performs no better than chance have an AUROC of 0.5. Models are considered to have reasonable discrimination when AUROC is greater than 0.7, strong discrimination when AUROC exceeds 0.8, and excellent discrimination if greater than 0.9. Although in principle MPMs with a greater AUROC may be considered 'better', a highly discriminatory model may have limited use if its calibration is poor (see later). A comparison of the AUROCs of common severity scoring systems can be seen in Table 3.1.

CALIBRATION

Calibration describes how close the predicted values for mortality are to the real observed values. Fig. 3.3 is an example of a well-calibrated local MPM (ANZROD) compared with a less well-calibrated model (APACHE III) for admissions to ICUs in Australia and New Zealand in 2014 and 2015. Application of a model to

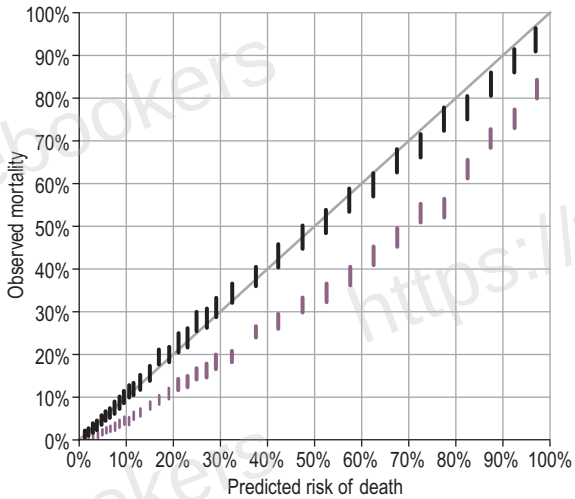

Figure 3.3 Calibration plot of predicted risk of death and observed mortality. Predicted risk of death is plotted against observed mortality for 163 Australian and New Zealand Intensive Care Units (ANZ ICUs) in 2014 and 2015. The *grey line* represents perfect prediction. The *black bars* represent 95% confidence intervals for Australian and New Zealand Risk of Death for 278,550 ICU admissions. The *purple bars* represent 95% confidence intervals for Acute Physiology and Chronic Health Evaluation for 257,278 ICU admissions. *ANZICS Adult Patient Database.*

data sets other than those used to generate it typically results in loss of calibration. This may be minimised by controlling for case mix, geographic location and time period. Many scoring systems (APACHE II, SAPS I and II, MPM I and II) exclude cardiac surgery and have poor calibration if the scores are applied in this cohort compared with use of specialised scores,[30] such as Euroscore[31–33] and the Cardiac Surgery Score (CASUS).[34] Some scoring systems, such as ANZROD and ICNARC, overcome this limitation by applying separate algorithms for specific cohorts such as cardiac surgery.[27,35]

Some systems take geography into account, as in SAPS III, which adds a variable for each region,[9,36] or create a score specifically for that region, such as ANZROD, developed specifically for Australian and New Zealand ICUs,[23] and the ICNARC model developed for England and Wales.[6] More complex modelling techniques such as mixed effects models, which treat patient level variables and ICU level or regional level variables differently in the creation of the model, are outside of the scope of this review.

Actual mortality tends to fall over time as quality of care improves, but predicted mortality remains as it was when the score was derived.[23,27] In addition, improvements over time may not be uniform across all patient groups, and the degree to which observed mortality falls below predicted may be different in specific patient subgroups. Thus the effect of variation in case mix also becomes progressively more important. When this occurs, 'recalibration' of predicted mortality should be performed.

It is worth remembering that even when mortality predictions are recalibrated and the risk of death is 're-estimated', the severity of illness score will remain unchanged. Patients with pneumonia, aged between 65 and 70 years and with APACHE II scores between 20 and 25 had a mortality of 27% in Australia and New Zealand in the early 2000s. Mortality fell to 23% between 2006 and 2010 and to 18% between 2011 and 2015: the same types of patients, with the same scores, had different mortality in different eras.

Calibration versus discrimination

A model can be well calibrated even if its discrimination is poor, and vice versa. The Baux score (age + % total body surface area burnt), which is used as a predictor of burns mortality, is a well-known example of strong discrimination (AUROC = 0.9) but poor calibration.[37,38] Patients with higher Baux scores are much more likely to die than those who score lower. However, a 50-year-old man with 50% burns does not have 100% mortality. In Australia in 2012, it was 35%.[37]

VALIDITY

Validity describes how accurately a model reflects reality and is divided into internal and external validity. Internal validity describes how well the model represents the population in which it was developed. External validity describes how reliably the model performs in other populations. Validity is a function of discrimination and calibration and with added contextual reference.

Restricting the scope of the score reduces heterogeneity and improves discrimination and calibration but also limits generalisability.[9] An example is qSOFA,[19] which was developed to identify patients who are at greater risk of death from infection and should be considered to potentially have sepsis. It is valid for use outside the ICU and in the emergency department (ED)[39] as a screening tool. However, due to its limited predictive capacity for identifying those at risk of death within the ICU, qSOFA has limited validity as a screening tool for sepsis within a critical care environment.[40] Other examples include the SAVE[16] and RESP[17] scores, which have been developed to predict mortality in patients who are already on ECMO. Although easy to calculate and potentially related to mortality, these scores are not validated for determining selection for ECMO treatment.

LIMITATIONS OF SCORING SYSTEMS

The application of severity scores is limited by the properties of the statistical methods used to generate them.

APPLICABILITY TO INDIVIDUAL PATIENTS

Severity scores predict the outcome of a cohort and are most accurate when the cohort comprises patients who are similar to each other. Models may become inaccurate when applied to an individual, so severity scores tend to be of limited benefit when making treatment decisions at the bedside. Although a patient with an APACHE II score of 8 is relatively well compared with a patient with a score of 25, the confidence interval is generally too wide to accurately predict mortality.[41]

Severity scoring systems are complex, and patients may be incorrectly scored, with one study concluding more patients are scored incorrectly than correctly.[42] At a cohort level, an approximately equal distribution of errors 'cancel each other out', but, at an individual level, incorrect scoring may result in significant changes to predicted mortality. The greatest effect occurs in the mid-range of scores because a small error in calculated score will have a large impact on predicted mortality. This is in contrast to an inherent limitation of logistic regression models where, even without any errors, predictions themselves may be inaccurate at extremes of low or high risk (see earlier).

In addition, using a score to make individual treatment decisions will change the predictive ability of the score. If treatment were withdrawn on all patients with greater than 95% predicted mortality, these patients may then have 100% mortality and the scoring system will now be inherently less accurate. This is analogous

to real-time traffic reports when driving. As congestion on one road increases, it will cause more drivers to avoid the area, paradoxically leading to less congestion on the original road but greater congestion elsewhere.

USING SEVERITY SCORES TO MONITOR INTENSIVE CARE UNIT OUTCOMES

Comparison of unadjusted death rates between ICUs lack context and can be misleading. One hospital might have twice the death rate, but their patients might also be twice as sick. Even with identical quality of care, patients who are more seriously ill, die more often. Severity scores and mortality predictions allow us to adjust for this baseline risk.

Common methods include the SMR for cross-sectional data comparing many ICUs, and control charts to monitor outcomes for a single ICU over time using exponentially weighted moving averages (EWMAs) and cumulative sum (CUSUM) charts. These standardised reporting methods produce results which are internally consistent and relatively easy to interpret.

STANDARDISED MORTALITY RATIO

The SMR is the ratio of the observed number of deaths to the predicted number of deaths, in which the latter is equal to the sum of the predicted risk of death—calculated by a severity scoring system—for all eligible patients.

$$\text{SMR} = \frac{\text{Observed number of deaths}}{\text{Predicted number of deaths}}$$

An SMR greater than 1 suggests the unit is performing worse than predicted because the observed mortality exceeds the predicted mortality.

Catches and caveats in interpreting the standardised mortality ratio

The SMR relies on an appropriate measure of observed mortality and accurate calculation of predicted mortality. Its interpretation is also dependent on knowing which groups are included. Readmission episodes to ICU and those with unknown survival outcomes are generally excluded. When reporting SMRs, some organisations either exclude patients transferred from an ICU or those transferred to another ICU.[15] SMRs for most adult ICUs consider in-hospital deaths.[1–3,6,9,27] However, it is common for paediatric ICUs to report and consider in-ICU deaths as the primary outcome.[15]

Observed mortality depends upon quality of all care delivered both within and outside the ICU. Some deaths may be inevitable, some preventable.[43] Several scoring systems account for this by excluding those admitted for organ donation or palliative care[27] (where survival is not the aim of the ICU admission) or by providing a statistical adjustment to mortality prediction for those with treatment limitations.[27] Accurate calculation of predicted mortality also relies on quality of data acquisition and the specific characteristics and calibration of the prediction model used to estimate the predicted number of deaths.

Anything which affects calibration of the MPM will also affect the calculated SMR. The annual fall in APACHE III SMRs in Australia and New Zealand is partly due to improved quality of care and better mortality outcomes. However, it has also been influenced by changes in data quality and the numbers and characteristics of contributing ICUs (Fig. 3.4).

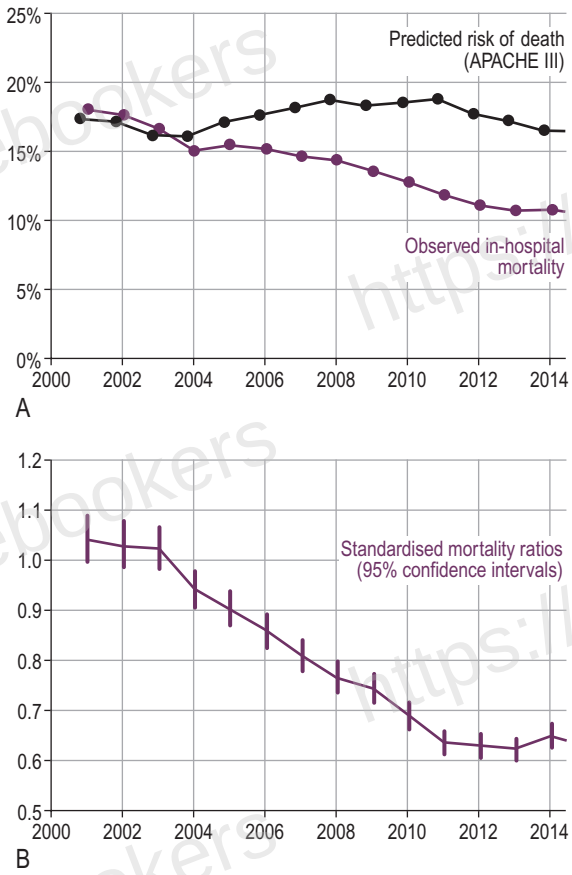

Figure 3.4 Changing standardised mortality ratio (SMR), observed mortality and predicted risk of death over time. The top panel shows observed in-hospital mortality *(purple)* and the Acute Physiology and Chronic Health Evaluation (APACHE) III predicted risk of death *(black)* for 206,770 admissions to a total 38 metropolitan Intensive Care Units (ICUs) in Australia and New Zealand between 2001 and 2014. In 2001, 22 ICUs contributed data, whereas in 2014, 36 metropolitan ICUs contributed data. The decline in SMR is partly due to mortality outcomes which have improved to be better than predicted by APACHE III but has also been influenced by improving data quality and changes in numbers and characteristics of contributing ICUs. *ANZICS Adult Patient Database.*

Sitting down with the SMR report, you use the 'Mohammed pyramid model' of investigation to try and identify the cause.[44,45]

First, you examine coding and data quality, consistency and completeness. You ensure there are no implausible values and that survivors and deaths are correctly coded. You concentrate on variables which may be systematically miscoded such as GCS.

Second, you evaluate the case mix. Are there patient groups where predicted mortality has been inaccurately estimated or where the prediction model systematically underestimates true observed mortality? Are there groups of patients where there is a true elevation of mortality above predicted?

Third, you assess clinical factors. These include staffing, bed availability and access to care, processes of care and guideline adherence and the clinicians themselves.

When ICU admission numbers are small, random variation has to be considered. Small changes in observed numbers of deaths may cause large changes in the calculated SMR. The estimate of SMR becomes more robust as the number of observed and expected deaths increase. It is important to consider the confidence intervals for an individual SMR or for the SMR of a group of ICUs (as used when a funnel plot is created—see later).

Graphing the standardised mortality ratio and identifying potential outliers

The most common graphical method used to report the SMR is a funnel plot (Fig. 3.5). Funnel plots graph the SMR for a group of ICUs over a period of time against the number of 'eligible cases' (typically number of ICU admissions or predicted number of deaths) on the x-axis.

Funnel plots also include a confidence interval derived from the mean SMR or overall number of deaths/predicted. The confidence interval indicates

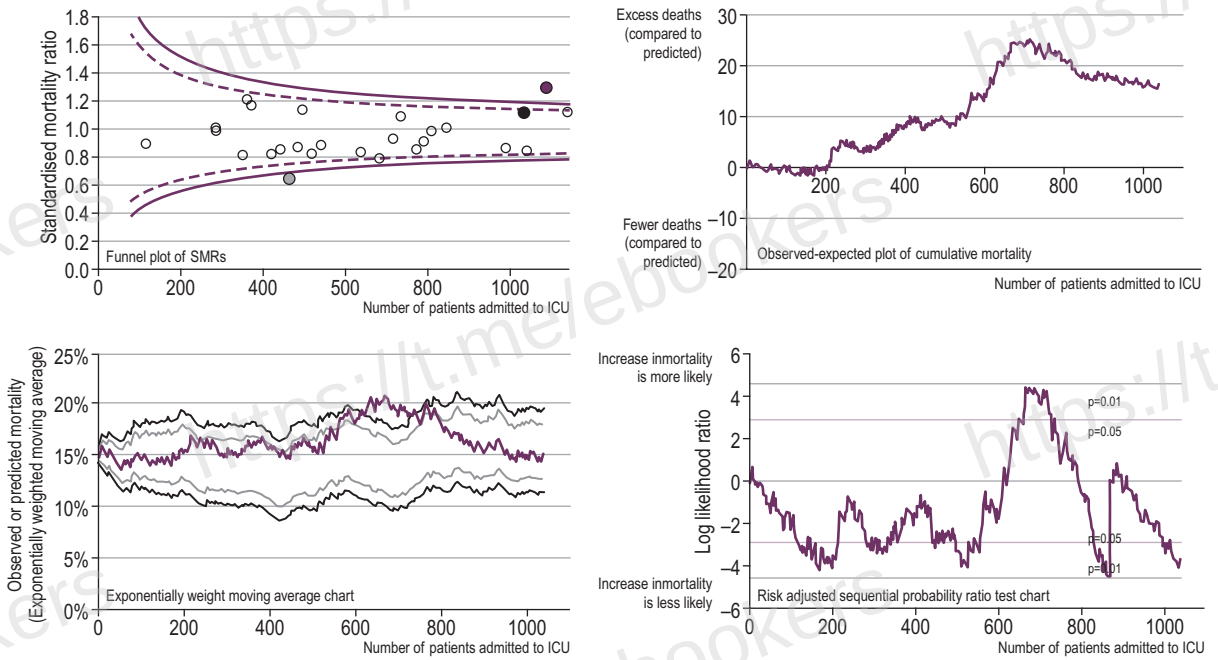

Figure 3.5 Funnel plot and continuous outcome monitoring (control) charts.
Top left: The panel shows a funnel plot of standardised mortality ratios (SMRs), with 95% (*purple* dashes) and 99% (*purple* line) confidence intervals drawn around the mean SMR of the group.
The ICU highlighted in *purple* has a higher (worse) SMR than the rest of the group. The ICU shaded in *grey* has a lower (better) SMR than the rest of the group. The ICU highlighted in *black* has an SMR within acceptable limits.
Bottom left: Exponentially weighted moving average of observed mortality (in *purple*) plotted against 2 (*grey* lines) and 3 (*black* lines) standard deviations for the predicted mortality.
Top right: Observed minus expected plot of cumulative mortality, with more deaths than predicted as the *purple* line climbs.
Bottom right: Risk adjusted sequential probability ratio test chart, with rising likelihood of an increase in mortality over predicted present as the *purple* line climbs.
Explanation: The continuous outcome monitoring (control) charts derived from the observed and predicted mortality for this (*red*) ICU are shown in the *top right*, *bottom right*, and *bottom left* panels. Despite an overall acceptable SMR, during the middle of the monitoring period, mortality outcomes appear to deteriorate. *ANZICS Adult Patient Database.*

the precision of the SMR, with its width inversely related to the number of patients. An ICU with an SMR greater than the confidence intervals of the whole group is considered a potential outlier with more deaths than predicted and may indicate poor performance.[46] Variation within the confidence limits is likely due to random noise.[47]

Funnel plots of SMR can accommodate some degree of loss of calibration in the MPM because confidence intervals are often drawn around the 'average SMR' of the group rather than around an SMR of 1. Hence the group of hospitals shown becomes the determinant of the overall acceptable performance and range of SMRs.

There are several reasons why an SMR may lie outside of the confidence interval. It may be random variation (1% of SMRs may lie outside of the 99% confidence intervals). Poor calibration of the prediction model, case mix variation (particularly important if mortality predictions are more inaccurate in one group than another) and coding errors (which can affect both observed mortality and the calculation of predicted risk of death) can commonly affect the SMR. If a funnel plot has a 'shotgun' appearance with large numbers of SMRs outside the confidence intervals (known as overdispersion), this suggests the 'risk adjustment' is inadequate and the predicted mortality rates are inaccurate (i.e. calibration is poor).

Despite these limitations, the funnel plot of SMRs is a useful screening tool to identify ICUs worthy of a 'closer look'.

EVALUATING PERFORMANCE OVER TIME FOR ONE INTENSIVE CARE UNIT: CONTINUOUS OUTCOME REPORTING

Display of outcomes over time for a single ICU typically uses CUSUM or EWMA control chart techniques. These methods compare differences in the observed and predicted outcomes at a specific ICU. Emerging trends can be identified early (possibly before a signal is seen on a funnel plot of SMRs), and clinical performance may be evaluated in real time.[48]

Cumulative sums, exponentially weighted moving averages and Variable Life-Adjusted Displays

The basic CUSUM control chart displays a running total of the difference between observed and predicted outcomes.[48] The simplest forms are called Variable Life-Adjusted Displays (VLADs) or observed-expected charts, but these often contain no control limits or confidence intervals to indicate when a trend has continued long enough to be considered significant. Risk-adjusted CUSUM and risk-adjusted sequential ratio probability charts are variants of these control charts, and sequentially assess whether an observed outcome rate is consistent with a specified baseline reference rate derived from the predicted outcome.[49]

EWMA charts are created by plotting the exponentially weighted mean of observed mortality along with a similarly weighted mean of the predicted outcome and its control limits.[48] They are able to detect small changes in mortality[50] because a small number of aberrant outcomes may reach a significance threshold. This sensitivity comes at the cost of a high false-positive rate, which can be decreased by increasing the run length of the chart.

Fig. 3.5 shows the same mortality data from one hospital displayed in three different ways, with an observed-expected chart, risk-adjusted sequential ratio probability chart and an EWMA chart.

COMMONLY USED FACTORS IN SEVERITY SCORES AND MORTALITY PREDICTION MODELS

All scoring systems rely on a limited number of patient factors to predict death (Fig. 3.6, Table 3.2). These can be loosely categorised into markers of acute physiological

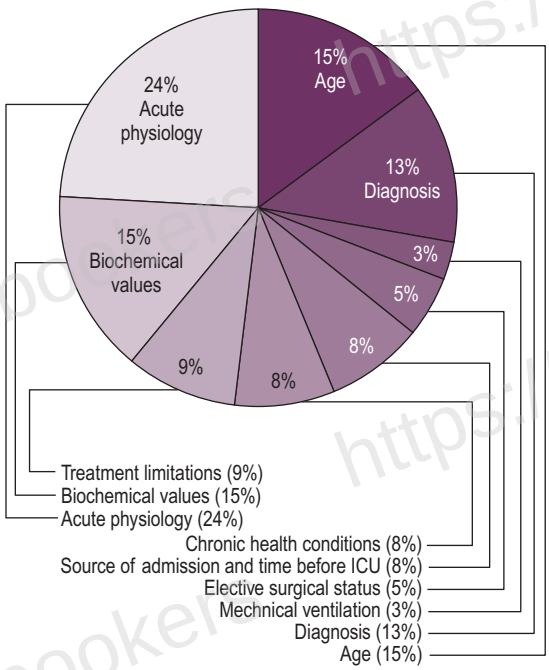

Figure 3.6 Relative contribution of variables to predicted risk of death. The figure shows the relative contributions of acute physiological disturbance ('acute physiology', 'biochemical values'), primary pathological process ('diagnosis'), physiological reserve ('age', 'chronic health conditions') and other factors ('source of admission and time before intensive care unit [ICU]', elective surgical status', 'mechanical ventilation', 'treatment limitations') to predicted risk of death in the ANZROD model. *Adapted with permission from Pilcher D, Paul E, Bailey M, Huckson S. The Australian and New Zealand Risk of Death (ANZROD) model: getting mortality prediction right for intensive care units.* Crit Care Resusc. *2014;16(1):3–4.*

disturbance, the primary pathological process driving admission, and indicators of physiological reserve (e.g. age and chronic disease state). This section will discuss the properties of these factors with respect to severity scoring.

ACUTE PHYSIOLOGICAL DISTURBANCE

Since APACHE I, measures of physiological disturbance have been used to objectively estimate severity of acute illness.[1] Initially, selection and weighting

of variables were done by expert consensus,[1] but later scores have used regression techniques to determine which variables should be included and how they should be weighted.

Commonly used markers of physiological disturbance are listed in Table 3.2. Less commonly used markers include albumin, bilirubin, urea, haematocrit, glucose, lactate, platelet count, serum potassium and urine output.[1,4,6,12,51]

SOURCES OF ERROR IN THE ACUTE PHYSIOLOGICAL CONTRIBUTION TO MORTALITY PREDICTION

Retrieval and critical care outreach services and emergency department care, as well as the impact of organ supports, will 'buff' these values and may cause a patient to be assigned a score that does not reflect the severity of their physiological derangement. Poorly performing services may have the opposite effect. This source of error occurs when treatment is initiated at a separate time to measuring physiological parameters.[52] Variables most at risk for this bias are heart rate, blood pressure, respiratory rate, blood glucose, pH and arterial partial pressure of oxygen (PaO_2).[52] Continuous variables (e.g. heart rate) are more prone to measurement bias than binary ones (e.g. presence of New York Heart Association (NYHA) III/IV heart failure).

The effect of error may be reduced by using scores such as MPM-II_0 and SAPS III[9,36] that use data from time of admission.[52] However, this strategy may also increase the proportion of missing values and reduce explanatory power and so was avoided by the APACHE scores.[53] In addition, some severity scores substitute default (normal) values for missing data, and cases with unknown outcomes are often omitted. Both of these methods bias the calculated severity score.[54]

In addition, 30% of deaths and discharges occur in the first 24 hours of ICU admission.[54] Because this provides little time to institute and see impact from ICU interventions, such 'short-stay' patients will have an SMR close to 1 irrespective of the quality of care provided.[54]

An alternative approach (used by APACHE and ANZROD) is to use the 'worst' value in the first 24 hours[3,54] following admission. This decreases the proportion of missing values, while allowing evaluation of care occurring after this period. However, this approach may disguise poorly performing units because the higher observed mortality will be attributed to increased physiological derangement which was a result of poor care in the first 24 hours of ICU stay.[53]

PRIMARY PATHOLOGICAL PROCESS

The cause of admission is an important factor[3] because the prognosis of a particular physiological insult will depend on the underlying pathology. For example, a patient presenting with severe diabetic ketoacidosis will have a comparatively low mortality compared with a patient with similarly deranged physiology due to respiratory sepsis.

It is therefore important to adjust for the primary disease process. The number of diagnostic categories used by different scoring systems vary widely: MPM III uses only 6,[12] SAPS III uses 39,[9] APACHE II uses 50,[2] ANZROD uses 177[27] and ICNARC uses 709.[6]

PHYSIOLOGICAL RESERVE

Physiological reserve is a broad term which encompasses a patient's capacity to respond to a physiological insult without significant decompensation. Several factors are commonly measured to provide an index of physiological reserve.

Age is both routinely measured and a good predictor of outcome and is included in all common scoring systems,[2–4,6,9,12,27] However, the predictive relationship is broad and a distinction should be made between chronological age and frailty. Severe chronic organ insufficiency or immunocompromise are also included in several scoring systems.[2,3,8]

Extreme physiological derangement is a strong predictor of hospital mortality on admission to and early in the ICU stay. However, with increasing ICU stay (in particular greater than 10 days) antecedent characteristics are more predictive.[55]

LOCATION AND EMERGENCY STATUS

The location from which a patient is admitted may provide an indirect measure of disease severity by the level of care required by patients in that location.[3,52] Consequently, patient location is included as a covariate in some scores. SAPS III has three locations: emergency, another ICU or 'other,'[9,36] whereas the ICNARC model has six: elective surgery, emergency surgery, ward, ICU transfer, emergency or home.[6] Although the predictive power of location may be low and its removal has almost no significant effects on model calibration and discrimination,[9] it is easily measured. In contrast, elective or emergency status can often have a large effect.[27]

SEVERITY SCORING SYSTEMS IN COMMON USE

ACUTE PHYSIOLOGY AND CHRONIC HEALTH EVALUATION I–IV

The prototype APACHE score was derived in 1981 by Knaus, to allow evaluation of case mix in trials, compare outcomes, evaluate the efficacy of new therapies and evaluate resource use in ICUs.[1] The model was developed using data from 805 patients admitted to a university hospital ICU and a community hospital ICU within the United States. Cardiac surgery

was excluded, and the values and weightings of each variable were decided by expert consensus of five physicians.[1] APACHE I has been superseded by later versions and is the only iteration not in current use.

A revised version (APACHE II) was released in 1985.[2] Infrequently measured physiological variables were removed, as were variables which demonstrated poor predictive power. APACHE II was developed and validated using data from 5030 admissions to 13 different US ICUs. Weightings were adjusted from APACHE I but were still determined by expert consensus rather than regression modelling. The final APACHE II score is a sum of three components: the acute physiology score (from the worst values in the first 24 hours of ICU admission), a chronic health score and a score based on age. APACHE II has been the most commonly used and reported scoring system. Modern mortality outcomes are much lower than the original mortality predictions derived from the score components and admission diagnosis, an example of poor calibration.

APACHE III was released in 1991.[3] The number of hospitals involved was expanded to 40 to provide a representative sample of US ICUs, and data from 17,440 admissions was used. Of the included hospitals, 23 were selected randomly to provide a representative sample. APACHE III used multivariable regression to weight the predictive variables. A later update included estimations for cardiac surgical patients, making it the first APACHE score to do so. APACHE III represented an advance over APACHE II, with improved discrimination (AUROC 0.9, compared with 0.85) and calibration.[3] Several updates to APACHE III have been released, using alphabetical designators (e.g. the 10th update is APACHE III-j, which is publicly available).

The latest iteration is APACHE IV, derived in 2006 from 110,558 admissions from 104 ICUs in 40 different US hospitals. APACHE IV was developed due to poor calibration of APACHE III in modern patient populations.[4] It takes into account sedative effects on the ability to score the Glasgow Coma Scale (GCS) and has a more extensive admission diagnosis list. APACHE IV has good discrimination and calibration within its validation data set but may not be valid in all countries, due to poor calibration outside the United States.[5,6]

SIMPLIFIED ACUTE PHYSIOLOGY SCORE I–III

The SAPS was developed in France in 1985 and was based almost entirely on physiological variables.[7] Like APACHE I, the variables and their weightings were determined by author consensus. SAPS I was primarily designed to overcome the complexity of APACHE I and was significantly easier to complete. SAPS I demonstrated equivalent discrimination to APACHE I in the derivation cohort of 679 patients.[7] Each range of scores corresponded to a particular mortality rate.

SAPS II was an expanded version of SAPS I and was released as in 1993. Logistic regression was used to select variables for inclusion, decide on groupings for each variable and convert the severity score to a mortality prediction.[8] SAPS II was an international effort, with data used from 13,152 patients from 10 nations across Europe and North America. Burns, coronary and cardiac surgical patients were excluded. Discrimination was greatly improved over SAPS I and was equivalent to APACHE III and MPM II while still being quick to use.

SAPS III was published in 2005 and was derived from a database of 19,577 admissions to 307 ICUs across Europe; North, Central and South America; the Mediterranean and Australasia.[9,36] The equation is customised for each geographic area. Interestingly, and in contrast to the APACHE III and ICNARC scores, the majority of predictive power for SAPS 3 is from patient characteristics known prior to admission, and the circumstances surrounding admission and the acute physiological component contribute 22.5 and 27.5%, respectively.[3,6,9] Although SAPS III has poorer explanatory power than APACHE IV, it applies to a greater proportion of the world than any other scoring system available and represents a significant improvement over SAPS II.

MORTALITY PREDICTION MODEL I–III

The MPM was an evidence-based response to APACHE I and used data derived from a single US institution to compute risk of death using a logistic regression equation.[10]

MPM II was released in 2005 and consisted of two versions: MPM-II_0 (assessed at ICU admission) and MPM-II_{24} (assessed at 24 hours). MPM-II_0 and MPM-II_{24} have similar discriminatory power to SAPS II, with AUROCs of 0.82 and 0.84, respectively.

MPM III was introduced in 2007 in response to falling calibration of MPM II.[12] The score was developed on a new dataset using the same variables, with the addition of whether the patient had a 'do not resuscitate' order at the time of admission. The subsequent analysis achieved significantly better calibration than the previous iteration, with an AUROC of 0.82.

The advantage of the MPM systems are that the burdens of data collection are low because the variables are binary and all data are recorded at time of admission. However, its simplicity is counterbalanced by poorer discrimination compared with other scoring systems.

INTENSIVE CARE NATIONAL AUDIT AND RESEARCH CENTRE MODEL

The ICNARC is a UK organisation dedicated to the collection and analysis of critical care data. The ICNARC model[6] was originally published in 2007 and

derived from data which was initially collected by the ICNARC for the derivation of APACHE II, APACHE III, SAPS II and MPM II scores. It uses several of the same physiological parameters of the other scores but incorporates an expanded list of diagnostic criteria.

The first ICNARC model included data from 216,626 patients from 163 ICUs. The model is recalibrated regularly using data from the Case Mix Programme to maintain accuracy within the derivation cohort. However, like APACHE, it is based entirely on a national cohort and may not be suitable for use outside the United Kingdom.

AUSTRALIA AND NEW ZEALAND RISK OF DEATH

The ANZROD model[5] was developed by the ANZICS CORE to replace APACHE III-j, the performance of which had been deteriorating over time. Data from 450,000 ICU admissions submitted to the ANZICS Adult Patient Database between 2004 and 2009 were used to develop the initial model. In addition to the 124 diagnostic categories, to increase accuracy, eight major diagnostic groups were defined by a specific equation.[57] Patients admitted for palliative care, organ donation, or who are younger than 16 are excluded, but (unlike many other models) burns and cardiac surgery are included. The model demonstrated better calibration and discrimination than APACHE III-j in Australasian hospitals and is routinely recalibrated to maintain accuracy.

SEPSIS ORGAN FAILURE ASSESSMENT

The SOFA (later renamed Sequential Organ Failure Score) is an organ failure score. Organ failure scores can be used to predict mortality based on the number and severity of organ system failures. This is slightly different from the more general severity scores, which predict mortality from a variety of different explanatory variables.

The SOFA score was originally constructed to provide a simple, objective and reliable score for daily assessment of organ dysfunction in sepsis trials.[26] It scores the function of six organ systems (brain, cardiovascular, coagulation, renal, hepatic, respiratory) from 0 (normal) to 4 (extremely abnormal), with parameter intervals defined by experts. These parameter intervals also include the effects of treatment, including mechanical ventilation, vasoactive supports and sedation. The final score is calculated daily using the worst values for each system.

The initial role of SOFA was not to predict mortality but to quantify the sequence of events that occur in the critically ill patient.[26] SOFA has since been evaluated as a mortality prediction tool, and several derivative scores have been described for this purpose.[25,58–60] These include the mean SOFA score (sum of all SOFA scores divided by the length of stay), the highest score and Δ-SOFA (defined differently in different trials but in principle evaluating the difference between two scores[58,59]). These derivative scores demonstrate strong discrimination. However, calibration was not assessed in all instances[60] and use of SOFA as a replacement of existing severity scores is not warranted.

PAEDIATRIC INDEX OF MORTALITY[1]

The PIM is a series of severity scores covering patients younger than 16 years, who are typically excluded from other severity scoring systems. PIM1 was published in 1997, using data from seven Australian and one UK PICU.[13] Two further iterations have been released,[14,15] with the latest version (PIM3) released in 2013. PIM3 was developed from 53,112 consecutive admissions to PICUs in the United Kingdom, Ireland, Australia and New Zealand and uses several physiological and admission variables. The PIM3 model includes all individuals less than 16 admitted to a PICU, excluding those who were transferred to another ICU. The model demonstrates strong discrimination (AUC 0.88) across a range of predicted mortalities.

The PIM series are not the only paediatric-specific scoring systems; others include the Paediatric Risk of Mortality (PRISM) series of scores[61,62] and organ failure scores such as the Paediatric Logistic Organ Dysfunction Score (PELODS) series.[63,64]

SCORES FOR SPECIAL POPULATIONS

QUICK SEPSIS ORGAN FAILURE ASSESSMENT

The quick-SOFA (qSOFA) score was developed in 2016 as a bedside screening tool for patients at risk of death and with suspected infection. The score used three criteria, with one point given for low blood pressure (systolic blood pressure ≤100), respiratory rate (>22 per minute) or altered mentation (GCS <15), to a maximum of three.[19] qSOFA showed better discrimination than either SIRS and SOFA with respect to in-hospital mortality outside of the ICU (AUROC 0.81 compared with 0.76 and 0.79, respectively) but had little relationship to mortality within the ICU.[40]

INJURY SEVERITY SCORE

The ISS is an anatomically based scoring system for trauma patients, released in 1974.[18] The ISS is based on the Abbreviated Injury Scale (AIS), which classifies the severity of injury to six body regions (head and neck, face, chest, abdomen and pelvic contents, extremities or pelvic girdle, external). Injuries are graded from 1 (minor) to 6 (currently untreatable).[65] The ISS is then calculated from the sum of squares of the highest score in the three most severely injured regions.

Unlike physiological scores, which typically use data obtained close to the height of acuity, all injuries in ISS are relevant irrespective of the time at which

they were detected. Therefore injuries identified in tertiary surveys, trauma follow-up and postmortem examination are included. The ISS also has weaker discrimination as it ignores chronic disease.

Other trauma scoring systems exist. These include the Trauma Score[66] (and Revised Trauma Score[67]), which are based on age and physiological variables; and the Trauma and Injury Severity Score (TRISS) series, which combines both the Trauma Score and the ISS to give a combined anatomic and physiological scoring system.[68,69]

Transport of critically ill patients

Evan R Everest, Roy Fischer

Critical illness and injury are not necessarily defined by patient location. In addition, patients may overwhelm the level of care at their current location or require specific investigations or treatments not immediately available to them. For this reason, the transport of critically ill and injured patients occurs frequently.

Critical care patient transport has traditionally been divided into two groups; patient movement within a hospital (intrahospital) or movement between hospitals (interhospital or interfacility). In addition, a select group of critically ill or injured patients not located in a hospital facility may be managed by physician-based medical teams prior to retrieval to a hospital. Therefore, a third division (primary response or pre-hospital care) is well recognised.

The internationally widespread deployment of medical teams for critically ill patient management and retrieval from both health care facilities and pre-hospital locations has resulted in the recognition of pre-hospital and retrieval medicine as a distinct subspecialty.[1]

INTRAHOSPITAL TRANSPORT

The safest place for the critically ill patient is in the intensive care unit (ICU) connected to a modern ventilator and physiological monitoring, a nurse present to care for the patient and rapid access to nursing and medical assistance. Transports are usually required to facilitate critical investigations and interventions or to move the patient from one critical care area to another. Critically ill or injured patients with limited or no physiological reserve undergoing such transports are at risk of clinical deterioration and adverse events are well reported.[2,3] In order to reduce the mortality and morbidity associated with patient movement, a structured approach utilising high-level clinical personnel who have the correct equipment, training and sufficient planning time is required.

Moving the patient should be associated with little or no compromise in their condition. Unfortunately, this is not the case with an adverse event occurring in up to 70% of transports. One-third of these events are equipment related.[4] Deterioration in gas exchange[5] and increased rates of ventilator-associated pneumonia are common.[6] However, management is changed in 40%–50% of patients, thus justifying the risk.

Patients with unstable physiology should not be transported for nonurgent interventions or investigations. However, where the intervention or investigation is deemed critical to achieving patient stability or providing definitive management, the benefits in patient outcome will outweigh the inherent risks of transport. Therefore the transport can be seen as part of the patient's therapeutic requirement and stabilisation process. On occasions when the patient's need is so acute, or the likelihood of irreversible deterioration in transit is so high, consideration should be given to facilitating such interventions or investigations in the ICU rather than the location where these procedures would normally occur.

When preparing for intrahospital transport, the following structured approach is recommended:

- Prior planning to ensure minimal manual handling and to minimise the time away from the ICU.
- Clinical reassessment should occur swiftly, systematically and, whenever possible, with the patient already supported on the equipment that will be used during transport.
- The airway should be checked and secured, endotracheal suction performed, ventilation and oxygenation optimised, adequate and patent vascular access secured and drainage devices measured and emptied.
- Sedation and analgesic requirements should be addressed and any drugs required for transport (including additional infused agents) pre-drawn and labelled for immediate use.
- Ensure that the patient's clinical record remains with the team caring for the patient.

COMPUTED TOMOGRAPHY AND MAGNETIC RESONANCE IMAGING SCANNING

Computed tomography (CT) scanning is the most common ICU diagnostic intervention requiring patient movement. Head-injury patients and those requiring previous administration of oral contrast with decreased gut motility (and thus increasing risk of aspiration) require

ABSTRACT

Critically ill patients often need to be moved within or between hospitals for investigations or treatments. Every movement is associated with an increased risk of an adverse event that may significantly impact on their chances of recovery. Transport of these patients must occur in a structured manner using experienced clinical personnel who are trained to recognise complications and to manage them in often less than desirable environments. The equipment and monitoring used during the transport is often less sophisticated and requires specific training in its use and recognition of its limitations. The transport vehicle for interhospital retrievals can be road ambulances or aircraft, either helicopter or fixed wing. Each modality has advantages and disadvantages and choice should be based on which will provide the best risk benefit.

extra attention. When the CT scan is booked it is vital to liaise with the radiologist and other treating teams involved to ensure that the scan will address all the clinical questions. It is important to secure adequate vascular access for the pressure injection of intravenous (IV) contrast prior to leaving ICU; standard multilumen central lines are not suitable. Specific peripherally inserted central catheter (PICC) or central venous catheter (CVC) lines that are suitable for pressure injection may be used or a secure large bore peripheral IV inserted. Single-lumen large-bore central catheters are an alternative but should be used only as a last resort.

Repeated CT scanning of head-injured patients is common. In these patients with decreased cerebral compliance, movement or changes in body position or partial pressure carbon dioxide ($PaCO_2$) can result in significant elevations in intracranial pressure (ICP). Although movement-induced changes in ICP can be reduced with sedation, very little can be done about body position. Changes in $PaCO_2$ are usually due to variation between ICU and transport ventilators. Technological improvements mean that modern transport ventilators can deliver ventilation much more accurately than older devices. However, differences in circuit design, calibration and end-tidal CO_2 ($ETCO_2$) sampling mean that it remains good practice, if time permits, to establish the patient on the transport monitor and ventilator 10–15 minutes prior to departure. This allows time to take an arterial blood gas sample to establish the relationship between $PaCO_2$ and $ETCO_2$ and define what $ETCO_2$ should be targeted. Ideally the ICP should also be measured but at times this may not be possible.

Radiation exposure for both the patient and staff needs to be considered. A stable patient who is adequately monitored with alarms activated can be observed by staff outside the room. The patient should be moved back to the ICU as soon as scanning is completed.

Magnetic resonance imaging (MRI) is increasingly used as a diagnostic and prognostic tool for a wide range of ICU patients. MRI scanning entails greater risk than CT due to the unique environment, longer duration of scans and greater need for patient immobility (potentially necessitating sedation in nonintubated patients). The major problems with MRI are the effect that the magnetic field may have on ventilators, monitors and infusion pumps, and the potential for these items to become effectively a missile by being attracted to the magnet. The last decade has seen the development of monitoring and ventilators that are MRI compatible and the acceptance of standards for equipment in the MRI. These magnetic resonance standards are: MRI safe, conditional or unsafe. Safe and unsafe are self-explanatory, while conditional relates to equipment that is safe when used under certain predetermined conditions, for example, distance from the magnet. While larger ICUs increasingly have MRI compatible transport equipment, this is not the case at every facility. More often facilities have MR safe anaesthesia machines for the provision of general anaesthesia during the MRI examination. This equipment is 'foreign' to most ICU staff and often is not used owing to lack of familiarity. The third option is to use non-MRI–compatible equipment but to keep it outside of the scan room; ventilator and infusion lines can be lengthened with long extensions and routed through openings in the wall. This then only requires a dedicated MRI monitor inside the scan room. Not all ICU patients may be suitable to undergo MRI scanning. The magnetic field of the MRI scanner may pull on some metal-containing implants or cause heating due to the radiofrequency energy; in addition, the magnetic field can cause malfunction of implanted devices (e.g. pacemakers). Prior discussion with the MRI unit must occur before the patient is moved from the ICU; this is important to ensure patient safety and to avoid denying patients the potential diagnostic benefit of MRI unnecessarily. With improving technology, some types of devices that were previously an absolute contraindication to MRI may now be suitable under some circumstances. Most MRI units will require an MRI checklist to be completed prior to scanning.

It is important to note that the magnetic field is always active and staff entering the scan room need to be screened for metallic devices either implanted or on their person that may be dangerous.

OPERATING THEATRE AND INTERVENTIONAL RADIOLOGY

Transfer to and from the operating room should be done by the anaesthetist who will be caring for the patient during the procedure. This allows handover in the controlled environment of ICU and minimises the number of people entering the sterile operating room environment. For complex interventional radiology procedures the same arrangement should occur. For diagnostic or simpler interventional procedures the ICU team undertake the transfer and care during the procedure. It is vital that the team has an understanding of the procedural requirements including patient positioning, the need for analgesia, the possible complications and the specific treatments/physiological targets required.

STAFFING

A team consisting of at least one ICU medical officer and nurse should be free from other duties. Both team members should be thoroughly familiar with the transport process, equipment and environment. The team should possess the requisite skills and knowledge to independently manage critically ill patients in transit and to deal with anticipated emergencies. The more complex and unstable the patient is, the more capable the team must be. For very unstable patients an additional nurse and more senior doctors may be required. Assistance with safe patient, trolley and equipment movement is also needed. Therefore nonclinical hospital support staff are part of the team and should be included in all briefs and contingency planning.

EQUIPMENT

Transport equipment should be regularly checked and serviceable. Powered devices should be fully charged, with power cords accessible to facilitate use of mains power in the event of delay. Where possible, equipment should be lightweight, robust and standardised throughout the ICU and hospital. In transit, equipment should be secured (not resting on the patient) but readily accessible. Dedicated transport bridges or gantries are commonly used. Dedicated transport packs or boxes ensure safe carriage of consumable items, resuscitation equipment and drugs. Equipment required for emergency airway management (e.g. bag valve mask, laryngoscope, airway devices and endotracheal tubes) must be immediately available.

MONITORING

As a minimum, intubated and ventilated patients requiring intrahospital transport should have the following monitoring instituted[7]:

- continuous $ETCO_2$
- continuous Sa_{O_2}
- continuous invasive or intermittent noninvasive BP
- continuous three-lead electrocardiography (ECG).

Ideally, a cardiac monitoring device should also provide cardiac defibrillation and external cardiac-pacing capability. Patients requiring transport with more advanced monitoring in situ should be considered on a case-by-case basis. For example, ongoing ICP monitoring is critical to ensure avoidance of profound unmonitored falls in cerebral perfusion pressure in an ICU patient with a severe head injury, whereas pulmonary artery pressure monitoring may be excluded from the transport requirements in the haemodynamically stable patient.

INTERHOSPITAL TRANSPORT

With rising expectations for high-level care by the community in both metropolitan and rural locations and with the care for critically ill and injured patients becoming increasingly centralised in large, tertiary, metropolitan ICUs, the need to transfer patients between health care facilities has also increased. Such a demand has seen the development of dedicated specialist retrieval teams. Historical models of interhospital patient transfer utilising junior medical staff as 'patient escorts' have much higher rates of hypotension, acidosis and death.[8] Thankfully this type of transport has become increasingly rare with the introduction of specialist retrieval services.

The general principles of patient transport regarding equipment, patient monitoring and clinical requirements remain the same irrespective of the physical location of the patient. Standards for transportation of the critically ill have been widely promulgated and must be followed whether it is a complex unstable patient being moved long distances or a semi-elective CT in a stable ICU patient.

RETRIEVAL CLINICAL COORDINATION AND ADVICE

Retrieval clinical coordination describes the process whereby specialist medical, nursing, paramedic and ambulance service staff are involved in direct supervision of the primary and interhospital transport or retrieval of patients. This is to ensure:

- the safe and efficient use of expensive transport and retrieval services
- that high-level clinical advice is available prior to and during transport
- the patient is delivered in a timely manner to the most appropriate receiving hospital.

Not all patients who are referred for retrieval will require transport. Of those who do, not all will require a retrieval team. To ensure that this is addressed, an integrated systems approach is required. In general, a retrieval service will be used when the complexity of the patient exceeds the ambulance service's ability to transport the patient. Tele-medicine is playing an important and increasing role in this process – not only in assisting decision making regarding retrieval activities (resulting in potential cost savings) but also in supporting remote and regional medical practitioners faced with acutely ill or injured patients, and in supporting a retrieval team before and during patient transport. For this reason, many retrieval coordination centres are co-located with ambulance service communication centres. In this way, clinical and logistic expertise is integrated. Knowing where key assets (transport platforms, such as road ambulances, helicopters and fixed-wing aircraft) and retrieval teams are at any one time is crucial to effective retrieval clinical coordination. Real-time asset tracking or mapping systems and advanced radio or phone communication networks assist in this regard.

RETRIEVAL TEAM STAFFING

The aim of the team is at least to maintain, but ideally to increase the level of care during transport. This requires a team of sufficient size and skill to provide the full complement of care for the majority of patients being transported.

The minimum team should comprise two people; occasionally a very-low-acuity stable patient may be escorted by a single person. If multiple patients are to be transported, a recommended staffing level is $n + 1$ where n equals the number of patients.[9]

Who makes up the team continues to be debated. In most cases a doctor will be one member while the other can be a person with either an acute care nursing or an ambulance background. Other requirements include the ability to work and communicate as a team, have

reasonable body habitus and physical fitness, and have no visual or auditory impairment or a susceptibility to motion sickness. In aviation transport the weight of the teams and their equipment is important as there is a maximum weight available. High team weights can limit the amount of fuel able to be carried, which may compromise some missions.

There may be some highly complex cases that will be outside of the team's capability, and supplementation of the retrieval team by additional specialist personnel may be required. For example, an obstetrician or neurosurgeon[10] may be added depending on the type of mission. It is mandatory that the specialist is added to a standard team because of the latter's familiarity with working in the retrieval environment.

TRAINING

Training should cover the following:

- standard operating procedures for the service
- the use of scenarios to teach common procedures and principles
- familiarity in the various transport platforms to be used; this would include safety briefings on aerial assets and may include helicopter underwater escape training (HUET) and crew (cockpit) resource management (CRM)
- communication procedures
- understanding of the effects of altitude and flight on patient (and team) physiology.

EQUIPMENT

GENERAL CONSIDERATIONS

Minimum equipment standards for supplies, equipment and monitoring have been published.[7] The equipment carried is often a compromise between providing for every conceivable situation and being lightweight and mobile. In some cases it is appropriate to have additional specialist packs that are taken only when warranted by the clinical situation; for example, a Sengstaken–Blakemore tube or temporary transvenous pacing wire is taken only when a gastrointestinal (GI) haemorrhage occurs in a patient who might have varices or the patient has symptomatic complete heart block. This requires good communication and a robust coordination process.

A suggested list of equipment is given in Box 4.1.

Transport monitors, infusion pumps and ventilators must work out of the transport vehicle. They must be battery powered whilst ideally allowing for utilisation of ambulance or aircraft power during transport. Batteries in most modern systems are either sealed lead acid or lithium. Battery life is quoted for new batteries and with time this value decreases. Planning on a battery life of 50% of that quoted is prudent. Spare batteries can be carried but changing them may result in temporary interruption of function. During transport the equipment must be securely stowed. There are international standards in the 'G force' that securing systems must withstand in the event of a crash. In some modern road vehicles or helicopters the requirement is 20 G. The use of a suitably engineered mount attached to the patient's stretcher to which the equipment can be secured provides the most safety.[11]

MONITORING

Clinical observation by experienced clinicians remains an important facet of monitoring.[12] However, there are significant limitations to this approach. It is difficult to auscultate adequately in a moving vehicle and impossible in a helicopter. As a minimum, ECG, pulse oximetry and noninvasive blood pressure (BP) measurement must be provided with the addition of $ETCO_2$ for any intubated patient. Noninvasive BP measurements are often subject to interference, and for critically ill patients invasive arterial access is essential, especially if the length of the transport is long.[13] Newer monitors that combine defibrillation and pacing with the monitoring aspects outlined above may be an advantage. However, noninvasive BP and defibrillation uses significant battery power and spare batteries are essential and must be carried. Portable blood gas analysers provide additional management information during long transports.

VENTILATORS

A mechanical ventilator must be used on all intubated patients as manual ventilation cannot reliably deliver constant tidal volumes and a stable $ETCO_2$.[14] However, a manual system must be available in the rare event of a ventilator failure. Transport ventilators are a compromise between portability and features. Over the last 10 years the desired features (as listed in Box 4.2) have almost been met. Small neonates often still require a specific ventilator; at the very least they require specialised circuits and ventilator software.

The provision of noninvasive ventilation (NIV) is now possible on most modern transport ventilators. An improvement with inspiratory valve-triggering technology has resulted in substantial reductions in circuit work with concurrent reduction in the work of breathing. Although Mapleson-based continuous positive airway pressure (CPAP) systems with high fresh gas flows provide the least circuit work and are optimal for patients with high work of breathing, the new transport ventilators are close enough to ideal to be used. Most patients will tolerate NIV with the modern ventilators,[15] but it does require a different approach by retrieval teams. There needs to be a period of observation prior to transport as the ability to provide advanced airway support in transit is limited. Modern NIV ventilators can at times 'chase' a circuit leak resulting in high gas consumption, and can increase the risk of depleting oxygen supplies. Gas consumption must be monitored.

In most cases, heat moisture exchangers (HMEs) will provide adequate humidification for intubated patients.

Box 4.1 Suggested equipment schedule for interhospital critical care transport

Respiratory equipment
Intubation kit:
- Endotracheal tubes and connectors – adult and paediatric sizes
- Introducers, bougies, Magill forceps
- Laryngoscopes, blades, spare globes and batteries
- Ancillaries: cuff syringe and manometer, 'gooseneck' tubing, HME/filter(s), securing ties, lubricant
- Difficult airway equipment

Alternative airways:
- Simple: Guedel and nasopharyngeal
- Supraglottic: laryngeal masks or similar
- Infraglottic: cricothyrotomy kit and tubes

Oxygen masks (including high Fi_{O_2} type), tubing, nebulisers
Suction equipment:
- Main suction system – usually vehicle mounted
- Spare (portable) suction – hand-, O_2-, or battery-powered
- Suction tubing, Yankauer, catheters and spare reservoir

Self-inflating hand ventilator, with masks and positive end expiratory pressure (PEEP) valve
Portable ventilator with disconnect and overpressure alarms, oxygen failure alarm
Ventilator circuit and spares
Capnometer/capnograph
Pleural drainage equipment:
- Intercostal catheters and cannulae
- Surgical insertion kit and sutures (see below)
- Heimlich-type valves and drainage bags

Main oxygen system (usually vehicle-mounted) of adequate capacity with flowmeters and standard wall outlets
Portable/reserve oxygen system with flowmeter and std outlet
Circulatory equipment
Monitor/defibrillator/external pacemaker, with leads, electrodes and pads
IV fluid administration equipment:
- Range of fluids: isotonic crystalloid, dextrose
- High-flow and metered flow-giving sets
- IV cannulae in range of sizes: peripheral and central/long lines
- IV extension sets, three-way taps and needle-free injection system
- Syringes, needles and drawing-up cannulae
- Skin preparation wipes, IV dressings and Band-Aid
- Pressure infusion bags (for arterial line also).
- Alternate vascular access equipment [e.g. Intra-osseous needle (IO)]

BP monitoring equipment:
- Arterial cannulae with arterial tubing and transducers
- Invasive and noninvasive (automated) BP monitors
- Aneroid (nonmercury) sphygmomanometer and range of cuffs (preferably also compatible with NIBP)

Pulse oximeter, with finger and multisite probes
Syringe/infusion pumps (minimum two) and appropriate tubing
Miscellaneous equipment
Urinary catheters and drainage/measurement bag
Gastric tubes and drainage bag
Minor surgical kit (for inter-costal catheters (ICC), CVC lines, cricothyrotomy, etc.):
- Sterile instruments: scalpels, scissors, forceps, needle holders
- Suture material and needles
- Antiseptics, skin preparation packs and dressings
- Sterile gloves (various sizes); drapes +/– gowns
- Basic thoracotomy equipment

Cervical collars, spinal immobilisation kit (e.g. Vacmat), pelvic binder, splints
Thermometer (nonmercury) and/or temperature probe for monitor
Warming equipment (e.g. reflective blanket, chemical blanket or fluid warmer)
Bandages, tapes, heavy-duty scissors (shears)
Personal protective equipment (PPE): gloves, gowns and eye protection (may need extra for pre-hospital response or aircraft, e.g. helmets, flame retardant flight suit, life vests)
Sharps and contaminated waste receptacles
Pen and folder for paperwork
Torch +/– head light
Drug/additive labels and marker pen
Nasal decongestant (for barotitis prophylaxis)
Pharmacological agents
CNS drugs:
- Narcotic and nonnarcotic analgesics
- Anxiolytics/sedatives
- Antipsychotics
- Anticonvulsants
- IV anaesthetic induction agents
- Antiemetics
- Local anaesthetics

Cardiovascular drugs:
- Antiarrhythmics
- Anticholinergics
- Inotropes/vasoconstrictors
- Nitrates
- Beta blockers
- Other hypotensives

Electrolytes and renal agents:
- Sodium bicarbonate
- Calcium (chloride)
- Magnesium
- Potassium
- Loop diuretics

Endocrine and metabolic agents:
- Glucose (concentrate) +/– glucagon
- Insulin
- Steroids

Other agents:
- Neuromuscular blockers: depolarising and nondepolarising
- Narcotic and benzodiazepine antagonists
- Bronchodilators

Box 4.1 Suggested equipment schedule for interhospital critical care transport—cont'd

- Proton pump inhibitors
- Anticoagulants
- Thrombolytics
- Vitamin K
- Antibiotics +/– antivirals
- Oxytocics
- Tocolytics
- Diluents (saline and sterile water)
- Treatment for elevated ICP (e.g. hypertonic saline or mannitol)

Additional/optional equipment

- Portable ultrasound machine
- Transvenous temporary pacing kit and pacemaker
- Blood (usually O negative) and/or blood products
- Additional infusion pumps and associated IV sets
- Obstetrics kit with neonatal equipment
- Additional paediatric equipment (depending on capability of basic kit)
- Antivenin (polyvalent or specific)
- Specific drugs or antagonists

BP, Blood pressure; *CNS*, central nervous system; *CV*, central venous; *HME*, heat moisture exchangers; *ICC*, inter-costal catheters; *ICP*, intracranial pressure; *IO*, intra-osseous; *IV*, intravenous; *NIBP*, noninvasive blood pressure; *PEEP*, positive end expiratory pressure.

Box 4.2 Features of an ideal transport ventilator

- Small, light, robust and cheap
- Not dependent on external power source
- Turbine driven (can function without high pressure oxygen)
- Easy to use and clean, with foolproof assembly
- Economical on gas consumption
- Suitable for patients from neonates through to large adults
- Fi_{O_2} continuously variable from ambient air to 100% oxygen
- Able to deliver PEEP, CPAP, synchronous intermittent mandatory ventilation (SIMV) and pressure support
- Ability to deliver noninvasive ventilation with leak compensation and low work of breathing
- Variable I:E ratios
- Flow or pressure generator modes
- Integrated monitoring and alarm functions with audio and visual signals
- Altitude compensated

A suction system and reserve are required. In most transport vehicles this can be provided by electrically powered devices with a gas-powered venturi system as a back-up.

INFUSIONS

Critically ill patients often need multiple infusions to be continued during transport. Some drugs that ideally should be given as infusions can be consolidated by combining sedation drugs, or the infusion stopped and given instead by frequent boluses. The older-style volumetric and drop-counting pumps have been superseded by lightweight syringe drivers, which should be the only method used for drug infusions in contemporary retrieval practice.

INTRA-AORTIC BALLOON PUMP AND EXTRACORPOREAL MEMBRANE OXYGENATION

Retrieval of patients with intra-aortic balloon pump (IABP) in situ has been occurring for many years and, in general, a team with some experience in troubleshooting any pump alarms can manage these patients. The IABP machines are reasonably bulky and heavy with an internal battery life of 1–2 hours. The type of transport vehicle has to be considered to ensure that the pump can be safely secured and can be connected to an external power source. Insertion of an IABP catheter requires some experience and some pre-departure consideration of the team's capabilities must be made. The addition to the standard retrieval team of an extra doctor experienced in IABP insertion should be considered.

The H1N1 influenza pandemic in 2009–2010 saw the rapid emergence of extracorporeal membrane oxygenation (ECMO) as a valid treatment for severe viral-induced respiratory failure.[16] It was recognised that ECMO should be provided in a relatively small number of institutions, and that, ideally, patients likely to need ECMO should be transferred early. However, significant numbers of patients deteriorated rapidly and rescue ECMO was instituted in many non-ECMO centres, hence requiring the patient to be transported on ECMO. Many ECMO centre staff will not be familiar with the retrieval environment. A common model to move such patients is to combine the ECMO team with a standard retrieval team. In these cases the role of the retrieval team is to assist by providing the logistical and interhospital expertise to allow the ECMO team to concentrate on caring for the patient.

MODE OF TRANSPORT

There are three common types of transport vehicle used: road vehicles, aeroplanes (fixed wing) and helicopters (rotary wing). The basic requirements are listed in Box 4.3 and their features and limitations are summarised in Table 4.1.

Box 4.3 Essential features of transport vehicles

- Readily available
- Adequate operational safety
- Capable of carrying (at least one) stretcher and mobile intensive care equipment set
- Safe seating for full medical team, including at head and side of patient
- Adequate space and patient access for observation and procedures
- Equipped with adequate supply of oxygen/other gases for duration of transports
- Fitted with medical power supply of appropriate voltage and current capacity
- Appropriate speed (coupled with) comfortable ride, without undue exposure to accelerations in any axis
- Acceptable noise and vibration levels
- Adequate cabin lighting, ventilation and climate control
- Fitted with overhead IV hooks, and sharps/biohazard waste receptacles
- Straightforward embarkation and disembarkation of patient and team
- Fitted with appropriate radios and mobile telephone

IV, Intravenous.

Ideally, dedicated vehicles should be used. Often the workload is insufficient to justify this, and nondedicated vehicles needing to be reconfigured are used. The mode of transport is based on a number of criteria:

- the availability of the transport vehicle
- the weather, especially if flying
- the distance to be travelled
- the location and capability of the retrieval team
- the urgency of the case
- the clinical capability of the referring hospital.

The coordination and tasking centre takes all these into consideration. All things being equal, the road is used for distances up to 40–80 km, rotary wing for 60–200 km and fixed wing for over 200 km.

ROAD AMBULANCE

This remains the most common form of transport and for some patients the safest – even for long distances.

FIXED WING

Both propeller-driven and jet aircraft are used. Compared with helicopters, their faster speed needs to be offset with the need for a road leg at each end of the transfer. In comparison to helicopters, fixed-wing aircraft have

Table 4.1 Properties of transport vehicles

	ROAD	HELICOPTER	FIXED WING
Launch time	3–5 min	5–10 min (more if IFR apply)	30–60 min
Speed	10–120 km/h dependent on roads and traffic	220–290 km/h, straight line	260–340 kph (piston) 420–500 kph (turboprop) 700–850 kph (jet)
Secondary transport	Not applicable	Sometimes	Inevitable
Effective range	0–100 km (longer if required)	50–300 km (longer or shorter in special cases)	200–2000 km
Noise	Low, except at high speed	Moderate to high (headsets required)	Low to moderate (cruise); higher on take-off/landing
Vibrations	Variable with speed and road surface	Moderate in most phases (varies with rotor type)	Low in cruise; moderate or high on take-off/landing
Accelerations	Variable and sometimes unpredictable in all axes	Minimal, and usually vertical only	Significant (fore/aft) on take-off and landing
Special features	Base vehicles readily available	Versatility; point to point capability	Cabin pressurisation and all-weather capability (most)
Acquisition cost	Lowest	High (US$5–15 million new, depending on capabilities)	Moderate (piston) to very high (jet)
Operating costs (per km)	Intermediate	Intermediate to high	Low to intermediate

IFR, Instrument flight rules.

lower cabin noise, the ability to pressurise the cabin (often to sea level), and the ability to fly in 'icing' conditions that increase their utility. Most aeromedical fixed-wing aircraft are specifically configured with stretcher-loading devices to assist in loading. Jets tend to be reserved for longer distance, greater than 800–1000 km.

HELICOPTERS

These remain the most high-profile and expensive vehicles used for patient transport but have been shown to be beneficial and cost effective.[9,17] Most will require significant adaption to provide a reasonable working space. The lack of space makes procedures such as intubation almost impossible. They are very noisy to work in, with conversation only possible via intercom systems. This makes communication with patients difficult. Whereas a mix of single-engine and twin-engine aircraft have been used in the past, changes by regulatory authorities in Europe and Australia mean that most helicopter transports are now being performed in more suitable, larger twin-engine aircraft. The optimal range for use is a 'donut' of 40–300 km and their main advantage is the ability to land on hospital helipads, removing an additional road leg. This, of course, requires the hospital to have a helipad. Helicopters may also have a role in the delivery of retrieval teams to trauma cases in high-traffic-density areas, such as London.

SAFETY

Any mode of transport involves some risk to patients and staff. In the aeromedical environment unfamiliar personnel perform clinical tasks poorly,[18] so teams must be appropriately trained and equipped to function effectively and safely in each mode of transport. A senior member of the professional group concerned should train and mentor new personnel on their first few trips.

A safety brief encompassing the use of safety equipment carried on the aircraft, emergency egress and actions to take during an emergency is essential. Daily meetings with helicopter flight crews can improve communication between all members of the 'team'.

Dangerous activities, such as unsafe driving and flying below safe minima, are unacceptable. For aviation missions, the decision whether a mission proceeds rests entirely with the aircraft pilot, and attempts to coerce pilots to take risks has been recognised as a contributor to air ambulance accidents.[19] The pilot should be provided with only the details of where the team needs to go. Clinical details should generally not be given as this may influence the decision to proceed with the mission.

ALTITUDE AND TRANSPORT PHYSIOLOGY

Teams need to be aware of altitude-related changes in gas, volume, temperature and partial pressures of oxygen (Table 4.2).

Patients already dependent on oxygen will be further compromised by even modest increases in height requiring further oxygen supplementation. It is the partial pressure not the percentage of oxygen that is critical. Monitoring of Sa_{O_2} during ascent is essential.

GAS EXPANSION

Expansion of trapped gas in accordance with Boyle's law occurs in physiological and pathological air spaces, and air-containing equipment such as endotracheal or tracheostomy tube cuffs, and Sengstaken–Blakemore tubes balloons. Endotracheal tube cuff pressures will need to be adjusted during flight. Delivered tidal volumes may increase spontaneously in some older ventilators, necessitating setting adjustments.

Physiological air spaces include the middle ear, nasal sinuses and GI tract. They can affect both patients and staff; consequently staff with upper respiratory tract infections or GI disturbances should not fly.

Pathological air spaces include pneumothoraces, emphysematous lung bullae, intraocular and intracranial open injuries, bowel obstructions and gas emboli. These patients need to be transported at the lowest altitude possible. Most modern fixed-wing aircraft are capable of cabin pressurisation, which decreases hypoxia and gas expansion. The pressurisation effectively replicates flying at a lower altitude – the so-called 'cabin altitude'. The difference between actual altitude and cabin altitude varies, with most air ambulances providing about 350 mm Hg (≈50 kPa) differential. This equates to a cabin pressure of 3000 ft (≈900 m) while flying at 20,000 feet (≈6000 m). Most commercial airliners fly with a cabin altitude of around 7000–9000 ft (≈2000–2700 m). Once the maximum differential is reached, a lower altitude cabin pressure can only be achieved by flying lower, which is often associated with more turbulence and increased fuel consumption. The medical team should only request a lower cabin height if clinically indicated.

The temperature falls 2°C for every 1000 ft (≈300 m) increase in height, as does the partial pressure of water, which is not corrected by cabin pressurisation. This can lead to dehydration, especially on long trips.

PREPARATION FOR TRANSPORT

The preparation phase for transport will depend on the patient's clinical condition. The ideal is to spend sufficient time, including any urgent surgery, stabilising the patient so that the transport phase is uneventful. As with intrahospital transport, this ideal may not be achievable, especially when the patient requires a time-critical intervention available only at the receiving destination. These missions are higher risk but are likely to be less futile than trying to stabilise an inevitably deteriorating patient. Prior to transport, all patients must have a secure airway, either self-maintained or intubated and ventilated, and well-secured intravenous access. External bleeding should be controlled, and investigations that may impact on the transport should be performed, if they can be done in a

Table 4.2 Changes with altitude

ALTITUDE (ft/m)	PRESSURE (mm Hg/kPa)	ALVEOLAR (ON AIR)	ALVEOLAR (100% O_2)	GAS SPACE EXPANSION (%)	STD TEMP (°C)	NOTES
Sea level	760 (≈100)	103	663	–	15	15°C is 'reference' average temperature – actual obviously varies
1000 (300)	733 (≈97)	98	636	+3.6	13	Minimum altitude above ground level for helicopter transports
2000 (600)	706 (≈94)	94	609	+8	11	Likely altitude for most visual flight rules (VFR) helicopter flights over sea-level terrain
3000 (900) 4000 (1200)	681 (≈91) 656 (≈87)	89 85	584 559	+12 +16	9 7	Likely range of *cabin* altitude for standard flights in most turboprop air ambulance craft (e.g. Raytheon–Beech King Air series)
7000 (2000)	586 (≈78)	73	489	+29	1	Standard *cabin* altitude for airliners and most jet air ambulances (e.g. Lear 35)
10,000 (3000)	523 (≈70)	61	426	+45	–5	Likely ceiling of helicopter ops and hypoxic threshold in normal individuals
15,000 (4500)	429 (≈57)	45	332	+77	–14.5	Threshold for hypoxic decompensation in nonacclimatised individuals
20,000 (6000) 25,000 (7500)	349 (≈50) 282 (≈37.5)	34 30	252 185	+117 +170	–24.5 –34	Likely upper range of cruise altitude for turboprop aircraft Decompression at these altitudes causes rapid loss of consciousness and death without O_2
40,000 (12,000)	141 (≈19)	<10	61	+439	–56	Cruise ceiling for airliners and jets Limit for survivable decompression, even with 100% O_2 for flight crew

short time-frame. Heimlich-type valves may be attached to any chest drains rather than bulky underwater seal drain devices. The patient is transferred to the stretcher and secured with the patient harness. Any equipment is also attached securely to the stretcher bridge. Any documentation and copies of investigations also need to be taken. A checklist for departure and transport is recommended and provided in Box 4.4.

During the early stages of movement, special vigilance must be employed as this is the stage when equipment disconnections or physiological decompensation is likely to occur. During transport the patient is vulnerable to hypothermia, and active warming should be considered. This can be achieved either by heating the vehicle or with a variety of commercial warming devices (e.g. blankets or fluid warmers).

HANDOVER

Handover to the receiving hospital is critical. Unless the patient needs immediate resuscitation there should be an opportunity for the retrieval team to have the exclusive attention of the receiving hospital. Various handover tools such as MIST (Mechanism of injury, Injuries suspected or found, Signs [vital signs] and Treatment given) are useful for trauma cases. ISOBAR has a wider application to all patient groups and is being promoted as the standard handover tool in many areas:

Box 4.4 Suggested pre-departure checklists

A. Before leaving hospital	
• Patient identity and next of kin	Recorded
• Consent for transport	Obtained and documented
• Paperwork and X-rays	Collected
• Drugs for transport	Present and sufficient
• Emergency drugs/ equipment	Available
• Medical equipment	Collected and repacked
• Monitors, ventilator and infusions	Connected, alarms set
• Tubes, lines, drains and catheters	Secured
• Altitude request (if applicable)	Passed to pilot
• Receiving unit	Contacted and updated
B. In vehicle and pre-departure	
• Stretcher and patient restraints	Secured and checked
• Oxygen supply	On and sufficient
• Monitors, ventilator and infusions	Working and secure
• Emergency drugs/ equipment	Stowed and accessible
• Other medical packs	Stowed
• Intravenous fluids	Hung and running
• Intravenous injection port	Accessible
• Medical power	On and connected
• Communications	Checked as applicable
• Seatbelts	On and checked
• Staff/patient headsets	On/checked (if applicable)

- I – introduction
- S – situation
- O – observations
- B – background
- A – assessment
- R – recommendations.

Retrieval teams should use the handover tool that is used in local practice. If one is not commonly used then ISOBAR will cover all the essential elements.

PRE-HOSPITAL CARE

Pre-hospital care of the acutely injured and critically ill is a complex and challenging field of medical practice. Ideally, patients should receive the most advanced required level of care at the earliest possible time, integrated with expedient transfer to the most appropriate definitive care facility. The ability to achieve this is both resource and system dependent with unique modifiers including transport platform logistics, environmental concerns and the need to integrate with other responding emergency services.

The benefits of adding a skilled critical care physician to the pre-hospital team are well recognised.[20] Service models across Australasia and Europe reflect this belief. The potential care delivered by such a team approaches or matches that only usually available in a tertiary hospital environment and may represent a 'definitive' requirement for the patient. However, the benefit of a physician and the safety and effectiveness of the team are maximised only if staff involved in such activities have the requisite skills and knowledge, and are familiar with the pre-hospital and retrieval environment.

APPROACH TO THE SCENE AND SCENE SAFETY

In any pre-hospital emergency situation safety is the primary concern. The pre-hospital retrieval (PHR) team should adopt the 'safe self, safe team, safe scene, safe patient' approach. Scene assessment is critical to ensuring team, scene and, ultimately, patient safety. It begins as soon as details of the task become available; plans for approaching the scene should be made on, or prior to, arrival.

PRE-HOSPITAL PLAN

A pre-hospital plan is a continuously evolving mental plan of action that the team will make as soon as it is activated, using the information given by the tasking agency. In many cases, this initial information is vague or incomplete, which reflects the problems experienced when receiving early phone calls about an incident. Although making a plan prior to arrival with limited information has drawbacks, there are clear benefits in arriving at the incident with a strategy for scene and patient management already in place. The plan often develops as the team travels to the scene and therefore valuable time en route should not be wasted.

When at the scene, the PHR team must have the skill to listen to all members of the emergency services and weigh up their suggestions as part of the overall plan. The ambulance service is the primary provider of pre-hospital care and paramedics are likely to be very experienced. It is worthwhile remembering that the physician-based pre-hospital teams are an extension of the ambulance service and not a replacement for them.

A generic pre-hospital plan could be:

- the scene:
  - a safe approach (self, team, scene and others)
- the patient:
  - likely requirements, need for extrication, assessment and stabilisation
- the destination:
  - triage options
  - transport platform options.

By having a pre-hospital plan, the team can add structure to their actions and, in doing so, develop a shared mental model inherent in teams that function in such high-acuity, high-consequence environments.

ENTRAPMENT AND EXTRICATION

Relative entrapment is a situation in which patients are trapped because of their injuries (e.g. a broken leg with disabling pain), location (e.g. a cave) or the ambient environment (e.g. a blizzard). If it were not for these factors, they would not require help in extricating themselves.

Actual entrapment occurs when patients are physically held in a location by the structure itself; for example, a major vehicle deformation with cabin intrusion, or a building collapse.

The aim is to remove the patient from an entrapped situation as safely and as quickly as possible. The key determinant in this plan (apart from safety) is the condition of the patient. The PHR team must decide on how to compromise between the slower, methodical extrication with total spinal control and the quicker extrication of the less stable patient. Clearly, unstable patients will need rapid extrication, but the ability to predict which patients are unsuitable for prolonged extrication due to the anticipated clinical course is more challenging. It may be better to compromise a degree of spinal protection earlier rather than have an emergency ('crash') extrication situation develop 30 minutes later.

The fire and rescue services will have access to the specialised equipment required. Without good teamwork between the services, the extrication will be significantly hindered.

ULTRASOUND IN THE FIELD

The availability of robust portable ultrasound machines has resulted in increased use in the pre-hospital or retrieval environment with good success; however, their use must be limited to people accredited in its use and must not result in undue delays in patient management.

Physiotherapy in intensive care

Mandy Jones, Fiona Moffatt, Evelyn Corner

Physiotherapeutic intervention is based on clinical reasoning following the identification of physiotherapy-amenable problems, which are elucidated from a thorough systematic assessment.[1]

There is still some debate about the precise role of the physiotherapist within the intensive care unit (ICU), which may vary,[2] but the main features include:

- optimisation of cardiopulmonary function
- assistance in the weaning process utilising ventilatory support and oxygen therapy
- instigation of an early rehabilitation/mobilisation program to optimise functional independence, assist in minimising the consequences of intensive care unit-acquired weakness (ICU-AW) and improve exercise tolerance
- advice on positioning to protect joints and to minimise potential muscle and soft tissue shortening, nerve damage and to effect muscle tone in the brain-injured patient
- management of presenting musculoskeletal pathology
- advice and education of family and carers
- close interdisciplinary team working and goal setting.

CARDIOPULMONARY PHYSIOTHERAPY

TREATMENT MODALITIES TO OPTIMISE CARDIOPULMONARY FUNCTION

Patients who are critically ill may present with impaired cardiopulmonary physiology secondary to both the underlying pathology and the therapeutic interventions employed to treat them. In their approach to any individual patient, the physiotherapist may use specific treatment techniques targeted at improving ventilation/perfusion (V/Q) disturbances, increasing lung volumes, reducing the work of breathing and removing pulmonary secretions. Physiotherapy treatment modalities may differ depending on the presence of an endotracheal tube, although patient participation with treatment is encouraged and promoted at the earliest point during intubation. Each intervention is rarely used in isolation, but rather as part of an effective treatment plan. Some physiotherapeutic techniques may have short-lived beneficial effects on pulmonary function, and some have no clear evidence to validate their effectiveness.

LUNG HYPERINFLATION

Therapeutic lung hyperinflation has been used for many years by physiotherapists in the management of patients in the ICU.[3–7] Lung hyperinflation can be achieved through two techniques: manual hyperinflation (MHI) or ventilator hyperinflation (VHI).

MHI uses a self-inflating circuit to deliver a volume of gas 50% greater than tidal volume (V_T), to airway pressures up to 40 cm H_2O, via an endotracheal or tracheostomy tube. An augmented V_T may improve pulmonary compliance and aid recruitment of atelectatic lung, secondary to reduced air-flow resistance and enhanced interdependence via the collateral channels of ventilation.[8] A manometer can be included in the MHI circuit to limit augmented breaths to a predetermined pressure, where there is a risk of barotrauma. Bronchial secretions may be mobilised by the increased expiratory flow rate and/or stimulation of a cough following a quick release of pressure from the bag on expiration.[9] The aim is to achieve an expiratory flow rate 10% greater than inspiratory flow to move secretions centrally up the bronchial tree for removal via endotracheal suction.[10] The net effect can result in improved oxygenation.[8] It is possible to incorporate a positive end-expiratory pressure (PEEP) valve within the MHI circuit to maintain adequate PEEP and limit de-recruitment and atelectotrauma during intervention. However, MHI may be contraindicated in some ICU patients; therefore the use of VHI offers an alternative method to augment lung volume whilst potentially avoiding cardiopulmonary instability associated with ventilator disconnection and loss of high levels of PEEP in dependent patients. VHI involves the delivery of an augmented V_T via the ventilator (200 mL increments until a peak airway pressure of 40 cm H_2O is reached). A recent systematic review evaluating the efficacy of VHI compared to MHI, reported no statistical differences in sputum wet weight, dynamic and static pulmonary compliance and oxygenation and cardiovascular stability between VHI and MHI in adults receiving mechanical ventilation.[11]

ABSTRACT

The physiotherapist has an important and varied role within the intensive care unit/high-dependency unit (ICU/HDU) setting working as part of the interdisciplinary team to optimise cardiopulmonary function and functional ability.

The role of the physiotherapist may include: optimisation of cardiopulmonary function, assistance in the weaning process utilising ventilatory support and oxygen therapy, instigation of an early rehabilitation/mobilisation program to optimise functional independence, assist in minimising the consequences of intensive care unit-acquired weakness (ICU-AW) and improve exercise tolerance. Additionally, the physiotherapist may advise on positioning to protect joints and to minimise potential muscle and soft tissue shortening, nerve damage and to effect muscle tone in the brain-injured patient, the management of presenting musculoskeletal pathology, and the education of family and carers and the close interdisciplinary team working and goal setting.

KEYWORDS

Cardiopulmonary function
weaning
ventilatory support
early rehabilitation/mobilisation programs
intensive care unit-acquired weakness

Box 5.1 Potential advantages and complications of manual hyperinflation

Potential advantages
- Reversal of acute lobar atelectasis[8]
- Alveolar recruitment via channels of collateral ventilation[8]
- Improvement in arterial oxygenation
- Mobilisation of secretions and contents of aspiration[12]
- Improved static lung compliance[12]
- Effectiveness may be increased when combined with appropriate positioning and manual techniques[1]

Potential complications
- Absolute contraindications include undrained pneumothorax and unexplained haemoptysis
- Cardiovascular and haemodynamic instability[6]
- Loss of PEEP, inducing hypoxia and potential lung damage. This can be minimised by incorporating a PEEP valve into the circuit of a 'PEEP-dependent' patient
- Risk of volutrauma, barotrauma and pneumothorax, which can be reduced by including a manometer in the circuit
- Risk of increased intracranial pressure
- Increased patient stress and anxiety

PEEP, Positive end-expiratory pressure.

Box 5.2 Potential advantages and complications of suction

Potential advantages
- Stimulation of a cough when reflex is impaired by mechanical stimulation of the larynx, trachea or large bronchi
- Removal of secretions from central airways when cough is ineffective or absent

Potential complications
- Tracheal suction is an invasive procedure and should be undertaken only when there is a clear indication
- Absolute contraindications to suctioning are unexplained haemoptysis, severe coagulopathies, severe bronchospasm, laryngeal stridor, base of skull fracture and a compromised cardiovascular system
- Hypoxaemia can be induced secondary to suctioning. This can be limited by pre- and post-oxygenation
- Cardiac arrhythmias may be more common in the presence of hypoxia
- Tracheal stimulation may produce increased sympathetic nervous system activity or a vasovagal reflex producing cardiac arrhythmias and hypotension

In an emergency situation, an Ambu-bag and facemask can be used to perform MHI in the self-ventilating patient. However, an alternative technique, such as intermittent positive pressure breathing (IPPB), should be considered when an augmented V_T is required during a therapeutic intervention (Box 5.1).

SUCTION

Suction is used to clear secretions from central airways when a cough reflex is impaired or absent. A suction catheter is passed via an endotracheal or tracheostomy tube or via a nasal/oral airway to the carina, which may stimulate a cough in a non-paralysed patient (Box 5.2). The catheter is pulled back 1 cm before suction is applied on withdrawal. The suction catheter diameter should not be greater than 50% of the diameter of the airway through which it is inserted as large negative pressure can be generated intrathoracically without air entrainment. The use of suction following effective MHI/VHI optimises the removal of secretions.[13] Instillation of normal saline prior to suctioning remains controversial; however, it may stimulate a cough, maximising secretion mobilisation and clearance. Endotracheal suction of bronchial secretions can be achieved using either a conventional open catheter system, or via a closed-circuit suction catheter sited within the ventilator circuit. As the closed circuit catheter is intrinsic to the ventilator circuit, disconnection of the ventilator is not necessary during usage, which prevents potential spraying of respiratory secretions, additional movement of the endotracheal tube, loss of oxygenation or de-recruitment secondary to loss of PEEP.[14] However, no significant difference was found in the incidence of ventilator-associated pneumonia or mortality rates between patients treated with open or closed circuit suction.[14]

INSPIRATORY MUSCLE TRAINING

Mechanical ventilation, sepsis and the iatrogenic effects of enforced immobility may result in widespread deconditioning, including weakness or fatigue of the respiratory muscles, resulting in slow or failed weaning from ventilatory support.[15] It has been suggested that mechanical ventilation may adversely alter diaphragmatic myofibril length and function, leading to rapid atrophy.[16] Residual inspiratory muscle impairment has been demonstrated in intensive care survivors ventilated for 7 days or longer.[11,17] This residual respiratory muscle weakness may contribute to on-going dyspneoa,[17] impaired physical function[17,18] and poor quality of life in ICU survivors.[19] The instigation of inspiratory muscle training (IMT) has been shown to improve respiratory muscle strength in patients during mechanical ventilation.[20–24] Systematic reviews evaluating the effect of IMT on muscle strength in adults weaning from mechanical ventilation reported a significant increase in inspiratory muscle strength following muscle training,[25] and suggested that IMT performed prior to extubation enhances weaning success, but did not reduce rates of reintubation or survival rate.[26] More recently, IMT following successful weaning has been shown to increase inspiratory muscle strength and quality of life.[27]

MANUAL TECHNIQUES

CHEST SHAKING AND VIBRATIONS

Shaking and vibrations are oscillatory movements of large and small amplitude performed during expiration, which are thought to increase expiratory flow rate, aiding mucociliary clearance.[28] The application of chest wall shaking and vibrations is not standardised, but their effectiveness is thought to be influenced by the timing of their application within the breath cycle. Shaking and vibrations applied early in the expiratory cycle have been shown to generate high peak expiratory pressures, whereas shaking and vibrations applied late in the expiratory cycle are not effective at increasing peak expiratory flow.[29] It has been found that vibrations increased peak expiratory flow rates by more than 50% compared to relaxed, passive expiration[28] and enhances sputum clearance.[30] The application of vibrations is of particular importance to increase expiratory flow rate when using VHI compared to MHI, in the absence of a quick release of the bag. Additionally, it has been demonstrated that the application of chest wall vibration in combination with positioning was associated with a 27% reduction in rates of ventilator-acquired pneumonia.[31]

CHEST WALL COMPRESSION

Compression of the chest wall can be used to augment an expiratory manoeuvre such as a 'huff' (see section on active cycle of breathing technique [ACBT]) or a cough by providing tactile stimulation or wound support.

MANUALLY ASSISTED COUGH

Patients with neuromuscular disease (NMD) or spinal cord injury may present with inspiratory and expiratory muscle weakness and an effective cough.[32] These patients are unable to access adequate inspiratory reserve volume to produce expiratory flow rates of sufficient force to mobilise secretions or generate an effective cough.[32] A manually assisted cough can be achieved via an inward and upward compression to the anterior chest wall, costophrenic or abdominal (Heimlich type manoeuvre), during the expiratory part of the respiratory cycle.[33–35] This significantly increases peak cough flow,[36] to move secretions in a cephalad direction, prior to removal via oral or endotracheal suction.

POSITIONING

A simple change of position can have a profound effect on cardiopulmonary physiology.[37,38] As such, positioning is commonly utilised to achieve several different goals: drainage of secretions using gravity-assisted positioning (GAP), reduction of the work of breathing/breathlessness or to recruit lung units and optimise V/Q matching.

GRAVITY-ASSISTED POSITIONING

GAP facilitates the removal of excess bronchial secretions by positioning a specific bronchopulmonary segment perpendicular to gravity (Box 5.3). This technique is not used in isolation but in conjunction with augmented V_T, either via VHI, MHI or the ACBT in a spontaneously breathing patient. An individual position exists for each bronchopulmonary segment based on the anatomy of the bronchial tree[39]; however, in patients with neurological, cardiorespiratory or haemodynamic instability, these may need modification in the ICU setting. In the ICU, side lying (modified GAP) is commonly used when treating a patient with manual or VHI[40]; in this position preferential ventilation occurs in the uppermost lung, allowing filling and recruitment of slower filling alveoli, whilst facilitating the drainage of bronchial secretions, thus optimising gas exchange.[41] Research has confirmed a significantly increased sputum yield with the use of side lying in conjunction with hyperinflation.[40]

A reduction in the work of breathing/breathlessness can be achieved by putting a patient in a position that optimises the length–tension relationship of the diaphragm, promotes relaxation of the shoulder girdle and upper chest and facilitates the use of breathing control.[42] This approach to positioning is particularly effective when used in conjunction with noninvasive ventilation (NIV). Adequately supported high side lying is a useful position to promote relaxation of the breathless patient. In addition, it can discourage the overuse of accessory muscles of respiration, which may reduce energy expenditure. Some patients prefer forward lean sitting with their arms placed in front of them on a high table. In this position, the length–tension relationship of the diaphragm is optimised secondary to forward displacement of the abdominal contents.

VENTILATION/PERFUSION

Appropriate positioning of a patient can maximise V/Q.[42,43] In the self-ventilating adult, V/Q matching increases from non-dependent to dependent areas of the lung.[44] However, in adults receiving positive-pressure ventilation, lung mechanics are altered producing V/Q

Box 5.3 Potential advantages and complications of gravity-assisted positioning

Potential advantages

- Maximises removal of excess bronchial secretions when combined with the ACBT
- Allows accurate treatment of specific bronchopulmonary segments
- Self-treatment can be included in a home programme on discharge

Potential complications

- Positions need modification when used in the presence of cardiovascular/neurological instability, haemoptysis or gastric reflux

ACBT, Active cycle of breathing technique.

inequality. In this situation non-dependent areas of lung are preferentially ventilated while dependent regions are optimally perfused; as such, a regular change of position is recommended. Additionally, evidence exists to support regular turning of patients from side to side with a 40-degree lateral turn, as this may reduce the incidence of ventilator associated pneumonia (VAP).[45] In an extreme form, prone positioning has been used to improve refractory hypoxaemia in patients with acute lung injury (ALI)/acute respiratory distress syndrome (ARDS). The mechanisms behind these improvements are complex, but probably centre around a combination of a redistribution of some pulmonary perfusion together with a more homogeneous distribution of ventilation leading to improved V/Q matching. Although prone positioning improves oxygenation in up to 70% of those with ALI/ARDS, its role in improving outcome remains controversial.[2]

ACTIVE CYCLE OF BREATHING TECHNIQUE

The ACBT is a cycle of breathing exercises used to remove excess bronchial secretions (Box 5.4).[5] The cycle can be adapted for each patient according to existing underlying pathology and presenting clinical signs. It consists of:

- breathing control × 4 to 6 breaths
- normal tidal breathing using the lower chest
- minimising the use of accessory muscles of respiration
- promoting relaxation
- lower thoracic expansion × 4 to 6 breaths
- can be used with/without an inspiratory hold
- forced expiration technique
- expiration with an open glottis ('huff'), combined with breathing control.

Box 5.4 Potential advantages and complications of active cycle of breathing technique

Potential advantages

Mobilises and clears excess bronchial secretions[28]

Improves lung function[28]

Minimises the work of breathing

Individual components of the cycle can be utilised/emphasised to target specific problems

Can be used in combination with other manual techniques, GAP, V/Q matching, positioning to reduce breathlessness, and during activities such as walking

Self-treatment can be included in a home programme

Potential complications

Without adequate periods of breathing control, bronchospasm and desaturation can occur

Poor technique can lead to ineffective treatment and unnecessary energy expenditure

GAP, Gravity-assisted positioning; *V/Q*, ventilation/perfusion.

Although mainly used in the self-ventilating patient, alert, cooperative, ventilated patients can participate with this technique. The ACBT can be delivered via MHI or VHI in sedated and ventilated patients requiring mobilisation of secretions and airway clearance.

MECHANICAL ADJUNCTS

INTERMITTENT POSITIVE-PRESSURE BREATHING

IPPB is a patient-triggered, pressure-cycled mechanical device mainly used in self-ventilating patients to increase ventilation, re-expand lung tissue, mobilise bronchial secretions and reduce the work of breathing by augmenting V_T (Table 5.1).[46] Delivered via a facemask, mouthpiece or via tracheostomy, positive airway pressure is maintained throughout inspiration; expiration is passive. IPPB requires constant adjustment of pressure and flow rates and careful patient monitoring to maintain effectiveness and cooperation. Effectiveness is increased when used in conjunction with positioning, ACBT and manual techniques (Box 5.5). Nebulised agents, such as saline or bronchodilator drugs, can be incorporated into the IPPB circuit to further facilitate airway clearance.

MECHANICAL INSUFFLATION–EXSUFFLATION

Mechanical insufflation–exsufflation is a device that initially delivers a positive inspiratory pressure above tidal volume to increase ventilation, re-expand lung tissue and mobilise bronchial secretions, followed by an expiratory negative pressure increasing expiratory flow rate and stimulating a cough.[47] In some patient groups, the use of mechanical insufflation–exsufflation may negate the requirement for tracheal suctioning[48] or delay the need for tracheostomy.[49] A manually assisted cough may also be applied by the physiotherapist during the negative, expiratory phase to further augment expiratory flow and cough stimulation.[32] This mechanical

Table 5.1 Medical Research Council sum score

Box 5.5 Potential advantages and complications of intermittent positive pressure breathing, continuous positive airways pressure and non-invasive ventilation

Potential advantages
Improves lung volumes
Improves gaseous exchange
Decreases the work of breathing
IPPB and NIV can mobilise excess bronchial secretions by improving V_T
IPPB and NIV can improve lung and chest wall compliance
CPAP reduces left ventricular afterload by reducing the transmural pressure gradient
Patients can be mobilised while on CPAP and some modes of NIV; alteration of ventilator settings might be indicated to maximise patient potential/exercise tolerance during treatment
Settings can be adjusted to augment physiotherapy intervention (e.g. increased IPAP to assist removal of secretions)
Potential complications
Absolute contraindications include severe bronchospasm, undrained pneumothorax, pneumomediastinum, unexplained haemoptysis and facial fractures; use with care in pre-existing bullous lung disease
Haemodynamic/neurological instability
Risk of decreased urine output with CPAP and NIV
Risk of carbon dioxide retention with CPAP
Risk of aspiration

CPAP, Continuous positive airways pressure; *IPAP*, inspiratory positive airway pressure; *IPPB*, intermittent positive pressure breathing; *NIV*, non-invasive ventilation.

device can be applied by face mask, tracheostomy or endotracheal tube.

CONTINUOUS POSITIVE AIRWAYS PRESSURE

Continuous positive airways pressure (CPAP) maintains a positive airway pressure throughout inspiration and expiration. It is used in both intubated and self-ventilating patients to increase/normalise functional residual capacity (FRC) via recruitment of atelectatic lung. Clinically, increased FRC is associated with improved lung compliance, improved oxygenation and reduced work of breathing.[46] Effectiveness increases when used in conjunction with appropriate positioning. The self-ventilating patient must be able to generate an adequate V_T as this volume is not augmented with CPAP (Table 5.2). Research supports the application of intermittent CPAP in the treatment of acute cardiogenic pulmonary oedema[50] and type I respiratory failure secondary to postoperative atelectasis[51]; however, non-invasive bi-level ventilation (NIV or bi-level positive airway pressure [BIPAP]) has greater efficacy compared to CPAP in the reversal of atelectasis in patients post-cardiac surgery.[52]

NON-INVASIVE VENTILATION

The role of NIV in the ICU is well established. This includes the prevention of invasive ventilation in patients with hypercapnic respiratory failure secondary to chronic obstructive pulmonary disease (COPD), cardiogenic pulmonary oedema and immunocompromise, and early weaning from mechanical ventilation; however, NIV should not be used routinely for unexpected post-extubation respiratory failure.[53] Physiotherapists play a key role in the instigation and application of NIV,[51] including the selection of delivery machine and patient interface. Careful and appropriate application of NIV has been linked to increased patient tolerance and successful outcome. Physiotherapy may be instigated whilst NIV is in situ, or during rest periods if the application of NIV is intermittent. Inspiratory positive airway pressure (IPAP) may be augmented to increase V_T during physiotherapy treatment to aid the removal of secretions, or to support mobilisation of the patient (see Table 5.2). In patients with NMD, if augmentation of IPAP is not effective to clear secretions, mechanical insufflation and exsufflation and assisted cough can be used.[53] Improved oxygenation may be achieved using NIV when the patient is positioning to optimise V/Q (see Box 5.5).

LONG-TERM TRACHEOSTOMY MANAGEMENT AND WEANING

Peripheral muscle weakness and respiratory muscle weakness are inter-related and must be treated accordingly. Weaning plans must be carefully balanced with functional rehabilitation, ideally with an integrated interdisciplinary team (IDT) weekly plan in place for the long-term patient.[54] The physiotherapist plays a vital role in this IDT.

A tracheostomy is a surgical incision in the trachea, which allows the insertion of a tracheostomy tube for the purpose of: airway protection, to facilitate prolonged mechanical ventilation, to bypass obstruction and/or for secretion management.[55]

There are many different types of tracheostomy tube available:

- *Cuffed and uncuffed*: The cuff is inflated around the tracheostomy tube to reduce aspiration risk and to ensure adequate ventilation and PEEP. Uncuffed tracheostomies can be used in patients free from mechanical ventilation with sufficient airway protection.[56]
- *Single or double lumen*: Most tracheostomies in adults will be double lumen, to allow the inner tube to be removed and cleaned thus reducing the risk of airway occlusion.
- *Fenestrated and non-fenestrated*: fenestrated tracheostomies have holes in the outer cannula, which

Table 5.2 Summary of functional assessment tools for intensive care unit

The Chelsea Critical Care Physical Assessment (CPAx)[105–107]	The CPAx is a scale of function which allows grading of patients on a Guttman scale from 0 (dependent) to 5 (independent) in 10 domains to give an aggregate score out of 50. These domains are: rolling, supine to sitting on the edge of the bed, sitting balance, standing balance, sit to stand, transfers, stepping, standing balance, respiratory function, cough and grip strength. The inclusion of the respiratory components makes this scale unique
The Functional Status Scale for ICU (FSS-ICU)[108,109]	The FSS-ICU is an ordinal scale evaluating a patient's function on a scale from 0 (unable) to 7 (completely independent) to give total score out of 35. The tasks included are: rolling, transfer from spine to sit, sitting at the edge of bed, transfer from sit to stand, and walking. The patient is given an aggregate score out of 35
Physical Function in Intensive care Test scored (PFIT-s)[110,111]	The PFIT-s is an interval scale from 0 to 10. It contains four items: assistance with sit to stand (i.e. 0, 1 or 2 people), cadence (steps/min), strength of the shoulder flexors and strength of the knee extensors (as per the MRC scale). The PFIT-s can be used to prescribe an exercise programme to patients on ICU
ICU Mobility Scale (IMS)[112,113]	The ICU Mobility Scale is an ordinal measure of mobility milestones from 0 to 10. The patient is scored based on their maximal level of activity progressing from bed bound (0), to bed exercises (1), passive transfer from bed to chair (2), sitting over the edge of the bed (3), standing (4), active transfer from bed to chair (5), marching on the spot (6), and finally walking with varying degrees of assistance (7–10)

MRC, Medical Research Council.

reduce airway obstruction and allow air to pass through the upper respiratory tract (URT). These can be used to facilitate weaning; however, they can cause the formation of problematic granulation tissue and increase the risk of aspiration.[57]

Although tracheostomy insertion is often essential, the placement of a tracheostomy has many negative consequences due to altered mechanics of the URT, these are[58,59]:

- preventing the patient from speaking, as air bypasses the vocal cords
- inhibiting a normal swallow by tethering the larynx, inhibiting epiglottal closure and preventing positive subglottic pressure
- inhibiting normal cough mechanics, which are dependent on sufficient vital capacity, respiratory muscle strength, expiratory flow and epiglottal closure
- reducing smell and taste due to lack of airflow through the URT
- bypassing the natural humidification systems
- losing intrinsic PEEP leading to atelectasis
- as glottal structures contribute to the control of expiratory airflow, and thus intrathoracic and intra-abdominal pressure, the presence of a tracheostomy may also reduce postural stability and the activation of core-stabilising muscles, therefore impacting upon the patient's functional recovery.[60]

SPEAKING AND SWALLOWING VALVES

Speaking valves can be used to facilitate weaning and decannulation by helping to restore normal physiology in the URT. The Passy-Muir speaking and swallowing valve (PMSV) is a one-way valve placed on the end of a tracheostomy, or in the ventilation circuit.[59] When a PMSV is in situ, air can be inspired both through the tracheostomy tube and the mouth; at the end of inspiration the valve closes occluding the tracheostomy tube and thus preventing expiration via the tracheostomy. This means that all expired gas will travel through the URT and past the vocal cords. It is essential that the cuff is deflated when using the PMSV to allow expiration.

Use of the PMSV allows the patient to speak, eat, drink, taste and smell, which has significant psychological benefits.[61] It also facilitates normal cough mechanics, may facilitate rehabilitation by allowing recruitment of core stabilising muscles, and has been shown to facilitate weaning from mechanical ventilation. The use of the PMSV should be an IDT decision, with input from speech and language therapy.[54]

DECANNULATION

Decannulation is the process of weaning/removing the tracheostomy tube.[54] The decision to decannulate is not always a simple one and requires an integrated approach,

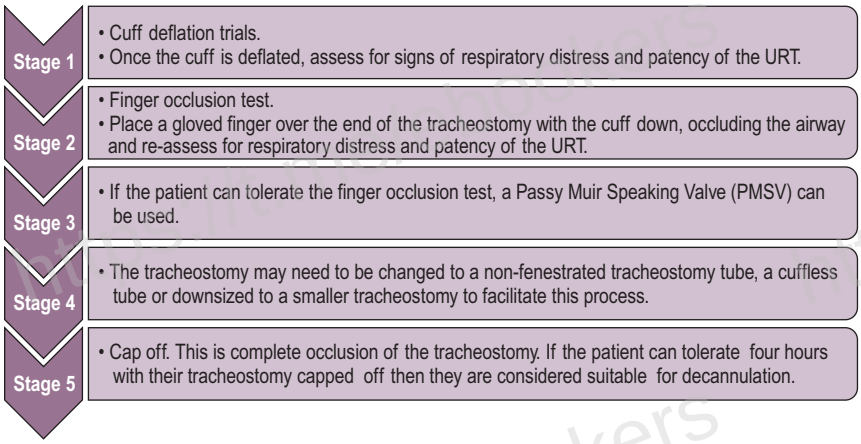

Figure 5.1 Step-wise approach to weaning and decannulation. *URT*, Upper respiratory tract.

as delays can lead to long-term complications. There are many factors that will need consideration prior to decannulation, and practice varies. A typical approach to weaning/decannulation is presented in Fig. 5.1.[56,62]

CRITICAL CARE REHABILITATION

PHYSICAL IMPAIRMENT AND INTENSIVE CARE UNIT-ACQUIRED WEAKNESS

The effects of deconditioning on the cardiovascular, respiratory and neuromusculoskeletal systems are well documented.[63–65] This phenomenon occurs as a result of restricted physical activity, and reduces the ability to perform work. Such physical impairment can occur with even relatively short periods of immobility. The addition of critical illness (which initiates a hypercatabolic response) further compounds muscle wasting and dysfunction, and often results in a state of global and persistent weakness that cannot be attributed to anything other than the critical illness itself.[66] Historically, this phenomenon of generalised weakness has been identified using a range of terminologies, but is now referred to using a clinical diagnostic label of ICU-AW.[67] A diagnosis of ICU-AW is made using, where possible, the Medical Research Council (MRC) sum score; a total score of <48/60 is considered indicative of ICU-AW.[68] Electrophysiological examination may also be used where the clinical presentation is atypical or where the patient is not awake and fully cooperative. Respiratory muscle strength should also be considered, using maximal inspiratory pressure measurement.[69,70]

The incidence of ICU-AW in patients admitted to adult ICU has been reported across studies as 9% to 86%.[71,72] A recent systematic review of 33 studies and 2686 patients reported an incidence of 40% (95% confidence interval 38%–42%) but concluded that this was influenced by the diagnostic technique used; clinical techniques were associated with a lower incidence than electrophysiological techniques.[67] The sequelae of ICU-AW are diverse, including: prolonged weaning from mechanical ventilation; increased length of ICU and hospital stay; increased hospital mortality; increased hospitalisation costs; increased 180-day mortality; persistent weakness; decreased physical functioning; and reduced quality of life post-ICU discharge.[67,70] ICU-AW may also play a contributory role in post-intensive care syndrome.[70]

ICU-AW is complex and multifactorial, involving functional and structural changes in both muscle and nerves.[66,70] Muscle atrophy results from imbalances in the breakdown and synthesis of muscle protein (especially myosin). This is thought to be directly influenced by pro-inflammatory mediators, immobility, stress-induced cytokines, nutritional deficits, impaired microcirculation and denervation.[70,73] Furthermore, other factors may impair muscle function, particularly reduced membrane excitability secondary to sodium channel dysfunction, altered excitation-contraction coupling due to changes in intracellular calcium, mitochondrial dysfunction and deficient autophagy.[70] A number of independent 'risk factors' for the development of ICU-AW have been suggested, including: sepsis; systemic inflammatory response syndrome (SIRS); multiorgan failure; severity of illness (high acute physiology and chronic health evaluation [APACHE] score); hyperglycaemia; duration of immobilisation; use of corticosteroids and neuromuscular blockade; age; and premorbid functional status.[70] Given that the consequences of ICU-AW are significant in terms of patient outcome, length of hospital stay, duration of rehabilitation and subsequent ability to function independently in the community,[74–78] there has been a paradigm shift in critical care management to reduce iatrogenic risk factors and to ensure daily screening for weakness.[66] Care bundles, such as the ABCDE approach (Awakening and Breathing coordination, Choice of sedative or analgesic exposure, Delirium monitoring

and management, Early mobility and Exercise), have been advocated in order to optimise patient recovery and outcome.[78,79]

PHYSIOTHERAPY REHABILITATION

The role of early mobility and exercise in attenuating the deleterious effects of immobility during critical illness is now widely reported.[80] Early mobilisation and/or exercise of critically ill patients via selected rehabilitation strategies has been demonstrated in certain studies to be safe and feasible, to reduce length of stay, decrease the incidence of delirium, increase the number of ventilator-free days and to improve physical function.[70,80–83] Based on growing evidence, the European Respiratory Society, the European Society of Intensive Care Medicine, and the National Institute of Health and Clinical Excellence have promoted early instigation of individualised rehabilitation programmes to prevent avoidable physical dysfunction.[84,85] Early mobilisation programmes may, however, face cultural and technological barriers.[77,86] There is certainly inconsistency in the delivery of early mobilisation practices globally.[87] As such, proponents advocate a shift from multidisciplinary 'silos' to collaborative interdisciplinary care.[78,88] The physiotherapist, possessing expertise in rehabilitation and exercise physiology, should play a key coordination role in these programmes by evaluating individual patients, devising a shared therapeutic strategy, and referring to other rehabilitative specialties (e.g. speech and language therapy, occupational therapy) as required.[84]

Careful assessment both before (and during) implementation of an early mobilisation/exercise program must be undertaken by a suitably experienced physiotherapist. A number of authors have suggested algorithms or criteria for this process.[80,83,89,90]

Traditionally, exercise rehabilitation has progressed linearly from activity in bed, then sitting, and finally to standing/walking. The model demonstrated in Fig. 5.2 represents a three-stage functional rehabilitation programme. It is supported by evidence that suggests a multimodal training regimen is required to maintain/restore both physiological and psychological performance after a period of immobility and illness.[91] The use of interlinking circles is intended to reflect the non-linear pattern of exercise progression more commonly utilised in patients with critical illness (e.g. patients may be able to stand using a tilt-table before they are able to tolerate sitting out of bed). The central shaded area represents the core components that should be addressed at every stage in the patient's recovery. The areas bordered by the broken lines represent the progression or regression from one stage to the next. During all stages, the patient's cardiopulmonary response must be closely monitored and exercise titrated accordingly. Modifications (e.g. temporarily increasing the FiO_2 and/or the level of ventilatory assistance) during exercise and in the early post-exercise

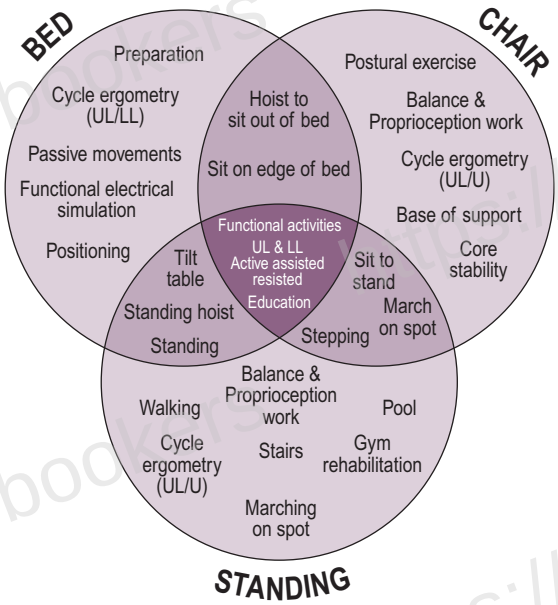

Figure 5.2 Schemata representing three-stage functional rehabilitation programme (the Nottingham Critical Care Rehabilitation Model). *LL*, Lower limb; *UL*, upper limb. *(From Douglas E. The Nottingham Critical Care Rehabilitation Model, University of Nottingham Division of Physiotherapy.)*

period may be necessary. Such modifications are commonly required as increasing physical activity often coincides with weaning from ventilatory support – both of which are significant challenges to the physiological reserve. All aspects of progressive exercise therapy should be considered, including positioning, passive and active mobilisation, aerobic training, balance and proprioceptive training and muscle strengthening.[70,84,92] Adjuncts, such as continuous passive motion, splinting, bedside cycle ergometry or functional electrical stimulation, may also be warranted.[70,92] To date, empirical data regarding the optimal timing, nature and dosage of early mobilisation remain equivocal.[87] Early mobilisation/rehabilitation of the diaphragm also should be a consideration with appropriate intervals of spontaneous breathing, and possibly IMT in the post-ICU phase.[69,70] The wealth of evidence regarding deconditioning should play a central role in planning treatment, both preventative and rehabilitative. For example, those muscle groups most adversely affected by disuse should be targeted first with a gradual, progressive regimen. During the re-mobilisation period, the IDT must be particularly mindful of those elements with delayed recovery; for example, orthostatic tolerance and bone mass (predisposition to falls and fractures), and muscle endurance (diminished exercise tolerance). It has been suggested that, in order to improve long-term outcomes for survivors of ICU (e.g. late mortality, ongoing morbidity, neurocognitive

defects, functional disability, quality of life, economic burden), critical illness and its management should be viewed on a continuum and not merely the time spent in a critical care facility.[74] As such, rehabilitation should reflect this, continuing into the community, outpatient or follow-up clinic setting.[73,93] Mitochondrial dysfunction is likely to persist well into the post-critical illness phase, impairing lactate clearance and contributing to other exercise metabolic dysfunction, thereby further adversely affecting exercise capacity.[73] Although the psychological, cardiopulmonary and functional sequelae of critical care survival may be profound, to date the optimal strategies for delivering post-critical care rehabilitation services remain unclear.[94,95] Contemporary debate suggests that individualised exercise prescription programmes, with tailored progression and patient education regarding self-monitoring of exercise, are likely to confer benefits.[73,93]

FUNCTIONAL ASSESSMENT IN INTENSIVE CARE UNIT

Clinical diagnosis and assessment of physical morbidity is an important part of the physiotherapist's role.[96] This allows the monitoring of response to physiotherapy interventions as well as tracking of functional recovery.[94]

The World Health Organisation International Classification of Functioning, Disability and Health (ICF) model categorises physical morbidity at three levels: impairment (issue with a bodily structure or function), activity limitation (functional tasks) and participation restriction (restrictions in the ability to integrate in wider societal activities).[94,97,98] In the ICU, assessment of impairment and activity limitation is the most common, that is, muscle strength, muscle mass and physical function.[97]

MUSCLE STRENGTH

Muscle strength can be assessed using the MRC sum score. This is recommended as a diagnostic tool for ICU-AW.[70,99,100] The MRC sum score is a volitional test that grades 12 major muscles groups on a scale of zero to five depending on the amount of muscle activity, giving a total score out of 60. A score of <48/60 is considered diagnostic of ICU-AW. The scale is summarised in Table 5.1. Although this is a useful clinical tool, it can lack reproducibility, and its volitional nature requires an alert and cooperative patient, which may limit its use.[70] Hand-held dynamometry and grip strength also can be used to assess muscle strength.[99]

MUSCLE MASS

Ultrasonography can be used reliably to measure the cross-sectional area of skeletal muscles as a measure of mass; this is associated with both muscle strength and ICU length of stay.[101–104] Changes in muscle mass are most commonly detected in the lower limb due to the impact of reduced mechanical loading associated with bed rest.[104]

PHYSICAL FUNCTION

There are 26 different measures of physical function that have been designed and trialled in the ICU[97]; however, the most clinimetrically robust are the Chelsea Critical Care Physical Assessment tool (CPAx),[105–107] the Functional Status Scale for ICU (FSS-ICU),[108,109] the Physical Functional Test for ICU (scored) (PFIT-s)[110,111] and the ICU Mobility Scale.[112,113] These scales are all reproducible and capable of accurately assessing function and detecting meaningful change.[97,114] Table 5.2 describes these tools in more detail.

SUMMARY

The physiotherapist has an important and varied role within the ICU/high-dependency unit (HDU) setting working as part of the IDT to optimise cardiopulmonary function and functional ability. The physiotherapist is often uniquely placed to follow and treat a patient from the acute stages at ICU admission, through the rehabilitation process to subsequent discharge from hospital and, if necessary, treatment can be continued in the outpatient setting.

There is no longer a place for routine physiotherapy treatment. Regular systematic assessment will identify physiotherapy-amenable problems that contribute to an interdisciplinary care plan. Implementation of any physiotherapy treatment should always utilise continuous analytical reassessment.

Critical care nursing

John R Welch

NATURE AND FUNCTION OF CRITICAL CARE NURSING

Nurses are the round-the-clock constant factor for critically ill patients and their families, providing continuity and acting as the 'glue' that holds the intensive care unit (ICU) together. Nurses fine-tune, coordinate and communicate the many aspects of treatment and care needed to manage their patients '*responses to actual or potential life-threatening problems*',[1] including

- continuous, close monitoring of the patient and attached apparatus
- dynamic analysis and synthesis of complex data
- anticipation of complications
- complex decision making, and the execution and evaluation of interventions to minimise any adverse effects
- enhancement of the speed and quality of recovery
- emotional support of the patient and family, including support through the end of life.

Nursing in critical care is influenced by the essential nature of nursing as well as the specific requirements of the specialty. Key concepts for all nurses are said to include an appreciation of holism and the whole range of influences on all areas of life, and the pursuit of health rather than the treatment of illness.[2]

However, inevitably, there is an emphasis on technology in ICU: the nurses must be technically competent. Even such relatively routine tasks as titration of continuous inotrope or vasopressor infusions and maintenance of the constant flow of the drugs when syringe drivers are switched is a significant skill.[3] This means that it is all too easy to neglect the human aspects of care. Expert nurses will connect with patients both physically and psychologically,[4] but patient-centred care and emotional support can be lost when the nursing resource is reduced.[5] One ICU patient described his treatment as '*rooted in the minute analysis of charts and the balancing of chemicals, not so much in the warmth of human contact*'.[6] Others report experiencing breathlessness, voicelessness and thirst, and feelings of helplessness, anxiety, desperation, desertion and powerlessness.[7,8] ICU patients are less heavily sedated and therefore more aware than previously – '*conscious but feeling doped*'[9] – but can rarely control what happens to them during critical illness, especially in the acute phase. They usually wish to reassert their autonomy as they recover (e.g. during weaning from ventilation or when moving to a lower level of care). Nurses can enable patients to have a say in the management of these processes while still ensuring a safe progression. Essential personal care is invariably undertaken or supervised by nurses; and although important functions, such as chest physiotherapy, mobilisation and administration of nutrition, may be prescribed by other specialists, they will still be integrated and delivered by nurses.

A SYSTEMATIC APPROACH TO CARE

Nursing critically ill patients is complex. The clinical review should be structured to clarify and prioritise patient needs so that all possible problems are addressed. In acute situations, assessment in turn of the fundamental A–B–C–D–E aspects of care is a useful method:

Airway: with establishment and maintenance of airway patency (using airway adjuncts or advanced airways as necessary; humidification, removal of pulmonary secretions, etc.).

Breathing: ensuring adequacy of oxygenation and ventilation.

Circulation: assessing blood volume and pressures; perfusion of brain, heart, lungs, kidneys, gut and other organs; control of bleeding, haematology, etc.

Disability: checking consciousness and the factors that affect it, systemic and localised neurology; assessing the need for analgesia, sedation and neuromuscular blockade.

Exposure: hands-on, head-to-toe, front-and-back examination, and review of everything else; with consideration of skin and mucus membrane integrity, wounds and drains.

Treatment strategies can be prioritised using this schema, which has the additional benefit that it will be familiar to colleagues trained in advanced life support and similar systems. Further detail may be gained from the review of:

Fluid and electrolyte balance, biochemistry.

Gastrointestinal function: nutritional needs; elimination.

ABSTRACT

Nurses are the constant factor for critically ill patients, acting as the 'glue' that holds the intensive care unit (ICU) together. They must be technically competent and be able to connect with patients both physically and psychologically – providing holistic, patient-centred care – while preventing iatrogenic harm by intercepting and mitigating errors made by others. New roles include 'Advanced Critical Care Practitioners' – usually from a nursing background – who can work autonomously in defined situations.

Nurses must measure the quality of, and take responsibility for, the care they deliver; assessing the care of randomly selected patients monthly, or, better, weekly. Analysis of the data will reveal which areas of care need attention, where variations in care exist, and trends over time. It is desirable to compare data and share learning with other ICUs. Research priorities include optimisation of recovery and rehabilitation from critical illness, plus management of delirium, agitation and critical care-related stress.

KEYWORDS

Patient-centred care
staffing
safety
quality improvement
stress management
competency

History and holistic overview of the patient as a person and their sociocultural background.

Infection and infection control; microbiology – and personal hygiene.

Lines, catheters/invasive devices: utility and risks.

Medications.

Nursing and multidisciplinary teamwork: ensuring that the staff resource is sufficient for the patient's severity of illness and the physical demands of care.

Oral/dental care.

Psychology (cognition, communication and mood) – and the **p**lan of care and prognosis in the short, medium and long term.[10]

Relatives and loved ones.

More sophisticated models can be used to frame a wider impression of the patient or to reflect a particular philosophy or approach to care.[11] There is a great benefit in developing a shared vision within the department, and in articulating how agreed values will be demonstrated in practice.[12] These might include emphasising the primary importance of patient safety and well-being, ensuring that the kindness an individual would want for their own loved ones is always offered, effective teamworking, and having systems in place to achieve continuous improvement.[13] Whichever method is used, there must be explicit definitions of the patient's problems and a clear statement of measurable therapeutic goals.

NURSING AND PATIENT SAFETY

Many patients suffer iatrogenic harm in the ICU,[14] but vigilant nurses can prevent such incidents by intercepting and mitigating errors made by others.[15] No particular system of critical care nursing has been shown to be definitively superior to others,[16] but nursing surveillance is key to patient safety.[17] Insufficient staffing has been linked to increased adverse events, morbidity and mortality.[18–20] At the minimum, 5.6 nurses need to be employed for each patient requiring 1:1 care 24 hours a day.

EVOLVING ROLES OF CRITICAL CARE NURSES

Critical care nurses' range of practice has widened in recent years, partly due to progress in technology and changes in the working of other professionals, although the benefits of developing new skills must be balanced against ensuring the maintenance of essential holistic care. There is considerable variation in the array of tasks undertaken by critical care nurses in different institutions, with invasive procedures and drug prescriptions still usually performed by doctors. However, suitably trained UK nurses are enabled – in theory at least – to prescribe licensed medicines for the whole range of medical conditions, although prescribing is not yet a widespread phenomenon in the ICU. It is likely to become a routine part of nursing practice in the future.

Critical care nurses do have a rapidly increasing role in decision making regarding the adjustment, titration and troubleshooting of such key treatments as ventilation, fluid, inotrope/vasopressor administration and renal replacement therapy. The use of less invasive techniques (e.g. transoesophageal Doppler ultrasonography for cardiac output estimation) mean it is easier for nurses to institute sophisticated monitoring and then modify treatments accordingly. There is evidence that nurses can achieve good outcomes in these areas, especially with the use of clinical guidelines and protocols (e.g. by reducing the time to wean respiratory support[21]). Further development of protocols, guidelines and care pathways can be used to enhance the nursing contribution to critical care in future.

NEW NURSING ROLES IN CRITICAL CARE

Maintaining adequate numbers of staff with the experience and skills to meet the increasing needs of critically ill patients is a challenge. Nurses constitute the largest part of the workforce and represent a significant total cost. Changes in training arrangements and the demographics of nurses in general have meant that there are relatively fewer applicants for ICU posts. This has driven the development of various new ways of working to deliver both fundamental and more sophisticated aspects of care. New nursing roles include some that substitute for medical roles, as well as those that retain a nursing focus and aim to fill gaps in healthcare with nursing rather than medical practice. For example, the United Kingdom has designated a number of senior 'Nurse Consultant' posts in all areas of healthcare, but with the largest proportion in critical care, particularly in Outreach roles.[22] These are experts focusing on clinical practice but who are also required to provide professional leadership and consultancy, as well as the development of clinical and academic education and training, as well as service development, research and evaluation.

Also, there is now widespread interest in developing 'Advanced Critical Care Practitioners' (ACCPs) who can work autonomously in defined situations. ACCPs may come from a range of health care backgrounds but are usually nurses. Training typically lasts at least 2 years at a postgraduate/masters degree level and includes advanced clinical assessment skills, performance of diagnostic tests, diagnosis and clinical reasoning, initiation and management of treatment plans, invasive procedures (e.g. advanced airway techniques, central line placement) and drug prescription.[23]

Other staff – such as nursing/health care assistants – are increasingly and successfully employed to deliver what has previously been seen as core nursing care in order to support trained nurses and free them to concentrate on more advanced practice.[24] Reductions in health care funding and shortages of trained staff are likely to make such developments more common, but

it is imperative that this is a managed process to ensure the best outcomes for patients, with proper arrangements for training, support and systems of work.

CRITICAL CARE NURSING BEYOND THE ICU: CRITICAL CARE OUTREACH

Around the world, general ward staff are required to manage an increasing throughput of patients who are, on average, older than before, with more chronic disease, and more acute and critical illness. Studies of critically ill ward patients show that the majority experience substandard care and experience adverse events before transfer to the ICU.[25,26] Various factors are implicated, including knowledge deficits and failure to appreciate clinical urgency or to seek advice, which is compounded by poor organisation. It is nurses who record or supervise the recording of vital signs, but there is often poor understanding of the importance of such indicators, ineffective communication with senior staff and difficulties ensuring that appropriate treatments are prescribed and administered. Nurse-led critical care outreach teams support ward staff caring for at-risk and deteriorating patients, and facilitate transfer to ICU when appropriate.[27] They can also support the care of patients on wards after discharge from ICU,[28] and after discharge from the hospital too. Potential problems with these approaches include a loss of specialist critical care staff from the ICU, and being sure that outreach teams have the necessary skills to manage high-risk patients in less well-equipped areas, particularly when there are limitations placed on nurses prescribing and administering treatments.

NURSING IN THE MULTIDISCIPLINARY TEAM

High-quality critical care requires genuine multidisciplinary teamwork, with

- clear individual roles
- team members that share knowledge, skills, best practice and learning
- systems that enable shared clinical governance, individual and team accountability, risk analysis and management.[29]

ICUs where team performance is not so well developed are likely to have less effective processes and worse outcomes. Aspects of team leadership, coordination, communication and decision making can be measured against defined criteria, as can outcome indicators relating to patients and staff,[30] for example:

- compliance with protocols
- adverse events/critical incidents
- patient length of stay
- mortality
- staff satisfaction
- staff retention.

Identified deficiencies in teamworking can then be addressed, although some investment may be needed. One study focused on nurses as the main drivers of improvement in the ICU. Units were engaged in a structured improvement programme entailing analysis of the prevailing culture in the department, followed by tailored training in teamworking, ways of achieving safer practice, and performance measurement.[31] ICUs that completed this programme had significantly better outcomes than those that did not, even though both groups were required to use the same clinical protocols.[31]

QUALITY OF CARE AND QUALITY IMPROVEMENT

Robust audit is the foundation of quality care. Potential indicators include pressure ulcer prevalence, nosocomial infection rates, patient satisfaction and errors in drug administration.[32] Nurses must measure the quality of, and take responsibility for, the care that they deliver, although it should be appreciated that nursing care cannot be considered entirely separately from other variables that influence patient outcomes: quality care depends on a collective interdisciplinary commitment to continuous improvement,[33] and continuous 'measurement for improvement'. One approach is to assess the evidence of care of randomly selected patients every month, or, better still, weekly: some descriptors of critical care nursing quality are shown in Box 6.1. Analysis of the data will reveal which areas of care need attention, where variations in care exist and trends over time. It is desirable to compare data and to share learning with other ICUs where possible.

CRITICAL CARE NURSING MANAGEMENT

The nurse manager role is crucial to service performance. The most important priority is the challenge of attracting and retaining a flexible, effective and progressive nursing team that works well with other health care professionals to meet patient needs, but within a limited budget.

STAFFING THE CRITICAL CARE UNIT

The starting point for calculations of staffing requirements is the detailing of patient needs – and of the knowledge and skills that will be required to meet those needs – with an appreciation that there will be unpredictable variations over time (Box 6.2).

Patient need has many components, including:

- the severity and complexity of acute illness and chronic disease
- other physical characteristics (e.g. mobility, body weight, skin integrity, continence)
- consciousness and cognition
- mood and emotionality (e.g. anxiety, depression, motivation to engage in rehabilitation)

Box 6.1 Exemplar critical care nursing quality indicators[34]

Randomly select patients and check:

Airway
1. Airway management and turning/repositioning plan.
2. Emergency equipment by the bedside (for those with altered airways).

Pain
1. Pain – and nausea – score recorded hourly.
2. Plan for managing postoperative pain.
3. Is the patient in pain at the time of review?

Sedation
1. Richmond Agitation and Sedation Scale (RASS) assessed hourly.
2. If appropriate, target RASS in Care Plan.
3. Confusion Assessment Method for ICU (CAM-ICU) assessed daily.

Maintaining skin integrity
1. SSKIN (**S**kin Assessment, **S**urface, **K**eep moving, **I**ncontinence, **N**utrition assessment) completed and documented within an hour of admission.
2. Risk assessment completed every shift.
3. SSKIN bundle completed every shift.
4. Patient on the correct mattress.
5. Patient on the correct turn frequency.
6. Nurse can describe an appropriate pressure ulcer prevention plan for patient.
7. Strategies in place to prevent incontinence-associated dermatitis/moisture damage.
8. Strategies in place to prevent damage from medical devices.
9. Patient/carer understands the pressure ulcer prevention plan.
10. Manual handling assessment completed in last 24 hours.

Monitoring
1. Safe alarm limits set.
2. Fluid balance target identified.
3. Fluid challenge used as per protocol.
4. Fluid balance target achieved.
5. Invasive lines: documented evidence of insertion and removal.
6. Lines visibly clean and dressings intact.
7. Infusion lines clearly labelled and in date.

Assessment and documentation
1. Time of admission/transfer clearly documented.
2. Multidisciplinary Team care plan with problems identified and clear treatment goals.
3. Accurate A–E nursing review and evaluation on each shift.
4. Documented evening review.
5. Documented night shift review.
6. Complete Multidisciplinary Team discharge summary (when appropriate).
7. Up-to-date patient information board.

Box 6.2 Standards for nurse staffing in critical care[35]

1. Level 3 patients (requiring advanced respiratory support alone, or basic respiratory support together with support of at least two other organ systems) require a registered nurse/patient ratio of a minimum 1:1 to deliver direct care.
2. Level 2 patients (requiring more detailed observation or intervention including support for a single failing organ system or postoperative care and those 'stepping down' from higher levels of care) require a registered nurse/patient ratio of a minimum of 1:2 to deliver direct care.
3. Each designated Critical Care Unit will have an identified lead nurse with overall responsibility for the nursing elements of the service.
4. There will be a supernumerary clinical coordinator on duty 24/7. (Units with <6 beds may consider having a supernumerary clinical coordinator to cover peak activity periods; i.e. early shifts.)
5. Units with >10 beds will require additional supernumerary registered nursing staff over and above the clinical coordinator to enable the delivery of safe care. The number of additional staff per shift will be incremental depending on the size and layout of the unit (e.g. in the case of multiple single rooms), and during events, such as infection outbreaks.
6. Each Unit will have a dedicated Clinical Nurse Educator responsible for coordinating education, training and continuing professional development for nursing staff and pre-registration student allocation.
7. All nursing staff appointed to Critical Care will be allocated a period of supernumerary practice.
8. A minimum of 50% of registered nursing staff will be in possession of a post-registration award in Critical Care Nursing.
9. Units must not utilise >20% of registered nurse from bank/agency on any one shift when they are NOT their own staff.
10. Where direct care is augmented using non-registered support staff, appropriate training and competence assessment is required.

- the frequency and complexity of observation/monitoring and interventions
- the needs of relatives.

The staff resource includes members of the clinical team, the whole range of ancillary staff and the support services. Collectively, these personnel must be adequate to meet patient needs. This requires evaluation of:

- nursing numbers and skill mix
- multidisciplinary team skill mix, with consideration of variations in the availability of team members (e.g. doctors, respiratory/physiotherapists, equipment technicians out-of-hours).

The context of care is also significant; that is:

- the physical environment (e.g. the ease with which patients can be observed, whether cohorted in groups or in separate rooms)
- workload variations – peaks, troughs and overall activity in the department (e.g. admissions, discharges, transport to other areas [e.g. imaging], transfers).

The manager is also responsible for

- coordinated operational management of the area
- quality of nursing care
- management of nursing pay and non-pay budgets
- personnel management
- dealing with complaints and investigating adverse incidents.

There are always dynamic political, social and economic forces bearing on the organisational objectives and resources of the hospital and the ICU. The nurse manager needs to understand these factors and how they influence the delivery of patient care and the maintenance of a healthy environment for individual and team development. The manager must be able to communicate the key issues to the whole team in the form of an agreed strategy and a clear, regularly updated operational plan for the department. There needs to be a working system that addresses and integrates the views and needs of all users of the service, including patients and their families. Such a system should enable a shared understanding of exactly what needs to be done in practice, and where each team member fits into the plan.

Externally, the manager represents the service and ensures that other disciplines and the bigger organisation are informed about critical care issues.

Teams perform most effectively when individuals believe that they are working towards some common and worthwhile goals. The principles of shared governance can be usefully applied in this perspective, whereby staff collectively review and learn from their own practices. This has to be in the context of:

- the strategic agendas of the unit and the hospital
- the development of the service
- financial issues, budgets and budgetary restraints
- an appreciation of day-to-day working issues.

STRESS MANAGEMENT AND MOTIVATION

The ICU can be extremely stressful, demanding considerable cognitive, affective and psychomotor effort from staff. Supervisory and feedback arrangements should be in place to alleviate such demands, and to enable identification of staff members who are having difficulties at work. Studies of human resource practices in hospitals have found an association between the quantity and quality of staff appraisal and patient mortality, with organisations that emphasise training and teamworking having better outcomes.[36] Regular individual performance reviews and the formulation of development plans provide positive assurance and encouragement, and can identify specific personal requirements, such as educational needs.

Providing staff at all levels with opportunities to feel that they can influence and perhaps modify the working environment tends to decrease stress and increase motivation. Flexibility to work in different ways at different times while still meeting the overall demands of the department is important. It is the manager's job to balance and meet the needs of staff, patients and the organisation. One method is to give staff a choice regarding rostering, partly to help with work–life balance, but also so that the nurse can opt to work with particular patients for a time to practice certain skills and to promote continuity of care. This can have real benefits for patients.

NURSE EDUCATION

There are well-established educational programmes for critical care nurses, although the content and quality vary. There is a role for the study of relevant philosophy, nursing theory and research methods, but the fundamental requirement is for learning that focuses on clinical practice and practical problem solving (Box 6.3).

A competency framework can be used to structure descriptors of the skills, knowledge and attitudes needed to achieve specific patient outcomes. There needs to be consideration of how individual actions are integrated into holistic care, and the role of independent clinical judgement. Developing nurses' critical thinking and decision-making skills is also important. Appraisal of learners' performances requires assessors to observe and question the nurse in practice, although this places significant demands on hard-pressed clinical areas. It may be that high-fidelity simulators can be used to test performance away from the practice setting in future.

Frameworks to identify different levels of performance have been developed; for example, based on Benner's novice-to-expert hierarchy (Table 6.1).[4] A group of UK critical care nursing organisations have described a three-stage version of the model, suggesting that novice critical care nurses should spend up to 12 months acquiring core competencies under supervision (Stage 1), should then undertake a formal course of training (Stage 2), and finally progress to practice without direct supervision (Stage 3).[37]

CRITICAL CARE NURSING RESEARCH

Research is most valued when it is relevant to practice. The researcher is more likely to gain support for the investigation of high-risk and high-cost processes, but many everyday methods and treatments warrant examination too, particularly when there are significant variations in practice. The researcher should determine how the topic of interest might be described in a measurable

Box 6.3 Key competencies for critical care nurses[37]

- *Respiratory system*: Anatomy & Physiology, Assessment, Monitoring & Observation, Non-Invasive Ventilation, Endotracheal Intubation, Invasive Ventilation, Chest Physiotherapy, Tracheostomy Care, Chest Drain Management, Associated Pharmacology.
- *Cardiovascular system*: Anatomy & Physiology, Assessment, Monitoring & Observation, Arterial Access, Central Venous Access, Fluid Management, Sepsis Management, Shock Management, Cardiac Rhythms, Associated Pharmacology.
- *Renal system*: Anatomy & Physiology, Assessment, Monitoring & Observation, Renal Replacement Therapy, Associated Pharmacology.
- *Gastrointestinal (including liver and biliary) system*: Anatomy & Physiology, Nutrition in Critical Illness, Assessment and Management, Associated Pharmacology.
- *Neurological system*: Anatomy & Physiology, Assessment, Monitoring & Observation, Sedation & Delirium Assessment and Management, Pain Control.
- *Integumentary system*: Anatomy & Physiology, Skin Integrity, Joint Positioning & Range of Movement, Venous Thromboembolism Assessment.

Other essential areas

- Promoting a Positive Patient Experience (Psychosocial Wellbeing, Visiting in Critical Care)
- Medicines Administration
- Admission & Discharge
- End-of-Life Care
- Intra- & Interhospital Transfer
- Rehabilitation
- Communication & Teamwork
- Infection Prevention & Control
- Evidenced-Based Practice
- Professionalism
- Defensible Documentation
- (Assessment of) Mental Capacity
- Leadership.

Table 6.1 Assessment of critical care nurses' performance[4]

RATING	DEFINITION	OBSERVED BEHAVIOUR	PROMPTS
Novice	Limited skill and/or knowledge, inconsistent practice, variable interpersonal skill Limited understanding of wider context, inflexible rule-governed behaviour	Lacks coordination and confidence Potential for omissions or inaccuracies Unable to demonstrate accurate and safe performance despite repeated attempts	Requires frequent directive prompts, supervision and advice
Advanced beginner	Some skill and knowledge, generally consistent practice and interpersonal skill; variable ethical thought Some appreciation of situational influences	Coordinated and confident in fundamental tasks Easily distracted or unable to integrate other aspects of patient care	Requires occasional directive prompts and some supervision
Competent	Consistent safe, accurate and effective practice, interpersonal skill and ethical thought Conscious and deliberate planning with consideration of immediate context	Skilful, confident and coordinated patient-focused practice, with evident integration of other aspects of care Prioritisation of workload	Self-directing without supervision
Proficient	Consistent safe, accurate and effective practice, higher-level interpersonal skill and ethical reasoning Conscious and deliberate planning with consideration of long-term goals Adapts care in response to changing situations	Skilled and accomplished practice, proactive and flexible approach to care Problem solving and decision making through reflection Role model	Capable of supporting and demonstrating skills to others

Adapted from Benner P. From novice to expert. *Am J Nurs*. 1982;82(3):402–407.

way, and formulate the investigation as a question, with consideration of how answers can be obtained.

Relatively small numbers of patients are treated in the ICU, at considerable cost, although many of the methods used do not have a robust evidence base. Patient outcomes are influenced by different organisational approaches, staff characteristics, varied working practices, as well as differences between patients themselves. Therefore, a range of quantitative and qualitative investigative procedures are needed to gain an understanding of the issues. The approach chosen depends on the nature of the research question, the objectives of the researcher and the resources available. For example:

- comparing different treatments generally requires quantitative measurements of particular end-points (e.g. the dose of a drug needed to achieve a target physiological variable)
- understanding how an individual thinks or feels usually involves analysis of qualitative material (e.g. data from interviews with patients and families).

It is noteworthy that few, if any, large-scale trials of medical treatments in the ICU have shown sustained, significant benefits in recent years. At the same time, there is increasing evidence that many patients suffer severe psychological problems in the ICU[38] and posttraumatic stress disorder later on.[39] Accordingly, a recent 'ICU Priority Setting Partnership' identified three critical questions for ICU patients, carers and clinicians[40]:

1. How might patients that would benefit from critical care be identified and admitted at the optimal time?
2. How can patients and their families be helped through the often lengthy recovery and rehabilitation from critical illness?
3. How best can delirium and agitation be prevented or managed when it occurs?

Nurses have already extensively researched questions (2) and (3) in particular,[7–9,41,42] and the qualitative methods they very often use are the most appropriate for further work in these areas. There is great potential for nurses to be leaders in such matters.

Ethics in intensive care

Andrew Hartle, (Charlotte) Stephanie Cattlin

Ethics is a normative science, or the study of human behaviour. More specifically, it aims to characterise behaviours that are 'right' or 'wrong'. Codes of medical ethics have existed for thousands of years; for example, the Hippocratic Oath[1], which has influenced medicine in the West for some 2500 years, but has now been replaced by guidance, such as the Declaration of Geneva[2], which is more appropriate in the late 20th and early 21st century.

Conflict may arise when there is a misunderstanding or disagreement between medical staff and patients (or their relatives) about the framework within which medical practice is acceptable. If it is not possible to resolve such conflict, then decisions may ultimately rest with judges and courts, but what is ethical may not be legal (and vice versa), and human behaviour is further constrained and influenced by cultural norms, religious beliefs (or the lack thereof) and more recently by concepts of Human Rights.

Guidance on research ethics has only achieved widespread acceptance since the Codes that arose from the Nuremberg Trials following the Second World War, although there are many examples across the world (e.g. the Tuskegee syphilis study) of research ethics abuse; it was not confined to the Nazi regime. More recently, research fraud has come under closer scrutiny; even in the 21st century there is evidence of significant unethical medical practice.[3] Detailed guidance on research in critical care should be consulted before beginning any study.

ETHICAL STUDY

There are many 'schools of ethics' (utilitarianism, hedonism, deontologism, epicureanism) but more recently principalism has gained popularity, at least as an easily remembered approach to analysing ethical challenges. The four principles as proposed by Beauchamp and Childress[4] are:

Autonomy – respecting the decision-making capabilities of those who have the ability to make an informed choice

Beneficence – the primary goal of treatment should be the best interests of the patient

Non-Maleficence – the avoidance of harm, whilst appreciating that all treatment may involve some harm, that this is not disproportionate to the benefits

Justice – patients should be treated fairly and equitably.

(It is interesting that the founding principles of the UKs National Health Service were healthcare, available to all, based on clinical need free at the point of use.)[5]

Whilst principalism is helpful in discussing the different elements, it may not always resolve conflict, as autonomy often outweighs the other three principles. Those that give autonomy this elevated impact may overlook that autonomy is only ever relative in any society, and subject to the limits imposed by that society.

Before considering whether the practise of intensive care medicine is ethical, it is important to establish its purpose or the goal of treatment; the ethics of a decision is context sensitive.

WHAT IS THE PURPOSE OF INTENSIVE CARE?

1. To keep people alive long enough to recover and be discharged
2. To delay death, to prevent the unavoidable
3. To prevent death

Patients may be admitted electively in the perioperative and periprocedural period, or as an emergency, and criteria for admission may vary depending on these.

We are well versed in the criteria that patients are required to meet to merit admission to intensive care; what is often more difficult is whether the decision to admit to intensive care is in the patient's best interests or whether these best interests involve ward-based ceilings or care, or indeed palliation. This is highlighted in those patients with increasing age (both chronologically and physiologically), chronic organ dysfunction, a large number of co-morbidities and poor functional reserve. Most patients whose intensive care admission is thought to be futile would prefer to die in their own home with an emphasis on comfort care rather than undergo invasive, intensive life-prolonging treatments.[6–8]

The context of admission decisions will inevitably include resources. Intensive care as discussed in this text is available only to a minority of the world population, and there is wide variation in provision even for that minority. Patients in the United Kingdom and the United States have similar demographics, as well as hospitalisation and mortality rates, but roughly three times more patients in the United States die in a critical care environment than in the United Kingdom, at all ages,

ABSTRACT

Ethics is a normative science, or the study of human behaviour. More specifically, it aims to characterise behaviours that are 'right' or 'wrong'. Codes of medical ethics have existed for thousands of years, but despite this, ethics continues to be an area of wide discussion and sometimes of conflict, and is often highly emotive for medical professionals, patients and their families alike. Ethical considerations in intensive care cover a wide variety of circumstances from consent through to futility, withdrawal or withholding of treatment, do not attempt resuscitation (DNACPR) and end-of-life care. The conflict that these topics potentially generate may be minimised with knowledge of the ethical and legal frameworks surrounding them, alongside excellent communication between all parties with the best interests of the patient remaining paramount.

and the difference is more marked in those over the age of 85.[9] There is more to this difference than just resources; although the United States has fewer hospital beds/population, it has far more critical care beds (relative and absolute numbers). Finally, US patients are more likely to die at home than those in the United Kingdom.

FUTILITY

Futility is a frequent reason for a decision not to admit to intensive care, often without defining what is futile or why. A treatment is futile if it cannot achieve its desired goal (hence the importance of defining **in advance** the purpose of admission and/or the goal of treatment).

Futility may be quantitative or qualitative: quantitative is where the likelihood of an intervention benefitting the patient is low (the patient is extremely unlikely to survive); qualitative is where the quality of benefit of an intervention is poor (the patient may survive, but their quality of life will not be acceptable to them). Futility is not a new concept; Hippocrates stated that doctors should 'refuse to treat those who are overmastered by their diseases, realising that in such cases medicine is powerless'.[10] What constitutes futility for a particular patient often lies at the heart of cases decided by courts about withholding or withdrawing intensive care treatment, and it is almost inevitably contentious.[11] Futility is a term that may have a different meaning for staff and patients/families and may be misinterpreted as 'not worth it' by some (author's opinion – AJH).

WITHHOLDING/WITHDRAWING TREATMENT

Despite admission to intensive care, some patients will reach a point when all treatment options have been explored and maximal therapeutic benefit achieved. This point, at which patients transition from illness to dying, is often only recognised in retrospect. If an escalation of treatment, or further treatment is not deemed to be in the patient's best interests (or 'futile'), it may be withheld or withdrawn. This decision is the most common precursor to death in the intensive care unit environment.[12] The rationale for reaching this decision must be explained carefully and sympathetically to the patient and/or their family with the aim of moving towards comfort care rather than active treatment.[13,14]

RELIGIOUS BELIEFS SURROUNDING END-OF-LIFE CARE

Patients, their relatives and staff, hold a wide variety of (or no) religious views and perceptions regarding aspects of care, particularly at the end of life, which in turn can influence how patients and their families approach decision making in this regard, and it is important for the medical professionals involved in their care to appreciate and take these views into consideration.[15] A detailed description of these is beyond this chapter but there are online resources, for example, about brain death and organ donation[16], and blood transfusion[17]. Often, further sympathetic exploration of their specific issues and beliefs in this area, and the early involvement of hospital chaplaincy services, will ensure a smoother transition towards end-of-life care.[18]

EUTHANASIA AND PHYSICIAN-ASSISTED SUICIDE

Euthanasia is the act of intentionally ending a person's life with the aim of relieving pain and suffering. Physician-assisted suicide is where a doctor intentionally provides a person with the knowledge or means to commit suicide.[19] This is a subject that inspires a great deal of debate worldwide and is only legal in a small number of jurisdictions; however, the availability of this is slowly increasing. There is a clear moral, ethical and legal distinction between (1) withholding or withdrawing treatment no longer deemed to be in the patient's best interest, and therefore is of no benefit to them and which may result in the patient's death; and (2) euthanasia, which has the patient's death as its primary goal.

THE ROLE OF DNACPR – DO NOT ATTEMPT CARDIOPULMONARY RESUSCITATION

Patients admitted to intensive care should be considered for all treatment options, but some limitations may be appropriate for some patients based on an assessment of their individual best interests (in accordance with the statutory, regulatory and institutional setting). One limitation of treatment is not to institute cardiopulmonary resuscitation (CPR) in the event of cardiac and or respiratory arrest – 'do not attempt cardiopulmonary resuscitation', (DNACPR), 'do not attempt resuscitation' (DNAR). It is important that everyone involved (patient, relatives, staff) understands that DNACPR is not a decision not to treat (or not to care), but to provide all treatment except CPR. Such decisions must be subject to regular review, and sensitive communication to the patient and their family, as it has been shown that patients have poor knowledge of the realities of cardiopulmonary resuscitation and what DNACPR really means.[20]

CONSENT/ADVANCED DIRECTIVES/PROXY DECISION MAKERS

No patient has absolute autonomy (see previous comments); for example, the limits to medical autonomy in the United Kingdom may be summarised as (1) patients with capacity may request but not require treatment, (2) patients must consent voluntarily to treatment, and (3) patients may make unwise decisions (such as refusing

treatment). Conversely, medical (and other) practitioners must only offer treatment **they** consider to be in the patient's best interests, or arrange for another to do so. But what of patients who, like many in intensive care, lack capacity? Patients may exercise their autonomy through an advance decision ('Advanced Directive', 'Living Will') or by nominating another person to decide for them. Details will vary in different legal systems (the situation is different in England and Wales, Scotland, and Northern Ireland – the three separate jurisdictions of the United Kingdom).[21,22] Despite this, it is thought that 16% of intensive care patients have no decision-making capacity and no surrogate decision maker.[23]

Even when such 'advanced autonomy' has been exercised, it must apply to the circumstances that pertain at the time; in the event of doubt or confusion, full active treatment must be the default until there is an opportunity for clarification. This area is littered with pitfalls, particularly over-legalistic language or terminology that is difficult to define (e.g. there is no standard definition of a 'life support machine' despite the phrase being used often in news and other broadcasts). Regardless of whether the documents themselves are sufficiently accurate or specific, they are still an indication of the patient's wishes, which deserve respect and consideration.

Decisions at the end of life are inevitably emotive for staff, patients and relatives alike. Conflict is perhaps inevitable but can be minimised by a sound knowledge of the ethical and legal principles and the medical evidence that underpins such decisions, which must be tailored to and involve the individual patient and their relatives. A structured multidisciplinary approach may aid in reducing conflict within the intensive care team. Particularly challenging cases may benefit from the involvement of independent Clinical Ethics Committees or mediation.[24]

Common problems after intensive care unit

Carl S Waldmann, Evelyn Corner

On admission to the intensive care unit (ICU) in a state of extremis, the patient, often unbeknown to them, is about to embark on a difficult journey. In around a fifth of patients this is a journey that will end their life[1]; for the rest it will almost certainly change it.

As critical illness progresses, the physical and psychological stress that the body is put under is immense. The deleterious effects of the illness itself can lead to rapid muscle loss, delirium and organ dysfunction. Combine this with the necessary medical management – enforced bed rest, mechanical ventilation, psychoactive drugs and neuromuscular blocking agents – and the consequences may be severe.

Insomnia, incontinence, muscle weakness, post-traumatic stress disorder (PTSD), depression, unemployment, the breakdown of interpersonal relationships and sexual dysfunction are among the reported sequelae of critical illness. The term 'post-intensive care syndrome' (PICS) is now used to describe these complex phenomena.[2]

Most patients will get back to some level of normality within 1 year after discharge; however, for an unfortunate few the physical and psychological morbidity can be longstanding.

Cuthbertson and colleagues[3] demonstrated a 58% mortality rate at 3.5 years after discharge, with survivors reporting a significantly worse physical health-related quality of life (HRQoL) than the general population. These results were similar to data from a Canadian study demonstrating limited exercise tolerance and poor physical HRQoL at 5 years after acute respiratory distress syndrome (ARDS).[4]

In 1989, a Kings Fund report on intensive care services in the United Kingdom concluded that 'there is more to life than measuring death'. This was the first report of its kind that highlighted the importance of measuring morbidity as an outcome following critical illness, as well as mortality.[5] Since then, there has been greater emphasis on the long-term physical and psychological consequences of critical illness.

POST-INTENSIVE CARE SYNDROME

The range of issues seen after intensive care is vast and encompasses both physical and psychological problems.

TRACHEOSTOMY

Since percutaneous techniques performed by intensivists started to replace surgical tracheostomy in 1991, there have been an increasing number of patients tracheostomised earlier in their ICU stay with around one-quarter of patients on prolonged mechanical ventilation receiving a tracheostomy.[6] The long-term sequelae have been assessed by lung function tests, nasoendoscopy and magnetic resonance imaging (MRI) screening (Fig. 8.1). There are sometimes minor cosmetic problems, such as tethering (Fig. 8.2), which can be easily dealt with in ear, nose and throat outpatients. A less common, but more difficult to manage, complication is tracheal stenosis, defined as a 15% reduction in tracheal diameter.[7]

MOBILITY

Critically ill patients, especially those with multiorgan failure, are at high risk of developing intensive care unit-acquired weakness (ICU-AW), which is the presence of diffuse global muscle wasting, with myopathic and/or neuropathic changes. A systematic review by Appleton and colleagues[8] demonstrated a 32% incidence of ICUAW in patients requiring 7 days of mechanical ventilation. Muscle loss can be rapid, reaching up to 15% within 7 days of admission in patients with multi-organ failure.[9] ICU-AW can lead to prolonged ventilatory weaning, but also frequently both complicates and delays rehabilitation.[10] Even in the absence of trauma, patients can expect to need 9 months to 1 year to regain full mobility. This is usually due to a mixture of joint pain, stiffness and muscle weakness, but it is also linked to prior chronic health status. If questioned, patients will often report climbing stairs on all fours and descending on their bottoms (Fig. 8.3). Muscle relaxants have been implicated in the development of neuropathy,[11] but have not been shown to cause statistically significant increases in time to, and duration of, stay in the ICU.[12]

SKIN

Patients complain of a variety of nonspecific disorders, poor skin integrity, nail ridging and reports of severe alopecia.[13,14]

ABSTRACT

Since the Kings Fund Report in 1989, it was realised that in intensive care success should not be measured by mortality alone; quality of life and patient satisfaction should also be included.

As a result, intensive care units (ICUs) have started to attempt to initiate physical and psychological rehabilitation from Day 1 and continue well into the post-intensive care and hospital episodes. Many ICUs have started to run a follow-up programme, which includes seeing patients in an out-patient setting. The National Institute for Health and Care Excellence (NICE) 083 Guideline for Rehabilitation after Critical Illness has been around since 2009, but it has not been universally implemented; in 2017 the guideline was replaced by a NICE Quality Standard.

KEYWORDS

Rehabilitation after critical illness
follow up clinics
PTSD

Figure 8.1 Sagittal magnetic resonance imaging demonstrating narrowing of the trachea at the site of a tracheostomy.

Figure 8.2 Tethering of tracheostomy.

SEXUAL DYSFUNCTION

Studies have estimated the incidence of sexual dysfunction after critical illness as high as 45%,[15,16] although in a small proportion of patients (2%) their sex life was enhanced. Sexual dysfunction improves over time, with a reported frequency of around 26% at 2 months post-ICU, down to 16% at 1 year.[17] There was no link with gender, but there was a close association with PTSD.

Withdrawing sexual intimacy can damage relationships. Often sexual dysfunction may go untreated because people are too embarrassed to mention the problem when they have recovered from a life-threatening illness. For management guidelines for erectile dysfunction, see Ralph and McNicholas.[18]

Figure 8.3 Patient climbing (A) and descending (B) stairs.

Sexual dysfunction affects both men and women. In men it usually manifests as impotence. Referral to a clinic dealing in erectile dysfunction should be considered for men, and referral for gynaecological expertise should be considered for women.

OTHER PHYSICAL PROBLEMS

A variety of other problems have been seen during follow-up:

- *Visual acuity:* particularly in patients who have been profoundly hypotensive, visual problems may occur. Occasionally, ischaemic changes may be seen on fundoscopy (Fig. 8.4A), which may be amenable to laser therapy (see Fig. 8.4B)
- *Facial scarring:* where the tape securing the endotracheal tube has been too tight; this scarring can affect the whole thickness of the cheek
- *Poor skin integrity, hair loss and nail ridging*
- *Unnecessary medication:* frequently, the medication started in the ICU as a temporary measure may have been continued (e.g. amiodarone started for sepsis-related arrhythmias).

Early mobilisation, minimising sedation, managing delirium, spontaneous breathing and early liberation from mechanical ventilation are safe and can help to mitigate the risk of long-term problems. As an international consensus, this is now established best practice, but data still suggest that these principles are delivered inconsistently, and in the case of early mobilisation, infrequently.[19–21]

PSYCHOLOGICAL PROBLEMS

Most patients admitted to the ICU have no warning of their admission (emergency admission) and these are the patients who are very much at risk of psychological sequelae post-ICU. The majority of patients do not have a structured memory of their ICU stay. Those who do

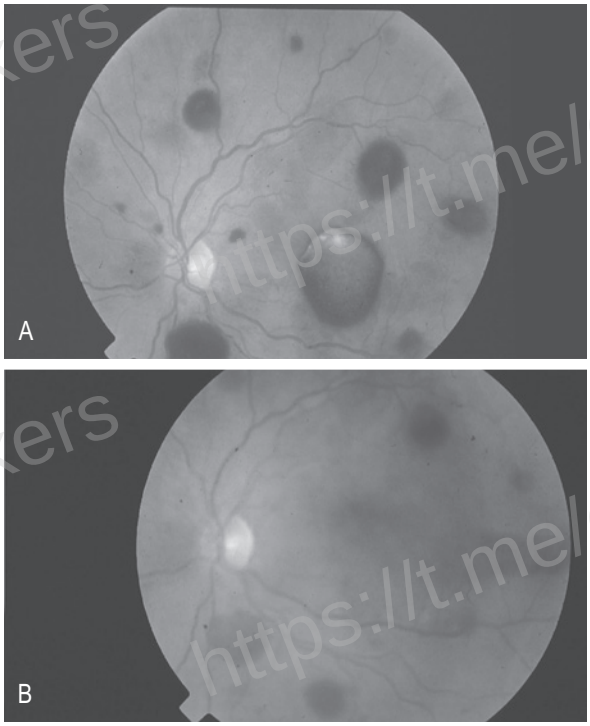

Figure 8.4 (A, B) Ischaemic changes in fundoscopy.

may have upsetting memories, which may be relatively innocuous, such as being thirsty and hearing a can of Coca-Cola being opened, or they may have memories of a far more profound nature.

A description of 'torture' experiences is not unusual when you talk to an ex-ICU patient. The psychological impact of the experience may be formidable. The memory of hearing the words 'let's bag the patient' was interpreted by the patient as if they were about to be put into a body bag rather than a physiotherapy manoeuvre, and the use of a tape measure was interpreted as being measured for a coffin and not as part of the cardiac output measurements. Previous studies demonstrate a high incidence of anxiety and depression.[22,23] It is common for patients to have memories of being trapped, of being unable to move easily, of being unable to see what is happening and of feeling intensely vulnerable. The anxiety of impending death is also reported.

Below is a typical nightmare experienced by an ICU patient:

> *I was in a tunnel knee-deep in mud. It was pitch black, but I could see light at the end. I felt a cold chill on my neck as if someone was breathing down my neck. I thought it was the grim reaper, I knew I had to get to the light.*

There may be several reasons for these experiences (Box 8.1). There is a common belief that, when on the ICU, it is better that a patient does not remember anything.

Box 8.1 Psychological issues

Illness
Sedation technique
Withdrawal
No communication aids
Lack of clear night/day
Continuous noise of alarms
Sleep disturbance – lack of rapid-eye-movement sleep

However, it is increasingly realised that false memories or delusions during an ICU stay can have a significant impact on psychological recovery, whereas factual memories of the ICU may reduce anxiety.[22,23]

It now seems likely that delusional memories of the ICU and nightmares are associated with PTSD. PTSD is the development of characteristic symptoms after being subjected to a traumatic event; this can be triggered by any memory or mention of something to do with the traumatic event and is characterised by intrusive recollections, avoidance behaviour and hyperarousal symptoms.[24] PTSD occurs in about 1% of the general population and increases to 10% in victims of road traffic accidents and 65% in prisoners of war. In the ICU, PTSD is common, with one-fifth of patients suffering from the condition 1 year after discharge.[25] In those with adult respiratory distress syndrome, the incidence increases to 27.5%.

Cognitive deficit is also common. Pandharipande and colleagues[26] found significant cognitive deficits in patients admitted to ICU in shock, with 40% demonstrating reduced global cognition at 3 months after discharge, and around one-third presenting with cognitive deficits equivalent to that of mild Alzheimer disease or moderate traumatic brain injury at 12 months.

Various strategies to deal with the psychological sequelae of an ICU stay have been tried:

- *During ICU stay:* Continuous intravenous sedation has been identified as an independent predictor of a longer duration of mechanical ventilation, ICU stay and total hospital stay.[27-29]

Kreiss and colleagues[30] demonstrated that, in 128 adults, ICU stay was reduced from an average of 7.3 to 4.9 days by the daily interruption of the sedative regimen. This regimen may have had an impact by reducing PTSD as the patients are more likely to have some recollection of their ICU stay, thus helping them to understand the reasons for their prolonged rehabilitation period. Concerns have been raised as to the type of sedative agent used in the ICU. Lorazepam has been promoted as the benzodiazepine of choice on the ICU and was preferred by a task force in the United States for adult patients in the ICU.[31] More recently, however, Panharipande and colleagues found a dose-dependent increase in delirium with the use of lorazepam.[32]

The whole concept of delirium in patients, including those who are critically ill, has now been reviewed, and the monitoring and management of delirium is now published as a National Institute of Health and Care Excellence (NICE) guidance document.[33]

- *When building or modifying ICUs:* 24-hour clocks visible to patients may help re-establish circadian rhythms, and the use of curtains to ensure patient dignity should not be forgotten. There has been some interest in appropriate colours that should be used in ICU décor, avoiding colours that cause alarm, such as red, yellow and black.

POST-INTENSIVE CARE UNIT DISCHARGE

Step down to the ward is often a difficult time for patients and relatives, and can lead to relocation stress. The RECOVER Randomized Clinical Trial investigated the use of a generic rehabilitation assistant to deliver physiotherapy, occupational therapy, dietetic, and speech and language therapy to patients on the ward after discharge from the ICU, to ensure a more cohesive approach to care.[34] The results showed no difference in functional outcome, although the sensitivity of the functional outcome used has been questioned; however, qualitatively, they showed better patient satisfaction, communication and better co-ordination of care.

ICU staff visiting patients on the ward post-ICU discharge and giving them an information booklet can also help to prepare them better for the long rehabilitation process ahead. Patient diaries have been suggested as a possible strategy to aid psychological recovery from critical illness. The diaries aim to provide a narrative of the patient's time on intensive care and fill in the memory gaps; however, a recent Cochrane review found the evidence inconclusive.[35]

POST-HOSPITAL DISCHARGE

Responsibility for the rehabilitation of patients after a critical illness has traditionally fallen between too many silos. Following multiorgan dysfunction, it is difficult to categorise a patient to an individual specialty, such as cardiac, respiratory or the stroke rehabilitation teams. Family doctors often have difficulty taking on the complexity of these patients, with the result that patients are denied vital advice and assistance, and lack an advocate with 'teeth' to ensure timely help. As a result, there has been a drive towards specialist post-ICU services in the form of rehabilitation programmes. However, until recently, few United Kingdom general ICUs were offering post-hospital rehabilitation programmes,[36] despite national clinical guidance to the contrary in the form of NICE Clinical Guideline 83 (CG83) entitled *Rehabilitation after Critical Illness*[37] and the Guidelines for Provision of Intensive Care Services published in 2015.[38] The NICE quality standard was published in 2017.[39]

SETTING UP A FOLLOW-UP SERVICE

Funding follow-up programmes has posed local problems in many trusts. Griffiths and colleagues[40] demonstrated that clinics are not widely established and show marked heterogeneity. Of those established, only two-thirds are funded, and most do not have pre-negotiated access to other outpatient services. The service at The Royal Berkshire Hospital in the United Kingdom was initially approved and funded by local, then regional, audit committees. The service is staffed by a follow-up sister who spends most of her time in this role helped by a staff nurse and an ICU consultant for the clinics held as a formal outpatient clinic 2–3 times monthly.

Invitations to patients who were in the ICU were initially extended to all patients that had been in the ICU for more than 4 days, but with time the invitation was extended to patients who have been in the ICU for a shorter time period. Patients are seen in clinic at 2 months, 6 months and 1 year after discharge and, occasionally, referrals are received from other hospitals where follow-up was not available. It is important to identify clerical and information technology support, and to achieve good collaboration with other hospital departments and general practitioners to ensure patients do not make unnecessary journeys to the hospital, by trying to coordinate the patients' visits and ensuring that transport is organised where necessary. Very often, patients will voluntarily come from long distances if they had initially been admitted from other geographical locations – out-of-area transfers.

The logistics of running the service include arranging specific tests that may be required for the visit, such as pulmonary function tests and blood/urine for creatinine clearance. There may be special tests, such as MRI for patients who had a tracheostomy during their stay in the ICU. It is important to assess patient satisfaction or dissatisfaction with their follow-up. This may be audited by questionnaires during their third visit to the follow-up clinic at 1 year post-ICU discharge.[41]

The service at The Royal Berkshire Hospital costs £30,000 annually, which, in the context of the bigger picture (£8 million annual budget for the ICU), is a small price to pay (Table 8.1). Recently the clinic visits have become funded in the same way as any other outpatient appointment and this, in part, funds the service.

Table 8.1 Budget for running a service

FOLLOW-UP CLINIC	COST (£)
Nursing	18,000
Medical	6,000
Administration	4,000
Laboratory tests and X-rays	2,000
Total	**30,000**

PEER SUPPORT GROUPS AND ONLINE RESOURCES

'ICU steps' is a United Kingdom-based intensive care charity, which was set up in 2005 by ex-patients and relatives. Their aim is to support patients and relatives through and after a period of critical illness, as well as increasing recognition and awareness of PICS and involvement in research. They do this through support groups and information booklets to guide patients through their recovery; these can be downloaded in 15 languages from their website (www.icusteps.org).[42]

MEASURING OUTCOME AFTER CRITICAL ILLNESS

Measuring morbidity outcomes after critical illness is complex, due to both the multifaceted needs of critical care survivors and the innate difficulties of developing robust scales. This makes it difficult to have a clear idea of the scale of the problem, but it is also problematic in interventional trials.

There are several quality-of-life tools used in follow-up studies (Box 8.2).[43–46] However, many of the objective measurements may be too generic. Lim and colleagues[47] compared two generic HRQoL measures, the Short-Form 36 Health Survey (SF-36) and EuroQol-5D (EQ-5D), to data from semi-structured interviews exploring perceived HRQoL in critical care survivors, and found that the generic tools lacked validity in this population. There is ongoing work through The COMET (Core Outcome Measures in Effectiveness Trials) initiative, by an international body of researchers, looking at developing a core outcome set for critical care research.[48] This may change the landscape of critical care research in the coming years.

CONCLUSION

The NICE 083 Rehabilitation after Critical Illness Guideline[35] has now been around for 7 years and is currently under review; however, it still has yet to be widely implemented in the United Kingdom. In the near future, it is expected that NICE will publish its Quality Standard in Rehabilitation after critical illness. Effective follow-up of patients after their critical illness may well be a future quality indicator of a hospital's critical care service.

More work needs to be done to provide an evidence base for the impact of critical care on carers and relatives. The King's College London and the King's Fund have tested the use of patient experience interviews using experience-based co-design (EBCD).[49] In EBCD, trained interviewers interview patients and staff over several months, and then use edited films of the patient interviews to stimulate work between patients and staff to redesign services.

In a recent modification of the EBCD known as AEBCD (accelerated experience-based co-design) edited films of patients talking about their experiences of two different conditions (intensive care and lung cancer) are being used in close partnership with patients, relatives and staff in two different hospital trusts to help them plan and implement improvements in care together.[50]

It is hoped that the publication of the NICE Quality Standard in 2017 *Rehabilitation After Critical Illness* will be available to all patients that have suffered consequences of an intensive care stay.

Clinical information systems

Phil Ward, Timothy Wigmore

The use of information technology to deliver patient care has perhaps no more obvious application than in the technology and data-rich environment of critical care. In this chapter we provide a background on relevant nomenclature, requirements, implementation and impact of critical care clinical information systems (CIS).

CONTEXT

THE DIGITAL HEALTH ECOSYSTEM

Unhelpfully, there are several inconsistently defined terms used to describe health information systems:

- Hospital information system (HIS) can be used to encompass all of an institution's information systems, but can sometimes refer just to administrative aspects of care encounters, such as scheduling or billing
- Electronic medical record (EMR), electronic patient record (EPR) and electronic health record (EHR) have overlapping definitions; EPR (used more in the United Kingdom) and EMR (used more in Asia and the United States) typically refer to the system and information pertaining to the patient and their care at a *specific* institution, whereas an EHR represents the information available across *all* institutions throughout the patient's lifetime[1]
- CIS describes a system that records, manages and displays data specific to a certain scope of clinical practice, for example, critical care

If one considers the breadth of data we utilise in making clinical decisions in critical care – a variety of vital signs, infusion rates, imaging and laboratory tests, for example – it is clear that accessing data from bedside devices and systems from other hospital services (interoperability) is key to a successful CIS. There are agreed international standards and specifications, such as HL7 ('Health Level 7') and IHE ('Integrating the Healthcare Enterprise'), which ensure that information can flow between systems both internally and externally.

An example of how these systems can be arranged is shown in Fig. 9.1. It should be noted that since the feature list of each CIS varies between vendors and depends on local procurement, an organisation may have one system meeting the needs of many departments or functions, or a multitude of products managing discrete parts of the clinical workflow (an arrangement known as 'best of breed').

INFORMATION GOVERNANCE

The transition from paper to CIS brings a host of information governance considerations. Although the same principles of access and confidentiality apply to paper clinical records, digital information potentially can be accessed from any location, as well as be shared more easily and more widely via interfacing, email or social media – either legitimately or illegitimately. Confidential data must be held and exchanged securely, and every user should undertake training in line with institutional and national policy.

NATIONAL INITIATIVES

The implementation of EMRs is increasing, but there remains disparity both geographically and in the complexity of the systems in use. The Healthcare Information Management Systems and Society (HIMSS) has developed an EMR Adoption Model, which classifies an institution on an eight-point scale depending on the capabilities and uses of its EMR. This ranges from having paper-based laboratory, radiology or pharmacy systems (level 0) through to a full EMR with data analytics (level 7), incorporating order communications, closed-loop medicines administration, clinical documentation and clinical decision support.[2]

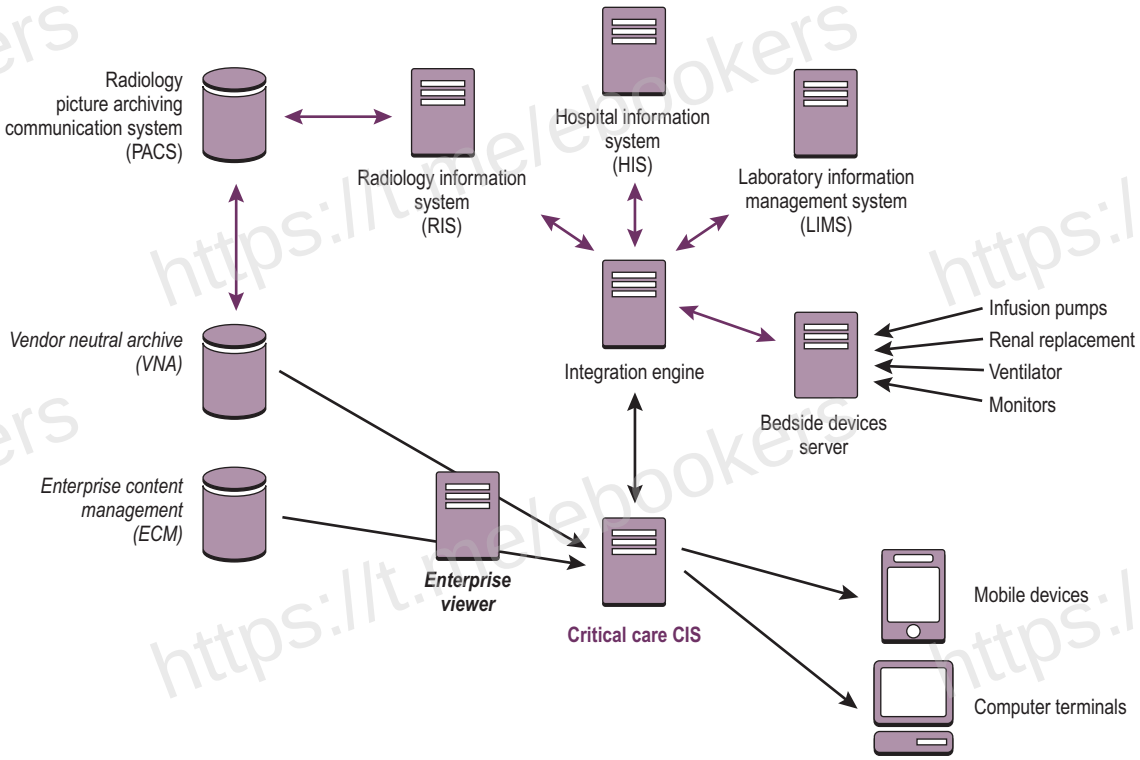
Several national projects have sought to expedite the uptake of digital health solutions. In the United States, the open-source VistA EMR is used across the Veterans Health Administration system, and under the Health Information Technology for Economic and Clinical Health (HITECH) Act, providers may receive financial incentives if they can demonstrate the use of an EMR against a timeline of requirements.[3] The UK National Health Service National Programme for Information Technology

ABSTRACT

The use of information technology to deliver patient care has perhaps no more obvious application than in the technology and data-rich environment of critical care. There are many perceived benefits, including reducing the documentation burden on staff, improving data quality through structured data entry, and improving patient safety through electronic ordering and clinical decision support. Here, we provide a clinician-orientated overview of the scope of clinical information systems, the practicalities of procurement and implementation, and the evidence base arguing their benefits – as well as disadvantages – in critical care.

KEYWORDS

Critical care
clinical information system (CIS)
electronic patient record (EPR)
eHealth
clinical decision support



System	Definition and scope
HIS	Hospital information system
LIMS	Laboratory information management system *Manages laboratory investigation orders, workflow and results*
RIS	Radiology information system *Manages radiology requests, workflow and reports*
PACS	Picture archiving and communication system *Stores images from modalities such as plain radiography or computerised tomography (CT)*
ECM	Enterprise content management *Manages scanned records such as clinic letters or investigation results from other providers, which are surfaced through an enterprise viewer*
VNA	Vendor neutral archive *Since multiple PACS may exist at one institution (e.g. cardiology, radiology), a VNA may be installed to provide a common archive, allowing all studies to be viewed together through an enterprise viewer*
Integration Engine	*Brokers exchange of data between systems*

Figure 9.1 Example critical care clinical information system and related systems architecture.

delivered a secure national healthcare network (N3) and an abbreviated national summary care record aggregated from primary care data, but was abandoned in 2011 amidst spiralling costs, slow implementation and lack of benefit in secondary and tertiary care.[4] This moved procurement of healthcare systems from regional back to the local level.

CRITICAL CARE CLINICAL INFORMATION SYSTEM REQUIREMENTS

BED STATE MANAGEMENT

A basic requirement is for users to admit, transfer and discharge patients to a virtual bed state. Along with

knowledge of elective bookings and the unit case mix, these data can be used to plan equipment and staffing allocations on a short-term basis, but by analysing trends over a longer period it also can be used to inform recruitment and procurement needs.

CLINICAL DOCUMENTATION

Arguably the most important clinical document in either a paper or a CIS-enabled unit is the bedside observation chart, and when implementing a CIS it is easy to underestimate the elegance of the paper chart that it supersedes. Many paper charts are oversized, allowing bedside staff not only to document hundreds of data points per hour but also, and more importantly, to quickly annotate and intuitively draw correlations between changes in treatments and vital signs. For example, a change in vasopressor dose and the effect on mean arterial pressure and urine output may be more difficult to identify on a chart presented on a smaller bedside display.

Regardless, a CIS can automate or mitigate a variety of manual charting processes:

- Data from bedside devices, such as vital signs, electrocardiogram waveforms, pump infusion rates, ventilator or renal replacement settings can be streamed direct to the CIS chart, removing the time and risk of error associated with manual transcription. This capability is dependent on the CIS and the bedside devices in use, and the renewal of older equipment may be necessary to realise this benefit
- Calculations (such as fluid balance and infusion concentration/dose/rate) and bedside assessment and severity scores (such as the Glasgow Coma Scale or Sequential Organ Failure Assessment [SOFA] tool) can be performed automatically
- Interfacing with other information systems and near patient analysers removes the need to transcribe results from blood gases, laboratory tests and imaging reports into the critical care record.

A CIS should provide an improvement in documentation standards, exceeding that expected by improving legibility over handwritten records alone. Acute problems, procedures, and past medical history should be coded via a standardised nomenclature, such as SNOMED (Systematized Nomenclature of Medicine) to improve audit, research and billing. A daily ward-round document can be designed with structured data fields, logic and mandatory items to ensure that key quality indicators, such as a ventilator-associated pneumonia care bundle, are consistently applied to every patient.

Finally, the CIS should provide a full audit trail for any data in the patient record. This should include the date and time that the entry was made (rather than the time on the chart it is recorded against) and the name of the user who made it. If the administration of a controlled medication requires a countersignature, then this should be catered for. If an entry is changed, then whilst the CIS should, by default, display the most recent version, it is vital that the previous entries are still accessible.

ORDER COMMUNICATIONS

Order communications (also referred to as computerised provider order entry [CPOE]) allows the caregiver to electronically request treatments, investigations and referrals. This feature may be managed by the critical care CIS or a separate institution-wide system.

Electronic prescribing of medications is often a main driver in CIS procurement. This is particularly true in critical care, where prescriptions may change frequently and are complex, involving specific quantities of diluent, weight-based dosing, or controlled rates of administration.

Investigation requests also can be enhanced by using validation logic, which can be used to ensure a minimum information standard, such as clinical findings or pregnancy status, is supplied before a request is accepted. However, the method by which results are conveyed back to the requesting team can be problematic. When a request a user has made produces an abnormal result, some systems can push messages to mobile devices or present an inbox of results, but this will depend on the CIS configuration. The feedback mechanism also needs to be flexible; as critical care providers especially work shifts, a message must be sent to a group of users to ensure it is actioned.

CLINICAL DECISION SUPPORT

Clinical decision support (CDS) describes the ability of a CIS to identify or group a constellation of information that is then used to flag potential diagnoses or requisite interventions, in order to promote adherence to unit protocols, policies or best practice. CDS can be classified as either passive or active:

- Passive CDS, where the user must proactively review information and decide its relevance to a clinical decision
- Active CDS, where the CIS applies rules to patient data in order to prompt the user with relevant alerts.

Using an example of a patient with acute respiratory failure, passive CDS might be used to present the user with a chart of a subset of patient data so that they might more easily identify a rising respiratory rate, pyrexia and inflammatory markers in the diagnosis of pneumonia. It might also include a link that displays the departmental antimicrobial prescribing guidelines in order to guide prescribing.

With active CDS, for the same patient the CIS may be configured to produce an alert when the clinical parameters exceeded their previous baseline values or an absolute limit. The alert could be displayed in the CIS user interface or routed to email or another messaging platform. When acknowledging the alert, the CIS could suggest the user order a chest radiograph and commence

antimicrobial therapy, and could use the recorded allergies in conjunction with the departmental prescribing guidelines to ensure an appropriate drug is prescribed.

REMOTE ACCESS

Data in the CIS can be accessed from outside the critical care unit or institution itself. This can provide some key logistical benefits, such as being able to prescribe remotely, allowing the intensivist to review progress whilst off site, or allowing a tertiary specialist to provide input on a case.

When used alongside videoconferencing technology, the system can be leveraged as a full critical care telemedicine solution. To date, this model of critical care delivery has been used principally in the United States, and although some studies and meta-analyses report reductions in mortality and length of stay, the findings are not uncontroverted and are based on observational before/after studies from a small number of US hospitals.[5,6]

IMPLEMENTATION

PROCUREMENT

Producing a business case for a critical care CIS begins with ascertaining the requirements of the service. This requires a detailed mapping of the clinical and information workflows, through which key stakeholders are identified. The importance of including users (both staff and patients), other relevant clinical units/services (such as radiology and pathology) and administrative services, such as billing and information, cannot be underestimated. The project budget must include the cost of seconding these staff to the project to support both the procurement and implementation phases, and backfilling their positions to prevent gaps in service.

There are two principal procurement strategies for EMRs: single vendor and 'best of breed'; a critical care CIS may be implemented as part of either. With the single vendor approach, the institution's EMR is broadly provided by the same product family. Whilst this provides a more consistent user experience and simplifies interfacing and ongoing maintenance, if the vendor cannot fully meet the requirements of a specific service, then their stakeholders will need to compromise on demands or seek a separate product, negating the single vendor approach entirely. With the 'best of breed' model, a different product may be selected based on its suitability for a particular clinical area. However, this approach brings the need to work with multiple suppliers, so this flexibility comes at a cost of more complex interfacing, contracting and maintenance requirements.

APPROACH

A successful implementation regards the CIS as a major change project, and uses it as an enabler and an opportunity to evolve existing business processes. If paper documents and forms are simply mirrored in an electronic solution, key opportunities to remove failure demand and detractors from the system will be missed.

Consideration must be also be given to data in legacy systems. The cost associated with migrating this to the new platform must be balanced against the need for the user to access two or more systems to view the complete patient record, as well as the ongoing maintenance costs of the existing data store.

CIS can be implemented across clinical areas and services incrementally, or simultaneously, as in a 'big bang' approach. Despite requiring greater support resources at the initial go-live, the latter is preferred by software vendors as incremental approaches are prone to implementation fatigue, where users become demotivated due to limited functionality and instead revert to paper-based workarounds.

RESILIENCE

Particularly in a high acuity area, such as critical care, the CIS vendor must provide assurances as to the reliability of their solution. A robust failover strategy must be in place, covering eventualities ranging from a remote server or local terminal hardware failure or power outage through to downtime associated with routine upgrades. The ability to retrieve a paper version of critical documents, such as the observations chart and drug record, is critical, and all staff should be clear of the operating procedure under such circumstances.

IMPACT

Given the disparity in global implementation and the capabilities of the products offered by different vendors, it is unsurprising that the evidence base for CIS implementation demonstrates both benefits, unintended consequences, and in some cases, harm.

DOCUMENTATION TIME

The perception of reducing documentation burden, freeing clinical staff for other aspects of patient care may not be realised. The impact varies depending on the care role, with tasks sometimes simply reallocated to other staff as part of the new digital workflow, rather than being eliminated altogether.[7,8] Time savings from automated calculations and the streaming of bedside devices data can be easily exceeded by complicating other aspects of documentation. These issues are compounded by the difficulties in training the large and transient critical care workforce.

PATIENT SAFETY

Several observational studies have looked at the effect of electronic prescribing in the ICU. Whilst reductions

in medication errors[9] and drug interactions[10] have been reported, the systems may introduce potential for new types of medication error at the same time.[11] Although there are obvious logistical benefits to remote prescribing, such as a reduction in verbal orders, to date no conclusive benefit in patient outcomes has been demonstrated, implying the reported improvements are in non-clinically significant errors.[12,13]

The evidence for CDS is particularly difficult to extrapolate to the wider ICU, given the variance in the types of intervention triggered by the system. Careful design and implementation of CDS is particularly important in the ICU, as the high prevalence of abnormal physiology and investigations may lead to 'alert fatigue', where staff dismiss advisories simply because the prompts appear too frequently. CDS has been shown to improve adherence to guidelines on mechanical ventilation,[14] sepsis[15] and antimicrobial prescribing.[16] However, systematic reviews of CDS across institutions have failed to demonstrate mortality benefit, and demonstrate only modest reductions in costs.[17–19]

UNINTENDED CONSEQUENCES

Following CIS implementation, both positive and negative behaviours can occur as users adapt to the change in their working environment. Frameworks to classify and avoid these unintended consequences have been developed.[20,21] The impact on interactions with the patient, team behaviour and the conduct of the intensive care unit (ICU) ward round also should be considered.[22]

RESEARCH AND AUDIT

An ICU CIS produces a vast dataset pertaining to each patient's stay. Acuity scores, unit activity and mandatory reporting datasets can be calculated, collected and presented automatically. When combined with data from other information systems, correlations can be drawn, for example, between the ICU visit and the surgical technique, or post-discharge patient reported outcome measures.

Also, there is an increasing requirement to submit such data sets to inform payment or as part of an externally mandated care quality and outcome assessment. An example from the United Kingdom is the ICNARC (Intensive Care National Audit & Research Centre) Case Mix Programme, to which all intensive care units must submit a quarterly dataset comprising patient demographics, acuity, treatments and outcomes for all admissions during that period.

Beyond this, the 'big data' opportunities for collaboration and machine learning are of significant interest. Although there are challenges, including appropriate anonymisation and cleansing of the dataset to exclude artefact and missing data points,[23] the last decade has seen major progress in the field. An example is the MIMIC-III (Medical Information Mart for Intensive Care) database, comprising data from over 40,000 critical care admissions to Beth Israel Deaconess Medical Center in Boston in the United States, which is freely available for research.[24]

SUMMARY

Whilst the benefits of CIS may seem many and obvious, they are far from guaranteed, and further research is required to validate their realisation as the software offerings improve and their use increases in clinical practice. The financial cost is significant and a well-planned and resourced implementation, with involvement of key clinical stakeholders from its inception through to completion, is vital to the success of the project.

Trials

Simon Finfer, Anthony Delaney

> *Evidence-based medicine is the conscientious, explicit and judicious use of current best evidence in making decisions about the care of individual patients. The practice of evidence-based medicine means integrating individual clinical expertise with the best available external clinical evidence from systematic research. Clinical expertise is reflected […] in the more thoughtful identification, and compassionate use of individual patients' predicaments, rights and preferences in making clinical decisions.*[1]

The most reliable evidence, and thus the best evidence for guiding clinical practice, will generally come from adequately powered and properly conducted randomised clinical trials (RCTs). It is commonly the case, however, that there are no RCTs that adequately address a particular question, so clinicians may have to assess the ability of other studies, such as cohort studies, case-control studies and systematic reviews to supplement their clinical expertise. It is important that clinicians are familiar with the underlying principles and potential sources of bias in each of these study designs, so they can incorporate evidence from reliable studies into their clinical practice and treat with appropriate caution those studies whose design makes it likely that they will produce unreliable results.

RANDOMISED CLINICAL TRIALS

The result of any clinical trial may be influenced by three factors: a true treatment effect, the effects of bias or confounding, and the play of chance. Randomised clinical trials, when properly designed, conducted and analysed, offer the optimal conditions to minimise bias and confounding, and to define the role that chance may have played in the results. As such, they represent the best study design to delineate true treatment effects under most circumstances. However, it is imperative that RCTs are designed, conducted, analysed and reported correctly. Studies that have not adhered to the principles outlined below may produce results that do not reflect a true estimate of treatment effects.

THE QUESTION TO BE ADDRESSED

Every trial should seek to answer a focused clinical question that can be clearly articulated at the outset. For example, 'we sought to assess the influence of different volume replacement fluids on outcomes of intensive care patients', is better expressed as the focused clinical question: 'we sought to address the hypothesis that when 4% albumin is compared with 0.9% sodium chloride (normal saline) for intravascular fluid resuscitation in adult patients in the intensive care unit (ICU), there is no difference in the rate of death from any cause at 28 days'.[2] The focused clinical question defines the interventions to be compared, the population to be studied and the primary outcome to be considered. This approach can be formalised using the PICO system: PICO stands for Patient, Intervention, Comparison, and Outcome. In the example above:

- Patient = adult ICU patient
- Intervention = albumin
- Comparison = saline
- Outcome = 28-day all-cause mortality.

The question that a trial is designed to address will vary somewhat depending on the stage of development of the proposed treatment. After development and testing in animal models, the testing of pharmaceutical agents in humans is generally conducted in three phases. Sometimes a fourth phase is added:

Phase I trial: testing in healthy volunteers

Phase II trial: first testing in a population of patients with disease to be modified, usually small trials focused on establishing safety and evidence of efficacy using surrogate outcome measures

Phase III: large-scale trial in patients that has sufficient statistical power to determine the effect of the treatment on the primary outcome of interest

Phase IV: post-marketing trials to confirm safety once the agent is introduced into clinical practice.

Trials may be designed to answer two quite different questions about the same treatment, and the design will be quite different depending on the questions to be answered. An 'efficacy trial' seeks to determine whether a treatment will work under optimal

ABSTRACT

The application of evidence-based medicine is a skill fundamental to the practice of critical care medicine. The best evidence to assess the risks and benefits of both new and currently used therapies will come from randomised clinical trials (RCTs). In order to conclude that the results of an RCT are reliable, it is important that bias is minimised. Key steps in minimising bias are randomisation that maintain allocation concealment, blinding whenever possible, control of confounding by assessing baseline balance and use of concomitant therapies, and complete follow up. It is also important that methods of analysis and reporting are robust and transparent. There are some questions faced by clinicians that will not be addressed by RCTs, and under these circumstances other study designs, such as cohort studies or case control studies, may provide the best available, although imperfect, evidence to guide care.

case control study

Table 10.1 Comparison of study characteristics using either an efficacy or an effectiveness approach when designing a study

STUDY CHARACTERISTICS	EFFICACY TRIAL	EFFECTIVENESS TRIAL
Research question	Will the intervention work under ideal conditions?	Will the intervention result in more good than harm under usual practice conditions?
Setting	Restricted to specialised centres	Open to all institutions
Patient selection	Selected, well-defined patients	A wide range of patients identified using broad eligibility criteria
Study design	Smaller RCT using parallel group or factorial or other approaches (crossover design)	Large multicentre RCT using parallel groups, or factorial cluster
Baseline assessment	Elaborate and detailed	Simple and clinician-friendly
Study intervention	Tightly protocolised. Optimal therapy under optimal conditions	Less tightly protocolised. Implemented in usual clinical practice
Co-interventions	Tightly controlled protocols for many aspects of care	All therapy based on local practice/ experience/minimal control
Compliance	Compliance essential	Noncompliance expected and considered in sample size/analysis
End-points	Disease-related. Related to biological effect 'Surrogate' end-points	Patient-related, such as all-cause mortality or quality of life
Analysis	By treatment received	Intention to treat
Sample size	Generally <1000 and often <100 patients	Several thousand patients
DATA MANAGEMENT		
Data collection	Elaborate	Minimal and simple
Data monitoring*	Detailed and rigorous	Minimal
Study management	Significant interventions and support from research staff	Minimal support and interventions from research team

*Data monitoring refers to the review of source documents and adjudication/verification of outcomes.

RCT, Randomised clinical trials.

Adapted from Hébert PC, Cook DJ, Wells G, et al. The design of randomized clinical trials in critically ill patients. *Chest.* 2002;121(4):1290–1300.

conditions, whereas an 'effectiveness' trial seeks to determine the effects of the intervention when applied in normal clinical practice. A comparison of the features of efficacy and effectiveness trials is given in Table 10.1 from Hébert and colleagues.[3]

POPULATION AND SAMPLE SIZE

The population to be studied will be defined by the study question. Efficacy trials may have a very narrowly defined population, with strict eligibility criteria and many exclusion criteria. Effectiveness trials are likely to have more broad inclusion criteria and few exclusion criteria. Regardless of the design, the population to be studied should be well described. This will allow readers to assess the scientific merit of the study and allows clinicians to judge whether the results of the study could apply to their patients, to assess the 'generalisability' of the results. Trials that include only a very narrowly defined population may also face difficulties in recruiting sufficient participants to reach a definitive conclusion.

How large do trials need to be to reach a definitive conclusion? In a parallel group trial, with a dichotomous outcome (e.g. alive or dead), the number of patients required to answer a question depends on four factors:

1. The percentage of patients expected to have the outcome in the control group – the control group outcome rate
2. The expected change (usually reduction) that may result from the treatment being tested – the treatment effect
3. The level of probability to be accepted to indicate that the difference did not occur by chance (i.e., the probability level at which a treatment effect will be deemed to be real) – significance level or α (almost always 0.05)

Table 10.2 Examples of sample size calculations

CONTROL GROUP OUTCOME RATE (%)	TREATMENT GROUP OUTCOME RATE (%)	ARR	POWER (β)	TOTAL SAMPLE SIZE
50	30	20	80	206
50	30	20	90	268
30	15	15	90	348
30	20	10	90	824
30	25	5	90	3428
15	10	5	90	1914
15	12	3	90	5582
10	8	2	80	6626
10	8	2	90	8802

ARR, Absolute risk reduction.

All calculations performed with STATA 8.2, assuming a two-sided $\alpha = 0.05$.

4. The desired percentage chance of detecting a clinically important treatment effect, if one truly exists (power: usually 80% or 90%).

In the past, trials addressing issues of importance in intensive care medicine were commonly too small to detect clinically important treatment effects,[4] but fortunately this is now changing.[2,5] The conduct of underpowered trials has almost certainly given rise to a significant number of false-negative results (type II errors) leading to potentially beneficial treatments being discarded. In order to avoid these errors, clinical trials have to include a surprisingly large number of participants. Examples of sample size calculations based on different baseline incidences, different treatment effects and different statistical power are given in Table 10.2.

RANDOMISATION AND ALLOCATION CONCEALMENT

Two components of the randomisation procedure are critically important. The first is the generation of a truly random allocation sequence; modern computer programs make this relatively straightforward. The second is the concealment of this allocation sequence from the investigators, so that the investigators and participants are unaware of the treatment allocation (group) prior to each participant entering the study.

There are a number of benefits to using a random process to determine treatment allocation. First, it eliminates the possibility of bias in treatment assignment (selection bias). In order for this to be ensured, both a truly random sequence of allocation must be produced, and this sequence must not be known to the investigators prior to each participant entering the trial. Second, it reduces the chance that the trial results are affected by confounding. A clinical characteristic (such as advanced age, gender or disease severity as measured by Acute Physiology and Chronic Health Evaluation [APACHE] or Sequential Organ Failure Assessment [SOFA] scores) that is associated with the outcome is known as a confounding factor. Randomisation of a sufficient number of participants ensures that both known confounders (e.g. age and severity of illness) and unknown confounders (e.g. genetic polymorphisms) are evenly distributed between the two treatment groups. The play of chance may still result in an uneven distribution of known confounding factors between the groups, and this is particularly likely in trials with fewer than 200 participants.[6] The third benefit of randomisation is that it allows the use of the probability theory to quantify the role that chance could have played when differences are found between groups.[7] Finally, randomisation with allocation concealment facilitates blinding, which is another important component in minimising bias in clinical trials.[8]

The generation of the allocation sequence must be truly random. There are a number of approaches to generating a truly random allocation sequence, most commonly using a computer-generated sequence of random numbers. More complicated processes where randomisation is performed in blocks, or is stratified to ensure that patients from each hospital in a multicentre trial or those with certain baseline characteristics are equally distributed between treatment groups, also can be used. Allocation methods based upon predictable sequences, such as those based on medical record numbers or days of the week, do not constitute true randomisation and should be avoided. These methods allow researchers to predict to which group a participant will be allocated prior to them entering the trial, which introduces the possibility of selection bias.

Whatever method is used to produce a random allocation sequence, it is important that allocation concealment is maintained. Methods to ensure the concealment of allocation may be as simple as using sealed opaque envelopes,[9] or as complex as the centralised automated telephone-based or web-based systems commonly used in large multicentre trials. In recent years, web-based randomisation has become the predominant method of assigning trial participants to treatment groups. Appropriate attention to this aspect of a clinical trial is essential as trials with poor allocation concealment produce estimates of treatment effects that may be exaggerated by up to 40%.[10]

THE INTERVENTIONS

The intervention being evaluated in any clinical trial should be described in sufficient detail that clinicians

could implement the therapy if they so desired, or researchers could replicate the study to confirm the results. This may be a simple task if the intervention is a single drug given once at the beginning of an illness, or may be complex if the intervention being tested is the introduction of a process of care, such as the introduction of a medical emergency or rapid response team.[11] There are two additional areas with regard to the interventions delivered in clinical trials that require some thought by those conducting the trial and by clinicians evaluating the results, namely blinding and the control of concomitant interventions.

BLINDING

Blinding, also known as masking, is the practice of keeping trial participants (and, in the case of critically ill patients, their relatives or other legal surrogate decision makers), caregivers, data collectors, those adjudicating outcomes and sometimes those analysing the data and writing the study reports, unaware of which treatment is being given to individual participants. Blinding serves to reduce bias by preventing clinicians from consciously or subconsciously treating patients differently on the basis of their treatment assignment within the trial. It prevents data collectors from introducing bias when recording parameters that require a subjective assessment (e.g. pain scores, sedation scores or the Glasgow Coma Score). Although many ICU trials cannot be blinded (e.g. trials of intensive insulin therapy cannot blind treating staff who are responsible for monitoring blood glucose and adjusting insulin infusion rates), the successful blinding of the Saline versus the Albumin Fluid Evaluation trial demonstrated the possibility of blinding even large complex trials.[2] Blinded outcome assessment is also necessary when the chosen outcome measure requires a subjective judgement. In such cases, the outcome measure is said to be subject to the potential for ascertainment bias. For example, a blinded outcome assessment committee should adjudicate the diagnosis of ventilator-associated pneumonia (VAP) and blinded assessors should be used when assessing functional neurological recovery using the extended Glasgow outcome scale; both the diagnosis of VAP and the assessment of the Glasgow outcome scale require a degree of subjective assessment and are therefore prone to ascertainment bias.

It has been traditional to describe trials as single blinded, double blinded or even triple blinded. These terms, however, can be interpreted by clinicians to mean different things, and the terminology may be confusing.[12] It is recommended that reports of RCTs include a description of who was blinded and how this was achieved, rather than a simple statement that the trial was 'single blind' or 'double blind'.[13] Blinding is an important safeguard against bias in RCTs and, although not thought to be as essential as the maintenance of allocation concealment, empirical studies have shown that unblinded studies may produce results that are biased by as much as 17%.[10]

CONCOMITANT TREATMENTS

Concomitant treatments are all treatments that are administered to patients during the course of a trial other than the study treatment. With the exception of the study treatment, patients assigned to the different treatment groups should be treated equally. When one group is treated in a way that is dependent on the treatment assignment but not directly related to the treatment, there is the possibility that this third factor will confound the outcome. An example might be a trial of pulmonary artery catheters (PAC) compared with management without a PAC. If the group assigned to receive management based on the data from a PAC received an additional daily chest X-ray to confirm the position of the PAC, they could conceivably have other important complications noted earlier, such as pneumonia, pulmonary oedema or pneumothoraces, and this may affect the outcome in a fashion unrelated to the data available from the PAC. Maintenance of balance in concomitant treatments is facilitated by blinding. When trials cannot be blinded, the use of concomitant treatments that may alter the outcome should be recorded and reported.

ADAPTIVE TRIAL DESIGNS

Traditional clinical trials have followed a fixed design from the start of participant recruitment until trial completion. This approach has many advantages, including simplicity and transparency, which may make the trial results more compelling to clinicians. In recent years, interest in the use of adaptive trial designs has increased. An adaptive trial is one in which the trial design is changed while the trial is being conducted. The change may be quite simple and easy to understand, such as changing the sample size, and in practice most trials have an adaptive design as they allow early stopping for either efficacy or futility in response to recommendations from an independent data-monitoring committee. A less well-established but equally simple adaptive design is increasing the sample size due to a lower than expected event rate; an example of this is the PROWESS-SHOCK study where a predetermined increase in the sample size occurred in response to a lower than expected mortality rate in patients with septic shock.[14] More complex adaptive designs are used in other fields of medicine such as oncology,[15] where design changes may include changing drug doses or dropping or adding trial arms or drug doses, changing the proportion of patients assigned to each arm of a trial or seamlessly moving from phase II to phase III within a single trial.[15] Although such designs have been rare in critical care research, the failure of clinical trials in areas such as industry-sponsored sepsis research may see adaptive

designs becoming more accepted in future years. The evaluation of multiple interventions or strategies in a single trial, the so-called "Platform Trial" may become a more efficient strategy to assess therapies for some syndromes that commonly lead to critical illness, but these types of trials are not yet common in critical care.[16]

OUTCOME MEASUREMENT

All clinical trials should be designed to detect a difference in a single outcome. In general there are two types of outcomes, clinically meaningful outcomes and surrogate outcomes.

A clinically meaningful outcome is a measure of how patients feel, function or survive.[17] Clinically meaningful outcomes are the most credible end-points for clinical trials that seek to change clinical practice. Phase III trials should always use clinically meaningful outcomes as the primary outcome. Examples of clinically meaningful outcomes include mortality and measures of health-related quality of life. In contrast, a surrogate outcome is a substitute for a clinically meaningful outcome; a reasonable surrogate outcome would be expected to predict clinical benefits based upon epidemiological, therapeutic, pathophysiological or other scientific evidence.[17] Examples of surrogate end-points would include cytokine levels in sepsis trials, changes in oxygenation in ventilation trials, or blood pressure and urine output in a fluid resuscitation trial.

Unless a surrogate outcome has been validated, it is unwise to rely on changes in surrogate outcomes to guide clinical practice. For example, it seemed intuitively sensible that after myocardial infarction the suppression of ventricular premature beats (a surrogate outcome), which were known to be linked to mortality (the clinically meaningful outcome), would be beneficial; unfortunately the CAST trial found increased mortality in participants assigned to receive antiarrhythmic therapy.[18] The process for determining whether a surrogate outcome is a reliable indicator of clinically meaningful outcomes has been described.[19]

ANALYSIS

Even when trials are well designed and conducted, inappropriate statistical analyses may result in uncertain or erroneous conclusions. A detailed discussion of the statistical analysis of large-scale trials is beyond the scope of this chapter but certain guiding principles can be articulated:

- All trials should adhere to a predetermined statistical analysis plan because otherwise the temptation to perform multiple analyses and report only those that support the preconceived ideas of the investigators may prove irresistible
- The convention of accepting a *P* value of <.05 to indicate 'statistical significance' is based on assessment of a single outcome. Assessing multiple outcomes increases the likelihood of finding a *P* value of <.05 purely due to the play of chance. Each trial should have a single predefined primary outcome measure. If more than one primary outcome measure is used then the *P* value used to indicate statistical significance should be reduced. The simplest method is to perform a Bonferoni correction, which divides 0.05 by the number of outcomes examined to determine the new level of statistical significance. Thus for two outcomes the *P* value must be below 0.025, and for three it must be below 0.017. The *P* value may also have to be reduced further if the trial employs interim analyses.

Clinicians should pay close attention to the analysis to make certain that a true intention-to-treat analysis is presented, and that any subgroup analysis is viewed with the appropriate amount of caution.

INTENTION-TO-TREAT ANALYSIS

Trials should be analysed using the 'intention-to-treat' principle. This means that all participants are analysed in the group to which they were randomised regardless of whether they received all or any of the treatment to which they were assigned. To some readers the intention-to-treat principle may appear intuitively incorrect; it is reasonable to ask why patients who did not receive the intended treatment should be included in the analysis. The use of intention-to-treat analysis prevents bias arising from the selective exclusion of patients – termed 'attrition bias'. In an appropriately sized trial, loss of patients at random should occur equally in both groups and the inclusion of those patients will not alter the result. If loss of patients is occurring as a nonrandom event (e.g. because of protocol violations or intolerance of the treatment in one arm of the trial) then the trial result will be different if the lost patients are excluded. Consider a trial of a 5-day course of L-NMMA for the treatment of patients with septic shock; in the trial a number of patients who receive L-NMMA die in the first 24–48 hours and are excluded from the analysis as they have received only a little of the study treatment. A trial report based on the remaining patients who completed the treatment protocol (per-protocol analysis) will not give a true estimate of the effect of using L-NMMA in clinical practice. Although this is an extreme example, once a patient is included in a trial his/her outcome should always be accounted for in the study report.

SUBGROUP ANALYSIS

Particular difficulties arise from the selection, analysis and reporting of subgroups. Subgroups should be

predefined and kept to the minimum number possible. When many subgroups are examined, the likelihood of finding a subgroup where the treatment effect is different from that seen in the overall population increases. A well-known example of this was the analysis of the treatment effect of aspirin in patients with myocardial infarction in the large Second International Study of Infarct Survival (ISIS-2) trial. Overall, the trial indicated that aspirin reduced the relative risk of death at 1 month by 23%. To illustrate the unreliability of subgroup analyses, the participants were divided into subgroups according to their astrological birth signs; the analysis showed that patients born under Libra or Gemini did not benefit from treatment with aspirin.[20] Although it is easy to identify this as a chance subgroup finding, this may be much harder when the choice of the subgroup appears rational and a theoretical explanation for the findings can be advanced. For example, in the Gruppo Italiano per lo Studio della Streptochinasi nell'infarto miocardico (GISSI) trial, subgroup analysis suggested that fibrinolytic therapy did not reduce mortality in patients who had suffered a previous myocardial infarct.[21] Although this finding appears biologically plausible, subsequent trials have shown quite clearly that fibrinolytic therapy is just as effective in patients with prior infarction as in those without.[22]

The separation of patients into subgroups should be on the basis of characteristics that are apparent at the time of randomisation. The selection of subgroups using features identified after randomisation risks introducing bias as the patients have already been subjected to the different study treatments, and the subgroup analysis will therefore not be comparing like with like.

TESTS OF INTERACTION VERSUS WITHIN-SUBGROUP COMPARISONS

Even when subgroups are selected appropriately, many readers will be tempted to draw inappropriate conclusions from the results. As the trial will have been designed to examine the effect of the treatment on the primary outcome in the whole study population, the best assessment of the treatment effect in any subgroup will be the effect seen in the trial as a whole. When analysing a subgroup result, the investigators should seek to answer the following question: 'Is the treatment effect in the subgroup different from the treatment effect seen in the remaining participants?' This is a test of interaction or of heterogeneity. Often the investigators err and perform within-subgroup comparisons, which instead answer the question: 'What was the effect of treatment A versus treatment B in this subgroup?' Within-subgroup comparisons are more likely to lead to unreliable results. Journals such as the *New England Journal of Medicine* provide guidelines for the analysis and reporting of subgroup effects.[23]

REPORTING

The reporting of randomised controlled trials has been greatly improved by the work of the CONSORT (Consolidated standards of Reporting Trials) group.[13,24] The consort statement provides a framework and checklist (Table 10.3) that can be followed by investigators and authors to provide a standardised high-quality report.[24] An increasing number of journals require authors to follow the CONSORT recommendations when reporting the results of a randomised controlled trial. The group also recommends the publication of a structured diagram that documents the flow of patients through four stages of the trial – namely, enrolment, allocation, follow-up and analysis (Fig. 10.1). It is likely that the use of the CONSORT statement to guide the reporting of RCTs does lead to improvements, at least in the quality of reporting of randomised controlled trials.[25]

Trials may report results using a number of values that, taken together, will give readers a full understanding of the trial results. These may include a *P* value, confidence intervals and the number needed to treat (or harm).

- *Probabilities:* the *P* value represents the probability that a difference has arisen by chance. In very large trials, small and clinically insignificant differences may give rise to *P* value of less than .05 and, conversely, a moderately sized trial may report a clinically important difference with a *P* value that is close to or greater than .05; *P* values should not be viewed in isolation but should be assessed in combination with other measures, such as confidence intervals and the number needed to treat (or harm).
- *Confidence intervals:* these give an indication of the precision of the result. Whenever a trial reports a difference it is reporting a difference found in a finite sample of the population of interest. If the same trial is repeated, it is highly likely that a slightly or very different result will be reported. If the trial is reporting a relatively small number of patients with the outcome of interest (small number of events) then the difference between the results may be large; if the trial reports a large number of events then it is likely the two results will be quite close to each other. Confidence intervals give a range of values within which it is likely the 'true' result lies – they give an indication of the precision of the result. The most commonly quoted are the 95% confidence intervals; these are the limits within which we would expect 95% of study results to lie if the study were repeated an infinite number of times, though they are often interpreted to mean that we can be 95% confident that the 'true' result lies within these limits.
- *Number needed to treat (or harm):* a useful concept for clinicians is the number needed to treat (or harm). This is the reciprocal of the absolute difference in outcomes arising from two treatments. For example,

Table 10.3 The Consort 2010 checklist of information to include when reporting a randomised trial*

SECTION/TOPIC	ITEM NO.	CHECKLIST ITEM
TIME AND ABSTRACT		
	1a	Identification as a randomised trial in the title
	1b	Structured summary of trial design, methods, results and conclusions (for specific guidance see CONSORT for abstracts)
INTRODUCTION		
Background and objectives	2a	Scientific background and explanation of rationale
	2b	Specific objectives or hypothesis
METHODS		
Trial design	3a	Description of trial design (such as parallel, factorial) including allocation ratio
	3b	Important changes to methods after trial commencement (such as eligibility criteria), with reasons
Participants	4a	Eligibility criteria for participants
	4b	Settings and locations where the data were collected
Interventions	5	The interventions for each group were sufficient
Outcomes	6a	Completely defined pre-specified primary and secondary outcome measures, including how and when they were assessed
	6b	Any changes to trial outcomes after the trial commenced, with reasons
Sample size	7a	How sample size was determined
	7b	When applicable, explanation of any interim analyses
RANDOMISATION		
Sequence generation	8a	Method used to generate the random allocation sequence
	8b	Type of randomisation; details of any restriction (such as blocking and block size)
Allocation concealment mechanism	9	Mechanism used to implement the random allocation sequence (such as sequentially numbered containers), describing any steps take to conceal the sequence until interventions were assigned
Implementation	10	Who generated the random allocation sequence, who enrolled participants, and who assigned participants to interventions
Blinding	11a	If done, who was blinded after assignment to interventions (e.g. participants, care providers, those assessing outcomes and how)
	11b	If relevant, description of the similarity of interventions
Statistical methods	12a	Statistical methods used to compare groups for primary and secondary outcomes
	12b	Methods for additional analyses, such as subgroup analyses and adjusted analyses
RESULTS		
Participant flow (a diagram is strongly recommended)	13a	For each group, the numbers of participants who were randomly assigned, received intended treatment, and were analysed for the primary outcome
	13b	For each group, losses and exclusions after randomisation, together with reasons
Recruitment	14a	Dates defining the periods of recruitment and follow-up
	14b	Why the trial ended or was stopped
Baseline data	15	A table showing baseline demographic and clinical characteristics for each group
Numbers analysed	16	For each group, number of participants (denominator) included in each analysis and whether the analysis was by original assigned groups
Outcomes and estimation	17a	For each primary and secondary outcome, results for each group, and the estimated effect size and its precision (such as 95% confidence interval)
	17b	For binary outcomes, presentation of both absolute and relative effect sizes is recommended

Table 10.3 The Consort 2010 checklist of information to include when reporting a randomised trial—cont'd

SECTION/TOPIC	ITEM NO.	CHECKLIST ITEM
Ancillary analyses	18	Results of any other analyses performed, including subgroup analyses and adjusted analyses, distinguishing pre-specified from exploratory
Harms	19	All-important harms or unintended effects in each group for (specific guidance see CONSORT for harms)
DISCUSSION		
Limitations	20	Trial limitations, addressing sources of potential bias, imprecision, and, if relevant, multiplicity of analyses
Generalisability	21	Generalisability (external validity, applicability) of the trial findings
Interpretation	22	Interpretation consistent with results, balancing benefits and harms, and considering other relevant evidence
OTHER INFORMATION		
Registration	23	Registration number and name of trial registry
Protocol	24	Where the full trial protocol can be accessed, if available
Funding	25	Sources of funding and other support (such as supply of drugs), role of funders

*We strongly recommend reading this statement in conjunction with the CONSORT 2010 Explanation and Elaboration for important clarifications on all the items. If relevant, we also recommend reading CONSORT extensions for cluster randomised trials, non-inferiority and equivalence trials, non-pharmacological treatments, herbal interventions, and pragmatic trials. Additional extensions are forthcoming: for this and for up-to-date references relevant to this checklist see www.consort-statement.org.

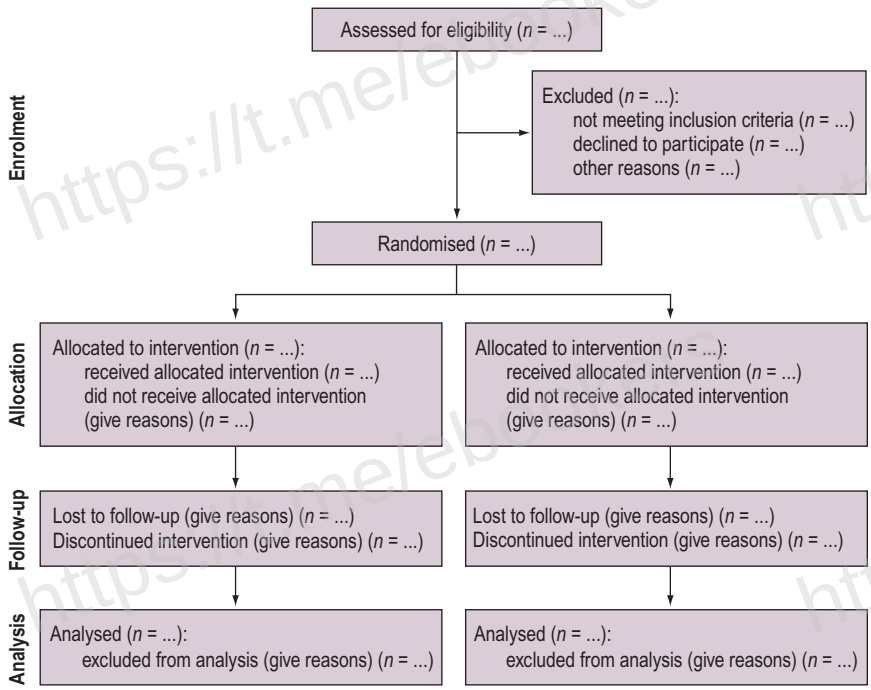

Figure 10.1 Flow diagram of the progress through the phases of a randomised trial. *From Schulz KF, Altman DG, Moher D, CONSORT Group. CONSORT 2010 statement: updated guidelines for reporting parallel group randomised trials.* BMJ *2010;340:c332, with permission.*

in the ISIS-2 trial, patients randomised to intravenous streptokinase had an absolute reduction in mortality of 2.8%. Thus the number needed to treat to prevent one death is 100/2.8 or 35.7 patients. As the trial was very large with a large number of events (17,187 participants and 1820 deaths), this relatively small absolute reduction in mortality (2.8%) yielded a *P* value of less than .000001. The same calculation can be performed to calculate the number needed to harm. For example, in the CRASH trial, patients with traumatic brain injury treated with high-dose steroids had a 3.4% increase in the absolute risk of death. The number needed to harm is calculated as 100/3.4, or one extra death for every 29.4 patients treated with high-dose corticosteroids. Again, as this was a large trial (10,008 participants and 1945 deaths) the *P* value is small (*P* = .00001).

ETHICAL ISSUES SPECIFIC TO CLINICAL TRIALS IN CRITICAL CARE

The ethical principles guiding the conduct of research in critical care are outlined in the International Ethical Guidelines for Health-Related Research Involving Human Subjects,[26] in addition country-specific guidelines are provided by various national bodies. The ethical principles of integrity, respect for persons, beneficence and justice, should be considered whenever research is conducted and an appropriately convened human research ethics committee or the equivalent should assess all research to ensure adherence to these principles. As the potential participants in critical care research are particularly vulnerable, owing to the nature of the conditions and the limitations to communication that exist, special consideration needs to be given to a number of areas including informed consent.

INFORMED CONSENT

That all mentally competent participants in clinical research should give informed consent prior to entering a study is an important ethical principle. This is rarely possible for people suffering critical illness, where the disease process (e.g. traumatic brain injury, encephalitis, severe hypoxaemia) or the required treatment (e.g. intubation, use of sedative medications) may make it impossible to obtain informed consent. Even awake, alert patients may not be able to give fully informed consent when they are facing stressful and potentially life-threatening situations.[27] This applies equally to surrogate decision makers. However, the treatment of critically ill patients can be improved only through the conduct of research and in many jurisdictions this has been recognised by making special provisions for consent in emergency research, including research in the critically ill. In some circumstances, it may be ethical to allow a waiver of consent for research involving treatments that must be given in a time-dependent fashion (e.g. in the setting of cardiac arrest). A waiver of consent may improve recruitment into clinical trials; it is unclear whether this approach is universally acceptable. Another approach has been to allow deferred consent or consent to continue, where patients are included in the study and consent from the patient or the relevant surrogate decision maker is sought as soon as practical. Neither approach is without problems.[28]

CRITICAL APPRAISAL

Clinicians reading reports of randomised controlled trials should use a structured framework to assess the methodological quality of the trial and the adequacy of the trial report. They should also address the magnitude and precision of reported treatment effects and ask themselves whether the results of the trial can be applied to their own clinical practice. There are a number of resources available to assist clinicians in this task, notably the Users' Guides to the Medical Literature, originally published in *JAMA* and the Critical Appraisal Skills Program from Oxford, United Kingdom, both of which are freely available on the Internet.[29,30] These resources provide a structured framework that allows any reader to perform a systematic critical appraisal of almost any piece of medical literature. A checklist is provided for the appraisal of randomised controlled trials (Box 10.1).

Box 10.1 Critical appraisal checklist for randomised controlled trials

I. Are the results of the study valid?

Primary guides: Was the assignment of patients to treatments randomised?

1. Were all patients who entered the trial properly accounted for and attributed at its conclusion?
2. Was follow-up complete?
3. Were patients analysed in the groups to which they were randomised?

Secondary guides: Were patients, health workers, and study personnel 'blind' to treatment?

1. Were the groups similar at the start of the trial?
2. Aside from the experimental intervention, were the groups treated equally?

II. What were the results?

How large was the treatment effect?

1. How precise was the estimate of the treatment effect?

III. Will the results help me in caring for my patients?

Can the results be applied to my patient care?

1. Were all clinically important outcomes considered?
2. Are the likely treatment benefits worth the potential harms and costs?

From *Centre for Health Evidence*. Users' Guides to Evidence-Based Practice. <http://www.jamaevidence.com>; 2007.

OBSERVATIONAL STUDIES

Although RCTs are the optimal study design for deciding whether or not a treatment 'works', not all research questions can be addressed with this type of study. When the disease is rare, the outcome is rare or the treatment may be associated with harm, other study designs may be more appropriate. In these circumstances a cohort study or case-control study may be used to explore potential associations between exposure to a treatment and the occurrence of outcomes.

DESCRIPTIVE STUDIES

Case reports, case series and cross-sectional studies are all examples of descriptive studies. These types of studies may be important in the initial identification of new diseases, such as HIV/AIDS[31–34] and severe acute respiratory syndrome.[35] The purpose of these studies will be to describe the 'who, when, where, what and why' of the condition, and therefore further the understanding of the epidemiology of the disease. It is important that clear and standardised definitions of cases are used, so that clinicians and researchers can identify similar cases from the information provided. Although there are some famous examples where data from simple observational studies have been used to solve particular problems,[36] in general only very limited inferences can be drawn from descriptive data. In particular, it is dangerous to draw conclusions about 'cause and effect' using data from descriptive studies alone.[37]

ANALYTICAL OBSERVATIONAL STUDIES

There are two main types of analytical observational studies: case-control studies and cohort studies.

Case-control studies are performed by identifying patients with a particular condition (the 'cases'), and a group of people who do not have the condition (the 'controls'). The researchers then look back in time to ascertain the exposure of the members of each group to the variables of interest.[38] A case-control design may be appropriate when the disease has a long latency period and is rare. Cohort studies are performed by identifying a group of people who have been exposed to a certain risk factor and a group of people who are similar in most respects apart from their exposure to the risk factor. Both groups are then followed to ascertain whether they develop the outcome of interest. Cohort studies may be the appropriate design to determine the effects of a rare exposure, and have the advantage of being able to detect multiple outcomes that are associated with the same exposure.[39]

Both types of observational studies are prone to bias. In particular, although it is possible to correct for known confounding factors using multivariate statistical techniques, it is not possible to control for unknown or unmeasured confounding factors. There are a number of other biases that may distort the results of observational studies; these include selection bias, information bias and differential loss to follow-up.[39,40] Critical appraisal guides for observational studies are available to help readers assess the validity of these studies.[41] These limitations and inherent biases mean that observational studies may not always provide reliable evidence to guide clinical practice, although it has been argued that this is not always the case.[42,43]

SYSTEMATIC REVIEWS AND META-ANALYSES

Systematic reviews have been proposed as a solution to the problem of the ever expanding medical literature.[44] A systematic review uses specific methods to identify and critically appraise all the RCTs that address a particular clinical question and, if appropriate, statistically combine the results of the primary RCTs in order to arrive at an overall estimate of the effect of the treatment. By systematically assembling all RCTs that address one specific topic, methodologically sound systematic reviews can provide a valuable overview for the busy clinician. They play an important role in providing an objective appraisal of all available evidence and may reduce the possibility that treatments with moderate effects will be discarded owing to false-negative results from small or underpowered studies.[45] The use of meta-analysis could have resulted in the earlier introduction of life-saving therapies, such as thrombolysis for acute myocardial infarction.[46] By using systematic methods, meta-analyses can provide more accurate and unbiased overviews, drawing conclusions that are often at odds with those of 'experts' and narrative reviews.[47,48]

In spite of these advantages and benefits, there are still problems with the conduct and interpretation of meta-analyses. Trial level meta-analyses may include trials that are subsequently retracted due to errors or even fabrication. Patient level meta-analyses (also known as independent patient data meta-analyses), in which researchers gather together and aggregate trial databases, may overcome these concerns but are expensive and time consuming to conduct, and not all investigators are prepared to share their trial databases. Like all research, meta-analyses need to be performed with attention to methodological detail. There are guidelines for performing and reporting systematic reviews.[49,50] It is clear that in the critical care literature these guidelines are not always followed.[51] Clinicians should critically appraise the reports of all systematic reviews and meta-analyses regardless of the source of the review, using an appropriate guide.[52,53] Problems with interpretation can arise when the results of meta-analyses are at odds with the results of large RCTs that address the same issue;[54,55] this is not uncommon, and

clinicians will have to compare the methodological quality of the meta-analyses and the RCTs included in it with the validity of the large RCT in order to decide which provides the most reliable evidence.[2,56]

Palliative care

Sarah Cox, Kate Urwin

The World Health Organisation defines palliative care as an approach that improves the quality of life of patients and their families facing the problems associated with life-threatening illness, through the prevention and relief of suffering by means of early identification and impeccable assessment and treatment of pain and other problems, physical, psychosocial and spiritual (Box 11.1).[1]

Palliative care clearly has a place in the care of patients identified as dying on the intensive care unit (ICU). In addition, the principles of palliative care may be appropriate for patients with life-limiting disease admitted to the ICU for treatment of reversible causes, such as neutropenic sepsis as a consequence of palliative chemotherapy. The palliative care team may also have a role in the care of patients with long-term conditions being considered for ICU admission. This chapter reviews the issues around identification and management of palliative and end-of-life care for ICU patients. It will also address some of the practical, ethical and emotional issues that arise.

PRE-ADMISSION TO INTENSIVE CARE UNIT

Admission to the ICU requires a judgement about the likelihood of benefit for the individual patient. Whilst this is often a discussion between the ICU or critical care outreach team, the usual medical team and the patient and family, the palliative care team may have an important role to play. Firstly, they can be part of a discussion about the appropriateness of aggressive treatment. Secondly, it may be helpful to underline that if ICU care is not the chosen course of action, there is another specialist team who will be involved to ensure good symptom control and emotional support. Their expertise in communication can be useful in clarifying goals aligned with the patient's wishes, if known, including access to pre-existing advance care plans from community health care teams. They can support family and ward staff with an alternative approach to care. They may become the point of contact for the family providing continuity and reassurance in what is often an emotionally fraught situation.

PATIENTS ON INTENSIVE CARE UNIT WHO ARE DYING

Around 5% of deaths in the United Kingdom and 20% of deaths in the United States occur on the ICU.[2–4] Not all of these deaths could or should be predicted, but the proportion that follow a period of treatment withdrawal is increasing in both North America and Europe.[2–4] This suggests an identifiable end-of-life phase, which could be managed with palliative care principles in mind, or as shared care with a specialist palliative care team.

There is great variability between services and cultures in identification of an end-of-life phase. Up to 90% of deaths in North American ICUs happen after decisions to limit life-sustaining treatment.[2] In northern Europe the figure is lower at around 50%, and 20% in southern Europe.[3,4] While these differences might be explained by the greater availability of ICU beds in America or less selective admission criteria, it is likely that they reflect, at least in part, cultural differences in the expectations of treatment.

Scales such as the Acute Physiology and Chronic Health Evaluation (APACHE III) have been developed to help predict outcomes of ICU intervention,[5] but they are not sufficiently precise to be helpful in end-of-life decision making for an individual.[4] Frequently, ICU admission represents a therapeutic trial with both clinicians and family sustaining hope until it is clear the trial has failed. Only then, which may be very late in the acute illness, will a transition to the goals of palliative care be considered appropriate. There may be an opportunity therefore to communicate uncertainty earlier on in the ICU stay so that active and palliative care can occur together.

What constitutes a good death depends on the views of the individual; however, there are some common themes from the literature including freedom from pain and other symptoms, and the ability to retain some degree of control, autonomy and independence.[6] For patients dying on the ICU the last three are difficult to achieve. However, they suggest delivering treatment that supports patients'

ABSTRACT

Palliative care is most obviously appropriate not only for patients who have a recognised dying phase on the intensive care unit (ICU) but also for symptom control and shared decision making in patients admitted with long-term conditions. This chapter discusses the place of palliative care for patients on the ICU, pre-admission to ICU and those dying patients who are stepped down from the ICU. The importance of excellent communication between patients, families and staff is highlighted, particularly as shared decision making results in better decisions and greater satisfaction. The assessment and management of the common symptoms seen on the ICU are explored. The ethical issues involved in withdrawing and withholding treatment are discussed. The chapter concludes with guidance around care for the dying patient and those around them.

KEYWORDS

Palliative care
end-of-life care
symptom control
shared decision making
withdrawal of treatment
care of the dying

Box 11.1 World Health Organization definition of palliative care

- Provides relief from pain and other distressing symptoms
- Affirms life and regards dying as a normal process
- Intends neither to hasten nor postpone death
- Integrates the psychological and spiritual aspects of patient care
- Offers a support system to help patients live as actively as possible until death
- Offers a support system to help family members cope during the patient's illness and in their own bereavement
- Uses a team approach to address the needs of patients and their families, including bereavement counselling if indicated
- Will enhance quality of life, and may also positively influence the course of illness
- Is applicable early in the course of illness, in conjunction with other therapies that are intended to prolong life, such as chemotherapy or radiation therapy, and includes those investigations needed to better

Based on Sepúlveda C, Marlin A, Yoshida T, Ullrich A. Palliative care: the World Health Organization's global perspective. *J Pain Sympt Manage.* 2002;24(2):91–96.

Box 11.2 Patients' and intensive care unit nurses' priorities for a good death

Patients[6]	*Intensive care unit nurses*[7]
Adequate pain and symptom management	Managing pain and other symptoms
Avoiding inappropriate prolongation of dying	Promoting earlier cessation of treatment or not initiating aggressive treatment at all
Achieving a sense of control	Knowing and following the patient's wishes for end-of-life care
Relieving burden on others	Communicating effectively as a health care team
Strengthening relationship with loved ones	

values and beliefs, including appropriate limitation of the use of aggressive treatments. Surveys of patients and ICU nurses suggest a clear overlap between them in the priority of avoiding prolongation of dying (Box 11.2).[6,7]

For relatives of patients dying on the ICU, a good death requires attention to comfort, and more particularly to pain management. Families rate whole-person concerns highly, including feeling that their relative was at peace and retained dignity and self-respect.[8] Satisfaction of families is also related to clarity around the processes of limiting treatment, with trials of treatment being explained and withdrawal or withholding of treatment occurring as expected.[9]

DECISION MAKING FOR PATIENTS AT THE END OF LIFE

INVOLVEMENT OF PATIENTS

In the 1990s, the Study to Understand Prognoses and Preferences for Outcomes and Risks of Treatments (SUPPORT) study team reported their prospective observation of over 9000 seriously ill hospitalised patients.[10] The authors identified overaggressive management, inadequate pain control and poor communication amongst a significant number of those who went on to die. There was evidence that physicians were often not aware of patients' wishes around medical care.

Patients' preferences for treatment may be accessed directly in only a small minority of cases admitted to the ICU. Occasionally, a valid and applicable advance directive exists, or patients have a statement of wishes or have discussed their preferences for treatment with close family. The majority (up to 95%) of patients requiring admission to the ICU will be unable to engage in discussions about treatment choices, and most will not have discussed their wishes with relatives or recorded them in writing.[11] Offering advance care planning to individuals with chronic progressive diseases is being encouraged, but as yet has only been taken up by a small minority. Ideally, in the future, advance care planning in patients with progressive medical conditions may be helpful in respecting patient wishes around ICU care.

Where patients are able to discuss options for treatment, it should be considered that they may have a variable understanding of medical interventions. Both patients and clinicians tend to overestimate the likelihood of success, with optimism on the part of the patient and a reluctance to be pessimistic on the part of the clinicians.[12] However, discussions about treatment that include details of the likely outcome and potential burden can significantly reduce patient preferences for those treatments where the medical benefit is uncertain.[13]

INVOLVEMENT OF FAMILIES IN DECISION MAKING

The realisation that active treatment is no longer in the patient's best interests comes to health professionals, patients and families at different times. Partly this is due to experience and training and partly a sometimes unrealistic belief in what ICU treatment can achieve. Managing the different expectations is challenging. Families want to be involved in decision making, especially around value-laden decisions, such as withdrawal of life support,[14] but they will need to have clear explanations of their relative's condition and the purpose and limitations of treatment. Their role, and the role of the health care team, should be to advocate for the patient, making the decision that the patient would have made had they been able.[15] Relatives are able to identify patient preferences with agreement of 80% or greater in situations where the impact of the physical insult is either mild

or devastating.[16] However, there is a dramatic drop in agreement (down to around 60%) for more ambiguous scenarios associated with long-term physical or cognitive morbidity. In these situations, relatives are more likely than patients to identify the clinical outcome as acceptable.

Effective, frequent and timely communication with relatives increases satisfaction with care and reduces anxiety in bereavement.[17] Insufficient time spent communicating with families results in poor understanding of the diagnosis, prognosis and plan of care, and in increased conflict.[18] Time spent is not, in itself, enough, and far more important is the clinicians' ability to elicit and respond to families' views and concerns. Families judge the quality of the discussion, at least in part, by how much time they are allowed to speak rather than encouraged to listen.[19] Although the communication skills of ICU staff may be excellent, the additional resource of the palliative care team can also be useful in these situations.

INVOLVEMENT OF OTHER HEALTH PROFESSIONALS IN DECISION MAKING

ICU nurses often feel frustrated by the medical plan, especially when, in their view, conflicting or overly optimistic messages are given to patients or family members.[20] In contrast, physicians are reported to feel the burden of making decisions about limiting treatment and that 'it's a lot easier to say it than to do it'.[21]

Collaboration between these professionals has the potential to produce better-informed decisions, which can lead to greater satisfaction with care for patients, families and the professionals involved.[22,23] Not surprisingly, inconsistent messages and non-collaborative interprofessional behaviours result in family dissatisfaction.[24] Shared decision making will reduce the burden of decision making on senior ICU physicians, but it still usually remains their ultimate responsibility. Three studies of collaborative decision making involving at least nurses, physicians and family have demonstrated the additional benefits of reduced length of ICU stay and lower costs with no increase in mortality.[22,23,25]

There is much literature published on the involvement of other professionals in end-of-life decision making. Lilly et al. included a social worker and a chaplain in their model of family meetings[22]; others have suggested the importance of considering other specialists, such as physiotherapists (respiratory therapists)[26] or palliative care clinicians.[27] Involvement of clinical ethicists has been demonstrated to improve satisfaction of both health care professionals and families, and to reduce length of ICU stay and costs for patients who died.[28]

WITHHOLDING AND WITHDRAWAL OF TREATMENT

Patients identify the avoidance of inappropriate prolongation of dying in their definition of what a 'good death' might look like.[6] There is agreement in the United States and northern Europe that where treatment is not going to succeed it should be withheld or withdrawn.[4,29,30] However, there is wide variation in withholding and withdrawing treatment across countries.[4] Differences have also been measured in what ICU physicians believe they should do and what actually happens, with physicians identifying a significantly greater need for withholding or withdrawing treatment than their practice demonstrates.[5]

The ethical basis for withholding treatment is the same as that for withdrawal; however, the practice of withdrawal is often emotionally more difficult for all concerned. This may be a result of the more active nature of withdrawal.[29] It is also possible that some ICU treatments, when withdrawn, result in rapid decline and death with a greater requirement for symptomatic medication, and this temporal association presents an uncomfortable comparison with the act of euthanasia. However, allowing inevitable death and euthanasia are ethically and, in most countries, legally distinct. It is the intention behind each decision to withhold or withdraw that is critical.

Decisions to limit treatment include discontinuing monitoring vital signs, withholding cardiopulmonary resuscitation, vasopressors, antibiotics and artificial hydration, and the removal of mechanical ventilation. All decisions should be considered individually in terms of the benefit and burden to the patient, and in the context of the goals of care. In the large, prospective study of end-of-life practices in European ICUs, the Ethicus study group identified wide variation in withdrawal (5%–69%) and withholding (16%–70%) of therapy.[5]

Decisions to remove or reduce mechanical ventilation at the end of life present particularly difficult ethical and practical issues. Differing practices of weaning ventilation from rapid to prolonged are described. Proponents of the former suggest that prolonged weaning prolongs dying and therefore unnecessary suffering.[31] Those in support of prolonged weaning argue that a rapid reduction in ventilation may be associated with more dyspnoea.[29] Extubation is practised by some ICU physicians who argue that there is discomfort associated with the endotracheal tube itself and that there is no ethical justification in leaving the tube in place once a decision has been made to discontinue life-sustaining treatment.[29,32] However, there is a significant incidence of stridor and laboured breathing in extubated patients, which suggests this approach may induce more symptoms than it relieves.[32]

There has been concern about the doses of opioids and benzodiazepines required to control dyspnoea and agitation, especially in rapid weaning or extubation, and whether in fact these medications themselves bring about the patient's death. The principle of double effect holds that the unintended consequence (death) is ethically acceptable because of the intended effect (symptom control). This is a controversial position with which some are uncomfortable. In fact the principle of double effect may not be relevant as small studies in ICU

Box 11.3 Recommendations for managing the transition from active to palliative care on the intensive care unit

- Inclusive and collaborative decision making
- Consistent communication with family that begins early
- Identification of trials of therapy with timed reassessment against clinical milestones
- Concurrent attention to symptom control, spiritual and psychological support of patient and family
- Clarity about withholding and withdrawing treatment
- Guidance for 'stepping-down' to general hospital wards
- Inclusion of organ donation in consideration
- Assessment of bereavement risk for onward referral if appropriate
- Support of staff

show that the doses of opioids and sedatives required for symptom control are relatively modest[33,34] and in dying palliative care patients these drugs do not appear to hasten death.[35,36]

Given such variations in practice and the potential for different interpretations of intentions in withdrawing or withholding life-sustaining treatment, excellent communication between the multiprofessional team and the family, and clear documentation of the intent and decision-making process leading to it, are paramount (Box 11.3).

SYMPTOM CONTROL

Patients on the ICU experience a high level of symptoms including pain, dyspnoea and anxiety.[10] Symptom assessment usually involves taking a detailed history from the patient to understand the cause and severity of the symptom. In many ICU patients at the end of life this is not possible, so physiological variables and behavioural observations are used as surrogate markers, such as heart rate and respiratory rate. The use of validated pain scales, such as the Behaviour Pain Scale[37] or Pain Assessment Behaviour Scale[38] may provide more objective records of pain to direct changes in dose of symptomatic medication. Involvement of the specialist palliative care team may be useful when the situation is unclear or symptoms prove difficult to control.

Dyspnoea correlates most strongly with tachycardia and tachypnoea[39] and may be treated symptomatically with opioids with the addition of benzodiazepines to reduce anxiety if necessary. Treatments, such as oxygen, corticosteroids and diuretics, may be appropriate if they improve symptomatic control of breathlessness. Signs of agitation, anxiety or behavioural markers of pain that do not respond to opioids, and may be caused by general distress, can be treated with benzodiazepines. Specialist palliative care input may be helpful if symptoms fail to respond to usual measures.

The choice of opioid and benzodiazepine varies; it is important for units to use the particular drug most familiar to them. Morphine is first line, but it should not be used in patients with moderate to severe renal impairment as accumulation can result in additional symptoms. Fentanyl or alfentanil are common alternatives in this situation. Drug doses should be titrated against symptoms and escalated in response to documented markers of distress.

SUPPORT FOR FAMILIES AND STAFF

Patients and families will need support in the form of effective communication and they may also need psychological support. This is often provided by ICU staff, particularly the nursing staff, with whom they may have spent significant time. Offers of additional psychological support should be made to patients and family members and accessed from the specialist palliative care team and from chaplaincy.

Palliative care continues as bereavement care after the patient dies. In practice, most bereavement support from the ICU is offered immediately after death or by external agencies. Needless to say, relatives need to be informed of the death in a sensitive manner; they also need to understand the cause of death. Features of a patient's illness and death can guide identification of family members who may be at risk of complicated bereavement, alongside features of the bereaved person, such as psychological morbidity, their relationship with the deceased and their social support. Referral to a local bereavement service or requesting permission to call the family doctor and arrange an appointment may be appropriate.

Bereavement surveys suggest ways we could improve the impact of relatives' deaths on the ICU, including skilled communication during the critical illness and after death. Post-traumatic stress-related symptoms are more common among family members who felt information giving was incomplete.[40] These symptoms can subsequently translate to increased rates of anxiety and depression.

ICU staff have emotional responses to the death of their patients, which need to be addressed to avoid burnout or other negative long-term sequelae.[41,42] Support might include debriefing around deaths, a supportive environment and access to psychosocial resources. Collaborative decision making would be expected to reduce staff stress about dying patients.

ORGAN DONATION

The topic of organ donation and the ICU is more fully discussed in Chapter 102. Involvement of the palliative care team may be helpful to provide additional emotional support to the family. Also, there may be an important role in managing signs of distress, especially during

withdrawal of treatment in donation by cardiac death (DCD). In DCD, the family may wish to be with the patient whilst treatment is withdrawn. This process is an opportunity for them to say goodbye, and they may have specific wishes around prayer or cultural rituals that should be elicited and honoured as far as possible. Provision should be made for appropriate symptomatic drugs to be with the patient during DCD to treat signs of distress, as these will be unpleasant for the family, although they may not be experienced as discomfort by the patient. In some units, the palliative care team takes over the care of patients if they do not die within the timeframe for DCD, moving them to another ward or palliative care unit within the hospital.[43]

CARE PLANS TO SUPPORT END-OF-LIFE CARE ON INTENSIVE CARE UNIT

Individualised care plans and protocols have been recommended to improve the care of dying patients on the ICU.[44,45] Care plans should address appropriate assessment of symptoms, communication with the family and patient if possible, psychological and spiritual support and support with practical issues, such as open visiting and free car parking.[44] They act as a reminder to consider the appropriateness of each treatment in terms of the burden and benefit, and support the nursing staff in monitoring and maintaining comfort on an ongoing basis.

STEPPING DOWN FROM INTENSIVE CARE UNIT

Some patients are able to transfer out of the ICU for their last days, but this transition needs to be managed carefully to avoid additional family distress. The initial suggestion of stepping down from the ICU is another opportunity to utilise the palliative care team's expertise.

This transition is both a physical and emotional one for patients and families who may feel that this step away from critical care in some way seals the fate of the patient. They will be concerned about losing the skilled staff and the environment they know. Their anxiety may be compounded by the knowledge that there is not the same ratio of staff to patients outside the ICU.[46] Clear information about changes in ward and treatments may help to reduce the anxiety.

A member of the palliative care team can be helpful in providing continuity around this transition. If invited to meet the patient and family before transfer, they can begin to understand the specific needs of the patient and family members, including symptom control, emotional and spiritual issues.

The move should take place in a planned way with the family given as much forewarning as possible. Ideally, the patient should not be transferred at night or weekends if this means there is less support available. Treatments and monitoring should not be discontinued immediately before transfer, although some changes may be necessary if the 'step-down' ward does not usually care for patients with arterial lines or intravenous opioid infusions. The palliative care team can help to advise about the practicalities of continuing symptomatic medications after the move, and managing this transition seamlessly.

CONCLUSION

With advances in technology, there is likely to be an increase in trials of ICU treatment, and a corresponding increase in the transition to palliative care on the ICU. How this is managed will depend on local access to specialist palliative care resources and the focus of the ICU staff. Limitation of treatment, in whatever guise, is a difficult area and constitutes a significant part of clinical practice on the ICU. It is immensely important to patients, their relatives and clinicians and deserves to be more openly discussed. Review of ICU deaths at mortality and morbidity meetings could include consideration of the quality of the patient's end-of-life care and family support to promote learning and improve care for subsequent patients.

Intensive care and the elderly

Linsey Emma Christie, Richard T Keays

The proportion of the elderly population is increasing in all developed and developing nations. Medical innovation and a belief that old age and disease can be defeated by a combination of personal choice and greater resources has led to rising, often unrealistic, expectations. Increasingly, intensive care medicine is becoming a specialty largely focused on care of the elderly and the age-acquired co-morbidities of this patient group complicate their management. This chapter seeks to bring together the current information on management of the elderly presenting to critical care.

DEFINITIONS

There is no agreed definition of 'elderly'. It has been defined by chronology, social role, physical capacity, threshold life expectancy and when 'active contribution is no longer possible'. Most commonly, it is taken as the pension age – though this is an inherently fluid end-point. In 1875, the over-50s were defined as elderly, whereas now it seems around the pension age of 65, although the over-80s are also becoming an 'identifiable' group. These chronological niceties are rarely relevant from a medical perspective, as clinicians understand the poor correlation between chronological and physiological age. The medical literature has no common definition and uses a wide range of arbitrary values from 67 to 70, over-70s and, more recently, over-80s to describe population groups.[1]

DEMOGRAPHICS

More people are living longer and this trend has shown little sign of stopping. In the UK, the 2014–2015 Office for National Statistics report demonstrated that the most common age at death was now 85 for men and 89 for women.[2] In 2015, there were over half a million people aged 90 or more in the United Kingdom (0.9% of the population).[3] The proportion of the population estimated to be over 65 by 2060 is 26%[4], compared to 2011 when it was 16%[5]. Current United Nations projections predict the population of over 80s will double by 2050, representing 10% of the total population in developed countries. There are some signs this inexorable rise in life expectancy may have peaked. In the United Kingdom, overall life expectancy at birth has remained virtually unchanged in recent years.[2] For the first time in 50 years Spain reported a fall in life expectancy,[6] a finding repeated in some parts of the United States.[7] These recent declines have been attributed to familiar factors accounting for poor health: obesity, tobacco and other preventable risks.

Nevertheless, the post-war increase in longevity means many more elderly people present to critical care than previously. This greater longevity may be attributable to improved diet and better lifestyle decisions, but is also explained by improved disease management; however, the resultant gain in survival is at the price of living with morbidity. Not only are there more elderly patients but also they have more significant co-morbidity and thus a greater likelihood of developing a critical illness.

These societal changes are reflected in the intensive care unit (ICU) demographics. In Australia and New Zealand, 13% of ICU admissions were over 80 years old and the numbers had been increasing by about 5% per annum between 2000 and 2005.[8] Unsurprisingly, the chances of being admitted to the ICU are somewhat related to resource availability. In 2005 the number of ICU beds per 100,000 population was 3.3 for the United Kingdom, 7.8 in Australia, 24 in Germany and 20 in the United States.[9] A study comparing the United States with the United Kingdom in terms of hospitalisation and the elderly found that 47% of British over-85s died in hospital, whereas this figure was only 31% in the United States; however, only 1.3% of these patients received intensive care in the United Kingdom compared with 11% in the United States.[10] Of all hospital discharges, only 2.2% of patients had received intensive care in the United Kingdom compared with 19.3% in the United States.

Approaching the problem from a different direction is to consider what happens to a whole cohort of elderly people. One such longitudinal study from America following over 1 million elderly patients over a 5-year follow-up period found that over half were admitted to a higher dependency care unit at some point.[11]

THE AGEING PROCESS

Individuals accumulate co-morbidities with pathophysiological consequences as they age, but these physiological changes are both unpredictable and extremely variable across any population. Ageing is the combination of

ABSTRACT

The elderly population is increasing and presents a challenge for those working in critical care. Decisions regarding admission and ongoing management of individual patients require the intensive care unit (ICU) team to consider not only the acute reason for potential admission, but also the physiology of ageing, possible co-morbid disease, frailty, disability and pharmacology concerns (including the use of multiple medications). Outcomes for the elderly in the ICU are worse than for younger patients, yet many do have a good outcome and return home. A risk-benefit analysis, incorporating patient views if possible, is required to identify those most likely to benefit and minimise harm.

physiological change and accumulated pathophysiology (Fig. 12.1). Examples of physiological changes associated with ageing include maximal oxygen uptake, cardiovascular function, muscle mass, tissue elasticity, memory and reaction time, but there are many more.[12]

THE ORGAN SYSTEMS

Each organ system undergoes age-related declines; however, in addition, there are specific disease-related organ alterations leading to a net impairment of organ function. A brief overview of changes associated with age and the impact of the more common co-morbidities follows.

CARDIOVASCULAR CHANGES

The heart has reduced contractility and overall mechanical efficiency[13] caused by:

- altered connective tissue compliance due to interstitial collagen being laid down
- reduction in myocyte numbers
- valve hardening and sclerosis, which can affect function
- fibrosis and cell loss in conduction pathways impairing conduction
- deterioration in the sinoatrial node
- ventricular hypertrophy with slower myocardial relaxation.

The result of these changes is a reduction in arterial compliance with an earlier return of the reflected wave in systole. Normally, cardiac pulsatile energy is absorbed at the arteriolar segmental level in the young but not in the elderly. Aortic impedance increases and higher blood flow organs show familiar signs of microvasculopathy. This, coupled with the tendency for pulse pressure to rise with age, means that ventricles hypertrophy and cardiac work increases. The resultant increasing oxygen demand occurs against a background fall in diastolic coronary blood flow with ventricular hypertrophy.

Both contraction and relaxation phases are slower. Diastolic filling time is reduced, which places an extra emphasis on the atrial component to maintain this filling resulting in a reversal of the E/A ratio (early-to-late diastolic-filling velocity). Subsequent atrial dilatation is more likely to lead to atrial fibrillation, significantly compromising ventricular filling. The smaller end-diastolic volume is poorly tolerated, and impaired cardiac performance ensues.

In addition to these changes, coronary flow reserve is limited, blood vessels are less easily dilated and there is a chronically elevated basal sympathetic tone. Baroreceptor reflexes are impaired and there is decreased sodium conservation.

In summary, the main ageing changes are myocardial and vascular stiffening, with impaired cardiac and vascular compliance. The blunted sympathetic responses produce the 'hyposympathetic heart' with a tendency to increased end-diastolic volume. Additionally, there is an age-related reduction in cardiac contractility. Overall cardiac reserve and flexibility of response are reduced, but are usually more than able to deal with the normal physical requirements of the elderly – though not with more excessive demands (Box 12.1).[13,14]

Box 12.1 Cardiovascular ageing

- Cellular changes: reduced excitation contraction coupling, calcium homeostasis, myocyte function and increased atrial natriuretic peptide
- Decrease in myocytes, altered connective tissues, increased ventricular wall size
- Reduction in conductive tissues and numbers of sinus node cells
- Decreased contractility, reduced ventricular compliance, increased ventricular filling pressure, blunting of β-adrenoceptor responsiveness, reduced coronary flow reserve
- Stiffer arteries, reduced elasticity
- Thicker media and intima
- Alterations in autonomic tone with reduced β-adrenoreceptor-mediated vasodilatation; reduced NO activity
- Reduced heart rate, increased end-diastolic volume, increased stroke volume, reduced peak values for ejection fraction, cardiac output
- Impaired conduction, atrial fibrillation
- Clinical effects: more arrhythmias, hypertension, reduced exercise tolerance, dyspnoea and heart failure

ACQUIRED CARDIOVASCULAR DISEASE

Atherosclerosis is detectable much earlier in life and starts to become relevant around 40 years of age in males and after menopause in females. For people older than 65 years, 40% of deaths are cardiovascular and this increases with age. Diabetes, smoking, poor blood pressure control and high cholesterol all increase the risk of death from cardiovascular disease and most become more common with age.[15] Myocardial infarction carries a higher mortality in the elderly and the risk associated with interventional treatments is also higher.[13,14] The Framingham study showed that 40% of myocardial infarctions in those over 75 were silent.[16] In addition, arrhythmias, such as atrial fibrillation, are more common as a chronic feature in the elderly but most particularly affect the postoperative patient. In one study, 22% of over-70-year-olds developed postoperative atrial fibrillation.[17] When it does occur, patients may be more at risk from hypotension, cardiac failure and myocardial infarction. The most common cause of death amongst the over-85s in the postoperative period is myocardial infarction.[18]

RESPIRATORY

Lung function decline starts at around the age of 35 years. Muscle function is impaired by a combination of reduced fast twitch fibres and muscle atrophy, so between the ages of 65 and 85 there is a decrease in maximum inspiratory pressure, maximum voluntary ventilation and forced expiratory volume-1. Impaired diaphragmatic strength impacts on force of coughing. Degeneration of elastic fibres in the lung parenchyma leads to air space enlargement. Chest wall compliance is reduced and a rise in closing volume results in increasing V/Q mismatching. This whole effect has been termed 'senile emphysema' and is often accompanied by age-related β-receptor dysfunction.

Gas transfer is also affected – diffusing capacity of the lungs for carbon monoxide (DLCO) declines with some impairment of oxygenation (about 0.5 kPa/decade) but there is no discernible effect on carbon dioxide clearance. Both the hypoxic and hypercapnic respiratory control responses are blunted. Exercise capacity, as shown by V_{max}, declines by about 1% per year after the age of 30.[18–20]

Less direct intrinsic and extrinsic changes also occur that will impair respiratory function. Diminished antioxidant defences have been observed and bronchial lavage sampling shows changes in both immunoglobulin and CD4/CD8 ratios implying chronic antigenic stimulation. There is also an increasing age-related burden of problems, such as nocturnal gastroesophageal reflux, kyphosis, vertebral collapse and sleep apnoea. The likelihood of environmental exposure to agents with the potential to cause lung damage, most particularly tobacco smoke, increases with age.

Hence it is predictable not only that more elderly patients will require respiratory support but also that ventilatory weaning is going to be more challenging. Mortality is also likely to be higher compared with younger populations. An American study confirms that the likelihood of requiring ventilation does increase with age, with an estimated 10% chance in the over-75s.[21] Amongst those who are ventilated, mortality in the over-70s is nearly double that in the under-40s,[22] and there is a high 3-year mortality in those discharged from the ICU with 57% of deaths occurring early after discharge.[23] This bleaker picture is offset to some extent in those with chronic obstructive airways disease; patients with acute exacerbations have a lower mortality at 28% compared with other causes of respiratory failure. Nevertheless, even among ICU survivors in this group the extent of premorbid problems and the need for ongoing care at discharge dictates outcome; if they were not fit to go directly home then mortality is higher[24] and a high proportion will still need help with at least one activity of daily living, and the quality of life scores are low – though not necessarily lower than they were premorbidly.

RENAL

Kidney size becomes smaller with age due to a reduction in the number of nephrons; 20% to 30% of glomeruli become sclerotic and the glomerular filtration rate may diminish by 50% by 80 years of age. However, this is neither consistent nor predictable.[25] Not only does creatinine clearance start to decline from the fourth decade of life, but renal blood flow also decreases by about 10% per decade. Tubular exchange of sodium and hydrogen

ions is also reduced, with impaired ability to handle fluid loads and acidaemia. Rarely is this ever seen as a clinical or biochemical entity, but it does represent a reduction in reserve capacity and manifests only when acute stressors are applied. In the elderly, the competing needs of the kidney versus the heart make the treatment of incipient failure of either organ problematic, and failure of one organ can cause failure of the other – this has been termed 'cardiorenal syndrome'.[26]

The risk of developing acute kidney injury increases with age and is especially associated with co-morbidities such as cardiac failure and renovascular disease, and acquired preconditions such as known nephrotoxic drugs, surgical interventions and sepsis. Obstructive uropathy may be a consequence of the increasing prevalence of prostatic disease. Many drugs have been implicated, but non-steroidal analgesics and angiotensin converting enzyme (ACE) inhibitors stand out. Surgery involves acute changes to blood pressure and volume status, but carries the additional risk of abdominal hypertension.

There is an attributable mortality associated with acute kidney injury, though it is difficult to tease out. It appears that this may be similar between the young and the old[27] and has been variously quoted at between 15% and 40%. The outcome from acute kidney injury is determined by cause and prior functional status, with drug-related renal failure doing better than most other causes. The mean survival of octogenarians after an episode of acute renal failure was 19 months, but complete recovery of renal function occurs in just over half of the survivors.[28] In one study, only 3 out of 23 biopsies of acute kidney injury showed evidence of acute tubular necrosis.[29] Those with pre-existing chronic renal failure are seven times more likely to progress to long-term dialysis.[30]

A secondary but important effect in the elderly is that there is often a reduced ability to excrete drugs. The consequence may be prolonged half-life (by a factor of 1.4), altered volumes of distribution (+24%) and reduced clearance.[31] This is probably a source of excess morbidity in the elderly.

LIVER

This is relatively unaffected and has huge intrinsic reserve so that a reduced mass of up to 30% at 80 years probably has little effect, other than loss of reserve. There is a tendency to reduced liver blood flow by up to 40% at 80 years and reduced metabolic function, in particular demethylation and the production of cholinesterase. It may have some effect on drug handling, but is rarely of clinical relevance.

It is acquired liver disease (most commonly cirrhosis) that is the potent predictor of mortality and this has a peak age of presentation in the sixth or seventh decades of life. Nevertheless, age itself is not a poor prognostic indicator in the context of patients with cirrhosis requiring intensive care.[32]

CENTRAL NERVOUS SYSTEM

There is often some decline in cognitive performance with age, though this is contentious. Memory loss is apparent in 10% of those over 70 years of age and about half of these are due to some variant of Alzheimer disease. This incidence doubles with each decade.[12] The neurocognitive decline is multifactorial but is associated with cerebral vasculopathy, decline in sex steroids, neurochemical alterations such as melatonin and sleep disorders, which are common in the elderly. Dementia has strong associations with cerebral vascular pathology and strokes, but previous head injury is also important. A new era of dementia treatment is imminent and may alter the ICU perspective about the irreversibility of this condition.

Unsurprisingly, patients with neurocognitive decline are much more likely to experience delirium. Up to two-thirds of patients aged over 65 years experience delirium in hospital and, in the ICU, one-third of patients are admitted with it and one-third develop it following admission.[33] Delirium is common after major surgery and trauma; for example, it occurs in up to 60% of patients following a hip fracture. Delirium can lead to long-term cognitive impairment[34], lengthens hospital stay and is an independent predictor of 6-monthly mortality.[35]

Age is a risk factor for persistent psychological issues and part of this may be related to post-traumatic stress disorder.

Psychological assessment of the elderly post-intensive care is in its infancy. The existing tools for assessing delirium are the Confusion Assessment Method for ICU (CAM-ICU) and Intensive Care Delirium Screening Checklist (ICDSC). An ICDSC score of more than 4 correlates with both increased mortality and, in survivors, persistent cognitive dysfunction. More recently, the 10-risk-factor assessment tool PREdiction of DELIRium in ICu patients (PRE-DELIRIC) has been validated for the ICU.[36] With increasing awareness of the problem, these scoring systems may be used more widely, and appropriate interventions implemented to both prevent and manage delirium.

METABOLIC

Over the age of 70 there is a tendency for weight loss with a general change in body composition, leading to increased fat and reduced muscle mass. This sarcopenia is manifested by a 30% reduction in main muscle group strength by the seventh decade of life.[37] With less musculoskeletal activity, there is less energy use, less heat production and a reduced calorie requirement with a 2% decrease in basal metabolic rate (BMR) per decade. Protein requirements stay broadly the same.

Malnutrition is common and calorific intake is often inadequate. This 'anorexia of ageing' is multifactorial and is not just psychosocial – there are some fundamental physiological changes: early satiation is common and gastric emptying is delayed with the feeling of fullness

suppressing ghrelin, thereby reducing appetite, as do raised cholecystokinin levels, which are also common. Dehydration and micronutrient deficiencies are also frequent. Loss of water-soluble vitamins such as thiamine occurs with diuretic therapy. B12 deficiency occurs due to atrophic gastritis and reduced intrinsic factor secretion. Calcium and vitamin D deficiency is also common in the elderly.[38]

Weight loss, frailty and reduced functional capacity will predispose to morbidity, complications, survival, and in survivors it will reduce the ability to regain independence.

SPECIAL CONSIDERATIONS

Having discussed the organ system considerations, both in terms of the physiological process of ageing and the acquisition of co-morbidities, it is notable that some elderly patients may also have additional issues, such as frailty or a disability, which can affect care. Whilst in many ways the elderly have the same requirements as any other intensive care unit patient, these other areas do require special attention.

FRAILTY

It is vital to consider in more detail the concept of 'physiological age' versus 'chronological age' – essentially frailty. Frailty has been defined as 'a condition characterised by loss of biological reserve and vulnerability to poor resolution of homeostasis following a stressor event'.[39] One method of frailty assessment is the 7-point Clinical Frailty Scale.[40] Recent studies demonstrate that assessment of frailty may be useful in predicting adverse events, morbidity and mortality post ICU.[41–43] Therefore, identification of frailty may help with prognostication, detection and intervention in this high-risk group.

DISABILITY

Some elderly patients may also have a disability that can affect care (e.g. hearing or vision loss).

PHARMACOLOGY

There are marked changes in pharmacokinetics and pharmacodynamics in the elderly. Due to the impaired ability of the kidneys to excrete drugs, drug half-lives may be prolonged. The volume of distribution may also either increase or decrease depending on the drug and the changes in body composition.[31] For example, the aminoglycosides not only may achieve higher concentrations than predicted through distribution changes, but also may remain higher for longer due to impaired excretion. Non-steroidal anti-inflammatory drugs may have profound and potentially toxic effects by the potent combination of a relatively smaller volume of distribution and the possibility of relative dehydration producing high drug levels; the associated drug-related inhibition of the prostaglandins would promote renal vasoconstriction, reducing renal blood flow and resulting in renal toxicity.

There may be changes in sensitivity to drugs, partly through altered pharmacokinetics as described, or through interaction with physiology, such as the decline in sensitivity to beta-adrenergic agonists and antagonists with age. By a similar mechanism, the incidence of orthostatic hypotension with antihypertensive drugs increases. The central nervous system, however, becomes more sensitive to centrally acting drugs.

Fluid management must incorporate some general considerations. These include the potential presence of both cardiovascular and renal impairment (cardiorenal syndrome), a reduced flexibility in cardiac output and an increasing dependence on alterations in systemic vascular resistance. This, along with changes in body composition, may alter fluid distribution. However, it is unpredictable across the population and therefore should be assessed in the individual.

The biggest single problem in the pharmacology of the elderly is poly-pharmacy. Elderly patients will often be on a panoply of medications depending on their chronic health problems. Most drugs have side effects and interactions and, as the number of medications increases, so too does the likelihood of complications from their use – especially when the patient is ill. The classic example is antihypertensive drugs in the elderly causing postural hypotension. The role of poly-pharmacy in hospital and ICU admission has two very different mechanisms: firstly, the drugs being the source of the problem and, secondly, the impact of inadvertent discontinuation of important medications.[44] It is not a minor issue, and an important part of the assessment of the elderly should be rationalisation of medication.

SURGICAL OUTCOME

Increasing numbers of elderly patients are having progressively more complex surgery performed upon them. Both operative mortality and postoperative complications are higher in the elderly and again relate to the existence of co-morbid disease, frailty and lack of physiological reserve. The fitter the patient the less likely he/she is to experience complications, and this is true for both cardiac and noncardiac surgery.[45,46] The National Confidential Enquiry into Patient Outcome and Death (NCEPOD) published a report in 2010 called 'An Age Old Problem'. This report examined all deaths in patients aged 80 or over within 30 days of surgery within a 3-month period. Some key findings were that (1) routine daily input from Medicine for the Care of Older People is vital; (2) co-morbidity, frailty and disability are independent markers of risk; (3) delays in surgery are associated with a poor outcome; and (4) there is an ongoing need to provide level 2 and 3 perioperative care. Furthermore, over 90% of this population had co-morbid disease.[47] In the over-80s age group, it has been shown that medical patients had longer ICU lengths of stay and higher ICU and

hospital mortality than surgical patients.[48] One study in the over-80s showed that 6-month mortality rates after ICU discharge were 30% for planned surgical patients compared with 76% for emergency surgical patients.[49] Elderly patients presenting as emergencies have been eloquently described as 'a heterogeneous cohort of both potentially treatable patients and those who are dying'.[50] Distinguishing the treatable from the futile is difficult across all age groups, but is particularly so in the elderly where limited life expectancy is usual and severe, but unrecognised co-morbidity may exist. Committing patients and their families to emotional and physical hardship is clearly justifiable with a good outcome, but far harder to defend if the outcome was never likely to be good. The patient's wishes or preferences should ideally be taken into account, but frequently that is not possible. This is an area of practice that has not been studied but anecdotally it is very poorly managed.

INTENSIVE CARE UNIT OUTCOME

How the interaction between age itself, the severity of the acute illness, or the accumulated co-morbidities and declining functional status due to ageing affects ICU outcome is uncertain (Fig. 12.2). Acute Physiology and Chronic Health Evaluation (APACHE) scoring attributes only 7% of the outcome predictive power to age alone. Nevertheless, in some studies of ICU admissions, increasing age does appear to be independently associated with higher 30-day hospital mortality.[51] One study suggests that, for the over-80s, half will not survive the ICU, but half the survivors will be alive 2 years later.[52] In a study in Canada, one-quarter of patients aged 80 years or over who were admitted to the ICU survived and returned to baseline function at 1 year. This recovery was significantly associated with younger age, lower APACHE II score, lower Charlson co-morbidity score, lower frailty index, lower baseline physical function score, and specific admission diagnoses.[53] Intuitively, the pre-morbid functional status and presence of co-morbidities should significantly affect ICU outcome. Even supposedly soft indicators, such as coming from a care home, was associated with higher in-hospital mortality; also the medium-term mortality at 6 months is increased if the patient is discharged to care facilities.[23] In a study of over 15,000 elderly patients compared with non-elderly ICU admissions, the elderly were more likely to have greater co-morbid illnesses and higher illness severity scores, which led to a higher ICU mortality. These patients were more likely to be discharged to either rehabilitation or long-term care.[54] Conversely, other studies have failed to find an association between outcome and pre-existing co-morbidities or functional status.[55] Elderly (aged 65 years or over) trauma patients in the ICU may have a worse outcome than previously thought, with a recent study demonstrating a 45% in-hospital mortality and only 23% of survivors being discharged home.[56]

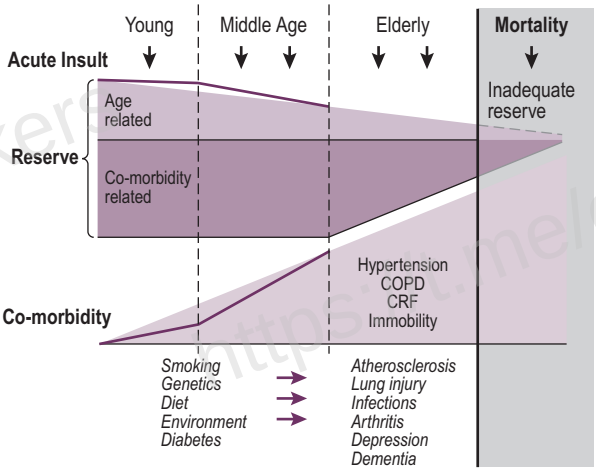

Figure 12.2 Factors affecting intensive care unit outcome. *COPD*, Chronic obstructive pulmonary disease; *CRF*, chronic renal failure.

Age itself is not a useful prognostic indicator and its use as a surrogate for general status is unpredictable. Nevertheless, it is possible to conclude that the outcome for elderly patients admitted to ICU is poorer than for younger patients, but that the outcome relates to the premorbid state (including co-morbidities and frailty), the severity of the acute illness and the presence of an underlying fatal illness, as in other populations.[52]

Quality of life is probably a more relevant factor than survival. Most patients will have significant functional disability on ICU discharge, which may improve, although the evidence is difficult to interpret. In general, those experiencing major acute events with little pre-existing co-morbidities report a substantially lower quality of life afterwards compared with those with significant pre-existing co-morbidities; this is most probably due to relatively lower expectations in the latter group. It is a contentious area with some studies showing no real impairment in quality of life, whereas others show a significant decline in quality of life.[57]

Probably the best indicators of real outcome for the elderly are measures, such as returning home, which has rarely been assessed but is often a very important consideration for the individual. Conti and colleagues assessed this with the results seen in Box 12.2; this approach is probably more relevant than mortality figures.[58] In a recent Canadian study, only 45% of medical and 41.6% of surgical emergency patients aged 80 or over were able to return home to live post-ICU.[48]

In the future, there needs to be more focus on both physical and mental functionality as an outcome measure. Patients need to be alive and have reasonable functional status, and ideally be able to return home. In order to achieve the best outcome for patients, multidisciplinary assessment, including the need for early rehabilitation, is crucial.

Box 12.2 Factors that influence elderly patients getting home from the intensive care unit

Important factors
- Over 75 years of age
- Neoplasia
- Chronic heart failure
- Neurological or neurosurgical cause for admission
- Trauma
- Respiratory failure
- Cardiology
- Neurological complication
- Cardiological complication
- Haematological complication
- Surgical complication

Less important
- Planned surgery
- Visceral surgery
- Chronic renal disease
- Living alone

From Conti M, Friolet R, Eckert P, et al. Home return 6 months after an intensive care unit admission for elderly patients. *Acta Anaesthesiol Scand*. 2011;55:387–393, with permission.

ASSESSMENT FOR ADMISSION

Premorbid functionality and the severity of co-morbid illnesses are of paramount importance when deciding on an elderly patient's suitability for admission. This must be put in the context of the acute insult and an analysis of whether the disease process is reversible, and if the patient is salvageable. If not, then the application of intensive care is likely to impose a physical and mental burden on the patient and their family that cannot be justified by the likely negative outcome. Objective decision making is problematic, and it is worth noting that physicians may overestimate the mental and functional status of patients accepted for admission and underestimate it for those whose admission is rejected.[59] Age has little role to play in this decision other than its association with physiological decline and the acquisition of co-morbidity. Further data may enable more accurate risk prediction systems to be created, thereby enhancing informed doctor–patient dialogue on the outcome. It is also worth remembering that many elderly patients will have one form or another of advanced directive.

HISTORY

This should involve speaking to the patient or, if impossible, to their relatives to make an assessment of their previous functionality physically and mentally. Establish whether co-morbidities are present and if so how severe. Determine whether the patient is living at home or in a home and how independent he/she is. Living in a nursing home may sometimes, but not always, be a surrogate for significant functional impairment.[54] In the elderly nursing home population, anaemia, cancer, heart failure, renal failure and chronic obstructive pulmonary disease (COPD) are all related to a poor 1-year outcome. For those with previous hospital admissions, a history of ventilation is also a potentially important feature. There is a need to know the physical and mental trajectory over the last few months or years, which may indicate significant functional decline. Details relating to level of activity (house, room, chair or bed bound) are powerful indicators (Box 12.3).

Box 12.3 History

Where do they live – at home or in care?
Independence – how much support?
Mobility – shopping, walking
Memory – confusion, sleeping pattern
Previous hospital admissions – in particular, ventilation or chronic renal failure
Co-morbidity – respiratory, cardiology and neurology, but also arthritis and mobility
Drugs
Patient's preferences if known

CLINICAL SIGNS

The general habitus is revealing. Posture, muscle bulk, or more often wasting, and the condition of the skin all help indicate long-term physical well-being or otherwise. Ill health is a potent cause of self-neglect, so the state of the teeth, the lower legs and the feet are very important indicators. Peripheral oedema and infection indicate potential co-morbidities, while chest wall shape may suggest chronic airways disease. Movement and agility are less easily evaluated in acute conditions, but again some impression can be gained by the factors above. Likewise, mental acuity may be difficult to assess in the acute situation.

All of these come together to provide a picture of the level of normal functionality and the degree of co-morbid illnesses, and how they may be contributing to the acute presentation. Then the acute nature of the presentation needs to be evaluated and its reversibility taken in the context of the other problems. The patient's preferences, either declared or previously informed, are a very important part of this assessment. Most importantly, no individual part of this should overwhelm all other considerations, and age itself is the least relevant factor.

TREATMENT INTENSITY

Elderly patients now present more frequently, have fewer co-morbidities and are more acutely unwell than in the past. They are also more likely to undergo more intensive treatment and are more likely to survive, although the intensity of their treatment may not match that offered to younger patients.[60,61] The conclusion is that high-intensity

treatment is appropriate and can produce good results, but careful patient selection is key. In a study that followed more than 1 million elderly patients after a diagnosis of serious illness, half were admitted to the ICU at some point and, of these, two-thirds were still alive 6 months later.[11] However, 3% of this cohort accounted for 23% of ICU usage.

In terms of cost effectiveness, a prospective, observational cohort study in Canada involving patients aged 80 or over demonstrated that the average cost of ICU admission per patient was CAN$31,679 ± $65,879.[62]

EXPECTATIONS AND PREFERENCES

Paradoxically, the aim of treating the elderly in the ICU may be more attainable than with younger patients, as they may already have adapted to a burden of co-morbid disease and disability, and have limited expectations when compared with young previously fit patients. End of life care increasingly occurs in a hospital setting, despite the fact that 86% of patients would prefer to die at home; therefore the level of medical intervention that elderly patients would want is relevant. Only 16% would take life-prolonging drugs if they made them feel worse, and most would want palliation even if it shortened life. Most would not want to be put on a ventilator to gain a week of life, and the numbers were similar if it were for a month of extra life.[63] Of those octogenarians who survived the ICU, half declared they would not want ICU treatment again if it were required.[64] However, one must be careful about making assumptions in this group of patients. The SUPPORT study showed a poor understanding by physicians of patients' preferences[65] and further declared that, despite the fact that more than half of over-70-year-olds would want cardiopulmonary resuscitation (CPR), most physicians substantially underestimated this.[66]

In 1999, Singer and colleagues identified the following as being most important to patients:

- receiving adequate pain and symptom management
- avoiding inappropriate prolongation of dying
- achieving a sense of control
- relieving burden on others
- strengthening their relationship with loved ones.[67]

END OF LIFE

Death in the ICU is usually through some form of withdrawal. Only 10% of patients dying in the ICU die through failed CPR. Limitation of life support is very common, as is withdrawing or withholding treatment. There is huge variation in practice between countries, not only in the decision process but also in the issuing of 'Do Not Resuscitate' orders, and the modes of withdrawal and withholding treatment.[68]

Patient preferences are very important, as is physician recognition of medical futility. The key to this area of management is (1) a clear view of what the ICU is intended to provide; (2) an understanding of whether the goals are achievable; and (3) acceptance that subjecting a patient and their family to the unpleasant rigors of the ICU in the sure knowledge that it will achieve no useful outcome is unacceptable. These determinations must be made objectively.

CONCLUSION

The APACHE score demonstrates that most predictive power for outcome is derived from the acute physiological condition; a much smaller component was the admission disease (13.6%) and age (approximately 7%).[51] The nature of the acute condition and the severity of co-morbid disease play a far greater part than the known physiological changes that accompany ageing, and thus absolute age itself. The reversibility of these factors should guide management, and this approach is the same for any patient of any age. It is more likely that an older patient will have advance directives and will have already voiced their personal preferences.

A simplistic view is that intensive care entails reversing an acute episode with the intention of returning the patient to the position they were in before that episode, or close to it. The majority of treatment is supportive and provides the physiological reserve that the elderly patient is likely to have lost until it can be regained. Those with less reserve will need more support. The patient will invariably need a certain amount of physical reserve to meet the challenges of the treatment and the recovery. The decision to use the ICU requires acknowledgement that the ICU has negative as well as positive aspects, and that it can be a very unpleasant experience with far-reaching sequelae, both physical and psychological, for patients and relatives. Justification is provided by a good outcome, so it is implicit that the opinion at the time of admission is that full recovery is possible or indeed probable. As in every other population, appropriate use of intensive care can produce impressive results, but inappropriate use can be disastrous for the patient and their family. Age itself is not a contraindication.

Team-based health care delivery

Gerry O'Callaghan

The concept of health professionals working in collaboration as part of multidisciplinary teams focused on the requirements of individual patients is a well-established historical tradition.[1] This chapter outlines the benefits of team participation to the individual, the team and the health care delivery organisation, (unit or department and hospital). The characteristics of successful teams and examples of effective team-based interventions are described in the context of intensive care medicine or comparable acute care delivery settings.

The specific interventions that have been applied to the intensive care setting, the composition of intensive care teams, their function and effect on patient outcome are explored. The objective of this overview is to provide practitioners of intensive care medicine with an opportunity to reflect on the variety of ways we work in teams as part of our daily professional activities.

WHAT IS A TEAM?

> *'If you want to run fast, run alone; if you want to run far, run together.'*
>
> (An African Proverb)

Shared purpose is the foundation of team success.[2] A team is defined as a group of people with clearly defined roles and responsibilities committed to a common purpose or task. The individuals who participate in a team share common values and commit to shared behaviours, for example low-tidal-volume ventilation for acute respiratory distress syndrome (ARDS) or use of a checklist prior to a procedure. The result of their collective effort is expected to produce more than they could working as individuals. The identity of the team is visible from both within and outside (Box 13.1).

Modern intensive care medicine is undoubtedly a challenge of both skill and endurance, with the latter increasingly described as resilience. While we benefit from decades of investment in education and training focused on required knowledge, we have only recently begun to interrogate the most effective strategies for the translation of this knowledge into practice. Specifically, what workplace characteristics and evidence-based practices are of greatest benefit to both patients and practitioners? The increasing array of investigations and complex treatments for critical illness is accompanied by increases in both the number and the diversity of team members; in this context it is of value to understand the fundamentals of team dynamics. Additional factors are emerging roles for non-physician providers and participation by intensive care personnel in roles that extend beyond the traditional physical boundaries of the intensive care unit (ICU).

The introduction of advanced practice nursing roles provided insight into the lack of role clarity and understanding of both traditional and new roles within intensive care teams and has led to a deeper understanding of the workforce competencies necessary to adopt team-based practices.[3] This poses the interesting question of whether successful adoption of team-based practices at a unit level is a reflection of these pre-existing competencies of communication and appreciation of professional roles, or confirmation that such practices and behaviours can be learned and implemented by motivated professionals. There is insufficient evidence to answer this question in the intensive care context; however, it is critical to develop the necessary competencies in the workforce prior to the adoption of team-based programmes on a significant scale.

Fig. 13.1 illustrates the diversity of individuals and the skills involved in caring for critically ill patients. ICU personnel include medical and nursing staff, plus allied health including physiotherapists, respiratory therapists, dieticians and pharmacists. Support personnel include clerks, cleaners and others. External ICU is almost limitless including physicians, surgeons, infectious disease physicians and radiologists. Although local factors influence the composition and profile of these categories, the variety and complexity are constant.

The composition of critical care teams has wide regional, national and international variability. Non-physician providers are more common in North America than in the United Kingdom, Europe or Australia, where advanced nurse practitioner roles are more common. Such roles are well established in paediatric and neonatal medicine and are often an adjunct rather than an alternative to physicians in training,

ABSTRACT

Team-based practices and behaviours are now well established in the intensive care context and have delivered clear benefits to patients, health professionals and delivery organisations. This chapter explores the theory of health care teams and how they work, as well as practical examples of successful practices and how to implement them. The overview aims to increase the understanding of the variety of teams within current intensive care practice, their relevance to particular activities and how an individual practitioner might identify the optimal approach to achieve a particular outcome. Clinicians and researchers interested in team work and patient safety have turned their attention to the challenges of contemporary intensive care practice, such as the delivery of complex therapies, cognitive biases, workforce diversity, conflict, distress and burnout, and explore team structure and function as a strategy to address these issues.

Box 13.1 Characteristics of a team

Common goals
Shared behaviours and values
Visible identity
Clear understanding of roles and responsibilities
Greater collective than individual effectiveness or potential
Understanding of shared tools and artefacts, such as vocabulary, skills, knowledge
Mutual trust and respect: solidarity

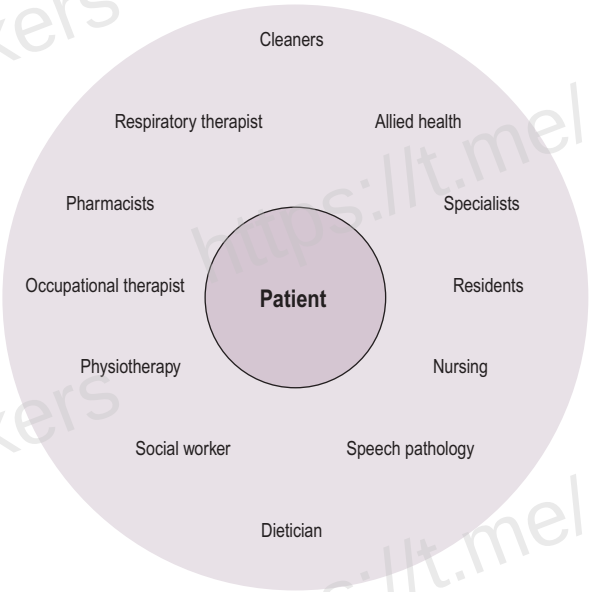

Figure 13.1 The clinical and ancillary care of patients in intensive care is provided by large diverse teams of health care workers. The size, diversity, variability and complexity of these teams make common training in non-technical skills highly desirable.

resulting in improved staffing levels and continuity of patient care.[4] More than a quarter of adult academic ICUs in the United States have physician assistants, and more than half have nurse practitioners as physician extenders.[5] They have a precisely defined scope of practice, may order tests, prescribe medications and perform diagnostic and therapeutic procedures under the supervision or on behalf of a nominated responsible physician or surgeon. Workforce planning in a recent review of the impact of non-physician providers on patient outcomes in critical care indicates this is likely to remain the case for the foreseeable future, and there is no evidence that non-physician providers are less safe or effective. Non-physician providers also contribute important increased capacity in additional areas of intensive care activity, such as quality improvement.[6]

The increasing diversity of clinical roles and complexity of therapies (e.g. extracorporeal membrane oxygenation) require frameworks for improved communication and coordination as well as role delineation. This view has been endorsed for over a decade by a wide range of professional, academic and government bodies, such as The Institute of Medicine, which recommended in *To Err is Human, Building a Safer Health System* that those who work in teams should train in teams.[7] There is an emerging literature that demonstrates improved outcomes across a range of parameters following implementation of various team-based interventions.[1] These innovations are examined later in this chapter.

Fig. 13.2 illustrates the varying and often asynchronous schedule of shift changes between nursing, resident and intensive care physicians challenging safe and effective continuity of patient care. The SBAR (situation–background–assessment–recommendation) approach to clinical handover is an early example of a shared behaviour to improve communication; it is an explicit team-based practice that facilitates continuity of care and effective transfer of information between teams.[8] Clinical handover is a common cause

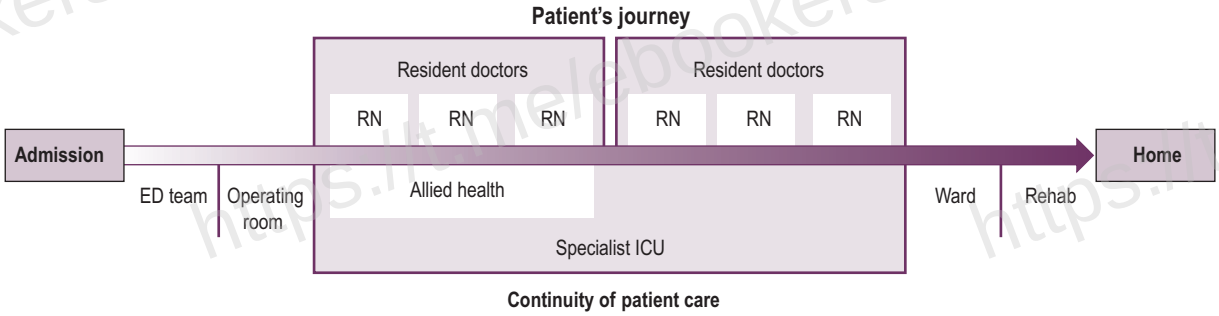

Figure 13.2 Continuity of patient care is the seamless provision of care, transfer of information and communication with relevant stakeholders over time and across multiple locations during a patient's hospitalisation or illness. *ED*, Emergency department; *ICU*, intensive care unit; *RN*, registered nurse.

of adverse events and malpractice claims. It is often of poor quality, infrequently written and generally perceived to be inadequate or unhelpful.[9] Other early examples of widely adopted team-based behaviours are the use of PDSA (plan-do-study-act) cycles and process mapping as tools in clinical practice improvement methodology, checklists, protocols, huddles and briefs.[10] The process of developing and implementing these common ways of working requires multidisciplinary collaboration and creates a shared sense of purpose and team identity. In addition, the shared mental model, which emerges from the specific context in which the proposed intervention is to be applied, consolidates team identity during the adoption process. These shared practices are now common practice in many ICUs and contribute to a shared sense of identity and purpose.

Patient safety is the main driver for adopting team-based interventions in health care following improvements in passenger safety achieved by the airline industry using a team training approach called Crew Resource Management (CRM), which is a simulation-based programme that teaches and assesses individual performance of the 'non-technical skills' necessary for effective delivery of complex technical tasks, particularly in high-stress situations. These can be defined as 'the cognitive, social and personal resource skills that complement technical skills, and contribute to safe and efficient task performance'.[11] The framework has four elements:

- *Situation awareness:* Understanding and anticipating the impact of the specific situation on the performance of workers and patient outcome. For example, requesting further information or using check-back to validate physiological information.
- *Decision making:* The ability to identify options, incorporate risk assessment and re-evaluate progress, if necessary recognising failure and changing direction in a timely way.
- *Team work and leadership:* Cooperative collaboration in complex task delivery in your assigned role; explicitly identify and claim the role that is appropriate to your level of skill and experience. This includes information sharing, seeking assistance, supporting fellow team members and coordinating efforts.
- *Task management:* Planning, preparing and prioritising the actions that need to be taken, identifying the resources necessary to achieve the planned tasks and performing them to an appropriate standard.

A training programme based on this approach has been developed for anaesthetists called Anesthetists' Non-Technical Skills (ANTS). Extensive task analysis describing the language and behaviours specific to situations encountered by anaesthetists formed the basis for identifying markers used for the assessment of good or bad performance. (For details see the website address www.abdn.ac.uk/iprc/ants.)

Rolling out a promising innovation is challenging:

1. It is essential to have a critical mass of course providers who have a sound understanding of the psychology of human performance, the methodology and language of non-technical skills and the teaching and assessment of colleagues and trainees. Where this is not the case there are unacceptable levels of inter-rater reliability and accuracy.[12]
2. Sustainability of benefit has been shown where training is provided in a similar manner to the CRM programmes in the aviation industry.[13] The authors' recommendation is for a minimum ANTS course length of 2 days to acquire sufficient knowledge and the techniques required.
3. This provides an insight as to why it is difficult to demonstrate the benefit to patient outcomes when few health care providers have the skills or experience necessary to plan and measure the quantum of team building required to address the relevant clinical issue (Box 13.2).

The quantity and quality of team interactions can be measured; face-to-face interactions are the most valuable, email or texting the least. Team behaviours and patterns of communication are consistent across different contexts and compositions (i.e. different industries including health care workers and a variety of different team sizes).[14] Individual talent and reasoning are less important than adopting successful communication patterns.

Successful teams share several defining characteristics:

1. Everyone on the team talks and listens in roughly equal measure, keeping contributions short.

Box 13.2 Characteristics of high-performing teams

Leadership that encourages participation from other team members
Effective decision making, clear, transparent, timely and consultative
Open and clear communication
Valuing diversity, welcoming diversity of experience, culture and knowledge
Mutual trust, committing to shared actions and strategies
Managing conflict – dealing with conflict openly and transparently, avoiding the gradual build-up of internal tensions and grudges
Clear goals that have personal meaning and relevance, which are supported by sharing data and resources
Defined roles and responsibilities – team members understand what they must do and must not do
Coordinative relationship, strong bonds between team members supporting frequent interactions
Positive atmosphere, team culture that is open, transparent and positive, and believes in the reality of success

Source: https://en.wikipedia.org/wiki/High-performance_teams.

2. Members face one another and their conversations and gestures are energetic.
3. Members connect directly with one another and not just with the team leader.
4. Members carry on back channel or side conversations within the team.
5. Members periodically break, go outside the team and bring information back.

Successful team participation can be learned, and advantage can be taken of the multiple opportunities that present themselves for team working. Intensive care physicians are generally expected to take on leadership roles, but few physicians receive any formal training in this area.

A simple checklist can be used for assessing team interactions with colleagues:

- Are my co-workers contributing to ward rounds and patient-centred discussions?
- Do they speak generally or just to one other person?
- Are individuals removing themselves from the group or not facing other team members when they are speaking or listening?
- Am I or the other leadership figures too dominant, speaking too much or too loudly?
- Does everyone get to finish sentences or are people interrupted and cut off?
- Am I (we) happy for any individual team member to speak on behalf of the team?

This final question is a test of mutual trust and respect within the team because it involves accepting reputational risk on behalf of co-workers.

In order for team-based interventions to positively contribute to patient safety and the wellbeing of health care workers, it is important for the host organisation (usually a hospital) to be receptive. Organisations' attempts to create a high-performance team culture may fail because of:

- Insufficient appreciation of the resolve, expertise and resources required to achieve cultural change
- Advocacy for team-based training being promotional rather than a sincere commitment
- Provision of insufficient time, opportunity, resources or executive support.

Similar issues have been demonstrated in the implementation of clinical therapeutic guidelines.

NECESSARY OR DESIRABLE ORGANISATIONAL CHARACTERISTICS THAT SUPPORT EFFECTIVE IMPROVEMENT IN CLINICAL PRACTICE AND PATIENT OUTCOMES

Bohmer characterised the four habits of high-value health care organisations[15] that perform well in terms of the ratio of long-term outcomes to costs:

1. *Specify and plan in advance:* with decisions based on predetermined explicit criteria
2. *Deliberate design of infrastructure:* including clinical microsystems that align physical environment, business process and clinical pathways in well-defined patient populations
3. *Measurement and oversight targeting:* by predefined metrics, quality and safety goals, which inculcates both accountability and performance
4. *Self-study:* using measurements so that knowledge, data and clinical information can be used not only for the assurance of best evidence-based practices but also to identify deviations. Information is shared and not considered to be the property of individuals or departments.

Organisational readiness is a prerequisite to building high-performance critical care teams.

TYPES OF TEAM

A *clinical microsystem* is the most fundamental unit of health care delivery that addresses the needs of a population of patients. It is the dynamic integration of personnel, clinical and support staff, technology, information, care and business processes.[16] The participation of all those who have direct patient care responsibilities is implicit (Fig. 13.3). Participation is compulsory; however, most participants will also be involved in other team types within this structure. The choice/volition of the individual within teams is variable. The greater the clinical focus of the team or activity

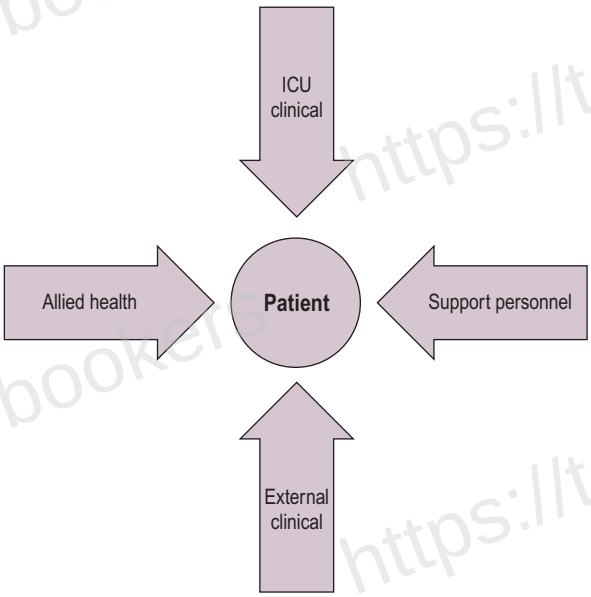

Figure 13.3 Clinical microsystems are the most fundamental units of health care delivery that address the needs of a specific population of patients. This system includes personnel, procedures, business processes and infrastructure. *ICU*, Intensive care unit.

the less choice individuals have in terms of choosing to participate. Resuscitation, diagnosis and treatment are core team activities, while research, safety and quality, and administration provide opportunity for choices that align with the interests and expertise of the individual. Collaborations beyond the immediate clinical microsystem in the hospital, professional, interdisciplinary and academic worlds have the greatest degree of choice. Team contexts are relevant to the broad understanding of health care teams.

CRITICAL INCIDENT RESPONSE TEAMS

Medical emergency teams, code and trauma teams need skills designed to meet the crisis, such as airway management, vascular access and trauma management. Teams may be nurse or physician led, are highly focused on a particular activity and often include individuals who interact infrequently owing to the rarity of certain events or rostering practices. Team membership is highly dynamic; opportunities for training are limited; and the level of familiarity with local procedures, policies and organisational characteristics varies with the individual team member (Fig. 13.4).

Leadership by an easily identifiable authority figure, who has both accountability and responsibility for the outcome, enables the application of well-defined clinical pathways or protocols. This leadership is variously described as top-down, autocratic or transactional[17] and has been demonstrated to improve both process metrics and patient outcomes (Fig. 13.5).

ACTIVITY- OR CONTEXT-RELATED TEAMS

These may be described as committees, working groups or parties with variable degrees of formality and stability. These range from ad hoc conversations or correspondence between senior clinicians to formal safety and quality committees with clear reporting protocols and accountabilities. The latter has defined terms of reference, meets regularly, involves clinical governance, keeps records and may be multidisciplinary from both within and outside the ICU. They may be temporary, such as implementing a new treatment, or consist of well-established groups responsible for monitoring and communicating clinical outcomes to their peers on a range of clinical indicators. Fig. 13.6 illustrates examples of such clinical contexts.

Critical incident and context teams (see Fig. 13.6) require and benefit from different styles of leadership. Leadership characteristics include inclusiveness, proactive mentorship of less experienced or confident team members, providing a personal example of ethical behaviour and maintaining the focus of team

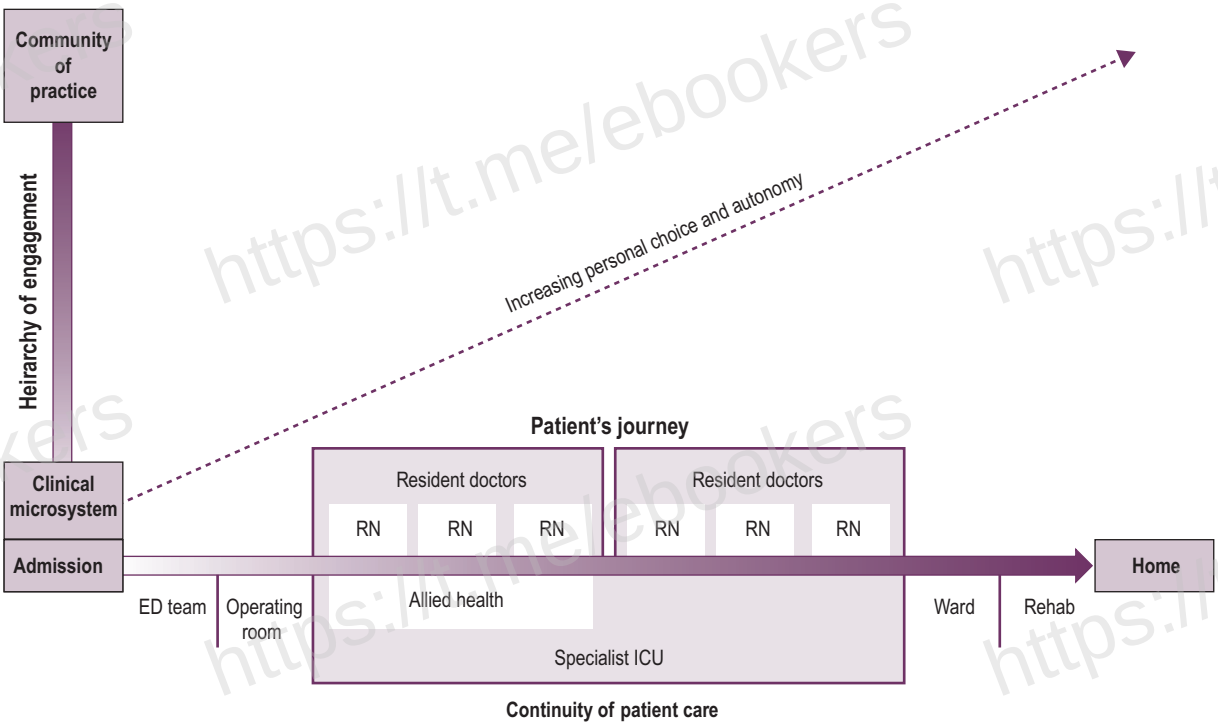

Figure 13.4 The hierarchy of individual integration of team participation represents the relationship between the interests and skills of an individual and the necessary activities that support a clinical microsystem, such as an intensive care unit *(ICU)*. Activities that are not directly related to patient care provide an opportunity for personnel to choose those activities that are of greatest professional interest. *ED*, Emergency department; *RN*, registered nurse.

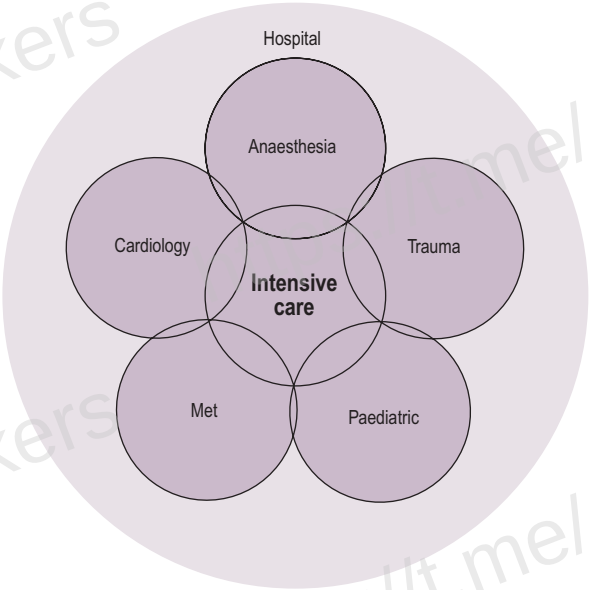

Figure 13.5 Critical incident teams are ad hoc teams of individuals from a range of clinical and professional backgrounds that assemble to meet the clinical needs of a patient experiencing acute physiological deterioration in an acute hospital setting. *Met*, Medical emergency team.

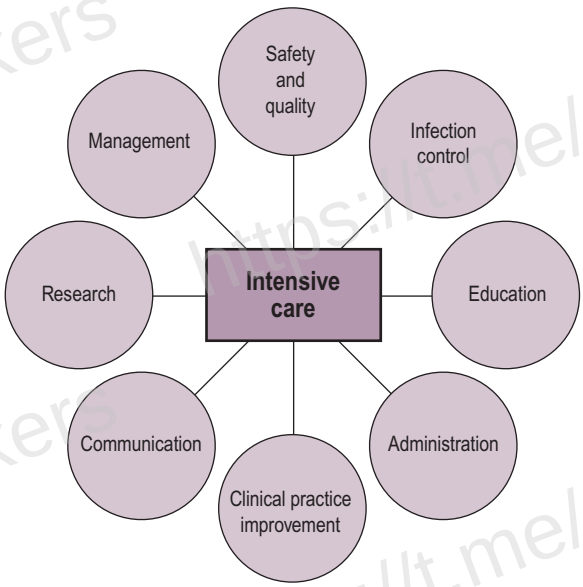

Figure 13.6 Context- or activity-based teams are comprised of individuals from a range of clinical and professional backgrounds who are collectively engaged in administrative, educational and professional activities that support clinical care.

members on the shared goal or purpose. This type of leadership is variously described as democratic, consensus driven or transformative[17] and is associated with improved staff commitment and participation in safety initiatives. The challenge is choosing the most appropriate leadership style for each situation. Adaptive leadership is the capability to deliberately move between a transactional approach for task-based time-critical goals and transformative approaches to create meaning, clarify purpose and challenge cultural assumptions or norms.

Long-term projects with outcomes over several years with strong connections to external colleagues and organisations require a different type of team. Members of these teams may not recognise themselves as participating in teams as activities are informal and self-organising, are often created by the commonality of learning activities and are consolidated through social interactions. Examples include research collaboration between clinicians working with laboratory-based scientists and other experts, often from disparate geographical locations. The Community of Practice model first described by Wenger[18] can be used to describe this type of group. The driving characteristics of working collaborations are a shared knowledge or practice domain, a workplace-based context of learning and fluctuating levels of participation. Professional development activities combined with social interaction form an ongoing mechanism that supports professional collaborations and exchange of information, such as best practice tools. This formal facilitation of social cohesion in professional groups is part of the community of practice model.

It is useful to reflect on the numerous types of teams to which intensive care practitioners may belong in order to:

- select the most suitable model for the assigned goal
- measure the overall impact on patient outcomes, staff satisfaction or other parameters
- assess and prioritise workload, taking into account the combination of team-based activities occurring in the ICU.

Effective team-based practices are most commonly described in terms of organisational characteristics or leadership responsibilities; however, this fails to emphasise the benefits of participation to individual team members. These benefits, which are summarised in Box 13.3, result in improved job satisfaction, staff retention, less sick leave, increased productivity and reduced costs.

SPECIFIC TEAM-BASED INTERVENTIONS AND INNOVATIONS

Broadly there are four categories of intervention that have been applied in critical care areas. These overlap

Box 13.3 How team members benefit from team participation

- Opportunity to be heard and for effort to be acknowledged
- Psychological safety
- Clarity of purpose resulting in clear action plans, relevant tools and strategies
- Mechanism to resolve conflict and address underperforming co-workers
- More positive work environments
- Support for professional development
- Improved performance in time-critical stressful situations
- Situational awareness

considerably depending on the programme methodology and content.

1. Leadership
2. Team building
3. Simulation
4. Organisational change.

Leaders are 'visibly responsible and accountable for achieving the goals of an organisation', and are the people on whom patients and colleagues depend to get things done. The style (autocratic vs. democratic) depends on the situation and may change as the situation demands (adaptive leadership). Leadership is the conglomeration of effective behaviours (see Box 13.2) enabling the team to achieve its goal.

In summary, leaders refine and define the team goal; they create a vision and subsequently include the team in the design of the tools and mechanisms to achieve this vision. They do not avoid hard discussions and difficult decisions; they are honest about the effort and commitment necessary. They create an environment where team members feel secure and are willing to contribute. The culture they create is one of psychological safety, which is important because within teams are hierarchies. Hierarchical discrimination is extremely variable and has a definite cultural association, so where there is a high level of respect or fear of authority individuals are extremely unlikely to either challenge or contribute without a specific request or mechanism to do so.

Explicit leadership behaviours, such as task assignment, directing co-workers and check-backs of vital signs are associated with fewer task failures and faster instigation of therapies, such as intubation and defibrillation in emergency situations. Any group implementation of training or clinical practice improvement process by definition creates leadership obligations and opportunities. There is no widespread leadership training intervention applied in the intensive care setting, although several studies demonstrate improved outcomes associated with intensive care specialist-led care.[19] Courses in leadership, management and communication as part of post-graduate training programmes, such as those now mandated by the College of Intensive Care Medicine of Australia and New Zealand, proactively develop competencies for leadership and teamwork.

For example, when the impact of multidisciplinary teams on the 30-day mortality of over 100,000 intensive care patients was assessed, intensive care specialist care combined with multidisciplinary teams was associated with a 16% reduction in mortality, which was consistent across patient cohorts and greater severity of illness.[20] This benefit was similar between intensivist-led care or mandatory consult and multidisciplinary care team input, but the greatest mortality reduction was seen when these were combined. The authors postulate that multidisciplinary rounds improve communication, enhance implementation of agreed daily goals and encourage evidence-based care (e.g. pharmacist participation may reduce drug errors). Effective communication may also reduce length of mechanical ventilation and ICU stay.

A combination of team training, coaching and checklists to instigate communication in the operating room impacted on surgical outcomes.[21] There was an 18% reduction in mortality at the hospitals that implemented the US Medical Team Training programme compared with a 7% reduction at the control hospitals; subsequently, implementation in over 187 sites in the United States resulted in the improved understanding of daily clinical goals following multidisciplinary rounds in the ICU and reduced lengths of ICU stay.[22] The programme requires ongoing support and follow-up at participating sites and mandatory executive support from site administration.

TRAINING

The TeamSTEPPS training tool is focused on improving patient safety by implementing an evidence-based teamwork system to improve communication and teamwork skills among health care professionals.[23] It has been used in paediatric, medical and surgical ICUs to train acute care teams, reducing times to placing patients on extra-corporeal membrane oxygenation (ECMO), and decreasing the nosocomial infection rate[24] Other team-based initiatives have reduced rates of ventilator-associated pneumonia[25] and reduced resuscitation time in trauma situations.[26]

Simulated scenarios can be used to explore, practice and refine the tools of communication, leadership and other team-based behaviours in a clinical context. Simulation may be high or low fidelity depending on the degree of accuracy with which the clinical scenario is replicated. Training may be stand alone, specifically designed and maintained by full-time professional educators or part of a clinical workplace. The important points are:

- participation requires an active choice to collaborate with colleagues

- simulation is an educational tool that has both strengths and limitations
- many common clinical situations in the intensive care setting are suitable for simulation-based training
- most do not require high-fidelity equipment; however, they do require expert and experienced facilitators.[27]

Using case-based or simulation-based learning, there were significant improvements in leadership, team coordination and verbalising situational information in the intervention group, and improved scores for clinical management.[28] Similar results were seen in the paediatric intensive care setting, where most found participation to be of benefit and with a highly effective impact.[29] The authors indicated that there is not only a 6- to 12-month learning curve in programme implementation, but also repeated exposure is necessary to achieve meaningful benefit.

ORGANISATIONAL CHANGE

This is the final area of intervention. It includes teamwork, simulation and leadership training; however, the context in which the team model operates is an important element of the intervention and is formally assessed as part of the change process.[30] The Integrated Team Effectiveness Model illustrates how organisational contexts, such as processes, goals and structure, have a direct effect on team effectiveness. The Breakthrough Collaborative Model uses organisational engagement and team alignment to a particular goal to achieve significant changes in clinical outcomes.[31] This has resulted in a significant increase in the rate of organ donation as measured by both donor identification and consent for donation. Teams use PDSA cycles to implement change in local practices supported by a senior clinical leader. Each team is provided with strategies and tools for change and participates in educational conferences, which allows the more successful strategies to be shared and adopted more broadly. These educational opportunities foster team development and identify clinical leaders. Although effective in accelerating clinical change, these large-scale interventions are expensive and require widespread government, professional and health care organisation support (Box 13.4).

Further consolidation of team-based practice has occurred through partnering with patients and families in the co-design of clinical pathways and other aspects of service delivery in response to national policy and regulatory settings. Similarly, collaboration with policy makers and funders in developing financially sustainable service delivery models also contributes to the habit of working in teams. Not all interprofessional interactions in the ICU conform to the idealised notion of teamwork. Alexanian and colleagues performed an ethnographic observational study in two large ICUs in North America and observed that most interprofessional interactions were more accurately described as collaboration, coordination or networking, and they raise the issue of medical dominance of decision making, which may relate to the particular legal responsibilities of physicians.[32] This study suggests that teamwork in isolation is inadequate to describe the variety of ways health professionals interact in ICU, and further analytic frameworks are required to capture the contextual factors that influence the outcome of improvement interventions.

More recently, clinicians and researchers interested in team work and patient safety have turned their attention to contemporary challenges of intensive care practice, such as cognitive bias in clinical decision making, workforce diversity, conflict, distress and burnout. Team-based practices improve communication, which has been demonstrated to reduce conflict and protect against burnout. Team diversity as described in terms of gender, experience, cultural background, range of disciplines and age groups is a marker of success for innovative thinking and avoids the cognitive trap of group think. This may be important for effective clinical diagnostic decision making. Team stability is recognised as being important to effectiveness and has clear implications for the length of clinical rotations in the ICU, rostering practices and participation in emergency response and outreach teams. All these factors should be considered in the proactive process of team composition, particularly gender balance, which has a positive impact on team performance.

A detailed exploration of the optimal size of the ICU is beyond the scope of this chapter; however, it is important to make the distinction between a social group or network and the individuals/teams embedded in the group. There are cognitive limits to the number of interpersonal relationships that can be effectively sustained by individuals, which should influence the scale or size of organisational structures. The optimal size of teams is intimately related to the nature/complexity of the tasks or activities undertaken (including learning), the stability of membership and the effectiveness of leadership. However, the team is rarely larger than six to eight participants.[33]

Box 13.4 How patients may benefit from team-based health care delivery

Improved continuity of care
Fewer adverse events
Shorter lengths of hospitalisation and mechanical ventilation
Better task delivery in emergency situations
Decreased mortality
Improved family outcomes through better communication

SUMMARY

Team-based innovation in the specific context of high-acuity environments, such as the ICU, is increasing

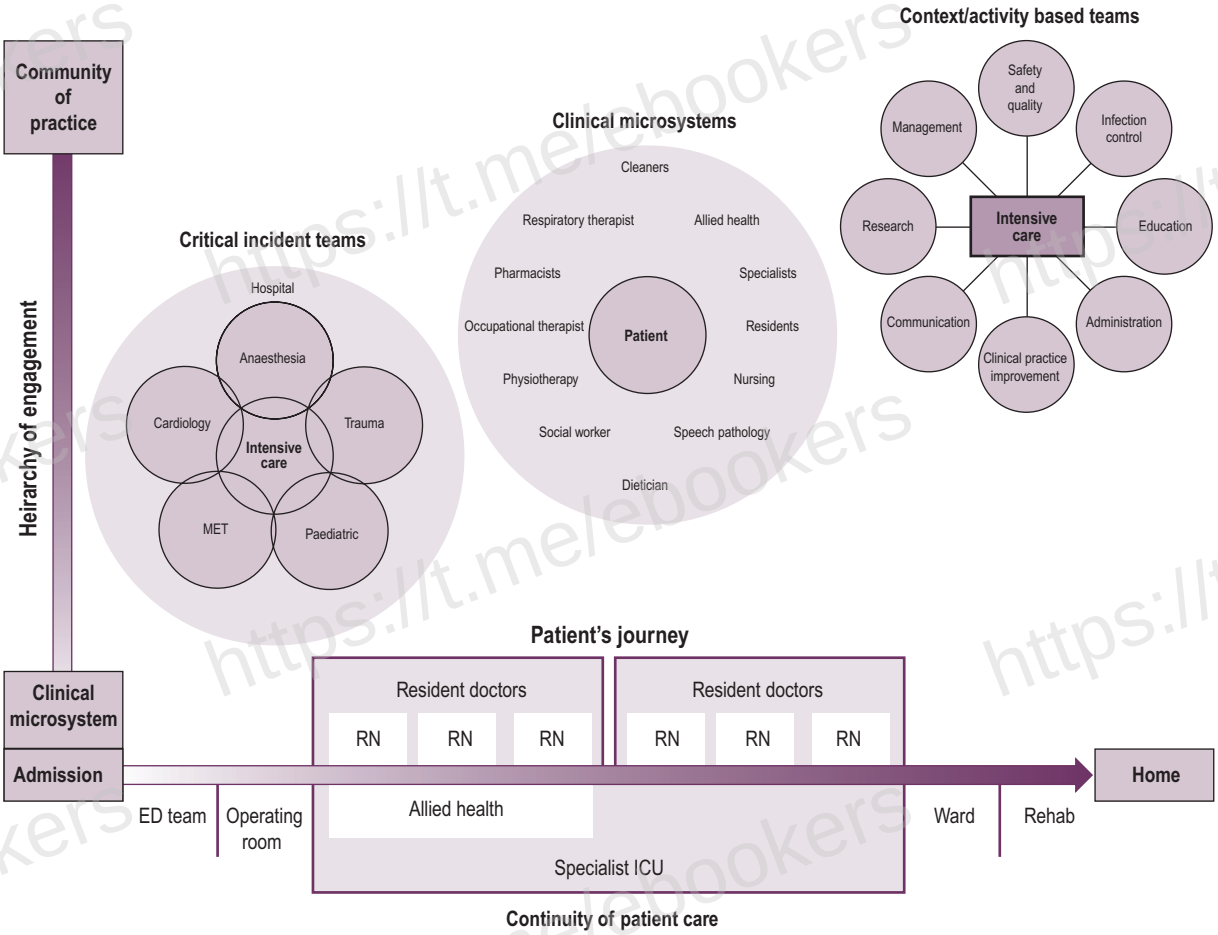

Figure 13.7 Participation in teams that provide specific aspects of clinical care, support professional development and improve quality of care are important articulations of personal preference and autonomy. Such choices are likely to represent important opportunities to increase staff satisfaction and retention, and to increase system capacity by matching skills and experience with personal interests. *ED*, Emergency department; *ICU*, intensive care unit; *MET*, medical emergency team; *RN*, registered nurse.

around the world (Fig. 13.7). There is a continuously growing evidence base that supports the following conclusions:

- Team-based interventions result in improved objective and subjective outcomes for patients, health care professionals and health care organisations.
- A broad range of well-developed tools, resources and programmes are available to implement team-based practices.
- Significant expertise, experience, commitment and resources are necessary to achieve potential benefits.
- The innovation or intervention should be prepared or adapted for the specific context in which it is to be applied.
- Sustained improvement in performance requires ongoing maintenance programmes.
- Multidisciplinary teams of intensive care health professionals are valuable assets that provide considerable dividends to the organisations in which they work.

Genetics and sepsis

Jeremy Cohen, David Evans, Balasubramanian Venkatesh

INTRODUCTION

Sepsis is an enigmatic condition. Originally described by Hippocrates, it has only been in the last 50 years that the concept has been refined to describe a syndrome characterised by both an invading microorganism and the host response to it. Improvements in our understanding of the pathobiology of sepsis have led to a recent re-evaluation of how the disease is defined, leading to the current consensus definition of sepsis as 'life-threatening organ dysfunction caused by a dysregulated host response to infection'.[1] It is clear that there is substantial heterogeneity in the host response, the magnitude of which is influenced by a number of factors: patient co-morbidities, pathogen virulence, site of infection and host genetics. In the last decade, there has been substantial research into investigating the contribution that genetic variation makes to this heterogeneity and an understanding of this is an essential part of developing future management strategies. In this review we will describe how developments in genomics have led to a greater appreciation of the importance of genetic factors in the outcome of sepsis, and how this might influence future research and treatment.

BASIC DEFINITIONS AND GLOSSARY OF TERMS

A glossary of terms can be found at the end of the chapter.

Deoxyribonucleic acid (DNA) is the chemical compound inside the nucleus of a cell that carries the genetic instructions to make proteins; it contains the hereditary information that is transmitted from parents to offspring. Each DNA molecule consists of two paired strands of repeating units called nucleotides, wrapped around each other in a double helix structure (Fig. 14.1). Each nucleotide comprises a sugar molecule (deoxyribose), a phosphate group, and one of four nitrogenous bases: adenine (A), thymine (T), guanine (G) or cytosine (C). The bases of nucleotides from one strand pair with complementary bases from nucleotides on the other strand so that an 'A' nucleotide always pairs with a 'T' nucleotide, and a 'C' nucleotide always pairs with a 'G' nucleotide. The sequence of bases along the length of the DNA molecule encodes the genetic information contained within each cell and is virtually identical in all cells in an individual (gametes and some immune cells being an exception to this rule).

The DNA in the nucleus of cells is arranged into discrete linear structures called chromosomes. In each nucleus, there are 23 pairs of chromosomes, with 1 chromosome from each pair being inherited from each parent. The total amount of hereditary information encoded in the DNA sequence across all 23 pairs of chromosomes is known as an individual's genome, and consists of over 3 billion nucleotide pairs.

Within the genome are elements called genes, which are discrete segments of DNA that code for proteins. There are estimated to be around 25,000 genes in the human genome. Genes serve as templates for making messenger ribonucleic acid (mRNA) molecules through a process known as transcription. The mRNA transcripts travel out of the nucleus into the cytoplasm where they are subsequently used to make the polypeptides that form proteins, through a process known as translation.

While the vast majority of the genome (99.9%) of any two unrelated individuals is identical in terms of the DNA sequence, sequence variation can occur in a number of ways. The most commonly studied form of variation is called a single nucleotide polymorphism (SNP – see Fig. 14.1). An SNP is a DNA sequence variation that occurs when a nucleotide (A, C, T or G) is substituted for one of the others at a single position in the genome. For example, where there is typically an 'A' nucleotide at a particular location in the genome in the general population, some individuals might be found to have a 'G' nucleotide. There are over 10 million known common SNPs across the human genome. Whilst the majority of these changes produce no observable effects, some of them have measurable effects on humans, including causing, or at the very least, altering the risk of disease. For example, some SNPs in genes may produce changes in the amino-acid sequence of their corresponding proteins and therefore exert a detrimental effect on protein function.

ABSTRACT

In this chapter we outline the evidence for a genetic influence upon susceptibility and outcome from sepsis. We summarise the results of family studies and early approaches based on the candidate gene technique. We describe how advances in molecular genetic techniques have altered our approach to the study of this question and the difficulties of achieving a personalised medicine approach based upon genetic factors. We also describe the potential role of emerging techniques and future studies in the field.

Other SNPs might produce changes in the rate at which a particular gene is transcribed. Within the context of sepsis, investigators are interested to see whether genetic changes like these may explain some of the considerable interindividual variation in risk of sepsis and/or the prognosis of individuals unfortunate enough to suffer from the condition.

In this chapter we will examine the evidence that there is a genetic basis for the susceptibility (and the response) to sepsis. We will then describe two broad strategies that have been used to try and understand the genetic basis of sepsis: genetic association studies (including candidate gene, genome-wide association studies, and whole genome sequencing studies), which attempt to find a correlation between genetic variation and risk of/response to sepsis, and studies that examine the differences in the expression of genes across the genome (including microarray-based and RNA-Seq-based studies) (Fig. 14.2).

FAMILY STUDIES

Genetic influences on lifespan have been recognised for many years.[2] In 1988 Sorenson and colleagues examined Danish adoption records and demonstrated that in adopted children whose biological parent had died before the age of 50 from an infective cause, the relative risk of death from infection was increased five-fold. There was no corresponding increase in risk to the child if it was the adoptive parent who died from the same cause.[3] This elegant study implied that genetic factors were an important determinant of outcome from infection, so they served as the foundation for future work in this field. Further analyses on this cohort suggested that genetic factors had a stronger influence upon the risk of dying from an infection compared to the risk of acquiring one – suggesting that acquisition and prognosis are likely to involve different sets of genetic and environmental risk factors.[4] Twin studies have also provided valuable information. Comparing outcomes in monozygotic twins who are genetically identical to those in dizygotic pairs who, on average, share only half their genetic material, can give an estimate of the relative contribution from hereditary factors. An increased concordance in susceptibility between monozygotic relative to dizygotic twins using this technique has been demonstrated in tuberculosis, sinusitis and *Helicobacter pylori* infections.[5–7]

CANDIDATE GENE STUDIES

Molecular genetic investigations into sepsis have been based upon two approaches. Historically the first approach, which is more widely used and simpler, is the candidate gene study. This technique relies on first identifying a gene or genes that are likely to be implicated in the pathobiology of the condition and subsequently comparing the allelic frequency of polymorphisms in those genes between cases and controls. The advantages of this sort of design are lower cost, fewer subjects are required to achieve a given level of statistical power and the analysis is less computationally intensive. As the study is hypothesis driven, any associations are likely to be biologically plausible. Given these advantages and the fact that the technology to perform genome-wide studies (see below) only

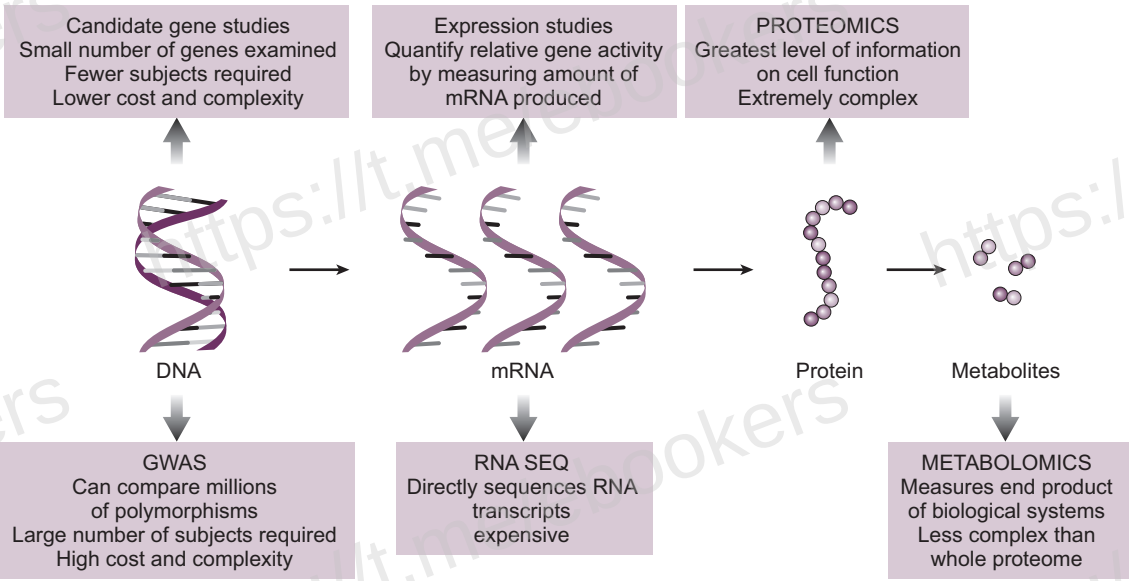

Figure 14.2 Overview of genomic, proteomic and metabolomics approach to investigation. *DNA*, Deoxyribonucleic acid; *GWAS*, genome-wide association study; mRNA, messenger ribonucleic acid.

became available a decade ago, it is unsurprising that the majority of initial studies into the genetics of sepsis have utilised the candidate gene approach. A 2006 systematic review identified 147 association studies examining 51 separate polymorphisms.[8] Many of these initial studies have reported positive associations. For example, there are reports of cases of increased mortality in sepsis associated with polymorphisms in the CRP gene,[9] the protein C gene[10] and genes for Toll-like receptors.[11] However, the candidate gene approach has many limitations, of which perhaps the most important is the low probability of correctly identifying genes of interest *a priori*. In a complex syndrome such as sepsis, there are likely to be many genes influencing the condition, some of which may be readily apparent from basic physiology, but others less so. Given that there are around 10 million common SNPs in the genome, the probability of correctly choosing one involved in risk of sepsis *a priori* is likely to be vanishingly small. Furthermore, the 2006 review identified numerous problems associated with sepsis studies in particular. Sample sizes were low, with the investigators estimating that only 7% of the studies were adequately powered to detect realistically sized associations at the 80% level. More tellingly, there was poor replication between studies, and given the undoubted heterogeneity in the condition, the effect sizes associated with genetic variants are likely to be very small.

Many of these problems are not unique to candidate gene studies of sepsis. A 2002 review found over 600 positive associations between common genetic variants and complex diseases in candidate gene studies, but noted that only six had been consistently replicated.[12] Thus it is highly likely that the majority of genetic associations reported to date in sepsis are likely to be artefactual resulting from statistical fluctuation and type I error, or latent biases producing spurious associations due to population stratification, for example.

Thus, while numerous polymorphisms have been described that appear to influence the course and outcome of sepsis,[13] none of the candidate gene studies to date have been successful in identifying reliable markers that have been used in either the stratification or identification of novel therapeutic pathways.

GENOME-WIDE ASSOCIATION STUDIES

A more recent approach is that of the genome-wide association study (GWAS). A GWAS typically utilises high-throughput microarray technologies to compare the allelic frequency of hundreds of thousands of SNPs between cases and controls. In addition, a statistical technique called imputation[14] can be used to infer genotypes at markers across the genome that have not been physically typed on the genotyping chips, meaning that literally millions of SNPs and other genetic variants can be tested for association in a GWAS. Thus, in contrast to candidate gene studies, a GWAS makes no *a priori* hypotheses as to the likely genetic mechanisms

of variability, as by their nature they examine a much larger area of the genome and have the potential to identify unanticipated associations, which could lead to novel therapeutic targets and better understanding of underlying biology. Another advantage of GWAS is that they permit statistical methods that allow investigators to detect and correct for potential underlying biases in genetic studies, like population stratification, whereas this can be difficult to do in candidate gene studies.[15] These features suggest that GWAS may be a superior technique than candidate gene studies in examining a complex multifactorial condition like sepsis. However, in order to have sufficient statistical power to detect alleles with even moderate effect sizes (e.g. allelic odds ratios of >1.3) a sample population of well over 2000 cases and controls is required.[16] This requirement is especially problematic in sepsis. Performing large-scale trials in an intensive care environment is logistically complex and expensive, and often requires multicentre, international collaborations. There are very few published critical care trials of any intervention which approach the numbers required for an adequately powered GWAS. Thus, despite the advantages that GWAS may offer, it is unsurprising that at the time of writing, there have been only two relatively small scale GWAS performed, both of which were on cohorts of patients that had been previously recruited into large-scale clinical trials.

Man and colleagues[17] examined a group of 1690 patients who had been recruited into a randomised, multicentre trial examining the effect of drotrecogin alfa in severe sepsis.[18] The primary outcome analysis was treatment response to the study drug. The authors also conducted a secondary analysis of 700 placebo patients using 28-day mortality as the primary outcome measure. The authors identified several genetic markers that may have influenced treatment response; however, as subsequent studies have failed to confirm the therapeutic efficacy of drotrecogin alfa in severe sepsis, the significance of this finding is unclear.[19] The secondary analyses failed to identify any markers associated with outcome; however, as noted, the low patient numbers suggested this analysis was underpowered.

Rautanen and colleagues performed a GWAS on over 2000 patients from three cohorts admitted to intensive care units with sepsis of pulmonary origin, including patients from two randomised, multicentre clinical trials.[20] They observed that a common variant in the *FER* gene appeared to have a significant protective effect; patients homozygous for the allele had 10% mortality at 28 days, compared to 15% for heterozygotes and 25% for the wild-type homozygous population, although the observed p value of 9.7×10^{-8} is above the commonly accepted value of $\alpha = 5 \times 10^{-8}$ for significance in a GWAS. The mechanism for the observed survival advantage is not yet clear; the *FER* gene codes for a non-transmembrane tyrosine kinase that may have a role in neutrophil chemotaxis. It is noteworthy that an attempt to replicate the findings of Rautanen and colleagues in a cohort of 740 patients with severe sepsis was unsuccessful.[21] However, this may reflect the relatively low sample size of the replication cohort and its mixed population. Pending further replication attempts, the relatively small sample size and large P-value of the Rautanen study suggest that the possibility that their findings represent a false positive association cannot be overlooked.

Given the difficulties associated with recruiting large numbers of patients into individual genetic studies, perhaps the most logical way forward will be to statistically combine the results of different sepsis GWAS in a meta-analysis.[22] This strategy has been spectacularly successful in elucidating the genetic aetiology of other complex traits and diseases,[23] although it remains to be seen how effective this will be in sepsis, given the likely underlying heterogeneity of the condition. It will also be important to differentiate between GWAS that examine risk of sepsis versus studies that investigate response to sepsis, as these may involve substantially different genetic aetiologies.

GWAS have proven to be an important tool in the investigation of inheritance. As of May 2016, the NHGRI-EBI catalogue of published genome-wide association studies contained 2437 studies and 16,617 unique SNP-trait associations.[24] However, it has become apparent that GWAS has explained only a fraction of the observed heritability of common diseases.[23,25,26] As genetic technology has advanced, next generation sequencing technology is enabling researchers to comprehensively examine the role of all genetic variations in the genome, in particular the role of rare and low-frequency variants.[27] However, whole genome sequencing studies are currently in their infancy, and the very low statistical power to detect rare variants means that sequencing studies will need to be extremely large in order to detect low frequency variants. Therefore, until the cost of sequencing a genome approaches that of a microarray chip, it is likely that GWAS will remain the method of choice for the genetic analysis of complex traits and diseases like sepsis.

GENE EXPRESSION STUDIES

Microarray technology also permits genome-wide gene expression profiling, providing a further layer of information in addition to that provided by GWAS. Typically, these studies are performed on samples of whole blood from patients, and therefore represent the combined expression of genes across many different varieties of blood cell, although it is obviously also possible to focus on specific cell types if steps are taken to purify the samples first (e.g. by flow cytometry).[28] Several studies in this area have identified

differential gene expression patterns in patients with sepsis, which may help identify individuals at a higher risk of mortality.

In 2010, Tang and colleagues published a systematic review of microarray studies performed in human patients with sepsis.[29] They identified 12 cohorts consisting of 784 individuals in total with genome-wide expression data. The largest single cohort comprised 176 individuals, with the majority of studies recruiting less than 100 patients. While a consistent finding across the studies was upregulation of receptors involved in pathogen recognition, the authors failed to observe any other consistent expression pattern relating to changes in the inflammatory response. Transcriptional changes in inflammatory genes appeared to be highly variable, and no repeatable change in the expression of genes involved in cytokine production or other inflammatory mediators were observed.

A substantial body of work has been performed in paediatric patients using these techniques. In 2009, Wong and colleagues described the results of genome-wide expression profiling using RNA derived from whole blood in 98 paediatric patients with septic shock.[30] They observed just under 7000 differentially regulated genes, and using a hierarchical cluster technique identified three subclasses of septic shock. Patients in subclass 'A' had a significantly higher sickness severity and a higher mortality rate. Of the genes that appeared to have the strongest predictive ability to identify subclasses, a majority corresponded to signalling pathways in the adaptive immune system and glucocorticoid receptor signalling. Additionally, patients in subclass 'A' appeared to have a large-scale repression of genes related to zinc biology. The authors subsequently validated their findings in a further cohort of 82 paediatric patients.[31] Of particular interest was the observation that adjunctive corticosteroid treatment was associated with a higher mortality only in the subclass of patients in whom the genes associated with glucocorticoid signalling appeared to be repressed.[32]

This observation will need to be confirmed in a prospective study, but represents the first description of a subclass of patients with septic shock in whom genetic techniques may predict the response to a specific treatment.

One of the largest and most recent studies in adult septic patients is that of Davenport and colleagues. They examined gene expression data from 265 adult patients with sepsis from community-acquired pneumonia, and identified two 'sepsis response clusters' with over 3000 differentially expressed genes.[33] Patients in the first cluster had significantly higher mortality (14-day mortality 59% vs. 29%). Gene network analysis identified the downregulation of genes associated with immune response in the first cluster, which suggested that relative immune deficiency might play a role in the outcome from sepsis.

RNA-SEQ

RNA-Seq is an emergent technique that uses deep-sequencing technologies. Its aim is to quantify the transcriptome, the complete set of transcripts in the cell. In contrast to microarray methods, which rely upon hybridisation to a set of probes, RNA-Seq directly sequences a cDNA library of fragments generated from the RNA sample of interest. It has several key advantages over microarray-based approaches, including much greater range of expression levels over which transcripts can be detected, and it is not limited to the detection of transcripts from known genomic sequences.[34]

To date there are limited data from this approach in patients with sepsis and septic shock.[35]

EPIGENETICS

Epigenetics describes the study of changes in gene expression that are not a result of modifications in the DNA sequence.[36] Potential mechanisms for epigenetic changes include DNA methylation, non-coding RNAs and modification to histones, the proteins around which the DNA double helix is wrapped. The study of how epigenetic changes may influence sepsis is in its very early stages,[37,38] but available data suggest this may be a further mechanism for explaining differences in the susceptibility and response to this condition.

FUTURE STUDIES

The ADRENAL Gene expression study (ADRENAL GEPS, NHMRC APP1085159) is an Australian National Health and Medical Council funded study, which began at the start of 2015. The aim of the study was to recruit 1500 individuals with septic shock, assay genome-wide gene expression in patients' whole blood, and endeavour to find an mRNA-based classifier that differentiates patients in terms of their response to corticosteroid therapy and risk of mortality. Blood and serum samples are also being taken from patients in order to enable future GWAS, metagenomic and other molecular studies of septic shock.

SUMMARY

Our understanding of how genetic factors may influence the development and outcome of sepsis has greatly increased over the last few decades, driven by the rapid development of new molecular genetic techniques. However, as our knowledge has increased, so has the appreciation that as a highly complex syndrome, there are unlikely to be simple genetic changes

that can serve to inform prognosis or therapy. Nevertheless, continuing research in this field may well yield the hoped for a 'personalised medicine approach', which is so essential for a disease characterised by heterogeneity.

> A. Einstein

GLOSSARY

Adoption study:
A type of epidemiological study design where the similarity between parents and their biological offspring is compared to the similarity between parents and their adopted offspring.

Allele:
Alternate forms of a gene/SNP.

Candidate gene study:
A type of genetic association study where a relatively small number of genetic polymorphisms is investigated in a region of the genome that the investigator thinks is likely to be involved in the trait of interest.

Complex disease/trait:
A disease/trait that is caused by many genetic variants of small effect and environmental factors. Most of the common diseases of major public health relevance (including sepsis) are complex diseases.

Epigenetics describes the study of changes in gene expression that are not a result of modifications in the DNA sequence.

Gene:
A simple definition of a gene is a part of the genome that codes for a protein.

Genetic variant:
A part of the human genetic sequence that varies between individuals in the population.

Genome:
The entire genetic sequence of an individual.

Genome-wide association study (GWAS):
A type of genetic association study where individuals typically have hundreds of thousands of SNPs genotyped across their genomes. GWAS are typically performed using microarray technologies that may not physically capture low frequency/rare genetic variants.

Heritability:
The proportion of variation in a phenotype that is due to genetic factors.

Microarray:
Comprises a silicon chip (or other medium) containing numerous oligonucleotide probes that are complementary to specific sequences in the genome. Microarrays can be used to assay hundreds of thousands of SNPs, or measure gene expression in thousands of genes simultaneously.

Nucleotide:
A single unit of DNA consisting of a deoxyribose sugar, a phosphate group, and a nitrogenous base.

Population stratification:
Refers to the situation in genetic studies where the sample consists of individuals of different ancestries. Population stratification may lead to spurious results in genetic studies and often must be corrected for.

(Statistical) Power:
The probability of correctly rejecting the null hypothesis of no genetic association. Genome-wide association studies typically need thousands of individuals in order to have adequate power to detect true genetic associations.

Sequencing is determining the exact order of the bases in a strand of nucleotides.

Single nucleotide polymorphism (SNP):
A single base change in the sequence of the genome that varies across individuals. SNPs are the form of genetic variation that is most often tested in genome-wide association studies.

Transcription:
The process by which the DNA sequence is coded into messenger RNA.

Transcriptome:
The sum total of all the mRNA molecules expressed from the genes of an organism.

Translation:
The process whereby messenger RNA is coded into a sequence of amino acids.

Type I error:
Refers to the situation where an association is claimed but in fact no such association really exists. In genetic studies, this may arise from a number of sources including statistical fluctuation, population stratification, and the unintended inclusion of related individuals in a genetic analysis of unrelated individuals.

(Classical) Twin Study:
This sort of epidemiological study design compares the trait similarity of identical twins (who share all their genes in common) to the similarity between non-identical twins (who share, on average, half their genes in common). Excess similarity in identical twins compared to the non-identical counterparts provides evidence that a trait has a genetic aetiology.

Whole genome sequencing:
Refers to sequencing the entire genetic sequence of an individual. It is currently expensive to do.

Overview of shock

Matthew J Maiden, Sandra L Peake

DEFINITION

Shock is a fundamental disease state of critical illness. Yet many who manage shocked patients, remain vague about what shock is. A commonly offered description is 'a patient with a low blood pressure', followed by some threshold blood pressure, below which, 'shock' is said to be occurring.

The reason for the uncertainty about what is an important concept, relates to the fact that the term 'shock' is used in a multitude of contexts (e.g. septic, haemorrhagic, distributive, hypovolaemic, cytotoxic, cardiogenic, anaphylactic, toxic, spinal, neurogenic, cervical, electrical and even emotional shock). Nevertheless, the unifying feature of shock, irrespective of the initiating disease or clinical features, is **acute circulatory failure associated with inadequate oxygen utilisation by the cells.**[1]

A thorough understanding of what constitutes shock is essential for all critical care practitioners. This chapter will outline the pathophysiology of shock, a classification of diseases that lead to shock and an approach to management.

CIRCULATORY PHYSIOLOGY

OXYGEN DELIVERY

Circulatory supply of oxygen is tightly regulated by the cardiovascular system. Oxygen delivery (DO_2) is the product of cardiac output (CO) and the oxygen content of arterial blood. DO_2 (mL/min) can be summarised by the following equation:

$$DO_2 = CO \times ([1.34 \times Hb \times SaO_2] + [PaO_2 \times 0.003])$$

where Hb is the haemoglobin concentration (g/L), SaO_2 is the arterial haemoglobin (Hb) oxygen saturation and PaO_2 is the arterial oxygen partial pressure. The exact value of the haemoglobin O_2-carrying capacity constant is variably listed as either 1.34 mL O_2/g Hb (directly measured) or 1.39 mL O_2/g Hb (theoretical maximum O_2 carrying capacity).

Assuming adequate arterial oxygen content, CO is the main determinant of DO_2. CO, in turn, is the product of heart rate (HR) and stroke volume (SV) with preload, afterload and myocardial contractility determining SV. Thus:

$$CO = HR \times SV\ (\text{preload, afterload, contractility})$$

Alterations in any of these determinants of CO will eventually lead to the development of different 'types' of circulatory shock (e.g. hypovolaemic, distributive, cardiogenic).

DO_2–VO_2 RELATIONSHIP

DO_2 in adults at rest is approximately 1000 mL/min, while oxygen consumption (VO_2) is about 250 mL/min. Under normal circumstances, the 'extra' O_2 being supplied is not required to meet metabolic demand and can conceptually be thought of as a 'reserve' supply (O_2 supply independency). If DO_2 decreases, VO_2 initially remains unchanged as the 'reserve' O_2 is utilised. If DO_2 falls further, oxygen extraction from Hb is increased to maintain adequate oxygen supply to the tissues. Any further reduction of DO_2 results in oxygen being maximally extracted from Hb and, at this point, VO_2 becomes dependent on DO_2 (O_2 supply dependency) and energy production in cells is limited by the supply of oxygen (Fig. 15.1).

DYSOXIA

Dysoxia occurs beyond the critical point of oxygen supply dependency (critical DO_2). Inadequate O_2 supply leads to anaerobic cellular metabolism, less efficient adenosine triphosphate (ATP) production and consequent cellular and organ dysfunction. If the process leading to shock is identified and managed early and appropriately, cellular dysfunction is limited. However, if shock persists, the ongoing limitation of oxygen supply affects cell membrane ion channels, leading to an influx of sodium and water, cellular oedema, breaching of cell membrane integrity, cell injury and eventually cell death.

The ability to withstand limited oxygen supply varies between organs. The heart and brain have high metabolic requirements with a relatively high oxygen extraction, and hence, are more vulnerable to reduced

ABTRACT

Shock is defined as acute circulatory failure associated with inadequate oxygen utilisation by the cells. It can be classified as hypovolaemic, distributive, cardiogenic or obstructive, based on the pattern of circulatory compromise. In some diseases leading to shock, such as sepsis, cells have a state of dysoxia where they have a limited ability to utilise oxygen despite an apparent increased oxygen delivery.

Not all forms of shock present with the same haemodynamic derangements. A low blood pressure is common, but is not required to define shock. Clinical characteristics will depend on the mechanisms leading to shock, the ability of the patient to mount a compensatory response, underlying comorbidities and the effect of medications.

Shock is usually lethal if untreated. The early recognition of shock, the optimisation of oxygen delivery and the prompt definite treatment of the disease triggering this condition are essential for survival. Repeated clinical assessment and monitoring of multiple haemodynamic and cellular parameters is necessary to ensure adequate management.

KEYWORDS

Shock
oxygen delivery
dysoxia
parenteral fluids
cardiovascular medications
haemodynamic monitoring

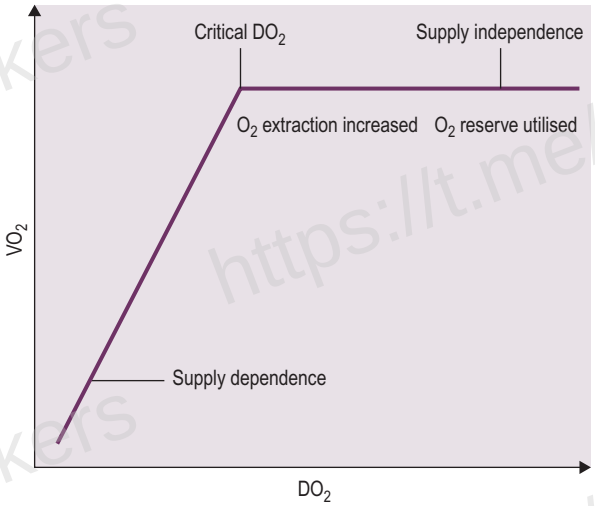

Figure 15.1 Oxygen supply and demand relationship.

oxygen supply. In contrast, the kidney and skin have relatively lower metabolic requirements and lower O_2 extraction and therefore are more tolerant of decreased DO_2. The critical DO_2 also varies between individuals and is affected by metabolic demand, age, disease states and medications.

Importantly, dysoxia may also occur despite adequate DO_2. In conditions such as sepsis and multiorgan dysfunction syndrome, DO_2 can appear to be adequate (and may even be supranormal as a result of increased CO). However, arteriolar shunting around the microvascular capillary beds prevents oxygen delivery to the cells, and inflammatory mediators can induce mitochondrial dysfunction, preventing cells from utilising available oxygen (cytotoxic shock).[2] Hence **hypotension is not required to define 'shock'.**

'TYPES' OF SHOCK

Impairment of circulatory supply of oxygen to the cells is commonly classified according to which component of the circulation is primarily disturbed, that is, hypovolaemic shock (inadequate preload), cardiogenic shock ('pump' failure), distributive or vasodilatory shock (altered vascular capacitance).[3] The classification of shock into various types is clinically useful as it has therapeutic implications – albeit this distinction is sometimes too simplistic. For example, in septic shock, hypovolaemia (decreased preload secondary to increased vascular permeability), vasodilation and myocardial dysfunction may all co-exist.

HYPOVOLAEMIC SHOCK

The total blood volume is 70 mL/kg and comprises blood cells and serum. Hypovolaemic shock occurs when acute blood loss or excessive fluid losses lead to decreased circulating blood volume (Box 15.1).

Box 15.1 Causes of hypovolaemic shock

Blood loss

Vascular injury (e.g. trauma, surgery)
Gastrointestinal bleeding (e.g. peptic ulcer, diverticular, angio-dysplasia, varices)
Obstetric bleeding (e.g. placenta praevia, postpartum haemorrhage)
Intra-abdominal haemorrhage (e.g. splenic laceration, liver injury)
Retroperitoneal (e.g. aortic aneurysm, ectopic rupture, femoral artery bleeding, pelvic fracture)
Long bone fracture
Pulmonary haemorrhage, haemothorax

Fluid loss

Vomiting
Diarrhoea
Ileostomy losses
Sweating
Polyuria (e.g. glucosuria, diabetes insipidus)
Burns
Pancreatitis

Loss of circulatory volume will reduce preload and SV. About 10% of circulating volume loss can be restored by the movement of interstitial fluid into the circulation. Blood loss beyond this invokes cardiovascular compensatory mechanisms in order to restore preload and maintain CO and systemic blood pressure. These mechanisms include:

1. *Increasing venous tone*. Venoconstriction is an early compensatory response to hypovolaemic shock. The venous system holds about 80% of blood volume and acts as a blood reservoir. The sympathetic nervous system controls venous tone and capacitance of the venous system. Reducing capacitance favours venous return to the heart in an attempt to maintain SV.
2. *Increasing arteriolar tone*. Sympathetic stimulation of arteriolar resistance vessels increases perfusion pressure to the organs. However, this does not necessarily equate with increased blood flow. The extent of change of arteriolar tone varies in order to redistribute adequate blood flow to the vital organs.
3. *Increasing HR*. To compensate for the reduction in SV, HR is increased in an attempt to maintain CO.
4. *Increasing contractility*. The heart will contract more vigorously in order to increase SV and maintain CO.

Priorities in the management of hypovolaemic shock are to (1) control the source of blood and/or volume loss, and (2) restoring the circulating volume.

Box 15.2 Causes of cardiogenic shock

Myocardial ischaemia
Acute valve dysfunction (e.g. chordae rupture, prosthetic valve thrombus)
Myocarditis
Contusion
Septal/ventricular rupture
Drugs (e.g. Ca^{2+} channel-blocker overdose, β-blocker overdose)
Extrinsic compression (e.g. tension pneumothorax, tamponade)
Pulmonary emboli, pulmonary hypertension
Bradyarrhythmias (e.g. complete heart block)
Tachyarrhythmias (e.g. atrial or ventricular tachycardias)

CARDIOGENIC SHOCK

The heart is central to the circulatory supply of oxygen and if the pump fails, then little compensatory mechanisms remain. Hence, cardiogenic shock has a very high in-hospital mortality rate ranging from 45% to 100%, depending on the aetiology.[4] Myocardial ischaemia is the most common cause of cardiogenic shock but other aetiologies must be considered (Box 15.2).

Treatment priorities in cardiogenic shock involve the urgent correction of the underlying acute cardiac disease and the consideration of afterload reduction while ensuring adequate organ perfusion.

OBSTRUCTIVE SHOCK

Mechanical obstruction to the flow of blood through the cardiac chambers will lead to a reduced cardiac output. Limitation of flow may be due to obstruction within the heart (e.g. valve thrombosis, myxoma), extrinsic compression (e.g. tension pneumothorax, cardiac tamponade) or cardiac outflow obstruction (e.g. pulmonary embolus, hypertrophic obstructive cardiomyopathy). Treatment is directed at urgent removal of the obstruction (e.g. drainage of pericardial effusion, lysis of thromboembolism).

DISTRIBUTIVE SHOCK

Arteriolar autoregulation, the autonomic nervous system and vasoactive hormones control distribution of blood around the vascular network. Distributive shock results from the failure of these mechanisms, leading to inappropriate distribution of blood (Box 15.3). Unlike other forms of shock, cardiac output may initially be increased as the heart endeavours to compensate for maldistribution of blood.

Management priorities are to identify and treat the precipitating cause and to improve organ perfusion with resuscitation fluids and vasoactive drugs.

Box 15.3 Causes of distributive shock

Septic shock
Toxic shock
Anaphylactic shock
Neurogenic shock
Adrenal/thyroid insufficiency
Toxicity (e.g. drugs)
As a component of multiorgan dysfunction syndrome

CLINICAL SIGNS

Clinical features of shock reflect an inadequate circulation and insufficient oxygen delivery and/or utilisation.

Hypotension is a typical feature of shock and often signifies circulatory failure. However, hypotension develops late as blood pressure is initially maintained by compensatory mechanisms (i.e. vascular constriction, tachycardia, increased myocardial contractility). A decline in mean arterial pressure (MAP) below the lower limit of autoregulation results in reduced perfusion to the vital organs. In a healthy adult, tissue perfusion is typically impaired with a MAP of ≤50 mm Hg. In contrast, elderly patients with pre-existing hypertension or vascular disease generally require a higher MAP to represent adequate regional blood flow.

Tachycardia is an early compensatory sign of shock. Note, however, that in some conditions bradycardia is the cause of shock (e.g. complete heart block, increased vagal tone in cervical shock, unopposed vagal tone in neurogenic shock).

Tachypnoea steadily increases with worsening shock but falls in the pre-terminal phase of shock.

Oliguria is secondary to reduced glomerular filtration and increased filtrate reabsorption. In shock, the rate of urine production may be a useful guide to adequacy of the circulation.

Altered mental status is a common feature of shock as cerebral function is very sensitive to altered oxygen delivery. During shock, mental state progressively changes from anxiety, agitation, confusion and delirium, towards drowsiness and coma.

Impaired peripheral perfusion provides a clinically useful clue regarding the likely mechanism of shock. Cool, clammy peripheries with pale or mottled skin are suggestive of hypovolaemic or cardiogenic shock, whereas warm peripheries are suggestive of distributive shock.

It is important to recognise that clinical features of shock are non-specific and will differ depending on the type of shock, the severity of the precipitating disease, the physiological reserve of the patient and the effects of medications. For example, patients on β-antagonists will not mount the same tachycardic response, and patients with pre-existing cardiac disease are less

capable of circulatory compensation, so they develop features of shock earlier. In contrast, young patients typically have greater compensatory reserves; hence clinical signs of shock in this group of patients represent profound cardiovascular compromise. Due to the non-specific and varied clinical signs of shock, repeated assessment with frequent monitoring of vital signs is essential.

MANAGEMENT

Resuscitation of shock is a medical emergency. The aim of therapy is to rapidly and effectively restore systemic DO_2 and improve tissue perfusion. History, examination and investigation (Box 15.4) must occur concurrently with resuscitation. The usual 'ABC' resuscitation principals of airway, breathing and circulation apply.

ENSURE ADEQUATE OXYGENATION

Ensure adequate FiO_2 and SaO_2, that ventilation is not impaired and that any reversible cause of pulmonary shunt is corrected (e.g. pleural collection, bronchus obstruction).

VASCULAR ACCESS

Insertion of intravenous cannulae is essential for the administration of fluids and medications. Cannula size is an important consideration as it has major implications for the rate of laminar fluid flow. Poiseuille's law describes the variables contributing to laminar flow rates.

$$Q \propto (\Delta P \times \pi r^4)/(8 \times \text{viscosity} \times \text{length})$$

This emphasises the effect of radius and cannula length on flow. Hence for rapid intravenous fluid administration, venous cannulation using short, wide-bore catheters is advised.

Flow rates achieved through different diameter intravenous cannulae are stated to range from 44 mL/min (22 G; 0.9 mm diameter) through to 286 mL/min (14 G; 2.1 mm diameter). However, the flow through cannulae is turbulent rather than laminar and actual flow rates are lower than those quoted.[5]

A central venous cannula should be considered in patients with persistent shock, particularly if they are requiring infusion of catecholamines, other cardiovascular medications or multiple infusions, or have difficult peripheral venous access.

Box 15.4 Investigations for shock (as clinically indicated)

Bedside
Haemoglobin
Arterial blood gas
Lactate
ECG
Ultrasound (e.g. FAST scan, AAA scan)
Echocardiogram

Laboratory
Full blood count, coagulation studies, D-dimer
Electrolytes, creatinine, urea, liver function tests
Cardiac enzymes, lipase
Cultures – urine, blood, sputum, pus
Toxicology assays

Radiology
Chest, abdominal X-ray
Trauma series radiology (chest, pelvis, C-spine)
CT
Angiography (e.g. coronary, visceral, pulmonary)

AAA, Abdominal aortic aneurysm; *CT*, computed tomography; *ECG*, electrocardiography; *FAST*, focused assessment with sonography for trauma.

FLUID RESUSCITATION

Fluid resuscitation is an important therapeutic strategy in the management of shock.[6] Although parenteral fluids are commonly used, there remain many questions regarding what 'dose' and type of fluid is best in shock. While hypovolaemia can contribute to states of shock, simply 'pouring in' fluids risks the development of hypervolaemia and its attendant adverse consequences and known association with mortality. Resuscitation should involve fluid administration provided in titratable aliquots, and the haemodynamic responses should be assessed before providing further fluid doses.

It is important to remember that not all patients will respond to fluid loading with a significant increase in CO. If the heart is working on the terminal (flat) portion of the Frank-Starling curve, increased preload will not result in a significant increase in SV. Furthermore, the relationship between preload and stroke volume is dynamic and is affected by many other variables extrinsic to the heart (e.g. autonomic tone, cardiovascular medications, ventilation, lung disease).[7] These need to be considered when determining the volume of fluids to administer.

TRENDELENBURG MANOEUVRE

A quick method to increase venous return is to tilt the patient's pelvis above horizontal (i.e. head down). This will 'auto-transfuse' blood from leg and pelvic veins into central veins, augmenting preload. Increases in CO, though, are minimal if venous capacitance remains high and the extra blood volume is accommodated. The haemodynamic response to passive leg raise can be used to assess whether fluid administration will enhance cardiac output.[8]

CRYSTALLOID SOLUTIONS

Crystalloid solutions comprise electrolytes (with or without dextrose) and water. These fluids cross semi-permeable membranes easily and are rapidly distributed through the intravascular and extravascular spaces. The time for fluid equilibration across the body compartments depends on: (1) osmolality of the fluid, (2) solute clearance, and (3) integrity of the vascular endothelium.

Whilst the choice of fluid should reflect the composition of the fluid lost, 0.9% saline is commonly used for initial volume replacement. Saline 0.9% is slightly hyperosmolar (300 mOsm/L) and hyperchloraemic (150 mEq/L) relative to plasma. When large volumes are used for resuscitation, hyperchloraemia can contribute to bicarbonate loss and a normal anion gap metabolic acidosis. Lactated Ringer solution (Hartmann) is isotonic and contains lactate (29 mEq/L) and electrolytes in a ratio similar to plasma. However, the calcium in Hartmann (4 mEq/L) is incompatible with certain drugs, and lactate levels may rise if hepatic function is markedly impaired, if a lot of fluid is administered or if blood is sampled from an arm receiving intravenous fluids. Other crystalloid solutions are available that contain different buffer anions and slightly different composition of electrolytes. These solutions are being studied to determine if they provide more favourable clinical outcomes.

Concentrated saline is theoretically a useful resuscitation fluid since a small volume can increase circulating volume (e.g. 250 mL 7.5% saline can increase circulating volume by 500 mL). However, the sodium also passes into the interstitial space, leading to increased interstitial fluid volume at the expense of intracellular volume.

ALBUMIN SOLUTIONS

Normal serum albumin at 4% (NSA 40 g/L; 260 mOsm/L) is iso-oncotic, and infusion rapidly increases circulating volume. Concentrated (20%) albumin is available in smaller volumes (100 mL). It increases circulating fluid volume by drawing fluid from the interstitium, but this process takes time and hence it is not a useful resuscitation fluid.

In 1998, a Cochrane review suggested that albumin use was associated with increased mortality,[9] but other reviews drew different conclusions.[10–12] To determine the safety of albumin as a resuscitation fluid, the Saline versus Albumin Fluid Evaluation (SAFE) study randomised 7000 patients to receive albumin or crystalloid as their resuscitation fluid.[13] This landmark study revealed that patients receiving albumin required less intravenous fluid, but clinical outcomes were no different to patients who received saline resuscitation. Subgroup analyses suggested that septic patients fared better with 4% NSA, while head injured patients given saline had better outcomes.

STARCH SOLUTIONS

Starch solutions contain a carbohydrate polymer (starch) as their oncotic molecule and differ according to the type and molecular size of the starch used (high starch 450,000 D, medium starch 200,000 D, low starch 70,000 D). The starch polymers undergo degradation by serum amylase with the fragments cleared by the kidney. The duration of oncotic effect is related to the size of the starch molecule and clearance rates. While starch solutions provide effective intravascular volume replacement and are convenient to administer, their use in patients with septic shock has been associated with increased risk of death, renal impairment and bleeding risk.[14,15] A recent clinical trial of 7000 intensive care unit (ICU) patients randomised to receive 6% hydroxyethyl starch (HES; 130/0.4) or 0.9% saline as resuscitation fluid found no difference in mortality; however, patients who received 6% HES had an increased need for renal replacement therapy and a greater incidence of skin reactions.[16]

RED BLOOD CELLS

The use of blood is essentially limited to shock from acute blood loss or for correcting anaemia that may be contributing to impaired oxygen delivery.

CARDIOVASCULAR MEDICATIONS

When fluid administration alone fails to restore adequate oxygen delivery, consideration should be given to augmenting the circulation with catecholamines or other agents. In extreme shock, it may be necessary to commence fluid resuscitation and vasoactive therapy concurrently. Note that increasing DO_2 *beyond* normal does not improve outcomes.[17–19]

Medications used to acutely enhance the circulation are commonly referred to as 'inotropes' as many of them increase cardiac contractility (i.e. inotropy). However, many agents have their primary effect on vascular tone rather than directly altering contractility. The choice of agent will depend on which aspect of the cardiovascular physiology is deranged, and the therapeutic effect desired.

For cardiogenic shock, medications may be required to increase contractility (e.g. dobutamine, milrinone, levosimendan), reduce afterload, maintain adequate systemic and coronary perfusion pressure, increase diastolic relaxation and increase (or decrease) HR. In distributive shock, medications are required that produce venoconstriction and restore the autoregulation of arterial flow. There is little role for cardiovascular medications in hypovolaemic shock.

The choice of which catecholamine to use in shock (i.e. noradrenaline vs. adrenaline vs. dopamine) has been the subject of considerable debate and opinion. Different catecholamines exhibit different pharmacological properties (e.g. β_1 vs. β_2 adrenergic receptor stimulation); however, the superiority of one

catecholamine over another has not been demonstrated in any large-scale clinical trials. A large, randomised trial of patients with shock reported no difference in 28-day mortality between noradrenaline and dopamine,[20] while an Australian trial found no difference between noradrenaline and adrenaline in patients with shock from any cause.[21] Similarly, in septic shock there is no mortality difference if adrenaline is used alone, or noradrenaline with dobutamine.[22] It is not surprising that there is no one 'ideal' vasoactive agent given the wide range of conditions contributing to shock and the heterogeneity of patient factors. Instead, these drugs should be chosen based on the desired therapeutic effects on the cardiovascular system.

While blood pressure is universally used as a guide to the adequacy of the circulation, and often a therapeutic target when using vasoactive agents, there are no randomised, controlled trials evaluating the ideal MAP. Choosing the ideal MAP remains empirical and should be based on the clinician's assessment of the minimum pressure thought to represent adequate blood flow. Current guidelines advocate a target MAP ≥65 mm Hg, but acknowledge that this should be altered depending on patient circumstances (e.g. chronic hypertension, penetrating trauma, head injury).[1]

MANAGE PRECIPITATING ILLNESS OR INJURY

As the circulation is being resuscitated, the cause of the circulatory disturbance needs to be identified and corrected. Time to definitive treatment of the cause of shock is related to survival. This has been clearly illustrated in cardiogenic shock (time to reperfusion),[23] haemorrhagic shock (time to haemorrhage control)[24] and septic shock (time to appropriate antibiotics).[25]

MONITORING

Outcomes from shock are greatest when it is recognised early and when the patient is managed in an environment that closely monitors clinical signs and physiological parameters (i.e. an ICU). Clinical monitoring involves frequent assessment of HR, blood pressure, respiratory rate, conscious state, urine output, peripheral perfusion and temperature. As there is no 'gold standard' measure of shock, multiple parameters should be assessed repeatedly to determine adequacy of resuscitation and treatment.[26,27]

A systemic arterial cannula is particularly useful for measuring blood pressure, while also permitting sampling for blood gas and lactate measurement. In some circumstances, the arterial waveform or its variations with ventilation can provide further insights into the haemodynamic volume status.[28]

A central venous cannula (CVC) allows measurement of central venous pressure (CVP), and is often used as an estimate of preload. However, CVP bears a variable relationship to venous volume, as it is dependent on the location of the catheter to the right atrium, intrathoracic pressures, venous compliance, position of the patient and tricuspid valve competence. Thus CVP is a guide to the *pressure* status of the venous system rather than a measure of intravascular volume and preload. The CVP does not predict whether administering a volume of fluid will change cardiac output or oxygen delivery. This has been illustrated many times, including in healthy volunteers and in patients with shock.[29–31]

There are CVCs available that contain an oximeter in the tip that measures O_2-Hb saturation of central venous blood ($ScvO_2$). This may be used as a guide to determine the O_2 demand and the adequacy of DO_2, and to help direct further resuscitation. An $ScvO_2$ ≥70% has been proposed as a resuscitation goal.[32] However, $ScvO_2$ is a general measure of global O_2 demand and does not measure the impact of coronary venous blood (from the coronary sinus). Inadequate DO_2 may still occur despite a normal or high $ScvO_2$ (e.g. anatomical shunts, microcirculation shunting). Similarly, blood sampled from a CVC and arterial cannula can be used to determine the arterial–venous difference in CO_2. Values greater than 6 mm Hg can represent increased metabolic demand, but this is not yet proven to be a reliable index to guide resuscitation.[33]

Measuring CO in patients with shock is not required routinely. For most patients, clinical assessment provides adequate information regarding CO. There is no evidence that routine monitoring of CO or targeting therapy to a specific CO improves outcomes. However, directly monitoring CO may be necessary if a patient's circulatory disturbance does not improve following initial treatment. There are an ever-increasing number of techniques available for estimating CO, all with inherent strengths and limitations. Further discussion of haemodynamic monitoring will be outlined in subsequent chapters.

Monitoring haemodynamics with ultrasound is becoming an increasingly used and recommended tool in ICU.[1,34] Echocardiography plays an important role in diagnosing the type of shock and is the recommended investigation modality if clinical examination does not lead to a clear diagnosis.[1,35] Other ultrasonic variables have been investigated to determine if they are clinically useful to guide the volume of fluid replacement. These include the size of the venae cava, the ventricular volume at end-diastole, the estimation of SV and the ejection fraction.[36] However, these techniques are operator and patient dependent, and their utility over repeated clinical assessment is unproven.

Blood gas, pH and lactate monitoring provide some guidance to the adequacy of cellular resuscitation. Inadequate oxygen delivery and/or utilisation are the most common causes of elevated serum lactate (generally defined as >2 mmol/L) in ICU patients.

Blood lactate levels, lactate clearance rates and falling base deficit are independently associated with poor outcomes[37–42] and are a better predictor of mortality than DO_2 or VO_2.[43] However, lactate is not specific for shock as elevated levels may also occur with liver failure (reduced lactate metabolism), thiamine deficiency (inhibits pyruvate dehydrogenase), lactate administration (e.g. in dialysis fluids), catecholamine administration (β-agonists) and prolonged exercise. Elevated blood lactate levels may also reflect regional dysoxia of an isolated anatomical organ or tissue (e.g. limb or bowel ischaemia) that may not necessarily be associated with a global circulatory disturbance. The role of targeting therapies to lactate clearance or base excess also remains uncertain.[44,45]

Standard ICU monitoring techniques focus on assessment of the macrocirculation. However, there is growing interest in how the microcirculation can be directly monitored. Microscopic analysis of the circulation with orthogonal polarisation spectral (OPS) imaging or near infrared spectroscopy (NIRS) provide fascinating insights into the microcirculatory status, but their use remains experimental.

Haemodynamic monitoring

David J Sturgess, Ryan P Watts

INTRODUCTION

Haemodynamic monitoring refers to the monitoring of blood flow through the cardiovascular system. In critical care, including the intensive care unit (ICU), haemodynamic monitoring is used to detect cardiovascular insufficiency, to differentiate contributing factors and to guide therapy. Ultimately, the goal is to optimise delivery of oxygen and nutrients to the tissues.

Historically, invasive techniques prevailed. The possibility of complications and limited data demonstrating improved survival due to invasive techniques have sustained a steady trend towards less invasive monitoring in the ICU.[1]

At the bedside, the clinician must work with inexact surrogates of preload, contractility and afterload, measured or derived from arterial blood pressure (systemic or pulmonary), volume or pressure indices of cardiac filling, stroke volume or cardiac output (CO) and various markers of tissue wellbeing.

As a rough guide to the layout of this chapter, clinical observation and evaluation will be considered briefly before progressing to monitoring that is primarily concerned with the measurement of pressures (including catheterisation, equipment and techniques) and flow (CO). Functional haemodynamic monitoring, including the prediction of fluid responsiveness, will also be considered. Monitoring of perfusion in the microcirculation will be briefly mentioned also.

CLINICAL OBSERVATION AND EVALUATION

The diagnosis of acute circulatory failure should incorporate the integrated assessment of clinical, haemodynamic and laboratory data.[2]

Electrocardiographic (ECG) monitoring is almost universally indicated in the ICU. Generally, a system requiring a reduced number (<10) of electrodes is used for both patient comfort and caregiver convenience. However, it must be kept in mind that when compared to the recorded 12-lead ECG, reconstructed 12-lead ECG data appear to retain specificity but can be significantly less sensitive across a range of rhythmic and morphological abnormalities.[3]

PRESSURE-BASED CARDIOVASCULAR MONITORING

This section will discuss pressure-based monitoring techniques. Equipment, methods and supplementary variables will be discussed under the most applicable headings also.

ARTERIAL BLOOD PRESSURE

During the passage of the arterial pressure wave from the aortic root into the peripheral vasculature, there is a progressive increase in systolic blood pressure (SBP) and a reduction in diastolic blood pressure (DBP). This process, known as distal wave amplification, results from the incorporation of standing and reflected waves. Consequently, systemic arterial pressure measurements vary according to the site of measurement.

Mean arterial pressure (MAP) is arguably more relevant than either SBP or DBP for three reasons:

- MAP is least dependent on measurement site or technique (invasive vs. non-invasive).
- MAP is least altered by measurement damping.
- MAP determines tissue blood flow via autoregulation (apart from the left ventricle, which autoregulates from diastolic pressure).

NON-INVASIVE ARTERIAL BLOOD PRESSURE MEASUREMENT

In critical care, most standard non-invasive arterial blood pressure (NIBP) instruments are automated intermittent oscillometric devices. Oscillometric NIBP provides rapid, easy assessment of blood pressure and can be used alone when beat-to-beat monitoring is not required. Contraindications to NIBP are relative and influence cuff placement. It is preferable to avoid extremities with severe peripheral vascular disease, venous cannulation, arteriovenous fistula or a predisposition to lymphoedema, as may occur after lymph node clearance.

To make an oscillometric blood pressure measurement, a pneumatic cuff is inflated around a proximal limb until all oscillations in cuff pressure are extinguished. The occluding pressure is then lowered

ABSTRACT

Haemodynamic monitoring refers to the monitoring of blood flow through the cardiovascular system. In critical care, it is applied to detect cardiovascular insufficiency, differentiate contributing factors and guide therapy. Haemodynamic monitoring encompasses a broad range of evaluation and measurement techniques. It is recommended that the clinician assimilates all available information to optimise patient management. A trend towards non-invasive techniques has been propagated by a number of factors including: the risks and complications of invasive monitoring; a paucity of data relating improved outcome to the invasiveness of the technique; and increasing availability, affordability and accuracy of less invasive devices. Rather than focusing on specific devices, this chapter aims to categorise techniques and explain their underlying principles.

stepwise, so that oscillations reappear over a discrete interval. Maximal oscillations concur with MAP, and proprietary algorithms compute reported pressures from the alterations in oscillatory amplitude during deflation.[4] Oscillometry overestimates low pressures and underestimates high pressures compared to intra-arterial monitoring, but for the normotensive range the 95% confidence intervals are ±15 mm Hg (2 kPa). Dysrhythmia increases the error, and reliability may be suboptimal in pregnancy and childhood. Cuff width should be 40% of the mid-circumference of the limb. Narrower cuffs overestimate and wider cuffs underestimate blood pressures. Oscillometric devices should be validated in a standard fashion and may not be automatically interchangeable. Complications are unusual. Repeated cuff inflations can cause skin ulceration, oedema and bruising – more so when the patient's consciousness is impaired by illness and sedation. Ulnar nerve injury is also possible, especially with cuff placement encroaching upon the elbow.

Continuous non-invasive blood pressure monitoring has also been developed. The benefits of such techniques may be nullified if frequent blood sampling is required for gas analysis and other tests, in which case an intra-arterial cannula is likely to be indicated.

The volume-clamp technique uses an infrared light transmission/receiving system to measure finger artery size. An inflatable pressure bladder around the finger is adjusted via a proprietary algorithm to clamp the artery to a constant size. A reference sensor is placed at heart level. The resultant changes in bladder pressure are then able to be displayed as an arterial blood pressure waveform. Manipulation of these data can produce derived haemodynamic variables, such as CO, stroke volume, stroke volume variation and systemic vascular resistance. The volume-clamp method is challenged by conditions that impair finger perfusion or plethysmography, such as vasoconstriction of finger vessels or oedema; these conditions are common in critically ill patients, but should be less of a hindrance in the perioperative setting.

Applanation tonometry is also capable of continuous measurement. The most appropriate position over the radial artery is determined by an electromechanical system, which places the sensor in such a way that the transmural pressure is zero. This allows direct measurement of the MAP and the arterial trace can be determined. Readings are easily interrupted by movement due to the patient or the care.

Original validation studies for these newer continuous techniques were not optimal. Further refinement has shown promising results.[1,5]

INVASIVE BLOOD PRESSURE MEASUREMENT

Invasive measurement is desirable in the presence of haemodynamic instability, end-organ disease requiring beat-to-beat blood pressure monitoring, during therapeutic manipulation of the cardiovascular system or if non-invasive methods fail.[2] Cannulation of a systemic artery allows continuous monitoring of the arterial pressure waveform, heart rate and blood pressure, and also facilitates blood testing. Relative contraindications include coagulopathy and vascular abnormality or disease.

To minimise the risk of infection in adults, the radial, brachial and dorsalis pedis arteries are preferred, whereas paediatric recommendations include the posterior tibial artery but not the brachial artery.[6] The radial artery is the most common site for cannulation due to ease of cannulation, relatively consistent anatomy and low complication rates (incidence of permanent ischaemic complications ~0.09%). Nothing larger than a 20-gauge cannula is advisable, and either a modified Seldinger technique or direct cannulation can be used. The modified Allen's test is sometimes employed prior to cannulation to assess for collateral flow. Evidence is lacking regarding its ability to predict ischaemic complications of radial artery cannulation.[7] Ultrasound might be a more reliable way of confirming collateral perfusion, as well as potentially improving cannulation rates with fewer attempts.

Once inserted, the cannula is usually infused with normal or heparinised saline at 3 mL/h, with a snap flush rate of 30–60 mL/h. The use of heparinised saline to prolong catheter patency must be balanced against the potential contamination of blood samples drawn through the cannula (especially activated partial thromboplastin time [APTT]) and concerns regarding sensitisation and development of heparin-induced thrombosis thrombocytopenia syndrome (HITTS).

Peripheral arterial catheters should be removed when no longer required and replaced only when clinically indicated.[6] Distal perfusion should be checked at least 8-hourly, and the cannula removed if there is persistent blanching, coolness with sluggish capillary refill, loss of pulses or evidence of raised muscle compartment pressures. Arterial cannulation may be associated with a number of complications (Table 16.1).[8]

Physical properties of clinical pressure measurement systems

In the standard setup, the arterial cannula is connected to a linearly responsive pressure transducer via fluid-filled, short, non-compliant tubing.[9] Modern disposable transducers are precalibrated using electrical signals, and are not normally calibrated further. The system is zeroed to the level of the phlebostatic axis, normally the mid-axillary line at the fourth intercostal space. Subsequent lowering of the transducer relative to this axis will cause pressure overestimation, while raising it will cause underestimation.

The *natural resonant frequency* of the system should exceed 36 Hz (>10 harmonics with allowance for optimal damping, which allows measurement of up to 67% of resonant frequency) for heart rates up to 180

Table 16.1 Complications of arterial cannulation, with suggested preventative and treatment option

COMPLICATION	PREVENTION	TREATMENT
Vascular thrombosis (ranges from 7% to 30% following radial artery cannulation). Risk factors for digital ischaemia include: shock, sepsis, embolus of air or clot, hyperlipoproteinaemia, vasculitis, female sex, prothrombotic states and accidental intra-arterial injection of drugs	Risks reduced by smaller catheter, larger artery, decreased duration of cannulation, avoiding traumatic insertion and multiple attempts. Allen's test (including modifications such as Doppler, plethysmography and digital blood pressure) is probably unhelpful	Remove cannula. Arterial thrombosis is usually self-limiting. Severe ischaemic damage estimated at <0.01%. Anticoagulation and/or vascular surgery/intervention may be necessary
Distal embolisation	Diligent catheter care and observation	As for thrombosis
Proximal embolisation of clot or air (can result in stroke)	Diligent catheter care and observation. Exclude air from pressurised system. Avoid axillary, subclavian or carotid access	Tailored to sequelae
Vascular spasm	Smaller catheter, larger artery, avoid traumatic insertion and multiple attempts	Remove cannula. Resite if necessary
Skin necrosis at catheter site	Diligent catheter care and observation	Surgical debridement and skin grafting may be necessary
Line disconnection and bleeding/exsanguination	Minimise connections. Diligent catheter care and observation	Control bleeding. Transfusion may be necessary
Accidental drug injection	Clearly label arterial line near ports	Leave cannula in situ to facilitate treatment if required. Depends on drug injected. May require papaverine or procaine, analgesia, sympathetic block of limb and anticoagulation
Infection – local or systemic	Diligent catheter care and observation	Remove cannula and send tip for culture. Resite if necessary. Immobilise and elevate affected upper limb. Start empiric antibiotics if sepsis or septic shock is present
Damage to nearby structures such as nerves, directly or due to haematoma (e.g. compartment syndrome or carpal tunnel syndrome). Arteriovenous fistula. Femoral approach can be associated with bowel damage	Careful insertion technique. Seek assistance from experienced operator	Haematomas can develop into pseudoaneurysms requiring surgery

beats/min (3 Hz), to prevent distortion of the biological signal by sine wave system oscillations. *Damping* refers to any property of an oscillatory system that reduces the amplitude of oscillations. Factors that increase oscillation in the system, such as increased tubing length, diameter or compliance, cause underdamping. Overdamping tends to smooth the waveform, causing underestimation of SBP and overestimation of DBP, while MAP tends to be preserved. Contributing factors include clots, air bubbles and loose connections.

Damping can be assessed clinically by the fast flush or square wave test. This test is performed by opening the valve, thus transmitting the pressure from the pressure bag, of the continuous flush apparatus. This is then released/closed abruptly, inducing oscillation. With appropriate damping, the measured pressure should come to reflect the biological signal within one or two oscillations.

Upstream resistance or turbulence can result in a flow-dependent pressure reduction at the cannula site that differs from damping in that the mean, systolic and diastolic pressures are all reduced. This is described as *attenuation* and is often observed in 'positional' arterial lines.

CENTRAL VENOUS CATHETERISATION

Central venous catheterisation (CVC) enables monitoring of central venous pressure (CVP) and administration of certain drugs or parenteral nutrition. In addition, it may be used as a component of transpulmonary indicator dilution systems for CO monitoring. Modified catheters are also available, which continuously monitor central venous oxygen saturation (Scv_{O2}).

Contraindications to CVC are relative and reflect potential complications of the procedure (Table 16.2).[10,11] The subclavian site is preferred to internal jugular or femoral approaches with regard to minimising the

Table 16.2 Complications of central venous catheterisation, with preventative and treatment options

COMPLICATIONS ON INSERTION		
COMPLICATION	PREVENTION	MANAGEMENT
Failure of insertion	Appropriate training, use of ultrasonography, understanding of anatomy and landmarks, appropriate site selection. Other advanced techniques may need to be employed (e.g. fluoroscopic insertion)	Appropriate training and supervision of junior staff
Damage to other structures in the region of insertion. Structures are dependent on location of insertion such as: Arteries (carotid, innominate, aorta, femoral, subclavian) Nerves (femoral, laryngeal, phrenic) Aerodigestive structures (pneumothorax, trachea, oesophagus, bowel) Other vital structures (hernial contents, thoracic duct)	Appropriate site selection, consideration of individual variation (such as prior lines, surgery, anatomical deformity). Appropriate training and understanding of insertion techniques, anatomy in the region of interest and supervision when required. Application of ultrasound	Management will depend specifically on the structure injured. Minor vascular injuries may require only local compression, however large injuries (e.g. after dilatation with a dialysis catheter) may require surgical repair. Consultation with the appropriate specialties
Damage to target vessel, including haematoma, fistula, laceration, bleeding (including massive haemorrhage)	Appropriate technique, including site selection and awareness of depth of insertion of needle. Care with stiffer catheters or equipment to avoid excessive force. Live ultrasound scanning, ensuring that the needle tip is not lost from view, may be considered	Dependent on the degree of injury. May require consultation with the appropriate specialties
Air embolism	Flushing of catheters with sterile saline prior to procedure, positioning of patient (including Trendelenberg for upper body access), cover potential sites of air ingress, monitor connections for seal. May also be a complication on removal of line	Position the patient to left lateral, 100% oxygen and initiate appropriate resuscitative manoeuvres, including CPR as necessary. Consideration may be given to attempting to aspirate air
Drug error and allergy	Confirm allergies prior to commencing procedure. Develop and implement systems to identify drug containing syringes from those with saline flush	Manage reaction as appropriate. This may include CPR or specific protocols (including local anaesthetic toxicity)
Dysrhythmia from cardiac irritation	Care with depth of insertion of wire at jugular and subclavian sites. Continuous cardiac monitoring	Removal or withdrawal of wire or catheter
Wire fracture, damage or loss	Care with insertion, avoiding resistance. Maintain control of wire at all times. Confirmation of complete wire removal at completion of procedure	May require removal via surgical or radiological intervention

Continued

Table 16.2 Complications of central venous catheterisation, with preventative and treatment options—cont'd

COMPLICATIONS ON INSERTION		
COMPLICATION	PREVENTION	MANAGEMENT
Malposition	Appropriate catheter length, depth of insertion and site selection. Patient positioning or other techniques (e.g. jugular vein compression for PICC lines) may assist with placement. Ultrasound guidance may be helpful. Confirmation during insertion, such as ultrasound scanning other related vessels (internal jugular when placing subclavian line), echocardiography or line pressure transduction. Blood gas analysis can discern arterial from venous placement. Radiological confirmation post insertion	Not using line until placement is confirmed reduces risks of complications. Readjust line, or remove and replace
LONGER TERM COMPLICATIONS		
COMPLICATION	PREVENTION	MANAGEMENT
Infection, including insertion site, remote sites such as valvular endocarditis, or sepsis	Proper insertion maintaining sterility. Use of antimicrobial/antiseptic patches, or impregnated lines. Minimising number of lumens. Surveillance of lines with removal if infection is suspected. Removal of lines that are blocked. Aseptic technique in accessing lines or ports	Removal of lines, antimicrobial therapy if appropriate
Thrombosis	Site selection (subclavian lower risk). Selection of catheters with smaller diameters. Correct placement lower SVC/high right atrium. Removal of catheter when not required. DVT prophylaxis as part of routine ICU care	Removal of line. Anticoagulation may be required. Surgical intervention or placement of caval filter may be considered
Erosion through vital structures (vena cava, atria)	Less common with modern catheters. Proper placement of line with confirmation. Removal of line when not required	Likely to require early surgical intervention
Vascular stenosis	Appropriate size catheter – smaller devices reduce vascular injury on insertion and while in place. Select appropriate location (avoid dialysis catheters in subclavian vein)	May require surgical or endovascular intervention
Line breakage, or disruption of connections with bleeding or air embolism	Minimising excess length of line outside of patient, care with line securement and avoiding kinks. Care with manipulation of lines, avoiding pulling or stress. Maintain connections	Removal and replacement of line (if required) depending on degree of disruption. Surveillance for evidence of line related infection in the case of disruption with exposure to non-sterile surroundings

Table developed from consultation of the following guidelines:

Australian and New Zealand Intensive Care Society [Internet]. Melbourne; 2012. ANZICS Safety and Quality Committee. Available from www.clabsi.com.au and www.anzics.com.au

risk of central-line-associated bloodstream infections (CLABSI).[6,11] However, routine replacement of central lines does not appear to reduce CLABSI.

Multiple societies now recommend ultrasound-guided central venous access.[12,13] Two-dimensional (2D) imaging with ultrasound can be used to localise the vein and define anatomy prior to placement of a CVC by landmark techniques. Ultrasound can also provide real-time, 2D guidance during CVC insertion, which is generally preferred.

For catheters inserted via veins draining to the superior vena cava, the right tracheobronchial angle and carina are common radiological markers of insertion depth. Ensuring that the catheter is parallel to the long axis of the vein reduces the risk of venous erosion.[14]

Many patients with chronic illness, such as malignancy, require long-term CVC (including peripherally inserted central catheters [PICC]). Complications, such as central line-associated bloodstream infection and thrombosis (concomitant risk of catheter infection, pulmonary embolus and post-thrombotic syndrome), may require ICU admission and management. The management of such complications is described in Table 16.2. In the setting of thrombosis, immediate removal is not necessarily advised.[15]

CENTRAL VENOUS PRESSURE

Jugular venous pressure, CVP and right atrial pressure are often used interchangeably. However, in situations associated with increased central venous resistance, such as central vein sclerosis and stenosis, these pressures may not be the same.

CVP is usually monitored using a fluid-filled pressure transduction system similar to that used to measure invasive arterial pressures. Waveform analysis is also possible (Table 16.3). The normal CVP in the spontaneously breathing supine patient is 0–5 mm Hg (0–0.65 kPa), while 10 mm Hg (1.3 kPa) is generally accepted as the upper limit during mechanical ventilation. In health there is a good correlation between CVP and pulmonary artery occlusion pressures (PAOPs), but this is lost in many types of critical illness involving cardiac function or pulmonary circulation. The relationship between CVP and right ventricular end-diastolic volume (RVEDV; preload) is altered in critical illness by changes in right ventricular diastolic compliance and juxta-cardiac pressures.[16]

Except at extreme values, static measures of CVP do not differentiate patients likely to respond to fluid therapy from non-responders (see Functional Haemodynamic Monitoring section). Traditionally, dynamic changes in CVP, either in response to volume loading or related to respiration, have been used to assist in evaluating volume status,[17] but these principles may be misapplied.

A steep increase in CVP following volume challenge may suggest that the heart is functioning on the plateau portion of the Frank-Starling curve. Severe hypotension with a low or normal CVP is unlikely to be solely due to acute pulmonary embolism, cardiac tamponade or tension pneumothorax.

CENTRAL VENOUS OXYGEN SATURATION

Central venous oxygen saturation (Scv_{O2}) is an additional variable that may be monitored with a central venous catheter (continuously or via blood gas analysis of samples). It has been proposed as a marker of tissue oxygen delivery (Chapter 18). Scv_{O2} rose to prominence as part of Early Goal Directed Therapy (EGDT) protocols for sepsis management but large international multicentre trials, including ARISE (Australasia), ProCESS (USA) and ProMISE (UK) and a consequent meta-analysis concluded that Scv_{O2}, as part of EGDT, is unnecessary.[18]

PULMONARY ARTERY CATHETER

Right-sided heart catheterisation using a flow-directed balloon-tipped catheter was introduced by Swan and colleagues in 1970.[19a] The ability to monitor sophisticated haemodynamic and gas exchange variables at the bedside appealed to clinicians, and the pulmonary artery catheter (PAC) was rapidly accepted into routine critical care. However, this device is potentially associated with a number of risks (Table 16.4).[19b]

Table 16.3 Analysis of central venous pressure waveform

CONDITION	PRESSURE CHANGES	WAVEFORM CHANGES
Tricuspid regurgitation	Increased RA pressure	Prominent *v* wave, *x* descent obliterated, *y* descent steep
RV infarction	RA and RV pressure elevated. RAP does not fall and may rise in inspiration	Prominent *x* and *y* descents
Constrictive pericarditis	RA, RV diastolic, PA diastolic and occlusion pressures elevated and equalised. RAP may rise in inspiration	Prominent *x* and *y* descents
Pericardial tamponade	RA, RV diastolic, PA diastolic and occlusion pressures elevated and equalised. RAP usually falls in inspiration	Y descent damped or absent

PA, Pulmonary artery; *RA,* right atrial; *RAP,* right atrial pressure; *RV,* right ventricular.

Table 16.4 Complications potentially encountered with pulmonary artery catheterisation with proposed measures for prevention and treatment

COMPLICATIONS	PREVENTION	TREATMENT
DURING INSERTION		
Damage to adjacent structures	As for central venous cannulation	As for central venous cannulation
Perforation of pulmonary artery	Ensure balloon inflated throughout insertion. Continuously monitor pulmonary artery waveform. Avoid distal PAC tip position	As for pulmonary artery rupture below
Air embolism	Raise venous pressure prior to insertion. Always occlude open ends during insertion. Use sheaths with pneumatic valve. Periodically check and tighten all connections. Remove air from fluid bag and tubing. Dress site with occlusive dressing after removal	Left lateral Trendelenburg position. Administer 100% oxygen and ventilatory support. If PAC in place tighten all connections and attempt to aspirate air from right atrium or right ventricle. Basic/advanced life support if necessary
Dysrhythmia (12.5%–70%)	Keep balloon inflated during passage from RA to PA. Minimise insertion time	For sustained ventricular tachycardia, remove PAC from right ventricle. For ventricular fibrillation, remove PAC. Advanced life support for persistent dysrhythmia
Right bundle branch block/complete heart block	Avoid PAC insertion in patients with LBBB if possible. Insert PAC with pacing electrodes in patients with LBBB	Use pacing equipment as required
Catheter knotting/ kinking/ entanglement	Minimise insertion time. Do not advance catheter against resistance. Check for waveform change from RA to RV or RV to PA after advancing 15 cm; if not withdraw catheter. Limit intravascular PAC insertion depth <60 cm. Use of fluoroscopy	Check chest X-ray. Pull knot back then remove the sheath and catheter. If no sheath used, a cut-down to vein under local anaesthesia may be required. Exploration by a vascular surgeon is indicated if unsuccessful (5% of occasions)
Valve/chordae damage (~0.9%)	Ensure balloon is inflated during forward passage through the heart and deflated prior to any retraction	Cardiothoracic consultation
DURING MAINTENANCE		
Dysrhythmia (37%)	Remove PAC when no longer required	See above
Thrombosis	As for central venous cannulation	As for central venous cannulation
Pulmonary artery rupture (0.2%)	Risk factors include pulmonary hypertension, anticoagulation and in situ duration >3 days. Maintain high level of suspicion. Avoid distal PAC tip position. Minimise wedge procedures. Continuously monitor pulmonary artery waveform – withdraw PAC if spontaneous wedging occurs, inflate with only enough air to change PA to PAOP waveform. Withdraw PAC if PAOP obtained with <1.25 mL air	Check PAC position on CXR, deflate and pull back. If applicable, stop anticoagulation therapy. Lateral position, affected side down. Selective bronchial intubation. PEEP. Surgical repair
Pulmonary infarction	As for pulmonary artery rupture	Check PAC position on CXR, deflate and pull back. Observe
Infection – including blood stream infection/ bacteraemia (1.3%–2.3%) and endocarditis (2.2%–7.1%)	As for central venous cannulation	As for central venous cannulation

Table 16.4 Complications potentially encountered with pulmonary artery catheterisation with proposed measures for prevention and treatment—cont'd

COMPLICATIONS	PREVENTION	TREATMENT
Air embolism	High suspicion of balloon rupture. Avoid repeating failed attempts to inflate	See above
Misinterpretation/ misuse of data	Anticipation and management of common pitfalls related to errors of equipment and data acquisition. Factors affecting data interpretation	Patient selection, individualisation of therapy, an understanding of potentially useful haemodynamic data, as well as an appreciation of alternative monitoring strategies are suggested

CXR, Chest X-Ray; *LBBB,* left bundle branch block; *PA,* pulmonary artery; *PAC,* pulmonary artery catheter; *PAOP,* pulmonary artery occlusion pressures; *PEEP,* positive end expiratory pressure; *RA,* right atrial; *RAP,* right atrial pressure; *RV,* right ventricular.

In 1996, a non-randomised cohort study of PAC use in American teaching hospitals appeared to show that PAC in the first 24 hours increased 30-day mortality (odds ratio, 1.24; 95% confidence interval [CI], 1.03–1.49), mean length of stay and mean cost per hospital stay.[20] An associated editorial called for a moratorium on PAC use, and for a prospective multicentre trial.[21] Although a moratorium did not eventuate, the debate contributed to clinical equipoise and paved the way for a number of randomised trials.

A recently edited Cochrane database systematic review of PAC monitoring in adult ICU patients incorporated data from 13 randomised controlled trials in adults.[22] The pooled odds ratio for mortality for the eight studies of high-risk surgery patients was 0.98 (95% CI, 0.74–1.29) and for the five studies of general intensive care patients was 1.02 (95% CI, 0.96–1.09). The authors conclude that PAC monitoring in critically ill patients is not associated with increased mortality, nor ICU or hospital length of stay.

The routine use of PAC is increasingly scrutinised. The possibility that application in specific cases might alter or guide therapy towards improved outcome remains valid. This should be balanced against the prospect of potentially serious complications and the availability of less invasive techniques that may deliver similar information.[23] Overall, the PAC still finds application in anaesthesia and critical care. It potentially offers unique insights into the right heart and pulmonary circulation.

Traditional indications for PAC monitoring have been to:

- clarify the cause of haemodynamic perturbation
- differentiate cardiogenic from non-cardiogenic pulmonary oedema
- guide use of vasoactive drugs and fluid management (including renal replacement therapy), especially when haemodynamic disturbances are coupled with increased lung water, right ventricular (RV) or left ventricular (LV) dysfunction, pulmonary hypertension and organ dysfunction.

Table 16.5 Reference range of measured and derived variables from pulmonary artery catheter

SITE	mm Hg	(kPa)
Right atrium mean	–1–7	(0.13–0.93)
Right ventricle: systolic	15–25	(2.0–3.3)
Right ventricle: diastolic	0–8	(0–1.1)
Pulmonary artery: systolic	15–25	(2.0–3.3)
Pulmonary artery: diastolic	8–15	(1.1–2.0)
Pulmonary artery: mean	10–20	(1.3–2.6)
Pulmonary artery occlusion pressure	6–15	(0.8–2.0)

Contraindications for insertion build upon those for CVC. If known in advance, atypical vascular or cardiac anatomy or electrophysiology should also be considered.

MEASURED VARIABLES

The PAC remains unique in its ability to measure right ventricular and pulmonary arterial pressures directly at the bedside. While echocardiography is a less invasive alternative, it is typically confined to intermittent 'snap-shot' evaluation, and can be technically challenging.[24] Normal pressures are given in Table 16.5.

Pulmonary artery occlusion pressure

PAOP is measured by the slow injection of air into the balloon while watching the pulmonary artery waveform. Over-wedging can lead to falsely high occlusion pressures or pulmonary arterial rupture. Less than 1.5 mL air (balloon volume) may be required.

Table 16.6 Derived haemodynamic variables

PARAMETER	ABBREVIATION	FORMULA	NORMAL RANGE	UNITS
Mean arterial pressure	MAP	DBP + 0.33 × (SBP – DBP)*	70–105	mm Hg
Mean pulmonary artery pressure	MPAP	PADP + 0.33 × (PASP – PADP)*	9–16	mm Hg
Mean right ventricular pressure	MRVP	CVP + 0.33 × (PASP – CVP)		mm Hg
LV coronary perfusion pressure	LVCCP	DBP – PAOP		mm Hg
RV coronary perfusion pressure	RVCCP	MAP – MRVP		mm Hg
Cardiac index	CI	CO/BSA	2.8–4.2	L/min/m^2
Stroke volume index	SVI	CI/HR	35–70	mL/beat/m^2
Systemic vascular resistance index	SVRI	(MAP – CVP)/CI × 79.92	1760–2600	dyn s/cm^5/m^2
Pulmonary vascular resistance index	PVRI	(PAP – PAOP)/CI × 79.92	44–225	dyn s/cm^5/m^2
Left ventricular stroke work index	LVSWI	SVI × MAP × 0.0144	44–68	g m^2/beat
Right ventricular stroke work index	RVSWI	SVI × PAP × 0.0144	4–8	g m^2/beat
Body surface area	BSA	Weight $(kg)^{0.425}$ × height $(cm)^{0.725}$ × 0.007184		m^2

*Modern monitors use a more accurate technique; they average the area under the pressure–time curve to estimate mean pressure.
CVP, Central venous pressure; *DBP,* diastolic blood pressure; *HR,* heart rate; *LV,* left ventricular; *PADP,* pulmonary artery diastolic pressure; *PAOP,* pulmonary artery occlusion pressure; *PASP,* pulmonary artery systolic pressure; *RV,* right ventricular; *SBP,* systolic blood pressure.

Deflation after PAOP measurement should re-establish the normal pulmonary arterial waveform. If not, distal migration has occurred and the catheter should be withdrawn until the waveform is re-established.

PAOP should be measured during end expiration and ideally in end diastole, using the ECG p-wave as a marker. When the catheter is wedged, it creates a static column of blood that equilibrates with downstream pressure at a site very near the left atrium. PAOP therefore closely approximates left atrial pressure (LAP), which approximates left ventricular end-diastolic pressure (LVEDP). The validity of PAOP as a surrogate of preload depends on a number of assumptions that are often incorrect in critically ill patients. The use of PAOP to reflect preload has been questioned.

Potential substitutes for pulmonary artery occlusion pressure

Measurement of PAOP requires wedging, which is associated with a number of risks. The normal pulmonary artery diastolic pressure (PADP) to PAOP gradient is less than 5 mm Hg (0.65 kPa), so that PADP may substitute as a close approximation for PAOP. However, tachycardia (>120/min) and conditions that increase pulmonary vascular resistance variably alter this gradient, invalidating direct substitution of PADP for PAOP. The relationship between PADP and PAOP tends to be stable over hours, allowing PADP to be monitored in the short term without repeated wedge manoeuvres.

B-type natriuretic peptide (BNP) is secreted by the heart in response to myocardial stretch or strain. It is potentially useful as a biomarker of heart failure. Its application to intensive care medicine has been hindered by a multitude of potential confounders.[25] BNP has not demonstrated value in the prediction of fluid responsiveness or in screening for left ventricular diastolic dysfunction.[26,27]

Echocardiographic measurements, such as transmitral flow, mitral annulus velocity (tissue Doppler) and pulmonary venous flow, can provide evidence of elevated left ventricular filling pressure (the hallmark of diastolic dysfunction).[28]

DERIVED VARIABLES

A number of variables can be derived from the measurements obtained with a standard PAC (see Table 16.5 and Table 16.6).

MIXED VENOUS OXYGEN TENSION AND SATURATION

These variables are discussed in Chapter 18.

CARDIAC OUTPUT MONITORING

Clinical estimation of CO is unreliable until extreme hypotension occurs.[29] A multitude of commercially available devices are approved for CO estimation in critical care. Most devices employ proprietary algorithms. Marketing strategies, patented/trademarked terminology and inconsistencies in nomenclature potentially contribute to confusion. A classification of techniques is presented in Table 16.7.

Table 16.7 Classification of methods for evaluating cardiac output in critical care: a variety of techniques primarily estimate stroke volume, multiplication by heart rate calculates cardiac output

CARDIAC OUTPUT	STROKE VOLUME
Fick method (O_2)	Ultrasound • 2D echocardiography (Simpson's method) • Doppler (continuous or pulsed wave)

Indirect Fick method (CO_2)
• Partial rebreathing technique
	Arterial pressure waveform analysis
	• Invasive
	• Non-invasive
	  • volume-clamp method
	  • tonometry

Indicator dilution • Thermodilution • Lithium • Indocyanine green • Ultrasound indicator dilution (saline) • Ultrasound contrast	Thoracic electrical bioimpedance

APPLICATION OF THE FICK PRINCIPLE

The Fick principle is an extension of the law of conservation of mass and states that the amount of a substance taken up by an organ (or the whole body) per unit time is the product of the arteriovenous concentration difference by the blood flow to the organ (or body).

A number of techniques used to measure CO are based upon the Fick principle. The substance measured can include oxygen (Fick method), carbon dioxide (indirect Fick method) or apply an indicator dilution method.

THE FICK METHOD

Historically the Fick principle has been applied to determine CO by analysing oxygen uptake from the lungs (direct Fick method). This method requires pulmonary artery catheterisation to sample mixed venous blood. It has been considered the 'gold standard', but in most ICU patients the stringent preconditions for accuracy are not met. Further error is introduced by the elevated oxygen consumption of inflamed lungs. Use is therefore mainly confined to cardiac laboratories.

THE INDIRECT FICK METHOD

The indirect Fick method employs carbon dioxide (CO_2) as an alternative to oxygen. The use of a partial rebreathing technique, incorporating several assumptions, can be used to eliminate the need to directly measure Cv_{CO2} with a PAC.[30] The rebreathing values are obtained by introducing an additional 150 mL of dead space into the ventilator circuit (disposable rebreathing loop) and taking measurements once a new equilibrium has been established. CO can be measured at 3-minute intervals. Assuming that the Cv_{CO2} concentration does not change significantly throughout the rebreathing period, the terms associated with Cv_{CO2} cancel each other out and are not needed to calculate CO.

Potential issues with the partial rebreathing of CO_2 method include the following:

- It is unsuitable for non-intubated patients (who have variable tidal volumes and leakage around face masks).
- Changes in mechanical ventilator settings that alter dead space or ventilation/perfusion relationships may result in an artefactual change in CO measurements. The accuracy of the technique also appears to be challenged by spontaneous mechanically assisted ventilation.
- $ETCO_2$ may not accurately reflect change in pulmonary end-capillary and $PaCO_2$, especially in chronic lung disease.
- Mathematical models rely upon a series of assumptions that may not be true under certain conditions relevant to critical care.
- There is overall lack of validation in chronic lung disease.

BOLUS THERMODILUTION CARDIAC OUTPUT

This technique utilises a PAC and is generally accepted as the clinical gold standard due to applicability at the bedside, clinician familiarity and reasonable accuracy.

A bolus injection into the right atrium of cold injectate transiently decreases blood temperature in the pulmonary artery (monitored by a thermistor proximal to the balloon). The mean decrease in temperature (calculated by integrating temperature over time) is inversely proportional to the CO, which can be determined by a modification of the Stewart–Hamilton equation:

$$Q = \frac{V \times (Tb - Ti) K1 \times K2}{Tb(t)\,dt} \quad (16.1)$$

where Q = cardiac output; V = volume injected; Tb = blood temperature; Ti = injectate temperature; $K1$ and $K2$ = corrections for specific heat and density of injectate and for blood and dead space volumes; $Tb(t)dt$ = change in blood temperature as a function of time.

This is an indicator dilution method, using lower thermal energy content as the indicator. Advantages of using thermal energy as an indicator are that it is non-toxic (temperature of injectate used does not cause thermal injury) and it does not recirculate. Repeat measurements are limited only by volume constraints and the time to regain temperature stability between

Box 16.1 Causes of inaccurate bolus thermodilution cardiac output measurements

- Catheter malposition
  - Wedge position
  - Thermistor impinging on vessel wall
- Abnormal respiratory pattern
- Intracardiac shunts
- Tricuspid regurgitation (common in mechanically ventilated patients)
- Cardiac dysrhythmias
- Incorrect recording of injectate temperature (minimised by siting an additional thermistor on the injection port)
- Rapid intravenous infusions, especially if administered via the introducer sheath
- Injectate port close to or within introducer sheath
- Abnormal haematocrit values (affecting *K*2 value)
- Extremes of cardiac output (room temperature injectate)
- Poor technique
  - Slow injection (>4 seconds)
  - Incorrect injectate volume

injections. A clinically significant change in CO cannot be diagnosed with certainty unless there is a difference of approximately 15% between the mean of three CO determinations and the previous mean.[31]

Too much or too little injectate will respectively underestimate and overestimate CO. Cold injectate (preferably 0–4°C but up to 12°C is usually accepted) improves the signal to noise ratio, but may cause a transient decrease in heart rate, reducing CO while it is being measured. Room temperature injectate introduces a small decrement in bias and precision, but has acceptable accuracy. However, the accuracy using room temperature injectate is further degraded at extremes of cardiac index, high ambient temperatures (and thus injectate temperature) or in patient hypothermia.[32]

Respiration causes fluctuations in CO and pulmonary artery temperature. Reproducibility is improved by taking measurements in expiration, though this may not reflect CO throughout the respiratory cycle. Timing can be difficult and in practice an average of three evenly spaced measurements is taken. The causes of inaccurate measurements are listed in Box 16.1.

SEMI-CONTINUOUS THERMODILUTION CARDIAC OUTPUT

This method uses the same principles as bolus thermodilution, but allows semi-continuous measurement by employing a thermal filament wrapped around the right ventricular segment of the catheter.[33] This transmits low-power pulses of heat. 'On–off' heat pulses in pseudo-random binary code are delivered in cycles. The downstream thermistor detects the heat pulses, which are then cross-correlated with the input sequence and power (to allow differentiation of thermal signal from noise).

Potential drawbacks of the technique include:

- inaccuracy during thermal disequilibrium, such as rapid infusions of cool fluids or after cardiac bypass
- delay in detecting sudden changes in CO
- magnetic resonance imaging is contraindicated (it can melt the thermal filament)
- electro-cautery can interfere with measurements.

Additional volumetric data

As well as allowing semicontinuous assessment of CO, incorporation of a rapid response thermistor into the PAC allows estimation of right ventricular ejection fraction (RVEF) and RVEDV. Thermodilution techniques appear to overestimate RVEDV and underestimate RVEF.[34] However, right ventricular geometry is complex and there are limited options for bedside volumetric evaluation.[24]

TRANSPULMONARY INDICATOR DILUTION

With this technique, thermal and other indicators injected into a central vein are detected in a systemic artery. Because the indicators pass through all chambers of the heart, as well as the entire pulmonary circulation, central blood volumes, and indices of extravascular lung water (EVLW) can be quantified (Fig. 16.1).

Transpulmonary thermodilution

A thermistor is usually positioned in the femoral artery at the tip of a modified arterial catheter.[35] CO is measured by administering a central venous bolus of cold injectate, constructing an arterial thermodilution curve and applying the Stewart–Hamilton equation. The axillary artery can also be used, but placing the sensor in more peripheral arteries causes overestimation of CO. Curves are longer and flatter than PAC curves due to thermal equilibration with intrathoracic blood and EVLW, but are unaffected by the respiratory phase of injection. Measurements are in good agreement with pulmonary thermodilution and direct Fick methods. There is a positive bias of about 5%, perhaps because of indicator loss or because transpulmonary measurements are less affected by the transient decrease in heart rate induced by cold thermodilution.

Mathematical models based on single- or double-indicator techniques allow the estimation of intrathoracic blood volume (ITBV), global end-diastolic volume (GEDV) and EVLW.[36]

Unlike CVP and PAOP, ITBV is a volumetric preload index. Interpretation is thus independent of alterations in juxta-cardiac pressures or myocardial compliance, and should be superior to conventional pressure indices. There is experimental and clinical evidence that this may be true.[37]

EVLW is a marker of the severity of illness. Following EVLW as a therapeutic end-point may reduce positive fluid balances plus ventilator and ICU days.[38]

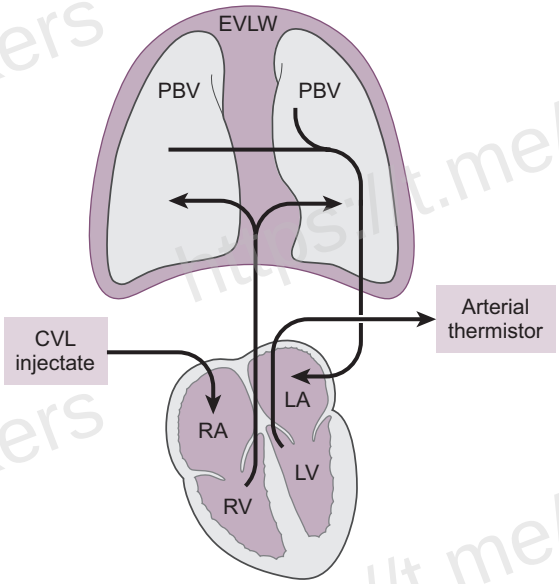

Figure 16.1 Conceptualisation of the transpulmonary mixing chambers of the cardiopulmonary system. Cardiac thermal volumes are proposed to approximate blood volumes at end diastole. *CVL*, Central venous line; *EVLW*, extravascular lung water; *LA*, left atrial thermal volume; *LV*, left ventricular thermal volume; *PBV*, pulmonary blood volume; *RA*, right atrial thermal volume; *RV*, right ventricular thermal volume. Intrathoracic thermal volume (ITTV) is the estimated total thermal volume between the points of central venous injection and peripheral arterial detection, including the EVLW. Pulmonary thermal volume (PTV) is the sum of PBV + EVLW. Intrathoracic blood volume (ITBV) is the sum of RA + RV + PBV + LA + LV, taken to be at end diastole. EVLW = ITTV – ITBV. Global end-diastolic volume (GEDV) is the sum of RAEDV + RVEDV + LAEDV + LVEDV. (With permission from PULSION Medical Systems SE, www.PULSION.com.)

EVLW also appears to offer prognostic information in sepsis and acute lung injury.

GEDV is said to represent the volume of blood in all chambers of the heart at end diastole. Like ITBV, GEDV has been shown to be a more reliable measure of cardiac preload than conventional pressure-based surrogates.[39]

LITHIUM DILUTION CARDIAC OUTPUT

Lithium can also serve as a transpulmonary indicator. The small doses of lithium required are non-toxic and easily measured with an ion-selective electrode attached to a three-way tap. A peristaltic pump limits sampling to 4 mL/min. Following injection, there is no significant first-pass loss from the circulation. After passing through the sensor, blood is discarded.

The main advantage over thermodilution is that more peripheral arteries can be used without loss of accuracy. Injection can be performed peripherally if central venous access is unavailable. The technique shows good agreement with bolus thermodilution (PAC). It is able to safely and accurately measure CO in adult and paediatric populations.

Potential limitations include the following:

- It cannot be used in patients receiving lithium therapy (background lithium concentration contributes to overestimation of CO).
- Electrode drift can occur in the presence of high-peak doses of muscle relaxants.
- Abnormal shunts can result in erroneous CO measurements (true for all indicator dilution methods).
- Ex vivo analysis requires disposal of the sampled blood.
- There is no reporting of volumetric haemodynamic variables, such as EVLW.[1]

TRANSPULMONARY DYE DILUTION

Transpulmonary indicator dilution can also be performed using injectable dye, usually indocyanine green. Dye dilution (arterial blood analysis) and pulse dye densitometry (transcutaneous fluorescent analysis) have been applied to CO measurement. Concerns exist regarding the accuracy of the transcutaneous method.[40]

ULTRASOUND INDICATOR DILUTION

Whereas transpulmonary thermodilution relies upon changes in temperature induced by injecting saline (other than body temperature), ultrasound indicator dilution relies upon resultant changes in the velocity of sound transmission. Body temperature isotonic saline is injected into a low-volume arteriovenous loop between existing arterial and central venous catheters. The measured change in ultrasound velocity (blood, 1560–1585; saline, 1533 m/s) allows the formulation of an indicator dilution curve with the calculation of CO.[41]

Another recent advance is the application of contrast-enhanced ultrasound.[42] This entails injection of an ultrasound contrast bolus while monitoring the atria using transoesophageal echocardiography. Acoustic intensity evolution over time is assessed and used to calculate indicator dilution curves. Bias exists compared to thermodilution techniques, though this method may find greater application in the future.

ARTERIAL PRESSURE WAVEFORM ANALYSIS

Estimation of stroke volume by analysis of the arterial pressure waveform, in particular various properties of the pulse pressure component, has been studied for many years.[1] It is to be recognised that pulse pressure, while proportional to stroke volume, is also dependent on aortic impedance, a value that is subject to significant inter- and intrapatient variability. Devices employ different proprietary algorithms (e.g. pulse contour

analysis)[43] to calculate CO from transduced pressure signals. Generic terminology, such as arterial pressure waveform analysis, is more broadly applicable.

A number of devices require calibration against another method, after which stroke volume can be trended continuously. Accuracy in the presence of arrhythmia has not been established.

Transpulmonary indicator dilution is the usual method of calibration. Devices that use thermodilution or lithium ion calibration are commercially available.[1]

Disadvantages of such techniques can include the following:

- Frequent recalibration is advisable to allow for changes in systemic vascular resistance. This is especially important if there is haemodynamic instability or during the administration of vasoactive drugs.
- Alterations in abdominal pressure or changes in body position, particularly in the obese, can alter aortic compliance, necessitating recalibration.
- Dependence on arterial site – clinical validation studies usually document femoral cannulation.
- Aortic aneurysms and significant aortic regurgitation are both difficult to model, and they invalidate the technique.

Proprietary algorithms for estimating stroke volume and CO from pressure-based signals without the need for calibration have been incorporated into a number of devices. The principal advantages of these techniques are ease of use and non-invasiveness. However, these devices frequently rely on the Windkessel model of the circulation, incorporating assumptions based on age, heart rate, MAP and aortic pressure waveform to estimate aortic impedance, Windkessel compliance and peripheral arterial resistance.[36] Furthermore, accuracy is impaired in the presence of major changes in vascular compliance, cardiac dysrhythmia, aortic regurgitation, or poor-quality arterial waveform transduction (under- or overdamping, attenuation).

ULTRASOUND

Ultrasound is increasingly used in the evaluation of haemodynamically unstable patients and frequently complements other monitoring techniques. Two main approaches are available to measure stroke volume (and thereby CO) using ultrasound–echocardiographic changes in ventricular volume and Doppler measurement.

ECHOCARDIOGRAPHY

Echocardiography may be used to estimate systolic and diastolic left-ventricular volumes from 2D images using Simpson's method (summation of discs). User dependence, potentially inaccurate assumptions about ventricular geometry and the cost of imaging equipment limit the usefulness of this technique for haemodynamic monitoring. Real time 3D evaluation of LV or RV volumes can be provided by state of the art transoesophageal and transthoracic echocardiography.[44] Clinical application is not yet mainstream.

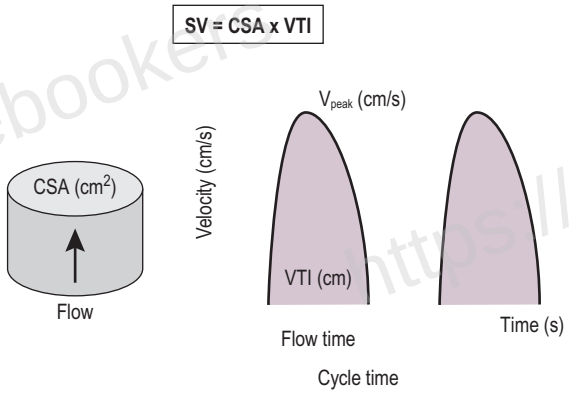

Figure 16.2 Doppler stroke volume calculation. The cross-sectional area of flow (CSA) is calculated as a circle from echocardiographic measurements or nomogram-based estimations. Velocity–time integral (VTI) is the integral of Doppler velocity with regard to time. Stroke volume (SV) is calculated as the product of CSA and VTI (mL/s in this example). Cardiac output is calculated from the product and SV and heart rate. Peak velocity of flow (V_{peak}) is also indicated.

DOPPLER TECHNIQUES

The Doppler principle states that the frequency of reflected sound is altered by a moving target, such as red blood cells.[45] This can be applied to measurement of stroke volume (Fig. 16.2). Continuous and pulsed wave Doppler are the main techniques employed to measure flow. Pulsed wave Doppler allows the site of sampling to be specified by transmitting a pulse of sound energy and then 'listening' for a period of time appropriate to catch the reflected signal. With continuous wave Doppler, a piezoelectric crystal transmits the ultrasound beam continuously, while another measures the frequency of reflected waves. The velocities of all the red blood cells moving along the path of the ultrasound beam are recorded. As a result, a continuous wave Doppler recording consists of a full spectral envelope with the outer border corresponding to the fastest moving blood cells. The flow velocity (V) of red cells can be determined from the Doppler shift in the frequency of reflected waves:

$$V = (2F_0 \times \cos\theta)^{-1} \times C\Delta F \quad (16.2)$$

where C is the speed of ultrasound in tissue (1540 m/s), ΔF is the frequency shift, F_0 is the emitted ultrasound frequency and θ is the angle of incidence. The most accurate results are obtained when the ultrasound beam is parallel to flow (θ = 0°, cosθ = 1;

$\theta = 180°$, $\cos\theta = -1$). However, angles up to 20° still yield acceptable results ($\theta = 20°$, $\cos\theta = 0.94$).

This methodology forms the basis of numerous monitoring devices. Doppler is less dependent on image quality, shows better agreement with thermodilution and demonstrates good reproducibility.

In addition to measuring stroke volume, Doppler assessment of aortic blood flow can provide additional haemodynamic information. For instance, a low duration of aortic velocity signal corrected for heart rate (corrected flow time; FTc) may prompt intravenous fluid challenge.[26,46] The peak velocity of aortic blood flow (V_{peak}) has been proposed as an index of contractility. Another index of contractility is the steepest gradient of the Doppler trace. This reflects the rate of the LV pressure rise in early systole (dP/dt max). Also, respiratory variation in V_{peak} (ΔV_{peak}) has been described as a predictor of increased CO in response to fluid challenge.[47]

Oesophageal Doppler monitoring

Oesophageal Doppler measures blood flow velocity in the descending aorta with a Doppler probe incorporated in the tip of a flexible probe.[1] The probe is positioned in the oesophagus about 30–40 cm from the teeth where the aorta runs parallel to the oesophagus and the systolic cross-sectional area varies least. The probe is rotated to obtain a characteristic aortic signal. The aortic cross-sectional area is either determined from nomograms, or calculated from a measured diameter.

Advantages of the technique include the following:

- Insertion is simple and only a short period of training is required.
- The probes (6 mm in diameter) are minimally invasive, and can be inserted nasally or orally.
- Contraindications are few. They include severe agitation, pharyngo-oesophageal pathology, aortic balloon counterpulsation, aortic dissection and severe aortic coarctation.
- Potential disadvantages include the following:
  - It assumes that the descending aortic flow remains as a fixed proportion of CO, which may not be the case in shock states or with vasoactive drug administration.
  - Flow in the aorta is not always laminar. Turbulent aortic blood flow may alter velocity measurements.
  - Assumptions that the aorta is cylindrical with a fixed systolic cross-section are not always valid. The cross-sectional area of the aorta is actually dynamic and is dependent on the pulse pressure and aortic compliance. If the aortic area is measured, errors through misplacement of the probe are compounded as the area is dependent on the square of the radius.
  - Finding and maintaining optimal probe positioning are important for consistency in trend measurements.
  - The probe may be poorly tolerated in non-sedated patients. Trends towards minimal sedation and shorter duration of endotracheal intubation might decrease the practicality of this technique in many patients.

Transcutaneous Doppler monitoring

Externally applied continuous wave Doppler can be used to monitor haemodynamics via transpulmonary (parasternal) and transaortic (suprasternal) windows. If not known or previously measured, flow diameters may be estimated by a proprietary algorithm based upon the linear association between height and cardiovascular dimensions.[48] Although this method may offer a clinically useful alternative, current data suggest limits of agreement compared to thermodilution are too wide for routine application in the critically ill.[49,50]

THORACIC ELECTRICAL BIOIMPEDANCE AND BIOREACTANCE

An alternating electrical current (high frequency, very low amplitude) is passed through the thorax. Thoracic electrical bioimpedance requires the current to be kept constant while fluctuations in electrical impedance are measured. Six electrodes are usually attached (two in the upper thorax/neck region and four in the lower thorax). These electrodes detect changes in bioimpedance and monitor cardiac electrical signals. The technique is very sensitive to any alteration in position or contact of the electrodes to the patient.

The change in aortic blood flow due to myocardial contraction (stroke volume) is measured from the changes in thoracic bioimpedance through the cardiac cycle. Other factors that contribute to a change in overall thoracic bioimpedance include changes in tissue fluid volume and changes in venous and pulmonary blood volume induced by respiration. Respiratory artefact is eliminated by averaging values over several cardiac cycles using the R–R interval (ECG) as a synchronising signal. Measuring whole body, rather than truncal, impedance by placing electrodes on wrists and ankles also appears successful.

Inaccuracies can arise from numerous sources that are prevalent in critical care. These include motion artefact, electrical interference, dysrhythmias (including frequent premature atrial contractions and atrial fibrillation) and acute change in tissue water content (such as pulmonary oedema, pleural effusions or expansion of interstitial fluid). Despite these limitations, it is clinically appealing due to its non-invasive nature.

Bioreactance has built upon the concepts of bioimpedance but, rather than changes in impedance, it measures changes in the frequency of the electrical currents traversing the chest. This potentially improves signal to noise ratio.[51]

Table 16.8 Variables described as indices of cardiac preload or fluid responsiveness in critically ill patients

STATIC	DYNAMIC
Intracardiac pressures	**Response to fluid challenge**
Central venous pressure (CVP)/right atrial pressure (RAP)	**Passive leg raising**
Pulmonary artery occlusion pressure (PAOP)	Change in aortic blood flow
CARDIOVASCULAR VOLUMES	Change in pulse pressure
Thermodilution right ventricular end-diastolic volume (RVEDV)	**Spontaneous respiratory effort**
Echocardiographic RVEDV	Inspiratory decrease in right atrial pressure (ΔRAP)
Echocardiographic left ventricular end-diastolic area (LVEDA)/volume (LVEDV)	**Mandatory mechanical ventilation**
Transpulmonary thermodilution global end-diastolic volume (GEDV)	Systolic pressure variation (SPV)
Transpulmonary thermodilution intrathoracic blood volume (ITBV)	Decrease in systolic pressure (Δ_{down})
Doppler	Pulse pressure variation (PPV)
Duration of the aortic velocity signal corrected for heart rate (FTc)	Pulse contour analysis stroke volume variation (SVV)
Respiratory variation in peak velocity of aortic blood flow (ΔV_{peak})	Respiratory variation in peak aortic blood velocity (ΔV_{peak})
	Respiratory change in the pre-ejection period (ΔPEP)
	Respiratory systolic variation test (RSVT)

Variables have been divided into static and dynamic categories. Static variables are estimates of ventricular preload at a point in time, usually end-expiration. Dynamic variables are characterised by the measurement of variation in haemodynamic measurements in response to changes in cardiac loading conditions.

FUNCTIONAL HAEMODYNAMIC MONITORING

Functional haemodynamic monitoring builds upon the observation that 'dynamic' haemodynamic variables are better predictors of response to fluid challenge than 'static' variables (Table 16.8).[52] Accurate prediction of fluid responsiveness allows rational fluid resuscitation while avoiding the consequences of excess fluid challenge; these consequences may include excess tissue and pulmonary oedema with deleterious impact upon respiratory function, wound healing and abdominal compartment syndrome.[53]

The potential value of fluid responsiveness hinges upon the ability to determine whether a patient's left ventricle is operating on the plateau (preload independent) portion of the Frank–Starling curve at the time of considering fluid challenge. Thus fluid challenge could be avoided, as it will be ineffective and potentially deleterious. Inotropic and/or vasopressor support should be considered in preference. It is crucial to appreciate that under normal conditions the left ventricle demonstrates recruitable stroke volume (ascending or 'preload dependent' portion of the Frank–Starling curve). Thus prediction of a fluid responsive state may be physiological and does not necessarily mandate fluid challenge.

It must also be appreciated that the majority of 'dynamic' variables posed as predictors of fluid responsiveness have been studied in small samples of highly selected patients under restrictive preconditions (including mandatory mechanical ventilation). In particular, techniques such as pulse pressure variation, have been validated only under a number of caveats including the absence of spontaneous respiratory effort, moderate tidal volumes and normal myocardial contractility. Assessing the response to fluid challenge or passive leg raising is more generalisable and is more commonly recommended.[54]

MONITORING THE MICROCIRCULATION

There is growing appreciation that perfusion of the microcirculation is adversely affected by many disease states directly relevant to critical care. These alterations can be related to poor outcomes. Evaluation of microvascular function at the bedside of critically ill patients remains challenging. Furthermore, many microvascular pathologies may be localised or heterogeneous, in which case the microcirculation being monitored might not offer generalisable data. Many monitoring techniques have been described, but these are currently recommended for research only.[2]

A number of techniques for evaluation of perfusion (rather than tissue oxygenation, which is discussed elsewhere) are briefly mentioned here. Clinically, mottled skin, acrocyanosis, delayed capillary refill and increased central to peripheral temperature gradients might disclose an impaired microcirculation. Biomarkers, such as plasma hyaluronan (experimental), might also indicate impairment. Laser Doppler flowmetry can be applied to a range of tissues. Microvideoscopic

techniques (nailfold videocapillaroscopy, orthogonal polarisation spectral [OPS] and sidestream darkfield [SDF] imaging techniques) can be applied to superficial capillary beds. Except at high levels, blood flow is the major determinant of venous to arterial CO_2 gradient (CO_2 gap). Alternatively, tissue CO_2 can be measured by tissue electrodes, probes or tonometry. Microdialysis and equilibrium analysis allow the measurement of molecules from the extracellular environment. These techniques are well suited to the quantification of lactate/pyruvate ratio.

Multiorgan dysfunction syndrome

Matthew J Maiden, Marianne J Chapman

Multiorgan dysfunction syndrome (MODS) is a complex process whereby an acute disease precipitates deranged function of a number of organ systems. MODS is encountered commonly in the intensive care unit (ICU) and accounts for 40%–50% of deaths.[1,2] Hence critical care clinicians require a sound understanding of the pathophysiology and management priorities for MODS.

HISTORY

During World War II, severely injured soldiers without thoracic trauma were noted to develop respiratory failure in the days following their initial injury. The incidence appeared related to the severity and duration of hypotension and the term 'shock lung' was used to describe the subsequent respiratory failure. While hypoperfusion was thought to initiate impaired pulmonary function, other factors including blood product transfusion, microemboli, fat emboli, endotoxin and excessive use of oxygen were postulated to contribute.[3]

Following the advent of ICU, similar patterns of 'remote' organ failures were reported in critically ill patients following trauma, surgical haemorrhage, abdominal sepsis, pneumonia and pancreatitis.[4,5] Although many pathophysiological mechanisms for this have been described, it is still not clear why only some patients develop MODS.

DEFINITION

Over 40 different names have been ascribed to the phenomenon of 'organ disease remote from the site of illness/injury'.[6] The terms 'multiple system failure' or 'multiple organ failure' have been commonly used; however, each description and definition differed.

A consensus conference in 1992 proposed the term 'multiple organ dysfunction syndrome' (MODS).[7] This term reflects a distinction between 'dysfunction' and 'failure'. 'Failure' implies a dichotomous outcome that is often irreversible, while 'dysfunction' describes a spectrum of organ impairment that may change over time. The term 'syndrome' was added to describe a pattern of multiple physiological changes that may have a similar pathogenesis.

However, this definition of MODS did not characterise or define what constitutes an organ dysfunction. Subsequently, many classifications and scoring systems have been developed in an attempt to quantify the severity of MODS. These have varied according to which organ systems are assessed, which parameters are measured and the thresholds for the organs to be considered dysfunctional.

The MODS and SOFA (sepsis-related organ failure assessment) scores were developed after the consensus definition of MODS (Table 17.1). They were primarily established to describe the severity of MODS and changes in organ function over time.[8,9] For each of six organ systems, one parameter of dysfunction was chosen. Scores for each organ were equally weighted and summed to provide an overall score. The score at ICU admission and the change in score over the course of the ICU stay correlates with the mortality rate, with both the MODS and SOFA scores performing similarly.[10,11] However, there are limitations to these scoring systems. Each organ system is assessed with only one parameter, and other features of organ dysfunction are not considered. Furthermore, organ dysfunction scores are influenced by therapies and hence may reflect the extent of treatment provided (or not provided). Nevertheless, these scores remain widely used.

AETIOLOGY OF MULTIORGAN DYSFUNCTION SYNDROME

Almost any disease that invokes tissue injury may progress to MODS (Box 17.1). It occurs most commonly following a microbial infection. Of note, the term 'sepsis-induced MODS' would now seem redundant given that the current definition of sepsis is 'infection with accompanying organ dysfunction' (Sepsis-3).[12]

Diseases without microbial infection account for a smaller number of patients developing MODS, but are an important consideration in anyone with an acute illness and organ dysfunction. For example, major trauma leads to MODS in about 30% of patients.[13] It

ABSTRACT

Multiorgan dysfunction syndrome (MODS) occurs in some patients following an acute infection, illness or injury. It is the consequence of impaired regulation of the processes involved in removing an invading pathogen and repairing injured tissue. An exaggerated inflammatory response becomes systemic, giving rise to derangement of organ function.

Many pathophysiological mechanisms contribute to the development of MODS. Disturbances to coagulation, the vascular endothelium, glycocalyx, epithelium, neuro-hormonal axis, macro- and microvascular blood flow, cell death processes, and metabolic and mitochondrial function play a role. The types of inciting acute disease, patient comorbidities and the potential harms of therapies provided are also significant factors in MODS.

Many potential therapies have targeted a range of mediators thought to promote MODS, but none have yet proved efficacious in clinical trials. Treatment priorities remain prompt recognition and definitive treatment of the acute disease, and provision of evidence-based supportive care.

Table 17.1 The multiorgan dysfunction syndrome and sepsis-related organ failure assessment scores: Note the similarity of the scoring systems

MODS SCORE	0	1	2	3	4
Respiratory[a] *(PO_2/FiO_2)*	>300	226–300	151–225	76–150	≤75
Renal[b] *(serum creatinine µmol/L)*	≤100	101–200	201–350	351–500	>500
Hepatic *(serum bilirubin µmol/L)*	≤20	21–60	61–120	121–240	>240
Cardiovascular[c] *(PAR)*	≤10.1	10.1–15.0	15.1–20.0	20.1–30.0	>30.0
Hematological *(platelet count × 10^3/mL)*	>120	81–120	51–80	21–50	≤20
Neurological[d] *(Glasgow Coma Score)*	15	13–14	10–12	7–9	≤6

SOFA SCORE	1	2	3	4
Respiratory *(PO_2/FiO_2)*	<400	<300	<200 With respiratory support	<100 With respiratory support
Renal *(serum creatinine µmol/L or urine output)*	110–170	171–299	300–440 or <500 mL/day	>440 or <200 mL/day
Hepatic *(serum bilirubin µmol/L)*	20–32	33–101	102–204	>204
Cardiovascular[e] *(MAP < 70 mm Hg or use of inotropes)*	MAP <70 mm Hg	Dopamine ≤5 or Dobutamine (any dose)	Dopamine >5 or Epinephrine ≤0.1 or Norepinephrine ≤0.1	Dopamine >15 or Epinephrine >0.1 or Norepinephrine >0.1
Hematological *(platelet count ×10^3/mL)*	<150	<100	<50	<20
Neurological *(Glasgow Coma Score)*	13–14	10–12	6–9	<6

[a]P/F ratio is calculated without reference to the use or mode of mechanical ventilation, and without reference to the use or level of positive end-expiratory pressure.

[b]Serum creatinine measured without reference to the use of dialysis.

[c]Pressure-adjusted heart rate (PAR) is calculated as the product of heart rate (HR) multiplied by the ratio of the right atrial (central venous) pressure (RAP) to the mean arterial pressure (MAP): PAR = HR × RAP/MAP.

[d]The Glasgow Coma Score is preferably calculated by the patient's nurse, and is scored conservatively (for the patient receiving sedation or muscle relaxant, normal function is assumed, unless there is evidence of intrinsically altered mentation).

[e]Adrenergic agents administered for at least 1 h (doses given are in µg/kg/min).

MODS, Multiorgan dysfunction syndrome; *SOFA*, sepsis-related organ failure assessment.

Box 17.1 Diseases that can progress to multiorgan dysfunction syndrome

Infection (sepsis)
No infection (nonseptic)
- Major trauma
- Burns
- Pancreatitis
- Aspiration syndromes
- Extra-corporeal circulation (e.g. cardiac bypass, ECMO)
- Large volume blood transfusion
- Ischemia-reperfusion injury
- Autoimmune disease
- Heat-induced illness
- Eclampsia
- Poisons/Toxins

occurs predominately in the first few days following injury and is most likely in patients with greater physiological derangement on presentation, and those administered more fluids and blood products.

Sepsis and the non-septic diseases associated with MODS are discussed in other chapters of this text.

PATHOGENESIS

MODS is a systemic process with complex pathophysiology. While systemic inflammation appears to be central to the development of MODS, a multitude of other factors also contribute. The pathogenesis of MODS is best conceptualised as a complex dynamic non-linear system involving a large number of variables that are highly interdependent (Fig. 17.1).[14]

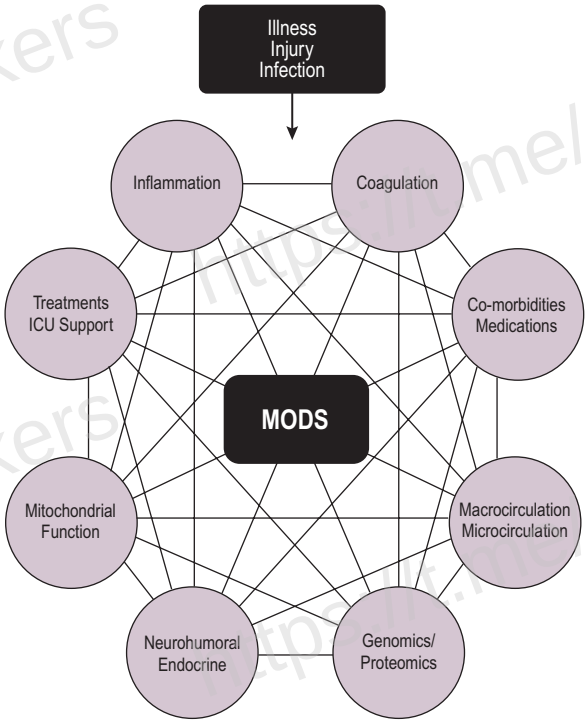

Figure 17.1 Multiorgan dysfunction syndrome *(MODS)* results from a complex interaction of a number of different pathogenic processes. *ICU,* intensive care unit.

INFLAMMATION

Inflammation is essential to contain infection, and for tissue repair. However, the inflammatory response to injury, illness or infection may become 'dysregulated', resulting in MODS and critical illness.[12,15] Increased levels of proinflammatory mediators are associated with worsening organ dysfunction[16] and MODS can be reproduced experimentally by the infusion of inflammatory cytokines.

As a systemic inflammatory response appears to be central to the development of MODS, the term systemic inflammatory response syndrome (SIRS) was defined in conjunction with the definition of MODS.[7] However SIRS is non-specific and provides little information about what is provoking the inflammation. It is important to recognise that clinical features of systemic inflammation may be an appropriate response to serious injury/infection and that most patients with these signs do not develop MODS.

Many inflammatory mediators have been identified and characterised over the last 50 years (Box 17.2). They are released from inflammatory cells and interact with the immune, endocrine and nervous systems to mediate host defence and tissue repair. With so many inflammatory molecules identified, it is not surprising they have complex interactions and that there is not one 'culprit' mediator in MODS. Given the convoluted and amplified inflammatory responses that follow injury, there has been much interest in understanding the early cellular responses to injury and infection.

Box 17.2 Some of the inflammatory mediators associated with multiorgan dysfunction syndrome

Interleukin-1β (IL-1β)
Interleukin-6 (IL-6)
Interleukin-8
Tissue necrosis factor-α (TNFα)
Interferon-γ (IFN-γ)
Colony stimulating factors
Eicosanoids/platelet aggregating factor
Soluble adhesion molecules
Complement activation
Nitric oxide
Heat shock proteins
Free radicals/reactive oxygen species
Pro-calcitonin
Angiopoietin
IL-1 receptor associated kinase (IRAK-1)

Nuclear Factor-κB (NF-κB) is a co-factor involved in the transcription of genes that encode inflammatory proteins, apoptotic signalling pathways and nitric oxide production. NF-κB is pre-formed in the cytoplasm and is activated when the inhibitory subunit (IκBα) is cleaved off, allowing NF-κB to translocate to the nucleus. NF-κB levels are increased in proportion to severity of disease.[17]

Toll-Like Receptors (e.g. TLR2, TLR4) are activated by bacterial products and necrotic cells. They in turn activate NF-κB and other factors that transcribe inflammatory mediators. The process of TLR activation differs between microbial and non-microbial precipitants.[18] Pre-clinical studies targeting the non-microbial activation pathways have yielded less organ dysfunction while maintaining antimicrobial efficacy. Mutations of TLR4 are associated with an attenuated inflammatory response.[19]

High Mobility Group Box Protein 1 (HMGB-1) is an evolutionary conserved protein that potentiates binding of inflammatory mediators to cells. It also acts as a nuclear co-factor that enhances DNA transcription of many inflammatory mediators. Plasma levels of HMGB-1 increase in sepsis and trauma in proportion to the severity of the illness or injury.[20,21] In experimental studies, anti-HMGB-1 attenuates the inflammatory response to infection, autoimmunity, ischaemia and trauma.[22]

COMPENSATORY ANTI-INFLAMMATORY RESPONSE SYNDROME

To ensure a controlled inflammatory response, mediators with anti-inflammatory effects (e.g. interleukin [IL-4, IL-10]) are increased during injury/infection.

This anti-inflammatory response has been termed the compensatory anti-inflammatory response syndrome (CARS).[23] Immunological changes include apoptosis of lymphocytes, release of IL-10, which suppresses tissue necrosis factor (TNF), decreased cytokine production and down-regulated human leucocyte antigen (HLA) receptors on monocytes.

Just as an excessive proinflammatory response may contribute to MODS, an exaggerated anti-inflammatory response, which tends to occur later in disease, can result in a state of immunosuppression and anergy.[24] Relative immunosuppression is often a feature of MODS and is thought to account for the late development of iatrogenic infections with organisms that are usually commensal or of low virulence (e.g. *Candida, Pseudomonas, Stenothrophomonas, Enterococcus*).

COAGULATION

Tissue factor, endotoxin, bacterial antigens and cytokines can trigger the clotting system. Thrombin is produced at the site of infection/injury to isolate infectious sources and initiate tissue repair. However, products of the clotting cascade are proinflammatory and the clotting system is central in the inflammatory response. For example, activation of the thrombin receptor induces transcription of NF-κB and stimulation of proinflammatory sequelae.[25]

Coagulation is normally controlled by the endogenous anticoagulant factors antithrombin III (AT-III binds to thrombin and endothelium to release endothelial prostacyclin and inhibit platelet aggregation) and protein C (complexes with Protein S to inhibit Va and VIIIa). Levels of these anticoagulants fall during critical illness proportional to the severity of MODS.[26]

ENDOTHELIUM

Vascular endothelium comprises a layer of endothelial cells and a layer of glycocalyx (Fig. 17.2). While endothelial cells comprise only a single layer of cells, they are distributed over the entire circulation and have a major influence on the integrity and function of the vascular network. The glycocalyx is a gel-like network of heparin molecules, glycoproteins and glycolipids that extend from the endothelial cell membrane into the vascular lumen. It also contributes to endothelial function including local inflammatory signalling, coagulation and detecting the shear force of the flowing blood.

The endothelium provides a dynamic barrier between the circulation and interstitial tissue. Normally the endothelium is relatively impermeable to inflammatory cells, proteins, and plasma fluid. However, following tissue injury, endothelial function and glycocalyx structure alter to permit inflammatory cells to reach the site of injury. As might be expected, the degree of disturbance to the endothelium and glycocalyx appears to be more pronounced in patients who develop MODS.[27,28] However, parameters of endothelial structure and function remain an experimental tool and their clinical utility remain to be determined.

NEURO-HUMORAL CHANGES

The autonomic system is closely intertwined with the inflammatory response. The sympathetic and parasympathetic nervous systems innervate lymphoid organs and most immune cells have neurotransmitter receptors. Neural stimulation of the immune cells inhibits cytokine release and suppresses the immune response.

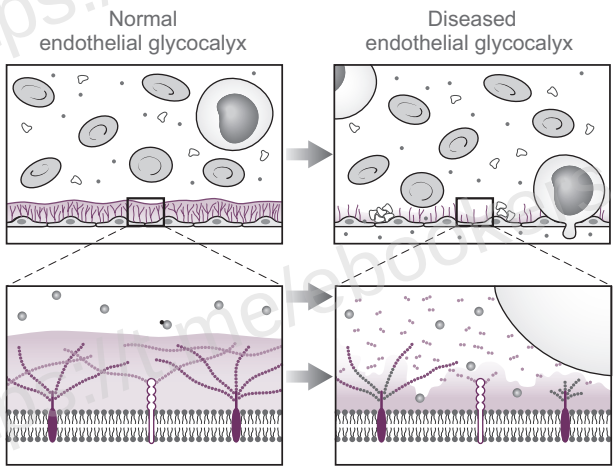

Figure 17.2 Schematic representation of the endothelium, comprising endothelial cells, and the glycocalyx. The endothelial layer normally provides a barrier between the blood and interstitium *(left image)*. In disease, the glycocalyx and endothelial structure alters allowing extravasation of inflammatory cells, proteins and plasma fluid *(right image). With permission from: Dane MJ, van den Berg BM, Lee DH, et al. A microscopic view of the renal endothelial glycocalyx.* Am J Physiol Renal Physiol. *2015;308:F956–F966.*

Some immune mediators also act as neuro-hormones providing neural feedback regarding the inflammatory state (Fig. 17.3).[29,30]

The 'stress response' to critical illness involves the release of the adrenal hormones. This is controlled by the hypothalamic secretion of corticotropin releasing hormone under direct neural control and is modulated by circulating cytokines. Inadequate hypothalamic-pituitary-adrenal response to critical illness or glucocorticoid resistance may contribute to MODS.

Changes to thyroid metabolism occur during MODS. In health, thyroxine (T4) is metabolised to the metabolically active tri-iodothyronine (T3), while during critical illness changes to the de-iodination pathways favour production of the biologically inactive reverse-T3. The consequential fall of plasma T3 levels is proportional to the severity of MODS and is independently associated with mortality.[31,32]

MACROCIRCULATORY CHANGES

Inadequate circulation of oxygenated blood can lead to cellular anaerobic metabolism and impaired organ function. While circulatory shock can initiate and perpetuate MODS, and is usually fatal if not treated, not all patients with MODS have impaired cardiac output or oxygen delivery. In fact, many patients with MODS have a preserved or increased oxygen delivery. Furthermore, attempts to prevent MODS by providing supranormal oxygen delivery by transfusing red cells or increasing cardiac output have not improved outcomes.[33]

Vascular tone is often reduced in MODS with excessive nitric oxide (NO) being a well-characterised culprit. Nitric oxide synthase (NOS) is found in endothelial cells and is induced by many inflammatory mediators. NO is toxic to micro-organisms, acts as an inflammatory signal, produces vascular smooth muscle relaxation and maintains patency of the microcirculation. However, excessive NO also leads to 'vasoplegia' with low systemic arterial pressures, venodilation and altered blood flow to the organs.

MICROCIRCULATORY CHANGES

Reduced blood flow through the microcirculation is associated with organ failure and death.[34] Microvascular thrombi, reduced red blood cell deformability and increased blood viscosity contribute to reduced microvascular flow and limited oxygen delivery to the cells.[35,36] Excessive NO alters the tone of the microcirculation contributing to mismatched microvascular flow and shunting.[37,38] Formation of interstitial oedema through endothelial permeability further restricts diffusion between the micro-circulation and cells. Images of the microcirculatory changes provide fascinating insights into the pathophysiology of MODS, but at the moment remain research tools (Fig. 17.4).

APOPTOSIS

Apoptosis is controlled cellular death that does not provoke inflammation. It is an essential process for normal coordinated control of populations of cells and

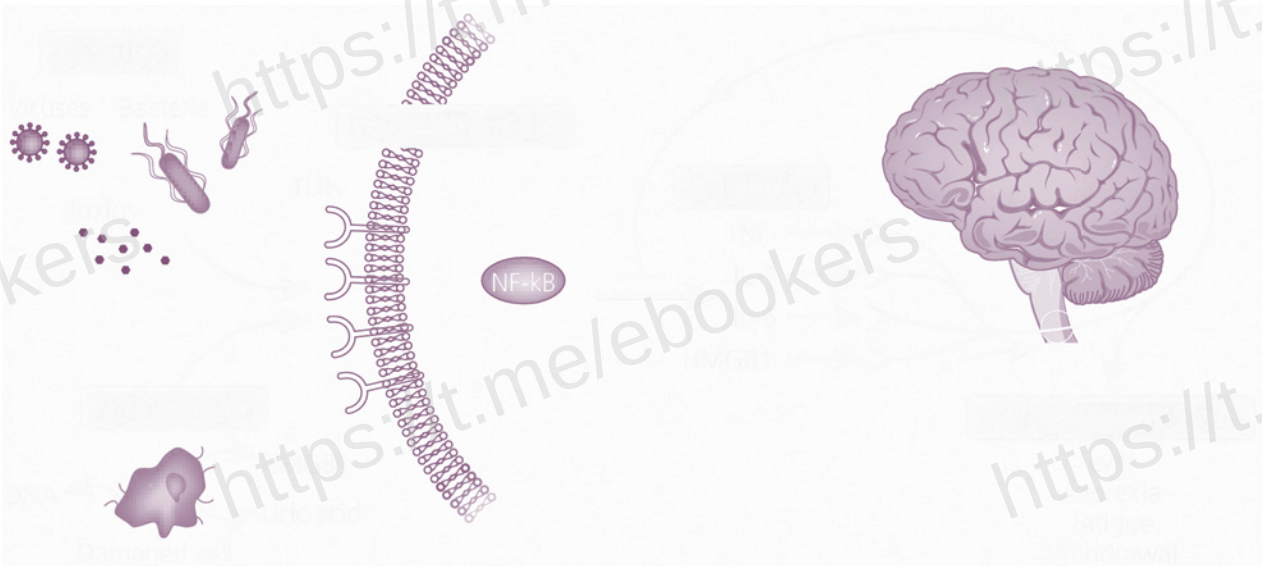

Figure 17.3 Neuro-humoral factors influence the response to illness/injury. *HMGB1*, High mobility group box protein 1; *IL*, interleukin; *NF-κB*, nuclear factor-κB; *TLR*, toll-like receptors; *TNF*, tissue necrosis factor. *Adapted from Tracey KJ. is involved in cell aging, immune regulation, epithelial cell turnover and resolution of inflammation. During critical illness, apoptosis is increased in lymphocytes, and in cells that typically have a barrier function (e.g. gut epithelium, vascular endothelium).[39] This increases susceptibility to further insults. In contrast, apoptosis of neutrophils is delayed and may lead to an exaggerated inflammatory response. Caspases are central in the regulation of apoptosis and may provide a therapeutic target.

Necroptosis is a recently identified mechanism of programmed cell necrosis that is mediated by receptor-integrating protein kinase-1 (RIPK1).[40,41] It can be triggered by a range of inflammatory mediators and is thought to primarily control intracellular microbial infection. Necroptosis is also seen in many other disease processes, and its role in MODS is an area of ongoing research.

MITOCHONDRIAL DYSFUNCTION

MODS appears to be primarily a functional rather than structural disorder. Overt cell necrosis is an uncommon finding in postmortem examination of organs that have failed due to MODS.[42] Mitochondrial function changes in MODS, and this may be induced by humoral factors, such as thyroid hormone, glucocorticoids, catecholamines and cytokines.[43] Cells appear to enter a state of 'hibernation' where metabolic activity is reduced and oxygen utilisation limited.[44,45] Interestingly, patients who progress to develop MODS, have a different profile of beta-oxidation, gluconeogenesis and citric acid cycle proteins.[46] This implies that there may be a metabolic predisposition to developing MODS.

CO-MORBIDITIES

An important consideration in the development of MODS is the patient's pre-morbid organ function. Patients with pre-existing organ disease are more likely to have further deterioration of organ function following an acute illness (e.g. compromised respiratory reserve in fibrotic lung disease, limited renal function in diabetic nephropathy, reduced marrow response in chronic leukaemia, impaired hepatic function in alcoholic liver disease). These patients will have a lower threshold for developing MODS.

IATROGENESIS

The recognition of MODS corresponded with the development of intensive care supports. It may be that some ICU interventions actually increase the risk of developing MODS or continue to drive the process once it is initiated. For example, the incidence of acute

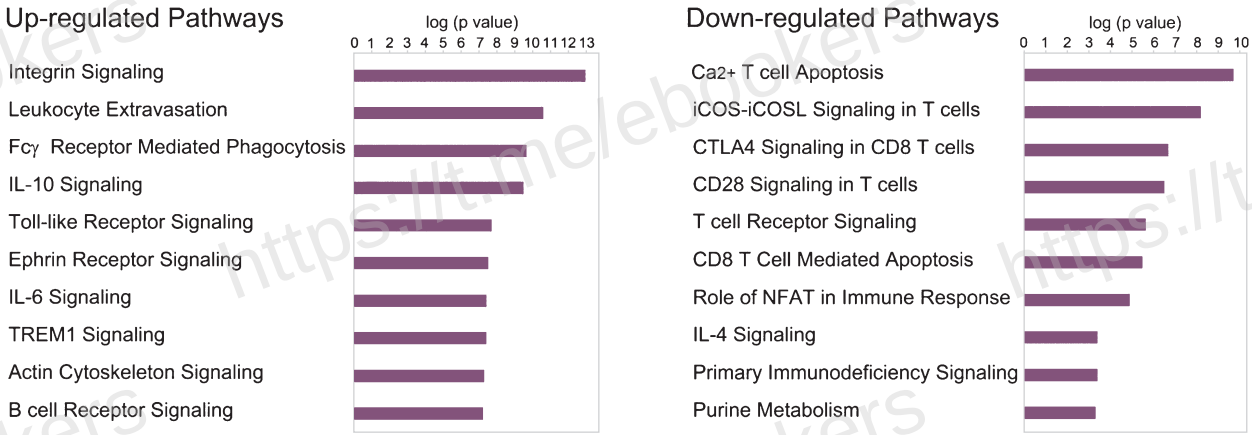

Figure 17.5 Genomic changes associated with severe blunt trauma. *With permission from from Xiao W, Mindrinos MN, Seok J, et al. A genomic storm in critically injured humans.* J Exp Med. *2011;208(13):2581–2590.*

respiratory distress syndrome (ARDS) and its mortality have reduced substantially since the recognition that larger tidal volumes and overzealous parenteral fluid administration were contributing to lung injury.[47,48] Other ICU interventions, such as parenteral fluids (type and volume), immobility, artificial cooling, extracorporeal circulatory support, catecholamines, medications, nutrition supplements and blood products may contribute. Providing evidence-based supportive care is a vital aspect of preventing MODS.

GENETICS

Genetic factors have been thought to contribute to the heterogeneity of MODS. Differences in genes coding for TNF, TLR, NF-κB, IL-1 receptor kinase and caspase-12 have been related to severity of organ dysfunction and extent of ICU supports following sepsis.[49,50] Similarly, in patients undergoing elective abdominal aortic aneurysm repair, the analysis of preoperative leucocyte genes predicted which patients subsequently developed MODS.[51]

However, recent studies suggest there is little genetic variability in the response to critical illness. An important study serially examined the leucocyte genome from patients with severe trauma, severe burns, healthy volunteers exposed to endotoxin and matched healthy controls.[52] Over 80% of the leucocyte transcriptome altered, with gene expression patterns typically representing stimulation of innate immunity and suppression of adaptive immunity (Fig. 17.5). The number of genes whose expression decreased was greater than the number of genes whose expression increased, and half of the altered gene expression had not returned to baseline by 28 days. The genomic changes were remarkably similar between major trauma, major burns and endotoxin exposure.

While the extent of genomic expression changes was independently related to disease severity, there was no gene or cluster of genes that were a unique identifier. A single genetic locus would seem unlikely to be prognostic or a therapeutic target in what appears to be a well-preserved, coordinated, reproducible genomic storm to acute severe illness.

THE GUT IN MULTIORGAN DYSFUNCTION SYNDROME

The gut and its enteric micro-organisms have been proposed to provide an inflammatory focus during critical illness. Normally, organisms in the gut remain commensal due to bowel wall integrity and maintenance of the normal microflora ecosystem. However, when normal conditions are disturbed (e.g. bowel mucosal changes, altered gastric pH, antimicrobial use, overwhelmed reticuloendothelial macrophages), the enteric organisms can invade and perpetuate an inflammatory response. Similarly, gut digestive enzymes can enter the circulation through compromised gut epithelium, contributing to the pathophysiology of MODS.[53] For these reasons, the gut has been described as the 'motor' of MODS.[54] Studies of gut decontamination in critical illness have illustrated a survival benefit, and larger trials are planned (NCT02389036).

CLINICAL FEATURES OF MULTIORGAN DYSFUNCTION SYNDROME

There is no one typical constellation or time-course of organ dysfunction that describes MODS. Some patients may develop only mild organ dysfunction, which, with supportive treatment, resolves in days, while others can develop fulminant MODS progressing rapidly to death.

Which organs become dysfunctional and the timing of their dysfunction depends on the patient's age and phenotype, the inciting injury/illness, the pre-morbid organ function, the extent and duration of physiological derangement, the treatments provided and consideration of all the pathogenesis factors discussed earlier.

Identification of MODS as a discrete clinical syndrome has been difficult due to lack of agreement about what characterises an organ dysfunction. There are many ways of measuring organ dysfunction: clinical features, monitored physiological derangement and altered biochemical markers. Each organ system can manifest dysfunction in many different ways. For example, the respiratory system can be considered dysfunctional based on hypoxia (e.g. PaO_2:FiO_2 ratio), hypercarbia, reduced compliance, radiological change, extent of ventilatory supports or lavage fluid content. The processes that lead to changes in these parameters can be quite different, and defining an organ dysfunction based on one variable alone is inadequate to describe the full spectrum of disease.

Note that criteria of SIRS are no longer recommended as diagnostic criteria for sepsis, and it is unclear if they are useful for detecting those patients who will develop MODS from other non-infectious disease processes.

THERAPIES FOR MODS

Priorities in the treatment of MODS are:

1. Early recognition of illness.
2. Early resuscitation.
3. Early definitive treatment.
4. Supportive care that is evidence based.
5. Consideration of pre-morbid disease.
6. Prevention of secondary insults.

The focus of management must be on the immediate treatment of the inflammatory focus (e.g. remove source of sepsis, repair injured tissue, control blood loss, debride burns, stabilise long bone fractures). Aspects relating to early recognition of the deteriorating patient, resuscitation, specific disease treatments and the methods of organ support are covered in other chapters.

Specific therapies that target the pathogenesis of MODS continue to be extensively studied. Each of the pathophysiological processes, described earlier, has been targeted in pre-clinical and clinical trials. However, despite promise in pre-clinical studies, no therapy has proven clinical efficacy in the treatment of MODS. The lack of a 'magic bullet' for treatment of MODS is not surprising given the complexity and variability of the pathophysiology, the lack of standardised treatments for some diseases and uncertainty regarding optimal timing of adjunctive therapy.

INFLAMMATION MODULATING THERAPIES

Proinflammatory mediators have been a logical therapeutic target. In pre-clinical studies many of these agents have provided physiological benefit, have reduced the severity of organ dysfunction and have improved mortality. However, when these therapies progressed to clinical trials, none have provided clinical benefit and some have worsened outcomes.[55] For example, pre-clinical studies of TNF-α antibodies and soluble TNF-receptors in bacteraemic primates, suggested that neutralising TNF-α improved organ function and reduced mortality.[56] However, not only did clinical trials fail to show a benefit, but higher doses increased mortality.[57] Similarly, the following agents have shown encouraging results in pre-clinical trials but no efficacy or adverse outcomes in subsequent clinical studies: endotoxin antibodies, nonsteroidal anti-inflammatory drugs, IL-1 receptor antagonists, platelet-activating factor (PAF) antagonists, bradykinin antagonists, interferon (IFN)-γ, NOS inhibition, NO antagonists, AT-III concentrate and activated protein C.

The lack of clinical efficacy of immunomodulating therapies for MODS may reflect misplaced attention on the harmful effects of cytokines rather than considering their beneficial role. While inflammatory mediators are associated with MODS, they are also vital for control of infection, tissue repair and healing. Furthermore, the proinflammatory mediators also have downstream effects that eventually attenuate inflammation. While elevated concentrations of proinflammatory cytokines are clearly associated with MODS, reduced levels are also associated with increased mortality.[58–61] The inflammatory response involves a very complex interplay of pro- and anti-inflammatory mediators, and it is not unexpected that targeting one proinflammatory mediator has not proven effective.

Future therapies to assist with recovery from MODS may aim to control excess inflammation without interfering with the essential components of the inflammatory process. Agents that modulate the inflammatory process without diminishing antimicrobial mechanisms are currently being investigated.

HUMORAL THERAPY

Glucocorticoids have been a popular experimental therapy. 'High dose' steroid treatment is known to suppress the inflammatory response, but when trialled in critically ill patients with MODS proved to be harmful. As MODS may be associated with relative adrenal insufficiency and/or glucocorticoid resistance, lower dose steroid treatment has been investigated. Initial studies suggested that septic shock patients with limited response to administered corticotropin had mortality benefit from steroid replacement.[62] However, in the CORTICUS trial, which studied a broader group of septic patients, hydrocortisone did not provide

mortality benefit.[63] Most recently, the ADRENAL study of 3800 ventilated patients with septic shock found that hydrocortisone (200 mg per day) slightly reduced the duration of catecholamine infusion but did not alter mortality.[64]

Thyroid hormone has received relatively little attention despite markedly reduced T3 concentrations during critical illness and physiological plausibility that this may contribute to cell hibernation in MODS. Clinical trials in cardiothoracic ICU patients with low T3 suggested replacement improves cardiovascular function[65]; however, in controlled experimental septic shock studies, providing supplementary T3 appeared physiologically inert.[66] Whether the cells are regulating their own T3 exposure by altering hormonal uptake or clearance is being investigated.

NUTRITION

MODS is a hypercatabolic state and nutritional support is required to ensure adequate energy, protein, fatty acids and trace elements. However, the ideal energy, protein and macronutrient composition in MODS remains unclear. Furthermore, the efficacy of supplementing feeds with amino acids (e.g. arginine, glutamine), nucleotides, fatty acids (e.g. omega-3, γ-linoleic acid) and antioxidants (e.g. selenium) is unproven. The priority is to understand how much energy to provide patients with MODS, and multi-centre studies are now underway to determine the effect on patient outcomes (NCT02306746).

OUTCOMES

Outcomes from MODS appear to have improved over time.[67,68] No specific therapies have been developed that 'treat' MODS; the improved outcomes are likely to reflect a greater awareness of the diseases that can progress to MODS, the importance of timely resuscitation, prompt treatment of the inciting disease and the application of evidence-based supportive care.

It is important to remain cognisant that many of the pathophysiological processes leading to MODS are part of a complex interdependent system that *usually* leads to the resolution of an acute illness/injury. Caution needs to be applied when considering the physiological changes that occur during a critical illness, and whether treating these changes is actually beneficial for each individual patient. Conversely, we must remain thoroughly aware that some patients are particularly sensitive to the physiological changes, or develop an exaggerated response to an acute illness/injury, progressing to MODS, permanent organ injury or death. How to identify which patients will progress to MODS and how they are best managed is a research priority.

Monitoring oxygenation

Thomas J Morgan, Balasubramanian Venkatesh

ROLES OF OXYGEN IN AEROBIC ORGANISMS[1]

- Bioenergetics. Aerobic mitochondrial respiration accounts for 90% of oxygen consumption, generating adenosine triphosphate (ATP) by oxidative phosphorylation. Oxygen is the terminal electron acceptor at Complex IV in the electron transfer cytochrome oxidase system, combining with two protons to produce water.
- Biosynthetics. Transferase systems incorporate oxygen into substrates including prostanoids, catecholamines and some neurotransmitters.
- Biodegradation and detoxification. For example, the cytochrome P-450 hydroxylases are mixed function oxidases requiring oxygen plus nicotinamide adenine dinucleotide phosphate (NADPH) as a co-substrate.
- Generation of reactive oxygen species (ROS). ROS functions include hypoxic signalling, maintenance of vascular tone and antimicrobial defence.
- Mitochondrial heat generation by 'uncoupled' oxidative phosphorylation.

HYPOXIA

The term 'hypoxia' connotes oxygen deficiency. As tissue P_{O_2} declines, a characteristic sequence is activated:

- Oxidative phosphorylation is initially supported: glycolysis accelerates; competing biosynthetic and biodegradation pathways are shut down.
- ROS released at mitochondrial Complex III activate hypoxia-inducible factor-1, up-regulating genes promoting hypoxic cell survival.[2]
- Oxidative phosphorylation ceases when intracellular $P_{O_2} < 0.1$ to 1 mm Hg.
- Low rate ATP production continues by anaerobic glycolysis.
- Cell death by apoptosis and necrosis.
- Release of ROS and reactive nitrogen species (RNS) on re-oxygenation causes oxidant stress.[3]

DYSOXIA

A suggested broader term 'dysoxia' describes any form of oxygen-limited cytochrome turnover causing progressive ATP depletion.[4]

THE DYSOXIA SPECTRUM

- 'Stagnant' hypoxia due to reduced blood flow.
- 'Hypoxaemic' hypoxia due to a low arterial oxygen tension (Pa_{O_2}).
- 'Anaemic' hypoxia due to a low haemoglobin concentration.
- 'Cytopathic' dysoxia, defined as impaired cellular oxygen utilisation despite adequate delivery and attributed to sepsis and other cytokinaemic states.[5] Multiple-organ dysfunction has been characterised as an adaptive 'hibernation' response to cytopathic dysoxia.[1]
- Oxygen toxicity: adverse effects of intentional or inadvertent hyperoxia.[6]

THE OXYGEN CASCADE

Oxygen diffuses from atmosphere to intracellular organelles down a series of partial pressure reductions known as the oxygen cascade.

Steps include:

- Inspired gas
- Alveolar gas
- Arterial blood
- Microcirculation
- Interstitium
- Mitochondria and other intracellular organelles.

Intracellular oxygenation can be jeopardised at any step. This chapter surveys current and potential monitoring options at strategic points down the cascade.

ABSTRACT

Monitoring oxygenation at strategic points along the oxygen cascade can mitigate both hypoxia and hyperoxia. Monitoring points extend from the inspired gas to individual tissues. Modalities include the distribution of ventilation by electrical impedance tomography, matching of ventilation with perfusion by the multiple inert gas elimination technique and other techniques, the A-a gradient, venous admixture, the Pi_{O_2}/Fi_{O_2} ratio, intermittent and continuous blood gas analysis and co-oximetry, dual and multiple wavelength pulse oximetry, oxygen delivery and consumption rates, mixed and central venous O_2 tensions and contents, the global CO_2 gap, regional CO_2 gaps including gastric and sublingual, dynamic circulatory imaging and near infrared spectroscopy with a functional occlusion test. Detecting dysoxic thresholds in individual tissues remains a research focus.

tissue heterogeneity

INSPIRED GAS

Regulating the inspired oxygen tension (Pi_{O_2}) can mitigate both hypoxia and hyperoxia. The Pi_{O_2} of humidified gas is determined by the fraction of inspired oxygen (Fi_{O_2}) the barometric pressure (BP) and the saturated vapour pressure of water (47 mm Hg).

$$Pi_{O_2} = Fi_{O_2} \times (BP - 47) \quad (18.1)$$

Monitoring includes:

- Gas supply and ventilator input pressures
- Oxygen concentrations (paramagnetic analysers) in inspiratory module and circuit.

TRANSFER OF INSPIRED GAS TO ALVEOLI

Open communication between oxygen delivery system and alveoli is evidenced by:

- No signs of upper airway obstruction
- Expired tidal and minute volumes and airway pressures in ventilated patients within correctly set alarm limits
- An appropriate end-tidal CO_2 waveform.

ALVEOLAR GAS

The P_{O_2} spread across individual lung units is wide, ranging from ~40 mm Hg to >600 mm Hg in a patient receiving 100% oxygen.

DISTRIBUTION OF ALVEOLAR VENTILATION

Clinicians observe chest movement, auscultate air entry, and examine plain chest radiographs. Computed tomography scanning can reveal occult overdistension, while magnetic resonance imaging (MRI) can provide regional functional lung analysis using techniques, such as oxygen-enhanced T1 mapping.[7] Both present logistic disadvantages.

Bedside monitoring techniques to track ventilation heterogeneity and recruitment responses can include:

- Electrical impedance tomography (EIT), showing promise in infants and children[8] and now adults.[9]
- Oxygen washout curves following Fi_{O_2} reductions,[10] with potential for serial monitoring of end-expiratory lung volumes and heterogeneity indices such as 'moment ratios'.

MATCHING VENTILATION AND PERFUSION

For efficient gas exchange, most lung units must receive well-matched alveolar ventilation (V) and perfusion (Q), with V/Q ratios clustered around unity. V/Q spread impairs both O_2 uptake (low V/Q) and CO_2 elimination (high V/Q).

The adult lung contains over 100,000 individual gas exchanging units,[11] with a complexity that resists simple bedside quantification. The gold standard remains the multiple inert gas elimination technique (MIGET), which models a 50-compartment lung with V/Q ratios spanning zero to infinity. Pre-equilibrated saline containing six inert gases with a range of solubilities is infused to steady state. Their measured pulmonary retention and elimination ratios are entered into software as iterative end points to compute corresponding 50 compartment distributions of ventilation and perfusion.[11,12]

Models with fewer compartments may suffice at the bedside,[13] with stepped Fi_{O_2} changes forcing measured responses in Pa_{O_2}, end-tidal P_{O_2} or Sp_{O_2} (see 'pulse oximetry').

The three-compartment model

A lung model dating from the mid-20th century[14] has just three compartments and no requirement for forcing functions, such as inert gas infusions or Fi_{O_2} switching. The trade-off is poor predictive capacity in many respiratory disorders. The compartments are:

1. 'Ideal', containing alveoli with matched perfusion and ventilation ($V/Q = 1$)
2. 'Venous admixture', containing perfused non-ventilated alveoli ($V/Q = 0$)
3. 'Dead space', containing ventilated non-perfused alveoli ($V/Q = \infty$).

The 'ideal' P_{O_2} (PA_{O_2}) is calculated from the alveolar gas equation:

$$PA_{O_2} = Pi_{O_2} - (1 - Fi_{O_2} \times (1 - R)) \times PaCO_2/R \quad (18.2)$$

R is the respiratory exchange ratio, usually assumed to be 0.8. Pi_{O_2} is calculated as in Eq. 18.1. $PaCO_2$ is arterial P_{CO_2}.

A common approximation is:

$$PA_{O_2} = Pi_{O_2} - PaCO_2/0.8$$

The A-a gradient and venous admixture calculations (see below) are derived from this minimalist model.

TRANSFER FROM ALVEOLI TO ARTERIAL BLOOD

The MIGET technique identified V/Q mismatch and right to left shunt ($V/Q = 0$) as the principal causes of reduced pulmonary oxygen transfer in critical illness.[15] The intrapulmonary shunt predominates in the acute respiratory distress syndrome (ARDS), lobar pneumonia and after cardiopulmonary bypass, whereas V/Q mismatch without shunt is prominent in chronic lung disease.[16]

TENSION-BASED INDICES

A-a gradient

The A-a gradient is calculated as $PA_{O_2} - Pa_{O_2}$, where PA_{O_2} is the 'ideal' alveolar P_{O_2} (Eq. 18.2). Hypoxaemia is then classified under two headings:

Normal A-a gradient

1. Alveolar hypoventilation (elevated PA_{CO_2})
2. Low Pi_{O_2} ($Fi_{O_2} < 0.21$, or BP <760 mm Hg).

Raised A-a gradient

1. Diffusion defect (rare)
2. V/Q mismatch
3. Right-to-left shunt (intrapulmonary or cardiac)
4. Increased oxygen extraction ($Ca_{O_2} - Cv_{O_2}$).

The A-a gradient is a component of the APACHE II, III and IV scoring systems.[17,18] Several drawbacks limit its clinical usefulness:

- Normals depend on Fi_{O_2} and age. The normal A-a gradient breathing air is 7 mm Hg in young adults and 14 mm Hg in the elderly. On 100% oxygen, values become 31 mm Hg and 56 mm Hg, respectively.
- Fi_{O_2} dependence in intrapulmonary shunt and V/Q mismatch.[19,20]

Pa_{O_2}/Fi_{O_2} ratio

The Pa_{O_2}/Fi_{O_2} ratio contributes to current ARDS diagnosis,[21] classifying severity as mild (<300 ≥ 200), moderate (<200 ≥ 100), or severe (<100). It is an input variable in Simplified Acute Physiology Score (SAPS) 2 and 3,[22] Sepsis-related organ failure assessment score (SOFA),[23] Acute physiology and chronic health evaluation score (APACHE) IV[18] and lung injury scoring systems.[24] Normal sea-level value is ≥500 mm Hg.

The advantage is simplicity. There are several disadvantages:

- Failure to distinguish hypoventilation from other causes of hypoxaemia (unlike the A-a gradient).
- Dependence on BP. A ratio of 380 mm Hg is low at sea level but unremarkable at 1600 m elevation.
- Fi_{O_2} dependence, both in right-to-left shunt and V/Q scatter.[19,20]
- Hostage to positive end-expiratory pressure (PEEP) settings and interventions such as recruitment manoeuvres and fluid balance manipulation.

Pa_{O_2}/Fi_{O_2} calculations repeated under standardised Fi_{O_2} and PEEP settings 24 hours post-intervention and stabilisation can reset ARDS classifications and improve hospital mortality prediction.[25]

CONTENT-BASED INDICES

Venous admixture (Q_s/Q_t)

Venous admixture is the proportion of mixed venous blood calculated to flow through the 'shunt' ($V/Q = 0$) compartment of the three-compartment model, which, on rejoining 'ideal' end-capillary blood flow, will reproduce the measured Pa_{O_2}. It is determined as follows:

$$\frac{\dot{Q}_s}{\dot{Q}_t} = \frac{Cc'O_2 - Ca_{O_2}}{Cc'O_2 - C\bar{v}_{O_2}} \quad (18.3)$$

Cc_{O_2}, Ca_{O_2}, and $C\bar{v}_{O_2}$ are the oxygen contents of 'ideal' end-capillary, arterial and mixed venous blood, respectively. Ca_{O_2} and Cv_{O_2} are calculated using data from arterial and mixed venous blood gas analysis and CO-oximetry (Table 18.1). Cc_{O_2} is calculated assuming $Pc_{O_2} = PA_{O_2}$ (Eq. 18.2). Sc_{O_2} is then computed from the Hb_{O_2} dissociation curve.

Advantages

- Unaffected by BP
- Unaffected by alveolar hypoventilation
- Independent of Fi_{O_2} despite variations in $Ca_{O_2} - Cv_{O_2}$ provided intrapulmonary shunt is the dominant pathology.[19,26]

Disadvantages

- Requires a pulmonary artery (PA) catheter
- Fi_{O_2} dependence in V/Q scatter without shunt, for example, in chronic obstructive pulmonary disease, virtually disappearing at $Fi_{O_2} > 0.5$.

When determined at $Fi_{O_2} = 1$, venous admixture quantifies 'true' right-to-left shunt. However, 100% oxygen exposure itself increases intrapulmonary shunt by the inhibition of hypoxic pulmonary vasoconstriction and absorption atelectasis.

Estimated shunt fraction

Assigning a fixed $Ca_{O_2} - Cv_{O_2}$ value removes the need for a PA catheter. However, because of the potential $Ca_{O_2} - Cv_{O_2}$ range (1.3–7.4 mL/dL), estimated shunt changes can be wrong in both degree and direction.[26]

ARTERIAL BLOOD

Indices of arterial oxygenation are Pa_{O_2} and Sa_{O_2}, linked by the Hb_{O_2} dissociation curve.

Hypoxaemia is defined as Pa_{O_2} <60 mm Hg or Sa_{O_2} <0.9, values near the descending portion of the Hb_{O_2} dissociation curve. A further Pa_{O_2} drop causes a marked fall in Sa_{O_2} and thus Ca_{O_2}.

BLOOD GAS ANALYSIS AND CO-OXIMETRY

Arterial blood is collected in a purpose-designed syringe containing lyophilised heparin to a final concentration of 20–50 U/mL. Pa_{O_2} is measured by a Clark electrode, and Sa_{O_2} by CO-oximetry. The Clark electrode works on polarographic principles, and a CO-oximeter computes the concentrations of haemoglobin species (Hb_{O_2}, Hb, COHb, MetHb, FHb) from light absorbance of haemolysed blood at several wavelengths.

Sa_{O_2} is 'functional' saturation, determined from concentrations of Hb_{O_2} and Hb (Table 18.1). Interference arises from substances with competing absorbance spectra, such as bilirubin, HbF, lipid emulsions and intravenous dyes. Increasing the wavelength numbers, for example, from 7 to 128, can reduce or eliminate interference.

Errors

Pre-analytic and analytic errors in P_{O_2} measurement are set out in Table 18.2.

Table 18.1 Oxygen dynamics – measured and derived indices

PARAMETER	ABBREVIATION	FORMULA	NORMAL RANGE	UNITS
Functional haemoglobin concentration	$[Hb_{funct}]$	$[Hb_{O_2}]+[Hb]$	12.0–18.0	g/dL
Arterial oxygen tension	Pa_{O_2}	Measured	95 ± 5	mm Hg
Mixed venous oxygen tension	Pv_{O_2}	Measured	40 ± 5	mm Hg
Functional saturation	S_{O_2}	$[Hb_{O_2}]/([Hb_{funct}])$		
Fractional saturation	FHb_{O_2}	$[Hb_{O_2}]/([Hb_{O_2}]+[Hb]+[COHb]+[MetHb])$		
Arterial functional saturation	Sa_{O_2}		0.97 ± 0.02	
Mixed venous functional saturation	Sv_{O_2}		0.75 ± 0.05	
Blood oxygen content	CO_2	$1.39\times[Hb_{funct}]\times S_{O_2}+0.0031\times P_{O_2}$		mL/dL
Arterial oxygen content	Ca_{O_2}		16–22	mL/dL
Mixed venous oxygen content	Cv_{O_2}		12–17	mL/dL
Cardiac index	CI	CO/BSA	2.5–4.2	L/min/m^2
Oxygen delivery index	$D_{O_2}I$	$CI\times Ca_{O_2}\times 10$	460–650	mL/min/m^2
Oxygen consumption index	$V_{O_2}I$	$CI\times(Ca_{O_2}-Cv_{O_2})\times 10$	96–170	mL/min/m^2
Oxygen extraction ratio	O_2ER	$(Ca_{O_2}-Cv_{O_2})/Ca_{O_2}$ or V_{O_2}/D_{O_2}	0.23–0.32	

BSA, Body surface area; *COHb,* carboxyhaemoglobin; *Hb,* reduced haemoglobin; Hb_{O_2}, oxyhaemoglobin; *MetHb,* methaemoglobin.

Table 18.2 Pre-analytic and analytic errors in P_{O_2} measurement

PRE-ANALYTIC	ANALYTIC
Oxygen diffusing into or out of air bubbles along tension gradients	Interanalyser variabilit. There is 7%–8% measurement variation on the same sample
Contamination with flush solution. Discard volume should be 2–3 times the internal volume of cannula and tubing	Inadequate anticoagulation, allowing protein deposits on electrodes
Pseudohypoxaemia. Oxygen consumption in vitro from extreme leukocytosis	Non-linearity at high P_{O_2} (>150 mm Hg)
Artefactual Pa_{O_2} elevations. With syringes stored on ice, the semi-permeable polypropylene allows oxygen ingress, facilitated by the cold-induced increase in oxygen solubility	Maintenance of electrode temperature within narrow limits (37 ± 0.1°C) is critical. P_{O_2} changes by 7% for every degree Celsius temperature change
	Minimal interference by nitrous oxide and volatile anaesthetic agents unless the polarising voltage of the electrode exceeds 600 mV
	Tonometry is the primary reference method. Quality control materials, such as aqueous, perfluorocarbon and bovine haemoglobin solutions, are used for convenience
	Arterial blood gas tensions fluctuate breath to breath.[27] Intermittent analysis is a snapshot

Temperature correction

All measurements are at 37°C. Temperature-corrected values can be calculated, but many clinicians prefer uncorrected data interpreted using normothermic reference ranges, except when evaluating the A-a gradient.

CONTINUOUS INTRA-ARTERIAL BLOOD GAS MONITORING[28]

Fibre-optic optodes calibrated with precision gases or solutions can be placed in the arterial stream to provide continuous measurements of pH, P_{CO_2} and P_{O_2}. Typical sensors are 0.5 mm in diameter, suitable for insertion through 20-G cannulas. Clinical trials have revealed varying bias and imprecision, with no evidence of improved outcomes. Along with expense, these factors have limited their bedside application.

Problems, such as flow and position artefact, prompted the development of monitors placed in line but ex vivo. Samples are drawn into an externally located cassette, analysed then returned, with results available in 2 minutes. In preterm neonates, this method can reduce red cell transfusion requirements.[29]

TRANSCUTANEOUS P_{O_2} AND P_{CO_2}

Continuous non-invasive assessment of blood gas tension is possible with transcutaneous P_{O_2} and P_{CO_2} monitoring. Systems incorporate integral thermistors and servo controlled heaters. P_{O_2} measurement utilises the principle of the Clark electrode, while the P_{CO_2} device is a pH sensitive glass electrode. The skin is warmed to 42–44°C for closest correlation with arterial values. Transcutaneous monitors generate reliable $PaCO_2$ values provided perfusion is unimpaired, but P_{O_2} measurements are more for trend analysis. Frequent site changes are necessary to prevent burns, and there is a need for regular recalibration. Monitoring is not recommended in haemodynamically unstable patients.

Transcutaneous monitors have a role in the prevention of neonatal hyperoxia,[30] plus monitoring potential in nocturnal noninvasive ventilation[31] and the diagnosis of sleep apnoea and hypoventilation syndromes.

PULSE OXIMETRY

Standard pulse oximetry[32] determines Sp_{O_2} from light absorbance at wavelengths 660 nm (red) and 940 nm (infrared) by capillary beds in digits, forehead, earlobes or the nasal septum. Two light-emitting diodes cycle on and off at multiples of mains frequency. A photo-diode detects transmitted light and corrects for ambient light. Subtraction of the background signal (tissue, capillary blood and venous blood) isolates the pulsatile arterial component.

Absorbance (A) for both wavelengths is determined as:

$$A = \log_{10}(I_0/I)$$

I_0 = incident light intensity, and I = emergent light intensity. For a given chromophore, A is proportional to its concentration (Beer's law) and the path length (Lambert's law). From the pulsatile (AC) and background (DC) absorbance signals at both wavelengths, a ratio (R) is derived:

$$R = (AC_{660}/DC_{660})/(AC_{940}/DC_{940})$$

Sp_{O_2} is computed using software 'look-up' tables of R versus Sa_{O_2} (FHb_{O_2} with some manufacturers) as measured in the arterial blood of volunteers breathing hypoxic gas mixtures.

Sp_{O_2} is usually displayed as a percentage. Restriction to two wavelengths necessitates an assumption that Hb_{O_2} and Hb are the sole haemoglobin species in the light path. The resulting error is trivial with normal dyshaemoglobin concentrations.

Speed of response

Sp_{O_2} is averaged over 3–6 seconds, and updated every 0.5–1 second. Forehead sensors respond to sudden Fi_{O_2} reductions within 10–15 seconds, whereas finger probe delay with peripheral vasoconstriction can exceed 1 minute.

Accuracy

In the 90%–97% saturation range, Sp_{O_2} has a mean absolute bias of <1%, and a precision (standard deviation of bias) of <3%. At Sa_{O_2} < 80% Sp_{O_2} readouts are extrapolated from higher saturation calibrations. Negative bias and imprecision progressively increase.

Error

Causes are listed in Table 18.3. A falsely high Sp_{O_2} is of greatest concern.

Unlike CO-oximetry, there is no interference from bilirubin, lipid emulsions and HbF.

Dyshaemoglobins and pulse oximetry

Dual wavelength oximeters cannot distinguish COHb from Hb_{O_2}. Sp_{O_2} therefore overestimates Sa_{O_2} when [COHb] is elevated, providing potential false reassurance for example after inhalational burn injuries.

MetHb absorbs both wavelengths. High [MetHb] causes Sp_{O_2} underestimation of Sa_{O_2} at normal saturations and overestimation at very low oxygen tensions. At [MetHb] ≥35% the R value is unity, which translates to $Sp_{O_2} = 85\%$.

Oximetric respiratory rate monitoring[33]

Opioid-induced hypoventilation can cause death or permanent injury when oxygen is administered to patients monitored by standard pulse oximetry.[34] Effective continuous respiratory rate monitoring should improve early detection. Algorithms analysing respiration-induced oximetric signal changes may supersede current methods, such as chest bands or nasal end-tidal CO_2.[33]

Table 18.3 Causes of error in Sp_{O_2} readings

FACTOR	COMMENT
COHb	Measured as Hb_{O_2}. Sp_{O_2} may be falsely high. See *Dyshaemoglobins and pulse oximetry* above
MetHb	Absorbs both wavelengths. See *Dyshaemoglobins and pulse oximetry* above
Low saturations	Progressive inaccuracy below 70%–80%, usually falsely low Sp_{O_2}
Prominent venous signal	Dependent limb, tricuspid regurgitation (venous pulsations) – falsely low Sp_{O_2}
Non-pulsatile flow	Cardiopulmonary bypass – poor signal
Vasoconstriction, limb ischaemia, shock states	Low pulsatile signal
Motion artefact	Tremor, voluntary movement – falsely low Sp_{O_2}
Ambient light	Strong sunlight, fluorescent and xenon lamps, flickering light – falsely low Sp_{O_2}
Anaemia	No effect
Dyes	Methylene blue, indocyanine green, indigo carmine – falsely low Sp_{O_2}
Black skin pigmentation	Variable precision and bias. May require separate calibration
Nail polish	Especially blue. Falsely low Sp_{O_2}. Acrylic nails do not interfere
Optical shunting	Due to inadequate probe contact – falsely low Sp_{O_2}
Radiofrequency interference	Reported with MRI scanners – falsely high Sp_{O_2}

MRI, Magnetic resonance imaging.

Importance of pulse oximetry

Pulse oximeters generate rapid real-time information without calibration. They detect unsuspected hypoxaemia during patient transport,[35] and are mandatory in highacuity areas, such as operating rooms, recovery rooms and intensive care units. They are useful screening tools.

On the down side, dual wavelength oximeters are insensitive to higher Pa_{O_2} changes (>70–100 mm Hg). They are also a common source of false alarms.

Multiwavelength pulse oximetry

The oxygen reserve index

Signal separation of venous and arterial saturations allows limited quantification of the oxygen reserve when $Sp_{O_2} \approx 100\%$ and $Pa_{O_2} = 100–200$ mm Hg.[6] Potential monitoring applications include:

- Adequacy of pre-oxygenation
- Responses to recruitment manoeuvres[36]
- Prevention of hyperoxia.

Pulse CO-oximetry[6]

Non-invasive tracking of total haemoglobin (SpHb) plus carboxyhaemoglobin (SpCO) and methaemoglobin (SpMet) concentrations is also possible with multiwavelength devices. This includes patients with low perfusion states and those requiring vasopressors. Accuracy is adequate for trend monitoring.[37]

HAEMOGLOBIN-OXYGEN AFFINITY

Haemoglobin-oxygen affinity is the relationship between the oxygen tension of blood and its oxygen content, described by the sigmoid shaped Hb_{O_2} dissociation curve. The P50 is the oxygen tension at $S_{O_2} = 0.5$. The normal adult value in humans is 26.7 mm Hg. Factors which decrease haemoglobin-oxygen affinity increase the P50. They include acidaemia (the Bohr effect), hypercarbia, increased erythrocytic 2,3-DPG and fever, whereas P50 is decreased (increased affinity) by alkalaemia, hypocarbia, low 2,3-DPG concentrations, hypothermia, COHb, MetHb and FHb.

It is possible to calculate accurate P50 values from a single measurement of blood gases and Sa_{O_2} up to $Sa_{O_2} = 0.97$. However, an impact of varying affinity on tissue oxygenation in critical illness is yet to be established.

TITRATING OXYGEN THERAPY IN CRITICAL ILLNESS

Avoidance of hypoxemia must be counterbalanced against risks of hyperoxia. The optimal oxygenation range is unclear. A 2016 single-centre, randomised, controlled trial (n = 480) supported the hypothesis that oxygen titrated to $Pa_{O_2} = 70–100$ mm Hg or $Sp_{O_2} = 94\%–98\%$ produces a lower "intensive care unit (ICU)" mortality and fewer new episodes of shock and liver failure than oxygen titrated to $Pa_{O_2} \leq 150$ mm Hg

or Sp_{O_2} = 97%–100%.[38] Results require validation in larger multicentre studies.

By contrast, two randomised controlled studies in preterm infants targeting Sp_{O_2} = 85%–89% versus Sp_{O_2} = 91%–95% to prevent retinopathy of prematurity demonstrated higher mortality in the permissive hypoxaemia groups.[39,40]

MONITORING OXYGEN DYNAMICS

Common indices are set out in Table 18.1.

D_{O_2}/V_{O_2} RELATIONSHIPS

An association reported in 1973 between hyperdynamic oxygen flow patterns and survival after high-risk non-cardiac surgery[41] led to the popular hypothesis that an induced hyperdynamic state could mitigate an acquired oxygen debt. Common goals were cardiac index (CI) > 4.5 L/min/m^2, $D_{O_2}I$ > 600 mL/min/m^2, $V_{O_2}I$ > 170 mL/min/m^2. However, the $V_{O_2}I$ targets were particularly difficult to achieve and outcomes unimproved in multicentre studies.[42,43]

Subsequent targeting of $D_{O_2}I$ values alone removed the need for PA catheterisation and was associated with reduced peri-operative morbidity.[44,45] However improved outcomes are still most likely in patients who achieve supranormal targets spontaneously.[46]

MEASURING $D_{O_2}I$

A PA catheter is not essential and normal ranges can be quoted (Table 18.1), but isolated $D_{O_2}I$ measurements are difficult to interpret due to varying oxygen demand.

MEASURING $V_{O_2}I$

Measurements can predict weaning success.[47] Two methods are the reverse Fick method (Table 18.1) and indirect calorimetry.

Reverse Fick method

This requires a PA catheter. With random errors ranging from 17% overestimation to 13% underestimation, changes <20% cannot be detected reliably. In lung inflammation, up to 20% of $V_{O_2}I$ arises directly from the lungs.

Indirect calorimetry

Indirect calorimetry has better accuracy. $V_{O_2}I$ is determined from the volumes and oxygen concentrations of inspired and expired gas. Relative errors are <5% up to Fi_{O_2} = 0.8. Higher Fi_{O_2} settings increase error.

MIXED VENOUS BLOOD

Mixed venous blood can be sampled by gentle aspiration of the distal port of an unwedged PA catheter. The distal site ensures adequate admixture of blood from superior and inferior venae cavae and the coronary sinus. Mixed venous O_2 and CO_2 tensions and content are flow-weighted averages of multiple venous effluents, insensitive to small pockets of hypoxia or hypercarbia.

MIXED VENOUS P_{O_2} (Pv_{O_2})

A Pv_{O_2} < 26 mm Hg is suggestive of cellular hypoxia.[48] Paradoxically, a normal or high Pv_{O_2} does not exclude regional dysoxia, whether cytopathic or as a result of tissue shunting.[49]

MIXED VENOUS OXYGEN SATURATION (Sv_{O_2})

Sv_{O_2} is measured either intermittently by mixed venous sampling and CO-oximetry or continuously by a PA catheter incorporating fibre-optic reflectance oximetry. Measurements have several potential applications:

- To calculate Cv_{O_2} (Table 18.1). Cv_{O_2} can then be used to determine Q_s/Q_t, $V_{O_2}I$ (reverse Fick), the oxygen extraction ratio (Table 18.1) and cardiac output (Fick).
- As an index of tissue oxygenation. Values between 0.7 and 0.8 imply but do not guarantee global oxygen supply and demand balance. Values >0.8 are seen in high flow states, such as sepsis, hyperthyroidism and severe liver disease. Lactic acidosis appears between 0.3 and 0.5,[50] although values <0.5 are surprisingly well tolerated in chronic heart failure.

Like Pv_{O_2}, Sv_{O_2} is insensitive to cytopathic dysoxia and tissue shunting. $Sv_{O_2} \geq 0.7$ as a therapeutic target failed to improve survival.[51]

CENTRAL VENOUS SATURATION (Scv_{O_2})

As with Sv_{O_2}, Scv_{O_2} can be measured either continuously using a central venous catheter modified for reflectance oximetry, or by intermittent sampling and CO-oximetry. In health, $Scv_{O_2} < Sv_{O_2}$ by 2%–3%. In shock, the difference can be reversed. Trends usually run in parallel.

Targets of $Scv_{O_2} > 0.7$ and $Sv_{O_2} > 0.65$ have equal billing in the 2012 management guidelines of the Surviving Sepsis Campaign, but at a low evidence level (1C).[52] Three subsequent randomised trials with $Scv_{O_2} > 0.7$ as part of early goal directed therapy protocols failed to show a mortality benefit, either individually or collectively.[53] Of note, targeting $Scv_{O_2} > 0.7$ has not been assessed as an individual strategy.

MIXED VENOUS-ARTERIAL P_{CO_2} GRADIENT (Pv-aCO_2), CENTRAL VENOUS-ARTERIAL P_{CO_2} GRADIENT (ΔP_{CO_2}) AND DERIVED VARIABLES

Pv-aCO_2 (normally about 6 mm Hg) increases markedly during low output states as a simple reflection of reduced CO_2 clearance. The signal is further modified by the Haldane effect, metabolic acidosis and haematocrit.[54] Similar comments apply to ΔP_{CO_2}.

A high or sudden increase in the respiratory quotient (V_{CO_2}/V_{O_2}) or in the Pv-aCO_2/arteriovenous O_2

content difference are more specific markers of tissue hypoxia and anaerobic metabolism. Corresponding ratios calculated from central venous samples (Δ cont CO_2/Δ cont O_2 and $\Delta P_{CO_2}/\Delta$ cont O_2) also show promise, with better specificity for anaerobic metabolism (defined as D_{O_2}/V_{O_2} dependence) in early septic shock than lactate concentrations or Cv_{O_2} values.[55]

REGIONAL INDICES

REGIONAL P_{CO_2}[56]

Regional P_{CO_2} reflects the balance between arterial blood CO_2 content, tissue blood flow and tissue CO_2 production. The CO_2 gap, which is regional $P_{CO_2} - PaCO_2$, controls for varying arterial CO_2 content. As tissue blood flow falls, reduced CO_2 clearance increases the CO_2 gap. Aerobic CO_2 production ceases with the onset of anaerobic metabolism, although progressive regional metabolic acidosis then generates further CO_2 by 'proton titration' of tissue and capillary HCO_3^-. A rising CO_2 gap thus signals falling tissue blood flow, but cannot identify the onset of anaerobic metabolism.[57]

GASTRIC TONOMETRY

Gastric tonometry was developed on the basis that splanchnic hypoperfusion is an early feature of circulatory shock and may persist as 'covert shock'. A gastric tonometer is a modified nasogastric tube with a silicone balloon 11.4 cm from the tip. Gastric mucosal CO_2 equilibrates with luminal CO_2, which equilibrates with (and is measured in) fluid filling the balloon. Early on, this fluid was saline. The medium was subsequently changed to air for more rapid equilibration.

Switching from pHi to the gastric mucosal-arterial CO_2 gap eliminated the questionable practice of substituting arterial for mucosal (HCO_3^-). The gastric CO_2 gap (normally 8–10 mm Hg) is an independent prognostic factor in critical illness.[58] Simultaneous end-tidal CO_2 measurement allows monitoring of the gastric to end-tidal CO_2 gap, a parameter linked to outcome in high-risk surgery.[59]

Several barriers to widespread application remain:

- The need for a nasogastric tube.
- Signal degradation by luminal contents, including feeds and blood. Feeds should be stopped 2 hours prior to measurements, jeopardising nutritional support.
  - Lack of a clear action threshold. Empiric recommendations target a CO_2 gap <25 mm Hg.
  - Gastric acidity must be suppressed to stop CO_2 back-generation by HCl titration of duodenal bicarbonate.
- Limited evidence that tonometry-guided therapy improves outcomes. A 2015 meta-analysis that included older pHi-based trials did report a composite mortality reduction.[60] Major beneficiaries were patients with normal initial pHi values, implying that the early institution of tonometry-directed management is key.

SUBLINGUAL CAPNOMETRY

The sublingual CO_2 gap tracks sublingual microcirculatory blood flow in septic shock.[61] It remains to be seen whether the technique can guide therapy. Transcutaneous ear lobe P_{CO_2} has also shown potential.[62]

DIRECT TISSUE P_{O_2} MEASUREMENT

Measurements have been recorded primarily in animal models in the brain, subcutaneous tissue, muscle and renal beds under a variety of perfusion insults. Tensions are commonly around 30–45 mm Hg, but can range from <10 mm Hg in the renal medulla to >70 mm Hg in subcutaneous tissue. This methodology is largely impractical in patients, although in vivo MRI is one possible approach.[63]

OTHER REGIONAL TECHNIQUES

DYNAMIC MICROCIRCULATORY IMAGING

Orthogonal polarisation spectroscopy (OPS) and side stream dark field (SDF) imaging allow real-time quantification of microvascular flow (0–20 µm diameter vessels) via indices such as the 'functional capillary density' and the 'mean flow index'. Image quality has improved with computer-controlled hand-held devices.[49] The sublingual circulation is most commonly evaluated. Rectal, oral, stomal and other microcirculations can be visualised.

The guiding hypothesis is that oxygen deficits are created by microcirculatory 'haemodynamic incoherence' with macrocirculatory parameters. There is a corresponding emphasis on vasodilator therapy.[49] Several derangements are described:

- Heterogeneity with functional shunting
- Obstruction from vasoconstriction (vasopressors or hyperoxia) or high venous pressures
- Haemodilution
- Tissue oedema from fluid overload and endothelial glycocalyx damage.

Of some concern, the relationship between sublingual and intestinal microcirculations may be inconsistent.[64] Moreover, clinical studies demonstrating improved outcomes in circulatory shock using microcirculatory resuscitation end-points are lacking.

NEAR-INFRARED SPECTROSCOPY[65]

Near-infrared spectroscopy (NIRS) quantifies the differential absorbance of Hb_{O_2} and Hb in muscle vessels with diameter <1 mm (arterioles, venules and capillaries) subjected to light of wavelengths 700–1000 nm. Approximately 95% of the signal is from tissue <2.4 mm in depth. Three parameters have potential

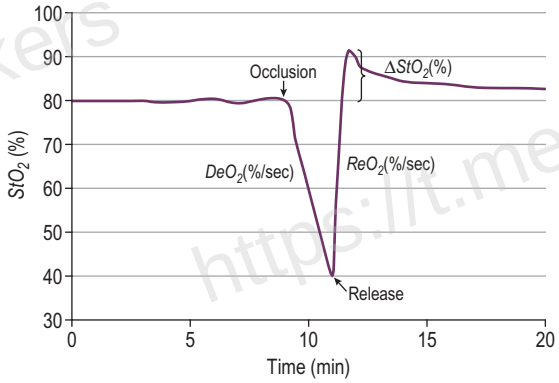

Figure 18.1 Schematic representation of a StO_2 curve measured at the thenar eminence during a vascular occlusion test. At the point marked 'occlusion' the sphygmomanometer cuff is inflated >30 mm Hg above systolic pressure and released when $StO_2 \leq 40\%$. The desaturation slope (DeO_2) reflects muscle V_{O_2}, and the resaturation slope (ReO_2) and saturation overshoot (ΔStO_2) quantify reperfusion dynamics and vascular recruitment. All decrease in sepsis and shock states.

as diagnostic and resuscitation monitoring adjuncts in hypovolaemia and shock states more generally:

- tissue haemoglobin saturation (StO_2)
- total tissue haemoglobin (TTH)
- absolute tissue haemoglobin index (THI)

The thenar eminence is normally selected for its low subcutaneous thickness and amenability to proximal vascular occlusion, although in one study of septic shock, tissue oxygen saturation measured over the knee was predictive of 14-day mortality.[66]

Vascular occlusion test

The vascular occlusion test (Fig. 18.1) detects subtle microcirculatory dysfunction, which may persist in covert shock and sepsis despite unremarkable resting StO_2 values. The sphygmomanometer cuff is inflated >30 mm Hg above systolic pressure either for 3 minutes or until StO_2 stabilises at 40%, then released:

- The desaturation slope (DeO_2) corrected for TTH is an index of muscle O_2 extraction ($\text{nir}V_{O_2}$). It is reduced in sepsis and shock states.
- On cuff release the resaturation slope (ReO_2) plus the induced StO_2 overshoot (ΔStO_2) and THI increment (reactive hyperaemia) quantify endothelial integrity, vascular recruitment and perfusion pressure. These are also decreased in sepsis and shock states.

In sepsis, DeO_2 abnormalities are associated with the development of organ failure, increased length of stay and mortality. However, for clinicians at the workface, NIRS and the vascular occlusion test may add little of value to tracking Cv_{O_2} and lactate.[67] Randomised clinical trials are awaited.

THE PROBLEM OF TISSUE HETEROGENEITY

Different tissue beds display important differences in both the magnitude and direction of responses to hypoxic or hypotensive insults,[68] and the identification of dysoxic thresholds in individual tissues remains difficult. More precise knowledge of these variables should eventually provide practical resuscitation end-points in hypoxia and shock, but at present the titration of therapy based on the monitoring of tissue oxygenation remains elusive.

Hyperlactataemia in critical illness

David William Cosgrave, Alisa M Higgins, D Jamie Cooper, Alistair D Nichol

Hyperlactataemia is a metabolic disorder commonly observed in critically ill patients, although the precise prevalence is unknown. The definition of hyperlactataemia has changed in recent times and it is now generally considered to be clinically relevant in critical illness if the lactate concentration is greater than 2.0 mmol/L.[1,2] The previous paradigm considered lactate as a toxin, or a pure waste product, but this has been challenged as we develop a greater understanding of lactate's production and physiological function. It is probable that lactate production in humans has evolved as a substrate for metabolism within muscle and brain, and as a signalling molecule for altering metabolic processes.[3] The work of Brooks et al.,[4-7] and detailed reviews in recent publications,[3,8] have developed this understanding further and in some respects challenge the previous paradigm.

Although it has long been understood that short duration hyperlactataemia occurs during both exercise in healthy athletes and seizure activity, the concept that hyperlactataemia primarily occurs in anaerobic conditions has shifted significantly. We now understand that increased lactate production occurs in response to an increased requirement for energy, and this production occurs simultaneously with increased lactate consumption in certain tissues, such as skeletal muscle.[9]

The concept of lactic acidosis itself has also changed. Acidaemia related to hyperlactataemia tends to only occur at higher lactate levels, whereas the prognostic implications of hyperlactataemia are evident at lower levels, even in the absence of acidaemia.[10,11] It has been suggested that rather than the term lactic acidosis, reference should be made to lactate associated metabolic acidosis, or even hyperlactataemia and metabolic acidosis as two separate entities.[10]

However, despite the increasing understanding of the role of lactate in the human body in times of stress or increased energy requirements, hyperlactataemia during illness correlates with prognosis in a number of settings, most notably during shock states.[10-14]

Understanding the clinical significance of hyperlactataemia is aided by the understanding that severe hyperlactataemia and even acidosis in healthy athletes during substantive exercise is not harmful at all.[15]

LACTATE PHYSIOLOGY

Lactate is produced mainly from glucose and alanine (Fig. 19.1). The intermediate substrate is pyruvate, which exists in equilibrium with lactate and is catalysed by lactate dehydrogenase. Glucose can be metabolised to lactate via either glycolysis or the pentose-5-phosphate pathway. Pyruvate can then be converted into glucose via gluconeogenesis in the liver and kidney.[8] Pyruvate can also be converted into Acetyl-CoA for metabolism within the tricarboxylic acid cycle (TCA) cycle. During this process, adenosine triphosphate (ATP) is produced. The metabolism of lactate also generates ATP, and therefore produces significant amounts of energy, though at a slightly reduced rate.

In health, there is a continuous cycle of lactate production and metabolism. Lactate is produced at about 0.8 mmol/kg per hour, mainly in the skeletal muscle, skin, brain, intestine and red blood cells.[18] Skeletal muscle accounts for ~40% of the net production of lactate in the body.[19] The old paradigm of lactate as a waste product is changing rapidly, with publications by Brooks,[4-6] Philp[17] and Adeva-Andany,[8] leading to an understanding that lactate has multiple functions, including as a fuel and potentially as an intracellular messenger. The liver and kidneys have a major role in production of glucose from lactate. Blood flow through these organs 'clears' lactate – that is, lactate production occurs in the organ, but at a lower rate than its uptake, resulting in clearance of lactate from the blood.[8] The liver has a decisive role in lactate homeostasis and many patients who develop hyperlactataemia have decreased metabolic capacity due to acute or chronic liver disease.[20] It is thought that hyperlactataemia in critical illness may, in part at least, result from impaired clearance rather than solely through increased production.[21]

Normal lactate concentration is 1.0 ± 0.5 mmol/L.[22] Hyperlactataemia is considered to be present in the context of critical illness when lactate concentration exceeds 2.0 mmol/L.[23] However, even at 'normal' levels, relative increases in lactate concentration have been associated with worse prognosis during critical illness.[11]

ABSTRACT

Hyperlactataemia is a metabolic disorder commonly observed in critically ill patients, although the precise prevalence is unknown. The definition of hyperlactataemia has changed in recent times. The previous paradigm considered lactate as a toxin or a pure waste product, but this has been challenged as we develop a greater understanding of lactate's production and physiological function. In this chapter, we examine the emerging paradigm for lactate metabolism and review the current place for lactate in critical care practice.

KEYWORDS

Lactate
lactic acidosis

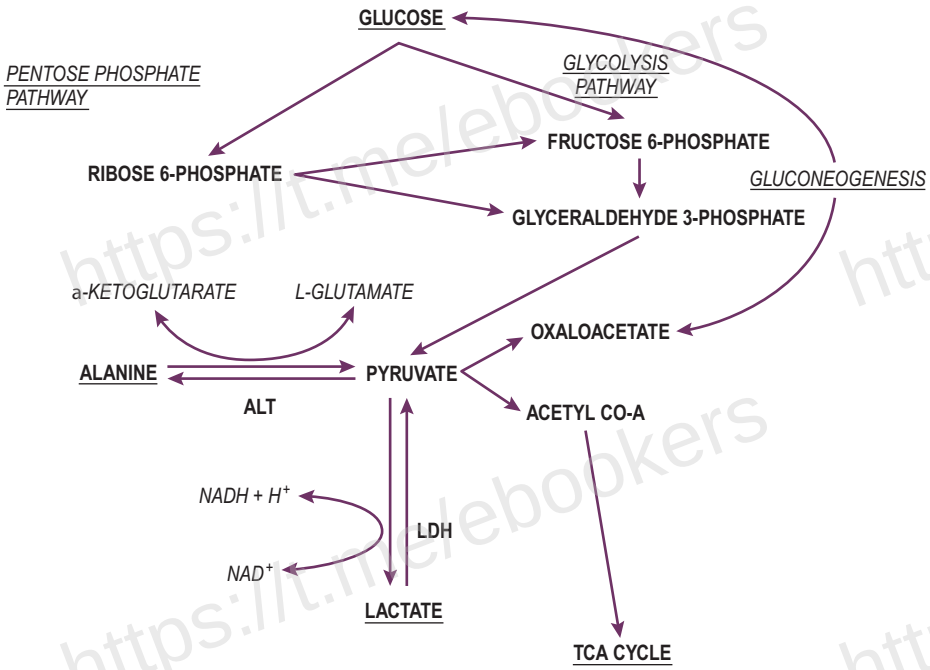

Figure 19.1 Overview of lactate metabolic pathway. *(Modified from figures in Phypers,[16] Brooks,[4-6] Philp,[17] Adeva-Andany.[8])*

In cardiogenic and hypovolaemic shock, hypoperfusion and tissue hypoxia are thought to lead to the increased lactate concentration, while decreased hepatic perfusion may contribute to the decrease in lactate clearance. In septic shock, hyperlactataemia is even more multifactorial, and contributed to by hypoperfusion by microvascular disruption causing regional hypoperfusion and by impaired mitochondrial cellular oxygen utilisation.[10] In critically ill patients, even in the absence of a lactate concentration greater than 2.0 mmol/L, higher admission, and time-weighted lactate concentrations within the normal range have been shown to correlate with poorer outcomes.[11]

The trend of lactate concentrations over time has been shown to be a good prognostic indicator in critically ill patients in numerous recent publications.[13,24-27] Nichol et al. showed significantly better performance of dynamic indices of lactate (namely time-weighted lactate and absolute change in lactate in 24 hours) as prognostic indicators in critical illness.[13]

CLASSIFICATION OF LACTIC ACIDOSIS

The Cohen and Woods classification of lactic acidosis defines two subgroups of lactic acidosis depending on the presence (type A) or absence (type B) of tissue hypoxia (Table 19.1).[28] Type A lactic acidosis due to tissue hypoxia is common in critically ill patients, although clinically, most patients have features of both type A and type B lactic acidosis, with increased lactate formation from tissue hypoxia, and decreased lactate clearance occurring together. Tissue hypoxia is most commonly due to hypoperfusion occurring due to shock (septic, cardiogenic or hypovolaemic), hypotension, cardiac arrest, acute heart failure, or regional hypoperfusion (in particular, mesenteric ischaemia), although it may also be due to reduced tissue oxygen delivery (DO_2) or utilisation due to very severe hypoxaemia, very severe anaemia or carbon monoxide poisoning. Type B lactic acidosis is subdivided into B1 (lactic acidosis occurring in association with an underlying disease), B2 (lactic acidosis due to drugs or toxins) and B3 (lactic acidosis due to inborn errors of metabolism). Given the current changing paradigm, the utility of this classification has been questioned.

SEPSIS

In sepsis, there has been much debate[29] whether the hyperlactataemia results from net increased cellular production[30] or decreased net clearance.[21] It is likely that, in these patients, the cause is multifactorial. As these patients are often haemodynamically unstable, lactate production can increase as a result of inadequate DO_2 from hypoperfusion. Other mechanisms thought to contribute to development of hyperlactataemia in sepsis include increased pyruvate production,[31] release of lactate from lung parenchyma,[32,33] decreased pyruvate dehydrogenase activity[34,35] and decreased clearance of lactate.[36,37]

Table 19.1 Classification of lactic acidosis

Type A	Shock
	Very severe hypoxaemia
	Very severe anaemia
	Carbon monoxide poisoning
Type B1 (underlying disease)	Sepsis
	Liver failure
	Thiamine deficiency
	Malignancy
	Phaeochromocytoma
	Diabetes
Type B2 (drug or toxin)	Epinephrine
	Salbutamol
	Propofol
	Nucleoside analogue reverse transcriptase inhibitor
	Ethanol
	Methanol
	Paracetamol
	Nitroprusside
	Salicylates
	Ethylene (and propylene) glycol
	Biguanides
	Fructose
	Sorbitol
	Xylitol
	Cyanide
	Isoniazid
Type B3 (rare inborn errors of metabolism)	Glucose-6-phosphatase deficiency
	Fructose-1,6 diphosphatase deficiency
	Pyruvate carboxylase deficiency
	Deficiency of enzymes of oxidative phosphorylation

Tissue hypoxia may not be a major mechanism for regional lactate production during sepsis: hyperlactataemia is thought to be linked to the severity of the septic cellular inflammatory response and hypermetabolic state.[29,38] Net lactate production from the hepatosplanchnic bed is uncommon in septic patients[39] and nuclear magnetic resonance spectroscopy suggests that hyperlactataemia may occur without tissue hypoxia.[40]

Despite this incomplete understanding of the exact cause of hyperlactataemia in sepsis, its role as a prognostic marker is clear, with mortality increasing with increasing lactate concentration.[41-43]

BRAIN INJURY

Recent research into the hypothesised astrocyte neuronal lactate shuttle has revealed that lactate may be an important energy substrate in brain metabolism.[44,45] It is hypothesised that lactate is transferred through monocarboxylate transporters as a substrate for ATP generation.[46] This process provides an alternative energy source to compensate for the decrease in glucose uptake in injured brain tissue.[47] Increased brain lactate as measured by cerebral microdialysis has been shown to be associated with improved survival,[48] leading to studies of supplemental lactate to improve outcomes after traumatic brain injury (TBI).[49-51] However, further trials are needed to confirm this potential beneficial effect.

LUNG INJURY

The lung is a primary source of lactate production in patients with acute lung injury, with pulmonary release of lactate being directly related to the severity of lung injury,[33,52] supporting the view that the primary contributors are the tissues with the most inflammation or injury. The increased lactate production by the injured lung is not only secondary to anaerobic metabolism in the hypoxic regions of the lung but also may be due to altered glucose metabolism and a direct effect of cytokines on pulmonary cells.[52]

Laboratory studies suggest that both metabolic and respiratory acidosis protect the lung against injury, whereas correction of acidosis compounds the injury.[53,54] Two ventilator trials,[55,56] which demonstrated a positive impact on mortality in acute respiratory distress syndrome (ARDS) by limiting tidal volume and airway pressures differed widely on how they regarded and managed the resultant hypercapnic acidosis. While Amato et al.[55] allowed elevation of the $PaCO_2$ (permissive hypercapnia) and resultant acidosis, the ARDSnet group[56] aggressively corrected the hypercapnic acidosis by increasing the respiratory rate and allowing administration of sodium bicarbonate. There is growing evidence that not only may hypercapnic acidosis be beneficial in lung injury,[53,57] but also the ARDSnet intervention aimed at correcting the acidosis may also be deleterious.[54,58] These findings have not only promoted a greater tolerance of acidosis during ARDS but also increased reluctance to buffer the acidosis exogenously towards 'normal' values.

ASTHMA

Hyperlactataemia often occurs in patients with acute severe asthma, and the acidosis is often attributed to

fatiguing respiratory muscles,[59] inadequate DO_2 to the respiratory muscles to meet the elevated oxygen demand[60] and liver ischaemia. However, severe hyperlactataemia also occurs in sedated, paralysed, mechanically ventilated patients who have no endogenous respiratory muscle activity.[61] Stimulation of β adrenergic receptors by β agonists, including salbutamol and epinephrine, leads to a variety of metabolic effects including an increase in glycogenolysis, gluconeogenesis and lipolysis[62] – thus contributing to hyperlactataemia. Decreasing intravenous salbutamol infusions to less than 10 mcg/min is usually associated with resolution of the acidosis. In asthma, hyperlactataemia does not have specific prognostic implications.

MESENTERIC ISCHAEMIA AND D LACTIC ACIDOSIS

The diagnosis of mesenteric ischaemia can be challenging to make in the critically ill due to lack of clinical and diagnostic signs, difficulty transferring unstable patients for diagnostic imaging and concern about the deleterious effects of inappropriately administering contrast agents. An ischaemic bowel can produce large amounts of lactate, and the presence of hyperlactataemia in the setting of acute abdominal disease has been proposed as an indicator of mesenteric ischaemia. Animal models have shown that lactate increases within 1 hour of induced intestinal ischaemia. In addition, elevated lactate at the time of diagnosis of mesenteric ischaemia is a predictor of mortality.[63] However, although plasma lactate is a very sensitive marker (100%) for detecting acute mesenteric ischaemia, the low specificity of this marker (42%) is a particular problem in the critically ill, who frequently have many plausible alternate diagnoses.

D-lactate is the isomer of lactate that is produced by intestinal bacterial metabolism and is not produced by humans.[64] Experimental work suggest that ischaemic bowel allows the translocation of D-lactate into the systemic circulation; as D-lactate is not eliminated by the liver, plasma levels may be more specific markers of mesenteric ischaemia. However, many issues need to be clarified, including the effect of antibiotic therapy on the intestinal bacteria, before D-lactate could be considered as a bedside diagnostic test.[65] It is necessary to have a high index of suspicion for mesenteric ischaemia[66] in a deteriorating patient with an elevated lactate in the absence of a convincing alternative diagnosis, as identification of mesenteric ischaemia is frequently made first at laparotomy in the critically ill.

D-lactate production also occurs in patients with short bowel syndrome, a history of jejuno-ileal bypass surgery or chronic pancreatic insufficiency. Since it was originally described in 1979,[67] there have been numerous subsequent reports.

As D-lactate is metabolised slowly, it can accumulate following a large carbohydrate load. D-lactic acidosis is characterised by a normal lactate level, as the assay for lactate only measures L-lactate and a D-lactate level must be specifically requested if D-lactic acidosis is suspected.[68]

CARDIAC PATIENTS

Of the energy requirements of the myocardium, 10%–40% are provided by pyruvate, obtained from both lactate and glucose.[69] Nonetheless, hyperlactataemia has been shown to correlate with poorer outcomes in acute heart failure,[70] acute myocardial ischaemia,[71] post coronary artery bypass grafting[72-74] and following cardiac arrest.[75] Hyperlactataemia during cardiopulmonary bypass is relatively frequent and is associated with an increased postoperative morbidity.[76] Recent work has suggested that this 'on pump' hyperlactataemia is secondary to inadequate peripheral DO_2, which creates a condition similar to cardiogenic shock, leading to both direct lactate formation by dysoxic tissues and to catecholamine release, insulin resistance and hyperglycaemia-induced lactate production.

The use of epinephrine after cardiopulmonary bypass precipitates hyperlactataemia in some patients.[77] This phenomenon is probably β-agonist mediated, is associated with increased whole body blood flow and resolves after substitution of norepinephrine. However, there is emerging evidence that the severity of hyperlactataemia following cardiac surgery is related to certain genetic polymorphisms in tumour necrosis factor and interleukin-10 genes.[78] Similar to asthma, hyperlactataemia associated with the administration of epinephrine in this setting does not have the adverse implications of hyperlactataemia associated with shock (provided that the clinical epinephrine is not an indicator of impaired cardiac function).

Similar to brain-injured patients, there is emerging evidence that supplemental hypertonic lactate infusions may improve cardiac function, without compromising other organ functions.[79,80] This early evidence requires further study before it is adopted into clinical practice.

OTHER UNDERLYING DISEASES

In patients with cancer, anaerobic glycolysis may be increased while hepatic lactate metabolism may be impaired by tumour replacement. Diabetic patients may present with shock, but in non-insulin–dependent diabetes there also may be a defect in pyruvate oxidation, and in diabetic ketoacidosis ketones may also inhibit hepatic lactate uptake. Thiamine and biotin are essential co-factors for pyruvate dehydrogenase activity and for the conversion of pyruvate to oxoaloacetate. Malnutrition (beriberi) and inadequate parental nutrition have therefore been associated with hyperlactataemia due to deficiencies of these co-factors. In

these cases, pyruvate accumulation increases lactate production.

METFORMIN-ASSOCIATED LACTIC ACIDOSIS

Metformin is an oral biguanide, which is used widely in type 2 diabetes mellitus, as it has been shown to decrease cardiovascular morbidity and mortality.[81,82] An Australian tertiary intensive care unit (ICU) reported an incidence of metformin-associated lactic acidosis (MALA) of 6 per 1000 ICU admissions, and a mortality of 29%.[83] A European study found that MALA accounted for 0.84% of all ICU admissions and was associated with a mortality of 30%.[84] In most cases, MALA occurs when the contraindications of metformin have been overlooked or, more commonly, when acute renal failure develops and leads to metformin accumulation.[81,85] Risk factors for developing hyperlactataemia while on biguanide treatment include age greater than 60 years, decreased cardiac, hepatic or renal function, diabetic ketoacidosis, surgery, respiratory failure, ethanol intoxication and fasting.[86]

A Cochrane study analysed pooled data from all prospective comparative trials and observational cohort studies up to 2009, and concluded that there was no current evidence that metformin is associated with an increased risk of hyperlactataemia compared with other antihyperglycaemic treatments.[85] However, MALA continues to be reported, frequently in ICU patients,[83,84,87,88] including in the Australian cohort described above, in which other causes of hyperlactataemia were excluded before a diagnosis of MALA was made.[83]

While the mechanism of MALA is not fully understood, it is thought that biguanides may inhibit oxidative metabolism, and increase the concentration of nicotinamide adenine dinucleotide (NADH), reduce glucogenesis, and suppress the gastrointestinal absorption of glucose.[86] A recent retrospective study comparing 10 MALA patients with 187 patients with hyperlactataemia of other origin (LAOO) found that the survival of MALA with an arterial pH less than 7.00 was significantly better (50% vs. 0%) if MALA was the underlying condition compared to LAOO.[88] These findings have since been supported by further publications.[89,90]

OTHER DRUGS AND TOXINS

The list of potential drugs and toxins that may contribute to the development of hyperlactataemia continues to grow. Nucleoside reverse transcriptase inhibitors (NRTI) used in the treatment of human immunodeficiency virus (HIV)-positive patients cause injury to the mitochondria, which can lead to hyperlactataemia. However, NRTI-induced hyperlactataemia is rare and is often associated with hepatic steatosis.[91] Acute ethanol intoxication can precipitate hyperlactataemia, as ethanol oxidation increases the conversion of pyruvate to lactate and inhibits other pathways of pyruvate accumulation. Underlying alcoholic liver disease and thiamine deficiency may exacerbate the hyperlactataemia. Propylene glycol has also been associated with hyperlactataemia as it is oxidised by alcohol dehydrogenase in the liver to lactate and pyruvate.[92] It is used as a diluent in many medications such as phenytoin, co-trimoxazole, phenobarbitol, lorazepam, diazepam, digoxin and nitroglycerine, and as such, is the most common alcohol intoxication in ICUs.[93]

CLINICAL PRESENTATION

Patients present with clinical signs appropriate to their primary disorder. Hyperlactataemia is a laboratory diagnosis. However, in critically ill patients with shock the severity of hyperlactataemia and dynamic indices of lactate concentrations can reflect a trend towards recovery from the underlying cause. Repeated measures of arterial blood gases and blood lactate are required. In hypovolaemic shock, resolving hyperlactataemia along with the clinical signs of improving perfusion is one of several indicators of successful resuscitation. Conversely, failure of hyperlactataemia to resolve in hypovolaemic shock suggests inadequate resuscitation or another undetected or unresolved clinical problem. In sepsis, the underlying cause of the hyperlactataemia is multifactorial, but slow resolution of hyperlactataemia is still associated with poorer prognosis.

Hyperlactataemia may also occur in the absence of shock. Examples include hypermetabolic states where accelerated aerobic glycolysis may contribute (trauma, burns, sepsis), conditions with increased muscle activity (seizures), labouring parturients and during exogenous lactate administration (lactate buffered haemofiltration fluid). In many of these patients (e.g. patients with seizures) very high blood lactate concentrations have no prognostic implications because the acidosis is rapidly cleared.

MANAGEMENT

GENERAL

The principles of management of patients with hyperlactataemia are to diagnose and correct the underlying condition (where possible), and restore adequate tissue DO_2. In critically ill patients, hyperlactataemia is often an indicator of major patient pathology. Therefore, the main focus is to identify and treat the cause rapidly. A clinical examination and search for occult sepsis, inadequate resuscitation, localised ischaemia or cardiovascular failure is urgently required. In each case, after diagnosis and initial management, hyperlactataemia may then be used as an ongoing monitor of disease progression or resolution. Lactate kinetics have been shown to have prognostic value

in the care of critically ill patients. Decreasing lactate levels over time have been associated with improved outcomes,[13] and appear to be independent of initial lactate values.[94]

TREAT THE PRIMARY DISORDER

Specific therapies and supports must be directed at each underlying cause. In hypovolaemic and cardiogenic shock, restoration of an adequate global DO_2 is required. Vasoconstrictors may worsen tissue perfusion and should only follow adequate intravascular volume and appropriate cardiac support. In septic shock, antibiotics appropriate to cover all likely sources of infections are a priority, and in patients with possible ischaemic gut, surgery may be required for both diagnosis and therapy. Postsurgical gastrointestinal leaks may sometimes be difficult to diagnose, may not be detectable on computed tomography and may require early laparotomy. In status epilepticus, hyperlactataemia is a result of muscle activity and the rapid use of effective anticonvulsants is indicated. In diabetic ketoacidosis, insulin, appropriate fluid and treatment of precipitants enable the resolution of all metabolic abnormalities, including associated hyperlactataemia. In thiamine deficiency, highlighted during a nationwide American shortage of multivitamins for patients receiving total parenteral nutrition,[95] high-dose intravenous thiamine corrected both the vasodilated shock and associated hyperlactataemia. In acute severe asthma, hyperlactataemia is commonly a result of high-dose intravenous β-agonist therapy.[62,77] Salbutamol dose reduction usually resolves the problem. In vasodilated patients after cardiopulmonary bypass, hyperlactataemia may also be related to β-agonist therapy and resolves after substitution of intravenous epinephrine with norepinephrine.[77] In these cases, hyperlactataemia is not related to decreased tissue perfusion, and adverse effects upon prognosis have not been noted. Patients with HIV receiving NRTI therapy have a high incidence of hyperlactataemia (8.3%), which can progress to a rapidly fatal metabolic syndrome. These patients with NRTI-induced mitochondrial dysfunction require withdrawal of the therapy (if lactate >5 mmol/L), and close monitoring.[91,96,97]

HYPERVENTILATION

Hyperventilation is a normal compensatory response to metabolic acidosis in conscious patients. Therefore, in mechanically ventilated patients with hyperlactataemia and acidosis, clinicians will usually use some hyperventilation to partially correct acidaemia. Clearly, in patients with pulmonary pathology, hyperventilation may be difficult or inappropriate, and in some patients, hyperventilation increases intrathoracic pressure, decreases venous return, decreases cardiac output and exacerbates the cause of hyperlactataemia.

BICARBONATE

Minimising bicarbonate therapy for the treatment of acidosis during hyperlactataemia is much less controversial than in the past.[2,98-100] It was thought that correction of the acidosis through the administration of bicarbonate might reverse depressed cardiac performance; however, there is no evidence in critically ill patients that hyperlactataemia depresses cardiac function, and laboratory studies report minimal depression in large animals.[101,102] Further, not all studies have actually demonstrated a rise in pH after the administration of bicarbonate.[103] One reason for these findings is that sodium bicarbonate also has adverse effects, including acute hypercapnia and ionised hypocalcaemia,[104] which outweigh the potential benefits in patients. Hypercapnia may increase intracellular acidosis (CO_2 crosses cell membranes rapidly) and hypocalcaemia decreases myocardial contractility.[105] Other side effects of bicarbonate occur because bicarbonate is a hypertonic solution; the side effects include acute intravascular volume overload and cardiac depression. In addition, bicarbonate increases lactate production by increasing the activity of the rate-limiting enzyme phosphofructokinase, shifts the haemoglobin–oxygen dissociation curve, increases oxygen affinity of haemoglobin and thereby decreases DO_2 to tissues.

While some clinicians continue to use bicarbonate in patients with a pH less than 7.20, the most recent Surviving Sepsis guidelines published in 2016 strongly recommend against the use of bicarbonate when treating hypoperfusion-induced lactic acidaemia in patients with a pH ≥7.15,[106] while others have recommended a lower target pH of 7.00 or less.[100] There are no large randomised controlled trials of the use of bicarbonate in hyperlactataemia, and the only two randomised crossover studies in critically ill patients with hyperlactataemia and shock found no improvement in cardiac function or any other beneficial effects of pH correction.[104,107] As such, bicarbonate has never been shown to be beneficial in any clinical trial of patients with hyperlactataemia, and its use in these patients is not recommended, regardless of the degree of acidaemia.[2]

However, there are two specific subgroups of patients with hyperlactataemia in whom bicarbonate should be considered. First, patients with pulmonary hypertension and right-sided heart failure (e.g. lung transplant recipients) often have pulmonary vasoconstriction, which is exacerbated by acidosis. In these patients, although there are other useful therapies, including inhaled nitric oxide, partial pH correction may improve right-sided heart function. Second, patients with significant ischaemic heart disease and hyperlactataemia with acidosis may be at increased risk of major arrhythmias because severe acidosis lowers the myocardial threshold for arrhythmias. In both of these subgroups, slow bicarbonate infusions to keep the arterial pH above 7.15 may be justified.

LACTATE AS A TREATMENT

HALF MOLAR SODIUM LACTATE

Evidence for the use of half molar lactate as a resuscitation fluid, and a treatment in specific circumstances is increasing. A growing body of evidence is emerging to support the potential benefit of infusion of hypertonic lactate in traumatic brain injury. The theory behind this research is that glucose metabolism is impaired in the injured brain, and therefore lactate provides a preferential or opportunistic energy substrate for the injured brain tissue.[46,50,51,108-111] In a pilot study of patients with acute cardiac failure, hypertonic lactate was shown to improve cardiac performance compared to compound sodium lactate.[79] In a trial comparing hypertonic lactate to compound sodium lactate post-coronary artery bypass grafting, hypertonic lactate resulted in a higher cardiac index with a lower infused fluid volume.[112] Animal studies have shown the infusion of hypertonic sodium lactate to have beneficial effects on haemodynamics and fluid balance in a pig model of endotoxic shock.[113] Whether it will become a resuscitation fluid in critical illness remains to be seen.[80]

Acute cardiac syndromes, investigations and interventions

Bradley Power, Ian Seppelt

Cardiovascular disease (CVD) accounts for one in three deaths in Western industrialised society, with coronary artery disease (CAD) being responsible for about half of these.[1] Up to 70% of CAD deaths occur outside hospital as 'sudden death' from cardiac arrest.[2] In persons over age 40, acute myocardial infarction (MI) is the cause of approximately 20% of all deaths. Of those who die acutely, 50%–65% have no previous history of cardiac disease. Of patients admitted to hospital, early mortality is 5%–7% (much higher in at-risk groups) and may rise to 7%–18% by 12 months.[2–5] Improving in-hospital and longer-term CAD mortality requires rapid identification of at-risk patients and the implementation of evidence-based treatments.

MYOCARDIAL INFARCTION

MI is present when there is evidence of myocardial necrosis in a clinical setting consistent with myocardial ischaemia. Diagnosis involves clinical suspicion, with supportive electrocardiography (ECG), biomarkers, echocardiography or autopsy findings confirming the diagnosis.

MI can result from different pathological and epidemiological mechanisms (Box 20.1).[2,6,7] Each mechanism may have a different prognosis despite similar biomarker or ECG changes and the patterns of MI may be different in an emergency department, surgery or intensive care unit (ICU) population. This may be clinically important when applying trial results or guidelines to such populations. Small amounts of myocardial necrosis can occur with heart failure (HF), arrhythmias, pulmonary embolism or after uneventful cardiac procedures; these are better labelled 'myocardial injury' rather than MI.[6]

ACUTE CORONARY SYNDROMES

Acute coronary syndromes (ACS) describe the spectrum of patients who present with chest discomfort or other symptoms of acute myocardial ischaemia (Box 20.2). ACS can be further divided into MI and unstable angina (UA). Both are invariably caused by recent thrombus formation on pre-existing coronary artery plaque, occasionally by embolism or artery dissection. In this sense, they differ from stable angina, which is usually precipitated by increased myocardial oxygen demand with significant background coronary artery narrowing. ACS are medical emergencies and are one of the most frequent causes of hospital and coronary care unit admission.

An immediate clinical imperative is identification of patients with ST-segment elevation (STE), as rapid reperfusion therapy is strongly indicated in this group.

AETIOLOGY AND RISK FACTORS

Atheroma deposits in coronary artery walls provide the substrate for ACS. Risk factors for CVD and CAD include cigarette smoking, diabetes, dyslipidaemia, hypertension and family history.[8] About 85% of patients presenting with an initial MI have at least one risk factor.[9]

Cessation of smoking, lowering plasma cholesterol (diet and medications), weight loss and adoption of an active lifestyle can all help reduce the development of CAD.[8,10] In a large meta-analysis of trials comparing antihypertensive regimens in patients at high risk of CVD, a 10 mm Hg reduction in systolic blood pressure (SBP) resulted in a relative risk reduction (RRR) in major CVD events (20%), coronary heart disease (17%), stroke (27%) and HF (28%) with a 13% RRR in all-cause mortality.[11]

PATHOPHYSIOLOGY[11,12]

Formation of thrombus upon ruptured, fissured or eroded atheromatous plaque is the usual precipitant of an ACS (Fig. 20.1).[6,8,13] Atherosclerotic plaque formation is probably initiated by vessel wall injury that may commence as early as childhood. 'Fatty streaks' formed from lipid engorged macrophages (foam cells), and T lymphocytes, accumulate in the intima of arteries. Such cells accumulate lipid, but are also pro-inflammatory. As large amounts of lipid accumulate they may become covered by a fibromuscular

ABSTRACT

Acute coronary syndromes (ACS) are predominantly caused by acute thrombus formation upon eroded or ruptured atherosclerotic coronary plaque. They include unstable angina and myocardial infarction (MI; identification of STEMI and NSTEMI strongly guides acute therapy). History, examination, serial ECGs and cardiac biomarkers usually allow the diagnosis to be made. Atherothrombotic processes require immediate antiplatelet and antithrombotic therapy. Immediate identification of STE facilitates urgent reperfusion using coronary cardiac catheterisation (PCI) or pharmacological therapy. Serial risk scoring of NSTEMI is necessary to guide the optimal timing and nature of invasive, non-thrombolysis therapies. Clinical guidelines from controlled trials define optimal acute and long-term therapies for the management of antiplatelet, antithrombotic and 'cardiac' risk factors. ICU management indications can include heart failure, cardiogenic shock, arrhythmias and bleeding. Current knowledge of MI therapies is vital in the care of patients with a history of cardiac disease and in patients undergoing non-cardiac surgery or therapy.

Box 20.1 Universal classification of myocardial infarction

Type 1: Spontaneous myocardial infarction
Spontaneous myocardial infarction related to ischaemia due to a primary coronary event such as plaque erosion and/or rupture, fissuring or dissection. The patient may have severe coronary artery disease (CAD) but on occasion non-obstructive or no CAD.

Type 2: Myocardial infarction secondary to an ischaemic imbalance
This occurs in instances of myocardial injury with necrosis where a condition other than CAD contributes to an imbalance between myocardial oxygen supply and/or demand; for example, coronary endothelial dysfunction, coronary artery spasm, coronary embolism, tachy-/brady-arrhythmias, anaemia, respiratory failure, hypotension and hypertension with or without left ventricular hypertrophy (LVH).

Type 3: Myocardial infarction resulting in death when biomarker values are unavailable
Cardiac death with symptoms suggestive of myocardial ischaemia, and presumed new ischaemic changes or new LBBB, but death occurring before blood samples could be obtained, before cardiac biomarkers could rise or, on rare cases, biomarkers were not collected.

Type 4a: Myocardial infarction related to percutaneous coronary intervention
Significant cardiac biomarker rise from normal or by more than 20% if previously elevated. In addition, either:

i. symptoms of myocardial ischaemia, *or*
ii. new ischaemic ECG changes or LBBB, *or*
iii. angiographic loss of patency or persistent flow abnormalities, or embolisation, *or*
iv. imaging demonstration of loss of viable myocardium or regional wall motion abnormality.

Type 4b: Myocardial infarction related to stent thrombosis
Myocardial infarction associated with stent thrombosis detected by coronary angiography or autopsy in setting of myocardial ischaemia and with a significant rise and/or fall of biomarkers.

Type 5: Myocardial infarction related to coronary artery bypass grafting (CABG)
Myocardial infarction associated with CABG arbitrarily defined by elevation of cardiac biomarker values from normal baseline to above 10 times the URL. In addition, either:

i. new pathological Q waves or LBBB, *or*
ii. angiographic documented new graft or new native coronary artery occlusion, *or*
iii. imaging evidence of new loss of viable myocardium or new regional wall motion abnormality.

Box 20.2 Classification of acute coronary syndromes

Acute coronary syndrome (ACS)
A spectrum of clinical conditions characterised by acute chest pain or myocardial ischaemia. Pain is of recent origin or is more frequent, severe or prolonged than known angina, is more difficult to control with medication or occurs at rest or with minimal exertion.

ACS includes myocardial infarction with ST-segment elevation (STEMI), myocardial infarction in the absence of ST-segment elevation (NSTEMI) and unstable angina. An initial clinical subdivision of ACS is made on the presence or absence of electrocardiography ST-segment elevation.

STEMI
Patients presenting with ST-segment elevation ACS will invariably display initial or subsequent troponin elevation, although the extent of myocardial infarction and complications may be significantly moderated by intervention.

NSTEACS
Patients who present without ST-segment elevation, may later (after testing of biomarkers) be determined to have:

i. *NSTEMI:* cardiac biomarkers elevated indicating myocardial infarction
ii. *Unstable angina:* no evidence of cardiac biomarker elevation.

cap forming a 'fibrous plaque'. Plaque development is often slow but may rapidly accelerate in people with risk factors.

'Vulnerable plaque' is often rich in lipid and covered by a thin fibrin cap. Fatal MI may demonstrate plaque **rupture (75%)** or plaque **erosion (25% of cases)**. Ruptured plaque may have a thin cap, large necrotic core, inflamed and neovascularised tissue, and haemorrhage. Eroded plaque is often thin walled with a core that has less necrosis and inflammation. Both expose thrombogenic lipid and collagen, which are potent activators of platelets.

Platelet adherence and activation, and subsequent activation of the clotting cascade, result in an 'atherothrombotic processes'. Platelets aggregate to form *'white thrombus'*. The final common pathway of thrombus formation is via activation of the platelet glycoprotein (GP) IIb/IIIa receptor, which binds fibrinogen and cross-links platelets. Activation of coagulation pathways by exposed lipid and fibrin, and by activated platelets, leads to thrombin activation and fibrin clot formation. Red cells are enmeshed in this so-called *'red thrombus'* complex, which surrounds the 'white thrombus'. While *'culprit lesions'* of ST-segment elevation myocardial infarction (STEMI) can be small (<50% stenosis), studies suggest that 86% of patients had at least a moderate stenosis (>50%) and 67% had a severe stenosis (>70%).[14,15]

The pathophysiology above has immediate relevance to treatment (see Fig. 20.1).

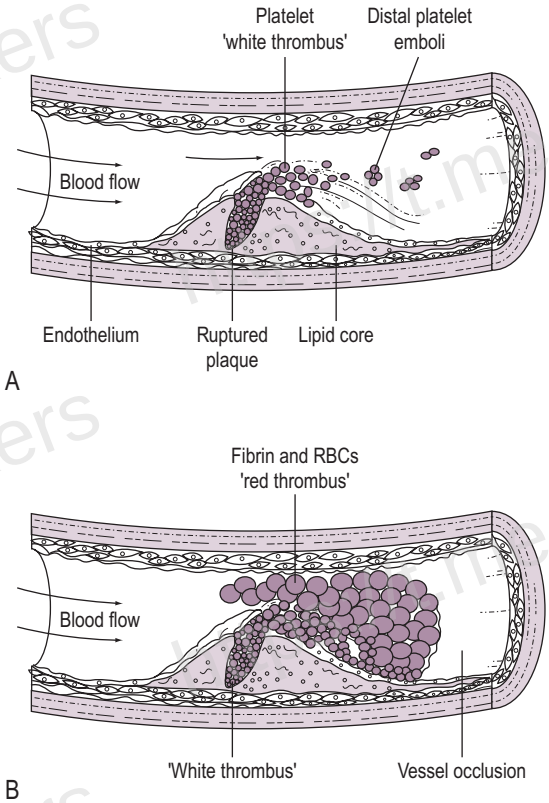

Figure 20.1 (a) Plaque rupture exposes thrombogenic lipid. 'White thrombus' is formed by adherent activated platelets. Coronary artery narrowing, distal platelet embolisation or arterial spasm can cause ischaemic myocardial pain and possible myocardial necrosis. This lesion is unstable and may lead to thrombin activation. 'White thrombus' is not removed by thrombolytic therapy. (b) Thrombin activation leads to a mesh of fibrin and red blood cells (RBCs) or 'red thrombus'. Arterial occlusion may result and, in arteries without adequate collateral circulation, myocardial necrosis follows. Complete arterial occlusion is suggested by ST-segment elevation on the electrocardiogram. Prompt reperfusion with thrombolytic therapy or with invasive coronary procedures may prevent extensive myocardial necrosis.

- **Antiplatelet agents** prevent platelet adherence, limiting and even reversing 'white thrombus' formation. Aspirin blocks thromboxane A_2 synthesis, but fails to block platelet activation by thrombin, adenosine diphosphate (ADP) and collagen. New agents may target ADP receptors (e.g. clopidogrel, prasugrel) or may inhibit cyclo-oxygenase (e.g. aspirin).
- **Fibrinolytic agents** lyse 'red thrombus' but not 'white thrombus'.
- **Antithrombin agents** (e.g. heparins) limit thrombin activation. Current fibrin-specific thrombolytic agents lyse fibrin and red cell thrombus, but paradoxically may increase surface thrombin activation.

Totally occluding thrombus causes myocardial necrosis unless there is collateral flow or rapid thrombus clearance. Occlusion is often accompanied by ECG changes of STE although this is not absolute. Non-occlusive thrombus may be asymptomatic, or may cause USA or MI, especially if spasm or distal thrombus embolisation occur. Thrombus retrieved 'early' during percutaneous coronary intervention (PCI) thrombectomy in STEMI patients surprisingly may be predominantly 'white thrombus' (up to 30% of samples), with smaller infarction. Red thrombus may be a sign of a maturing clot.

Infarct size determines

- left ventricular (LV) systolic function impairment
- stroke volume decrease
- ventricular filling pressure rise (leading to pulmonary congestion and hypotension that may impair coronary perfusion pressures and exacerbate the myocardial ischaemia)
- LV diastolic dysfunction.

CLINICAL PRESENTATION

The diagnosis of myocardial ischaemia is usually made (suspected) on the basis of clinical history and ECG.[2,4–7,16]

HISTORY[17]

Patients with myocardial ischaemia can present with chest pain or pressure, syncope, palpitations, dyspnoea, fatigue or sudden death. Prodromal USA symptoms may occur in the days preceding infarction in 20%–60% of patients although this is less likely in young patients.

Typically, the pain of acute MI:

- is severe, constant and retrosternal, spreading across the chest
- lasts greater than 20 minutes and is without a clear precipitant
- may radiate to the throat and jaw, down the ulnar aspect of both arms and to the interscapular area
- autonomic symptoms of sweating, nausea, pallor, dyspnoea, anxiety are common

The pain of USA may be similar but milder. Ischaemic features are:[4,5]

- waxing and waning
- reproducibility upon minimal exertion or emotion
- autonomic symptoms.

The pain can be atypical, leading to misdiagnosis:

- epigastric
- confined to the jaw, arms, wrists or interscapular region
- burning or a 'pressure-like' sensation.

Differential diagnosis includes may include pericarditis, aortic dissection or massive pulmonary embolism.

Atypical or silent presentations are common (25% of STEMI patients and 45% of non–ST-elevation

myocardial infarction [NSTEMI]).[7,16,18] Patients who present without classic chest discomfort are less likely to receive definitive treatment. Such presentations are more common in patients who are elderly, female, diabetic, obese or have a history of HF.

The assessment of clinical symptoms alone is insufficient for risk stratification and severity of pain does not usually correlate with the extent of infarction.

PHYSICAL EXAMINATION

Examination of patients with USA is often unremarkable. With severe ischaemia and extensive MI, autonomic activation (pallor, sweating, agitation, clamminess) as well as HF and even shock may be apparent.

LV failure (LVF) is associated with increased mortality, signs including gallop rhythm, tachycardia, tachypnoea and basal crackles.[18] A fourth heart sound is common, but a third heart sound usually indicates a large MI with extensive muscle damage. Soft systolic murmurs may be present and may be transient or persistent. These murmurs may result from mitral regurgitation (MR), due to papillary muscle dysfunction or LV dilatation.

Cardiogenic shock (CS) (poor peripheral perfusion, hypotension, oliguria and other features of 'low cardiac output') is associated with particularly poor outcome unless perfusion can be rapidly restored. Right ventricle (RV) infarction[2,19] results in hypotension and marked elevation of the jugular venous pressure, with clear lungs.

Conditions that can mimic ACS but do not benefit from thrombolysis include pericarditis and Takotsubo syndrome. Aortic dissection may be present in 1.3% of STEMI, and diagnosis may be realised during PCI. If suspected on presentation, immediate echocardiography (and possible computed tomography angiography) is indicated to confirm the diagnosis and assist with surgical planning. Coronary artery involvement may cause associated MI.

INVESTIGATIONS

The presence of MI should also be qualified by:

- anatomical location and size
- causation (e.g. MI Type 1–5) (see Box 20.1)
- time from occurrence (acute, early, late).

Technological advances in biomarker assays allows detection of very small infarcts.

ELECTROCARDIOGRAPHY[20–24]

The ECG is the initial single most cost-effective, clinically useful and predictive test for diagnosis and guidance of the emergency treatment of MI. All patients presenting with symptoms suggestive of MI should have an ECG performed and interpreted by an experienced person within 10 minutes of arrival.[25] Initial ECGs may (i) reveal significant STE-ACS, (STEACS); or (ii) suggest non-STE-ACS (NSTEACS). Serial 12-lead ECGs are necessary as STE may develop after initial assessment and changes may indicate response to therapies.

Acute and complete occlusion of a coronary artery usually leads to serial ECG changes in leads subtending the area of ischaemia, where the:

- number of leads involved broadly reflects the extent of myocardium involved
- height of initial STE is only modestly correlated with the degree of ischaemia[24]
- acute resolution of STE correlates well with reperfusion.

Recognition of STE and its evolution indicates patients in whom reperfusion therapy may interrupt, or minimise myocardial necrosis (Fig. 20.2). These changes are not stereotyped and may vary significantly but include:

- *hyperacute* (0–20 minutes): tall, peaking T-waves and progressive upward coving and elevation of ST-segments
- *acute* (minutes to hours): persisting STE, gradual loss of R-wave in the infarcted area. Progressive inversion of T-waves
- *early* (hours to days): loss of R-wave and development of pathological Q-waves in area of ischaemia. Return or fall of ST-segments to baseline. Persistence of T-wave inversion
- *indeterminate* (days to weeks): pathological Q-waves with persisting T-wave inversion. ST-segments normalise (unless there is aneurysm)
- *old* (weeks to months): persisting deep Q-waves with normalised ST-segments and T-waves.

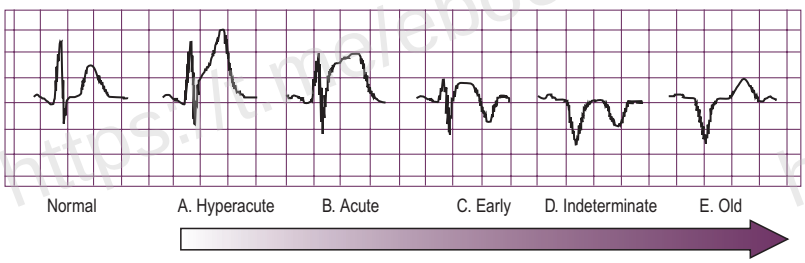

Figure 20.2 Total acute coronary occlusion leads to serial electrocardiogram changes. The evolution is variable and may be interrupted or altered by successful reperfusion. ST-segment elevation is an early and relatively specific indicator of the need for acute reperfusion in patients with acute coronary syndrome.

Clinical skill is needed to identify those ECG changes that are probably due to MI (true positive but also false negative). Other causes of STE and T-wave changes that should *not* lead to thrombolytic therapy are shown in Box 20.3.[6,26,27]

Takotsubo syndrome[28,29] may mimic an ACS and can represent up to 1%–2% of STEACS-like presentations.

Box 20.3 Electrocardiogram patterns mimicking ST-segment elevation myocardial infarction

Normal variant (non-ischaemic STE mainly V2–V3)
Early repolarisation (notched J-point mainly in anterolateral leads)
Metabolic disturbance (mainly hyperkalaemia, hypercalcaemia)
Drug toxicity
Brugada syndrome
Pre-excitation (Wolff–Parkinson–White syndrome)
Pericarditis
Myocarditis
Previous (old) myocardial infarction
Left ventricular aneurysm
Spontaneously reperfused myocardium
Apical ballooning syndrome (Takotsubo or 'broken heart') multiple causes, for example severe emotion, physical stress

Data from Thygesen K, Alpert JS, Jaffe AS, et al. Third universal definition of myocardial infarction. *Eur Heart J*. 2012;33(20):2551–2567; and Pollak P, Brady W. Electrocardiographic patterns mimicking ST segment elevation myocardial infarction. *Cardiol Clin*. 2012;30(4):601–615.

Patients with ACS but with 'non-significant STE' (NSTEACS until further subdivided by biomarker studies) are also at risk of MI and death. They commonly have active, non-occluding thrombus, or occlusion if present may be to an area with collateral flow or with poor detection of by standard lead placements. ECGs in these ACS patients may be normal or display[20–24]:

- ST-segment depression
- STE (insufficient to meet thrombolysis criteria)
- T-wave inversion or 'normalisation' of previous inverted T-waves.

LOCALISATION OF INFARCTION[20–24,30] (Fig. 20.3)

Coronary artery anatomy is displayed in Fig. 20.3. A very general relationship of ECG, MI locating leads and likely 'culprit arteries', is outlined in Table 20.1 and in cited references.[20–24] ECG 'localisation' may differ from angiography, echocardiography and autopsy findings, however, especially where there is collateral circulation or previous coronary artery bypass grafting (CABG). Approximately 40%–50% of patients may present with anterior infarctions which may be septal, anterior or lateral (Fig. 20.4a).[21] About 50% may present with acute inferior MI (see Fig. 20.4b),[20–24] which may involve extension to the lateral, posterior or RV myocardium.

Standard ECGs generally only record from anterior body leads and thus important ECG patterns that must not be missed can include.[20,22–24,31]

- **True or 'isolated' or 'strictly' posterior wall MI** (3% of MI, although posterior involvement may accompany 15% of STEMI) is important to diagnose as its amount of threatened myocardium is similar to that

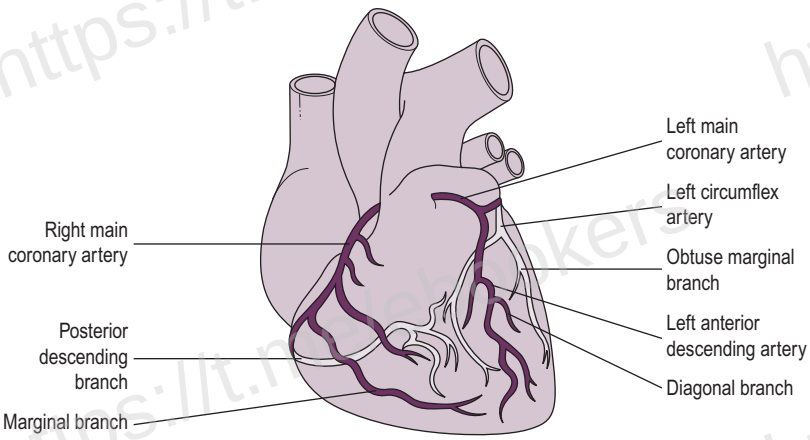

Figure 20.3 Coronary artery anatomy. The left anterior descending artery supplies the anterior two-thirds of the interventricular septum (septal perforators), anterior and lateral wall of the left ventricle (LV: diagonal branches) and sometimes part of the right ventricle (RV). Circumflex (Cx) supplies the LV lateral (anterolateral marginal branches) and posterior walls, and occasionally its inferior aspect (posterior LV arteries: 15% of patients) and the posterior septum. The right coronary artery (RCA) supplies the RV wall, and usually the posterior septum and inferior (diaphragmatic) wall of the LV (posterior LV arteries; 85% of people). The RCA is 'dominant' (as opposed to the Cx) if it gives rise to the posterior descending coronary artery and the posterior left ventricular arteries.

Table 20.1 Electrocardiogram patterns of myocardial injury

ANTERIOR WALL	ST-SEGMENT ELEVATION	
'Extensive anterior' (anterolateral)	V_1–V_6, I, aVL	Proximal LAD occlusion
Septal	V_1–V_3, disappearance of septum Q in leads V_5, V_6	LAD-septal branches
Anterior (localised or true)	V_2–V_5, I, aVL	Diagonal (supplies anterior LV wall) Occasionally marginal branch of CX
Lateral	V_5, V_6, I, aVL,	Distal LAD or circumflex
INFERIOR WALL		
Inferior (localised)	II, III, aVF	RCA (80%) or postlateral branch of CX (20%)
Inferior (extended)	II, III, aVF ***plus***	
Inferolateral	I, aVL, V_5, V_6	RCA or dominant CX
Inferoposterior	V_7, V_8, V_9 with ST depression V_1–V_2	RCA post descending branch or posterolateral branch of CX
Right ventricular	V_1, V_3R, V_4R	Proximal RCA
Posterior (localised)*	V_7, V_8, V_9. (Elevation II, III, aVF may not be marked) Initial V_1, V_2 ST depression may evolve to tall R waves	RCA

*Posterior infarctions are usually identified as lateral on angiography but guidelines suggest that the name be retained. Lack of ST elevation on standard leads may lead to failure to appreciate that they are a STEMI and will benefit from reperfusion therapy. Clinicians should also be aware of novel patterns of ischaemia and 'STEMI equivalents' that may include 'Wellens phenomenon', STE elevation in aVR, ST changes in the presence of left bundle branch block (LBBB) and the de Winter ST/T complex.

The sensitivity, specificity and predictive value of these patterns in determining the culprit artery (as subsequently determined by angiography) are not perfect. This is especially true of occlusions of the RCA and CX.

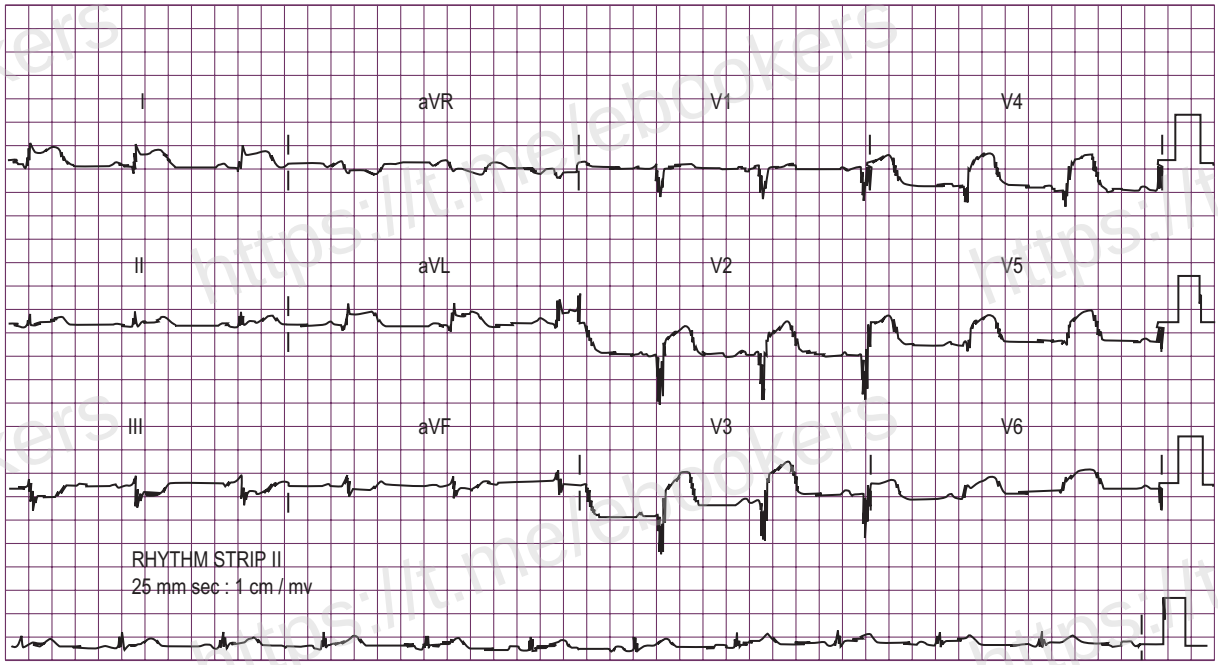
CX, Circumflex coronary artery; *LAD,* left anterior descending coronary artery; *RCA,* right coronary artery; *STEMI*, ST-elevation myocardial infarction; *VF,* ventricular fibrillation.

of inferior MI.[30] It usually causes 'mirror' changes in leads V_1–V_2 and although there might be STE in inferior leads II, III, AVF it might not have met diagnostic criteria for reperfusion. Non-standard posterior chest leads (V_7–V_9) usually show STE. Such MIs are usually lateral but the term 'posterior' is still retained.[20,22–24,31]

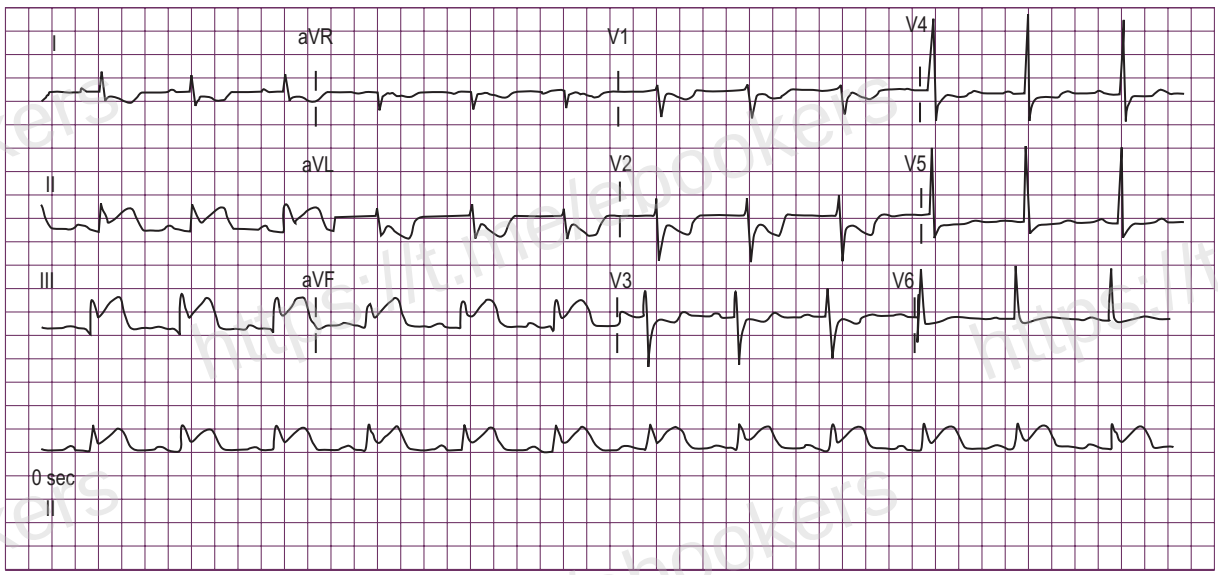
- **RV MI** is usually concurrent (20%–60%) with inferior wall MI where suspicious findings include STE in V_1 (overlies the RV), and STE lead III greater than lead II. A V_4R lead may show STE and is sensitive and specific for RV MI, although in 50% of cases it lasts less than 10 hours.[32] Sinus bradycardia and AV node block may be present.
- Resting ECG changes revealing significant ST-segment depression in six or more body surface leads coupled with STE in aVR and/or V_1 are highly suggestive of **left main coronary artery (LMCA) obstruction** or **multivessel disease** (severe 3-vessel disease or 'left main equivalent').[2,21,22] These changes may even completely disappear when the patient is asymptomatic and should not be ignored.
- The specific pattern of deep T-wave inversion in V_2–V_4 with QT interval prolongation may suggest severe **proximal left anterior descending coronary artery (LAD) disease**. It may occur **after** chest pain but be associated with imminent occlusion.[21,22]
- **A normal ECG** may be present in 15%–20% of NSTEMI, although a normal ECG during pain is unusual.[20,22–24] A small percentage of patients progressively lose R-wave height and develop evidence of Q-waves and a small number progress to CS.

CARDIAC BIOCHEMICAL MARKERS (TROPONINS)[6,7,20] (Fig. 20.5)

Cardiac troponins (cTn) can be detected in serum by monoclonal antibodies to epitopes of cTnT and cTnI. These antibodies are highly specific for myocardial, and not skeletal, muscle. Myocardial necrosis produces an initial release of cTn within the cell cytosol. Serum levels are usually detectable 4–6 hours post-MI, with a peak level at 18–24 hours. Return to normal usually occurs over 7–14 days. Renal failure prolongs excretion.



A



B

Figure 20.4 (a) Evolving anterolateral myocardial infarction. There is ST-segment elevation (STE) in anterior leads V_2–V_6 and lateral leads I, aVL. There is loss of anterior R wave height, and reciprocal ST-segment depression in leads III and aVF. If within time frames or if shocked, urgent reperfusion is indicated. (b) Acute inferior myocardial infarction (STE in the inferior leads II, III and aVF). There is ST depression in leads I, aVL, V_1 and V_2. The addition of right-sided (V_4R) and posterior leads would help identify the presence of right ventricle and posterior infarction (STE). Reciprocal ST-segment depression in leads remote from the site of infarction is a highly sensitive indicator of myocardial infarction. It may be seen in 70% of inferior and 30% of anterior infarctions.

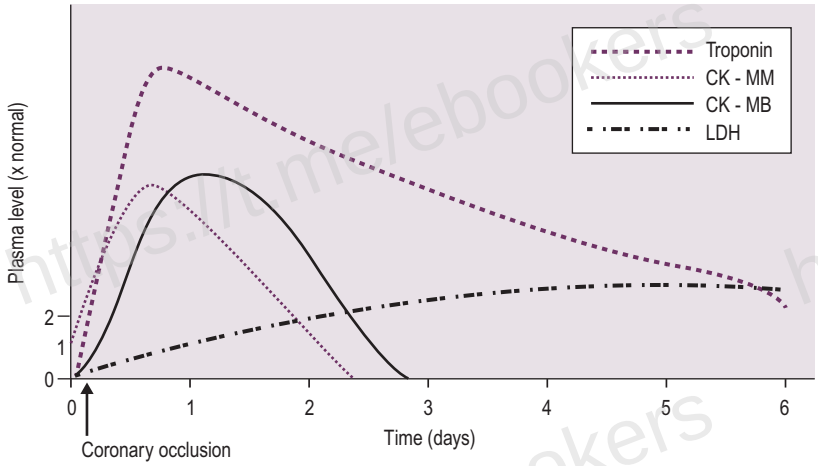


Figure 20.5 Serum biochemical marker changes after acute myocardial infarction. The sensitivity and specificity of cardiac troponins makes them useful for the early diagnosis of myocardial infarction. Their delayed fall may allow diagnosis where presentation is late. CK or CK-MB is useful if re-infarction with secondary biomarker rise is queried. *LDH*, Lactate dehydrogenase.

- High sensitivity and specificity has made cTn the gold standard for the confirming MI.[6,7]
- cTns should be measured in all patients with ACS. Levels should be taken on arrival, and at 3–6 hours. Acute rise and fall help separate ACS from other cTn elevations.
- Elevated levels of cTN in Type 1 MI (see Box 20.1), correlate well with unstable plaque, risk stratification and evidence-based therapies.
- The high sensitivity of cTn means that many people, previously diagnosed as USA, now meet diagnostic criteria for MI.[7,20,23,33]
- Troponins do not differentiate the cause of the myocardial injury (e.g. ischaemia, myocarditis, trauma), thus the clinical context must always be considered.[6]
- New markers of myocardial necrosis, including cardiac myosin binding protein C (cMyC), and soluble mRNA for vascular cell adhesion molecule-1 and interleukin-6, are currently undergoing clinical evaluation. At the time of writing, cMyC is showing promise as a rapid diagnostic test of myocardial necrosis.[34]

The importance of troponins in critical illness is discussed in Chapter 24.

ECHOCARDIOGRAPHY[35] (See Chapter 27)

Echocardiography is one of the most powerful diagnostic and monitoring tools available to assist with diagnosis and management of ACS. All tertiary ICUs should have 24-hour echocardiography access.[35] Two-dimensional transthoracic (and transoesophageal) echocardiography is used to assess presence degree of regional or global LV dysfunction. It identifies regional wall motion abnormalities (RWMAs), helping confirm or exclude the diagnosis of MI in cases where it is uncertain (e.g. left bundle branch block, or old MI with atypical presentations). RWMA and loss of wall thickening with contraction are often present in these cases if due to ischaemia.[6]

Echocardiography is useful subsequently and in ICU populations to:

- assess infarct size, especially if thrombolysis has interfered with biomarker measurement
- identify RWMA where Tn is elevated but the MI predictive value is uncertain (43% of ICU patients may have an elevated Tn when it is tested)[36]
- rapidly assist differential diagnosis (e.g. aortic dissection, pericardial effusion)
- diagnose specific complications (e.g. MR or papillary muscle rupture, pericardial effusion, myocardial rupture, ventricular septal defect)
- assess mural thrombus and thromboembolic risk
- diagnose RV infarction and infarct extension
- myocardial perfusion scanning using echocardiography is currently an experimental tool but is useful in critically ill patients where coronary angiography is logistically difficult.

OTHER STUDIES AND STRESS TESTING

Radionuclide studies have limited use in ICU patient care, although they may be useful for surgical planning in high-risk patients.[37] Exercise or dobutamine stress testing may provide information in the preoperative assessment of some vascular surgery.[38,39] High-risk CVD patients might have a small benefit but with harm in low risk. Perioperative interventions included 'monitored admission' and preoperative statins. The benefits and risks of testing asymptomatic patients, with interventions, antiplatelet therapy and its perioperative disruption are discussed on page 202. Coronary

angiography and PCI remain vital in defining and treating CAD in ICU patients, suggested by findings including echocardiography.

RISK STRATIFICATION OF ACUTE CORONARY SYNDROME (Fig. 20.6)[4,5]

STEMI

STEMI (including new or presumed new left bundle branch block [LBBB]) is the most acutely lethal form of ACS, usually due to complete occlusion of a coronary artery (>90% of patients).[33] It is an indication for immediate reperfusion therapy as successful reperfusion will significantly reduce the size of the evolving MI, although some troponin rise is inevitable. Patients who develop STE after admission should also receive thrombolytic therapy.

At the commencement of the thrombolysis era, LBBB was also recognised as gaining the largest benefit from thrombolysis. Unless the LBBB could be proven old, sentinel guideline suggestions were that it be '*presumed new*' and thrombolysis be administered.[40]

Aging populations with more co-morbid illness, see such 'not known to be old' LBBB, arrival ECGs, present in 2%–9% of ACS emergency admissions.[41–43] However, only one-third of patients presenting with LBBB are found to have a STEMI ACS (occluded culprit artery), one-third have non-ACS cardiac disease and up to one-third have non-cardiac illness.[44] Concerns of 'missed diagnosis' and of thrombolysis risk, see many referred for angiography. While 'false activations' of a catheter laboratory for ACS might be less than 14%, in this LBBB setting it may be 44%.[41] Strategies for improvement include, rapid senior cardiology review, urgent echocardiography and telemedicine or ECG reviews. The Sgarbossa ECG criteria are specific but have low sensitivity, and views on their value vary.[41,42]

Considerable variability in mortality risk exists among patients with STEMI. Readily available bedside clinical risk score tools may give insight into predicted 30-day mortality (Fig. 20.7).[45] The addition of in-hospital complications data may allow hospital discharge, longer term, 1-year prognostication after STEMI (Dynamic TIMI Risk Score).[46]

NSTEACS

Patients may have ischaemic chest pain but have 'non-specific' ECG changes (normal, ST-segment depression or minimal elevation, or T-wave inversion). After serial biomarker testing, these patients will later prove to

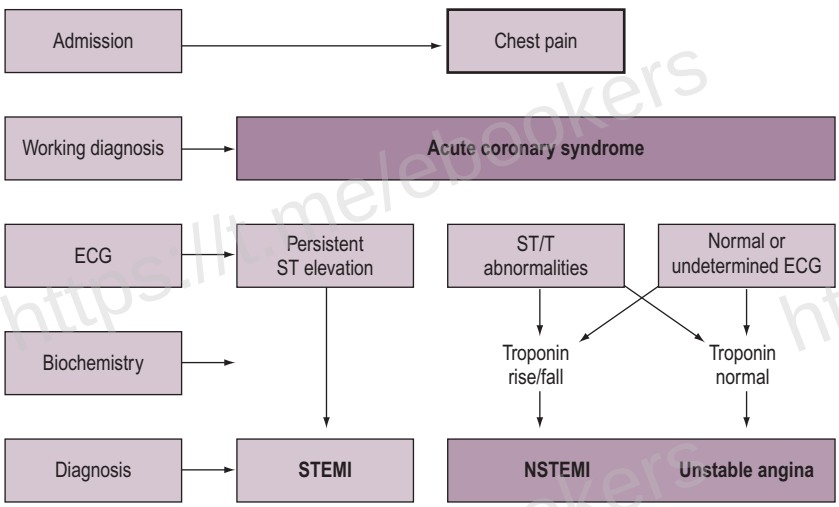

Figure 20.6 The spectrum of ACS. Physicians should obtain, interpret and stratify patients with ACS within 10 minutes of arrival. STE in this clinical setting is usually due to complete coronary occlusion and most patients will ultimately have some biomarker elevation (STEMI). Rapid and sustained coronary artery reperfusion (PCI or fibrinolytic therapy) may significantly decrease myocardial damage. Well-organised systems of care should be in place to minimise delays. In patients without STE (non-STEACS), serial biomarker measurements may define those patients with elevated levels (NSTEMI) and those with ACS but normal biomarkers (unstable angina). Clinical review and further tests may lead to a non-ischaemic cause of chest pain in some patients. Subsequent echocardiography and imaging may help define the extent of injury, coronary anatomy pathology and its clinical importance. *ACS*, Acute coronary syndrome; *ECG*, electrocardiogram; *NSTEMI*, non–ST-elevation myocardial infarction; *PCI*, percutaneous coronary intervention; *STEMI*, ST-elevation myocardial infarction. *(Adapted from Hamm CW, Bassand JP, Agewall S, et al. have either USA (Tn normal) or NSTEMI (Tn elevated). In contrast to patients with STEMI, thrombolysis in patients with ST depression or normal ECGs was associated with increased mortality.[25,40] Only 35%–75% of patients have evidence of 'significant' coronary thrombus formation.[33,40,47] Of note, some myocardial regions may have few 'facing ECG leads'; for example, 27% of inferolateral NSTEMI may actually be demonstrated to have occluded culprit arteries and, if detected, an early invasive management strategy should be established.[48]

NSTEMI therapy aligns more clinically with that of USA than with that of STEMI. These two conditions, comprising NSTEACS, represent a spectrum of disease with common treatments directed at platelet inactivation and 'plaque stabilisation'. Despite the heterogeneous nature of this group of patients, and variable prognoses, early stratification using ECGs, troponins and simple clinical variables may define risk and guide evidence-based therapy (Fig. 20.8).[49] The more severe the ischaemia, the stronger the indication for more aggressive anticoagulation and invasive procedures.

Fig. 20.9a[47,50] displays the higher mortality of STEMI patients (compared to patients presenting with and without STE) present in hospital, and at 6 months, despite lower early, in-hospital mortality in NSTEACS patients. Fig. 20.9b[47,50] shows that the subsequent rates of ongoing fatal events may be higher.

Historical 'Q-wave MI' (QWMI) and 'non–Q-wave MI' (NQWMI) correlate poorly with the clinically useful terms of STEACS and NSTEACS so that 63% of the former and 27% of the latter will have transmural infarction.[22,24] Importantly, the simple detection of STE is the most clinically useful, cost-effective and evidence-based diagnosis to make.

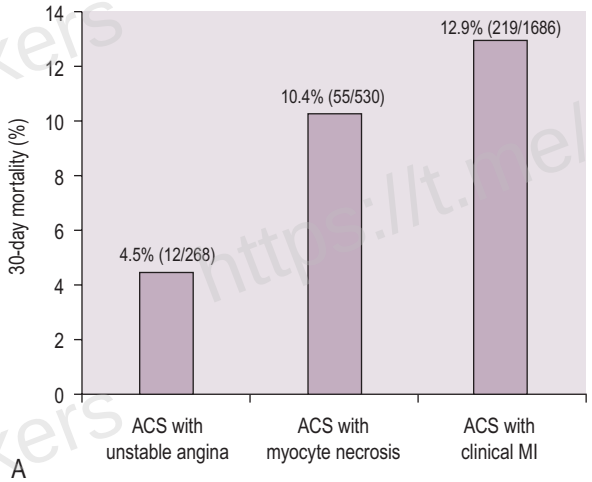
IMMEDIATE MANAGEMENT OF ACUTE CORONARY SYNDROMES

PRE-HOSPITAL CARE

Fifty per cent of deaths from MI occur within the first hour of symptom onset. These deaths are usually due to ventricular fibrillation (VF). Treatment is defibrillation.

IMMEDIATE HOSPITAL CARE

1. Cardiac monitoring.
2. Oxygen supplementation[18,51] (2–4 L/min via facemask or nasal prongs) is recommended for



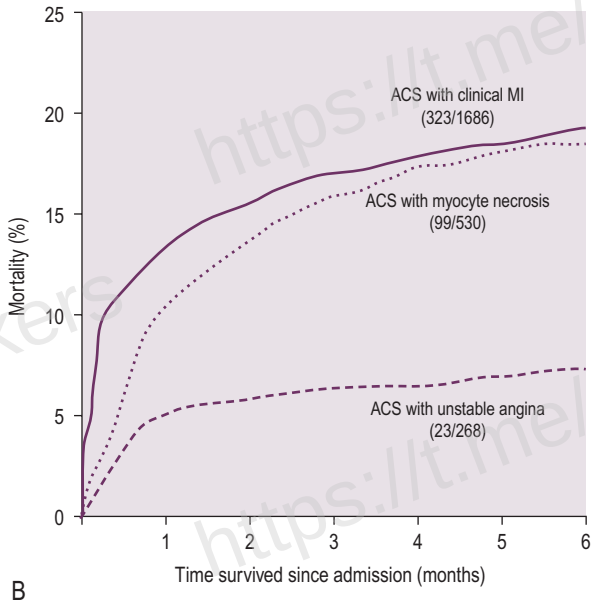


Figure 20.9 (a) Thirty-day mortality according to British Cardiac Society category. (b) Kaplan–Meier survival area curves for events from admission to 6 months. *ACS*, Acute coronary syndrome; *MI*, myocardial infarction. *(Reproduced from Das R, Kilcullen N, Morrell C, et al. The British Cardiac Society Working Group definition of myocardial infarction: implications for practice.* Heart. *2006;92:21–26, with permission.)*

breathless or hypoxic patients (<94%). Administration to non-hypoxic patients has not been shown to have a beneficial effect on 12-month all-cause mortality.[2,52,53]

3. ECG (12-lead) should be taken within 10 minutes of arrival and regularly thereafter. Pre-hospital ECGs have been shown to have a favourable effect on outcome, mediated through shorter times to thrombolysis and primary PCI.[51]
4. Aspirin at 160–325 mg (not slow release) should be chewed or dissolved, and swallowed, then continued at a dose of 100–150 mg/day. International guidelines have some differences in their recommended doses, guiding regional practice.[54] Aspirin reduces mortality and complications of MI with minimal side effects.[2,5,17,54,55] Clopidogrel or prasugrel is given if there is aspirin sensitivity or high risk.[18,33] Dual antiplatelet therapy (DAPT) with clopidogrel or prasugrel added to aspirin, may occur where regional networks anticipate primary PCI.[51]
5. Sublingual glyceryl trinitrate (GTN) given by spray may provide symptomatic relief of active chest pain. Side effects include headache. Hypotensive reactions and a hypotensive bradycardic response (the Bezold–Jarisch reflex) can occur. Recent phosphodiesterase inhibitor use (e.g. sildenafil) should be excluded.
6. Venous access is usually established.
7. Pain relief must be provided.[56] Pain produces catecholamines, which increase ischaemia. Reassurance and small incremental, titrated boluses of intravenous (IV) morphine (1–2 mg) or fentanyl (20–40 µg), can be given. A concern is that gastric emptying delay, or vomiting, may interfere with absorption of antiplatelet agents. Admission non-steroidal anti-inflammatory drugs (NSAIDs) should be ceased immediately, as use in the week prior to admission is associated with increased risk of death and cardiac complications at 6 and 30 days.[33,57] Pain relief is best served by rapid reperfusion.
8. Rapidly identify ACS patients with STE or new and presumed new LBBB (Box 20.4).[2,18,51,58] Reperfusion is critically time dependent ('time is muscle').
9. Emergent primary PCI (or rapid transfer to a PCI centre) is generally superior to thrombolytic therapy. Thrombolysis should be performed where the benefits of urgent primary PCI cannot be obtained.
10. Pulmonary oedema is treated with upright posture, sublingual or IV nitrates, and if moderate to severe, with continuous positive airway pressure (CPAP) ventilation. Response to IV furosemide has slow onset, and may be variable depending upon volume status.
11. Beta-adrenergic blockers (oral) should be commenced in haemodynamically stable patients as soon as possible (usually after thrombolytic therapy has been given or before PCI), but only where there are no contraindications.[2]
12. Prophylactic antiarrhythmics are *not* administered, but all patients should be monitored with rapid access to defibrillation.

ACUTE MANAGEMENT OF STEMI (Fig. 20.10)[2,18,59]

REPERFUSION THERAPY

Prompt 'reperfusion therapy' (mechanical or pharmacological), to establish coronary artery flow is the

Box 20.4 Typical indications for reperfusion therapy in acute myocardial infarction

Reperfusion therapy

Presentation ≤12 hours with acute coronary syndrome (ACS), unrelieved by sublingual nitroglycerine, *and*

New ST segment elevation in two or more contiguous leads with the cut-off points:

≥2 mV in men, >0.15 mV in women in leads V_2–V_3 and/or ≥1 mV in other leads, *or*

New-onset LBBB (include presumed new-onset), *or*

Posterior infarction (dominant R wave and ST depression ≥2 mV in V_1–V_2), *or*

Presentation 12–24 hours after onset of ACS with continuing pain and evidence of evolving infarction

Posterior myocardial infarction is an important presentation of STEMI where STE is not present in standard chest leads. STEMI (2%–4% of cases) may present with new or presumed new LBBB, although many such patients will not have an occluded culprit artery favouring PCI over thrombolysis. International guidelines[5,17] may vary in definitions,[54] with some having a more conservative response to LBBB.[54]

Neeland IJ, Kontos MC, de Lemos JA. Evolving considerations in the management of patients with left bundle branch block and suspected myocardial infarction. *J Am Coll Cardiol*. 2012;60(2):96–105.

'gold standard' for STEMI treatment and is far superior to non-reperfusion ('conservative') management. It should be considered for all patients presenting within 12 hours of STEMI onset.[2,18,60]

Both primary PCI and thrombolysis (fibrinolysis) are proven treatments with maximal benefit being achieved when performed early. Age is strongly related to mortality, often reflecting comorbid illness.[49,61] Underrepresentation of elderly in trials has left questions about best practice. Their large numbers (30% of ACS are >75 years) and high risk, identifies the elderly as a group where 'aggressive intervention' offers significant potential benefit.[61]

Reperfusion reduces infarct size, preserves LV function, reduces mortality and prolongs survival.[62] Strategies to achieve reperfusion can include:

- PCI (e.g. angioplasty, usually with stent insertion)
- thrombolytic (fibrinolytic) therapy
- urgent CABG.

Primary percutaneous coronary intervention[2,18,58,59]

- Primary PCI delivered in centres of excellence and without transfer delay, was far superior to thrombolysis, with reduced short-term mortality (5% vs. 7%), non-fatal re-infarction (3% vs. 7%) and stroke (1.0% vs. 2.0%). The combined trial endpoint of short-term mortality, non-fatal reinfarction and stroke was lower in the primary PCI group (8% vs. 14%)[63,64]
- Current data suggest that thrombolysis produces an ***absolute reduction*** in 30-day mortality of 4%, and that primary PCI is a further 1.5%–2% better.[60]
- Current data suggests thrombolysis has a 2% risk of stroke (number needed to harm, 50), and primary PCI technique a 1% risk of stroke.[60]

Emergency PCI can be divided into:

- primary PCI
- *rescue PCI* after failed thrombolysis.
- *pharmaco-invasive PCI* (thrombolysis with routine transfer to PCI centre for assessment)[65]

Immediate, urgent PCI when available in STEMI is strongly indicated in patients with:[18,33,59]

- presentation to cardiological centres of excellence
- contraindications to thrombolysis (e.g. bleeding risk) presentation greater than 12 hours
- uncertain diagnosis (e.g. pericarditis, LBBB)
- high-risk but predicted low benefit from thrombolytic therapy (e.g. elderly, diabetic and with presentation >3 hours)
- CS even up to 12–36 hours post MI[66]
- previous CABG.

Contraindications to primary PCI are uncommon, the major risk factor being complications from obligatory adjunctive antiplatelet or antithrombin therapy. Caution is needed in those at risk of contrast-associated renal failure.[62,67] Primary PCI is limited by the risk of abrupt vessel closure (early), and late thrombosis and stenosis. Coronary stenting reduces restenosis risk.[68]

Thrombolytic therapy

Thrombolytic therapy (in absence of contraindications) should be given to patients with STEMI and onset of ischaemic symptoms within the previous 12 hours when it is anticipated that primary PCI cannot be performed within 120 minutes of first medical contact (FMC).[2,18] Better outcomes from primary PCI have significantly decreased the percentage of people receiving thrombolysis, although in much of the world it remains a cost-effective and essential treatment.[65] Outcomes are critically dependent upon time from symptom onset ('The Golden Hour').

Thrombolytic agents (fibrinolytic agents)[69,70]

1. *Non–fibrin-specific:* these catalyse systemic fibrinolysis (e.g. streptokinase [SK]).
2. *Fibrin-specific:* these produce limited plasminogen conversion in the absence of fibrinogen. Current agents include alteplase (rt-PA), reteplase (r-PA) and tenecteplase (TNKase)

The above grouping is based on the *pharmacology* and physiology of agents. A historical grouping by *'generations'* outlines clinically driven need for agents to achieve best patient outcomes.

The ***first-generation*** fibrinolytic agent SK, formed complexes with plasminogen, releasing the protease

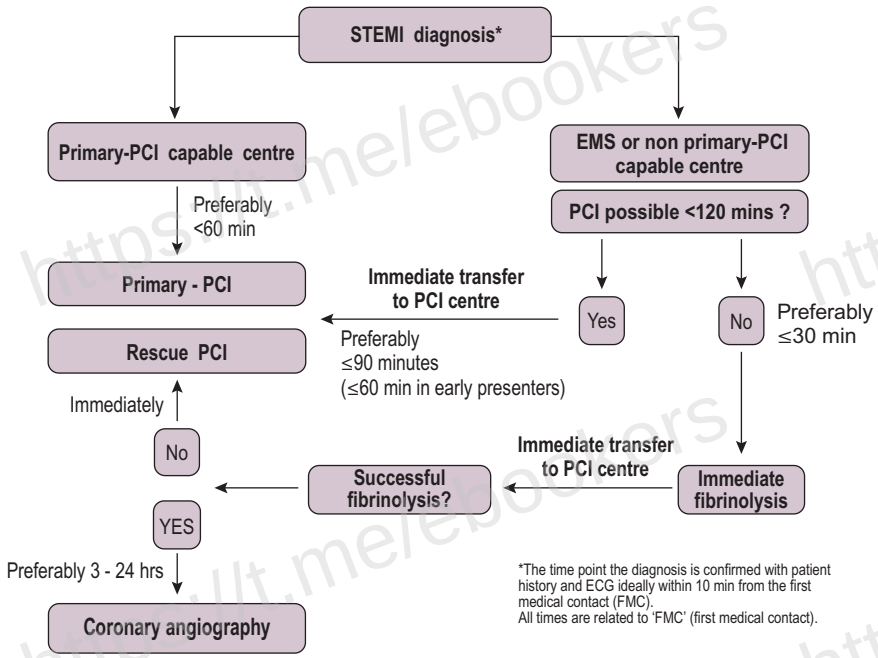

Figure 20.10 Pre-hospital and in-hospital management and reperfusion strategies within 24 hours of FMC. *Cath*, Catheterisation laboratory; *ECG*, electrocardiography; *EMS*, emergency medical system; *FMC*, first medical contact; *PCI*, percutaneous coronary intervention; *STEMI*, ST-segment elevation myocardial infarction. *(Steg PG, James SK, Atar D, et al. ESC Guidelines for the management of acute myocardial infarction in patients presenting with ST-segment elevation: the task force on the management of ST-segment elevation acute myocardial infarction of the European Society of Cardiology (ESC).* Eur Heart J. *2012;33(20):2569–2619. doi:10.1093/eurheartj/ehs215. Modified with permission of Oxford University Press (UK) © European Society of Cardiology.)*

plasmin which created a systemic lytic state. 'Fresh' local coronary thrombus was lysed, significantly reducing mortality. Low systemic fibrinogen levels and a lytic state, however, were associated with a 0.6% incidence of lethal or disabling cerebral haemorrhage, which was higher in the elderly. SK became the agent against which newer ***second-generation* 'fibrin specific' agents,** provided more localised coronary artery clot lysis. Trials of rt-PA (alteplase) versus SK found a 1% mortality reduction (6.3% vs. 7.4%) at 30 days.[70] Outcomes were superior, but complex infusion rates and doses could be problematic. ***Third-generation*** agents have been trialled against the second-generation agents on a 'non-inferiority basis' to improve safety and efficacy. Reteplase and tenecteplase (TNKase) enjoy simpler administration, more fibrin specificity, less allergencity and more resistance to the plasminogen-activator inhibitor. The shorter duration of action of the fibrin-specific agents often requires early administration of unfractionated heparin (UFH) or low-molecular-weight heparin (LMWH).[18]

Major and minor contraindications are shown in Table 20.2.

Side-effects and choice of agent[18,62] Bleeding complications are the most serious thrombolysis complication. Approximately 1% of patients may suffer early cerebral haemorrhage but this figure can be 4% in high-risk populations. Risk factors are advanced age, significant admission systolic and diastolic hypertension, female gender, prior cerebrovascular disease and low weight. Major non-cerebral bleeds requiring transfusion or significant intervention may occur in 4%–13% of patients.

Failure to adjust the dose of fibrinolytic correctly to body weight may be associated with increased mortality and intracerebral haemorrhage. Guidelines outline similar caution with weight-based dosing of heparins.

PRIMARY PCI VERSUS THROMBOLYTIC THERAPY

Duration of symptoms, and time to achieve transfer, are critical.[62,71] Advantages of more reliable revascularisation from PCI can be lost if transfer is not expedient and if the delay is more than 60–120 minutes.[62,71] The importance of transfer for an individual patient will vary significantly depending upon the baseline risk. Many patients present to centres that do not offer primary PCI. Given the superiority of PCI over thrombolysis, transfer to such a centre has significant benefits.

- thrombolysis is a most effective treatment in patients with low bleeding risk and with arrival soon after symptom onset. Current outcomes from thrombolytic therapy in patients presenting early (≤3 hours post-onset), and PCI not on-site or immediately

Table 20.2 Contraindications and cautions for fibrinolytic use in myocardial infarction (advisory following clinical consideration)

ABSOLUTE	RELATIVE (ADVISORY FOLLOWING CLINICAL CONSIDERATION)
• Previous haemorrhagic stroke • Other stroke or cerebrovascular accident ≤6 months • Intracranial neoplasm • Active internal bleeding ≤2 weeks (menses excluded) • Aortic dissection, known or suspected	• Severe uncontrolled hypertension on presentation (≥180/110 mm Hg) • Oral anticoagulation therapy (INR >2.5); known bleeding diathesis • Recent major trauma, surgery (≤4 weeks) including head trauma • Previous allergic reaction to drug to be used • Traumatic CPR • Active peptic ulcer disease • Pregnancy • Recent streptokinase; use different agent (risk of allergy, antibodies may reduce effectiveness) • History of prior CVA or intracerebral pathology not covered in contraindications • Chronic hypertension

Specialist advice should be sought urgently where doubt exists and PCI is not available. Patients with contraindication may still benefit from urgent PCI and indeed it is usually the preferred option. PCI is generally the desired treatment in all of the above. *CPR*, Cardiopulmonary resuscitation; *CVA*, cerebrovascular accident; *INR*, international normalised ratio; *PCI*, percutaneous coronary intervention.

available, are very good as fresh clots seem more likely to be lysed.
- such benefits of thrombolysis are not present in those who present later (≥3 hours after symptom onset) or who have a high risk of bleeding or another contraindication to thrombolysis.[62,71]

Invasive strategy (PCI) is generally superior to thrombolysis if[33]:

- ineligible for thrombolytic therapy (see Table 20.2)
- CS or severe HF, Killip Class ≥3
- significant ventricular arrhythmias
- skilled PCI lab is immediately available with surgical back-up:
  - FMC-to-balloon or door-to-balloon is less than 90 minutes
  - door-to-balloon time minus door-to-needle time less than 60 minutes
- transfer can be achieved in less than 120 minutes and ideally less than 60 minutes
- diagnosis is uncertain (apical ballooning syndrome [ABS], myocarditis, aortic dissection)

Other indicators that transfer to an expert centre for PCI should be considered are:

- elevated risk from STEMI, advanced age[72]
- extensive anterior infarction with late presentation (symptom onset ≥3 hours)
- high risk of bleeding, symptom onset more than 3 hours
- previous MI or CABG

Thrombolysis may be preferred if[18,33,62]:

- transfer to a centre for primary PCI may be harmful to patients where:
  - early presentation (≤3 hours, delay to invasive strategy)
  - invasive strategy not available

COMBINATIONS OF TREATMENTS: THROMBOLYSIS AND PRIMARY PERCUTANEOUS CORONARY INTERVENTION[33,58,62,65,73,74]

In patients with failed thrombolysis, further thrombolysis is not beneficial and may cause harm.[75] Urgent transfer to a PCI centre is required, and **'rescue angioplasty'** has shown a significant, lower combined end-point of death, reinfarction and HF, but with bleeding risk.[2,18,60] Immediate, routine early PCI of all thrombolysed patients (<3 hours) could not guarantee benefit because of frequent bleeding. The transfer of all patients after thrombolysis, for reassessment and then 'optimally timed' PCI (usually within 3–24 hours or before discharge) on a case-by-case basis, is beneficial.[2,18,60,76] Trials of administration of reduced doses of thrombolytic or antithrombotic loading to 'facilitate' immediate PCI, have not shown benefit.[72,75,77–79] For patients with late onset CS, time frames for benefit from 'rescue PCI' may be extended.

ADJUNCTIVE THERAPY USED WITH REPERFUSION TREATMENTS (Fig. 20.11)[67,80]

Early adjunctive therapy is necessary with thrombolysis (and PCI) as at infusion completion, 50% of patients may not have TIMI 3 flow. Antithrombin agents facilitate ongoing 'catch-up' lysis and with antiplatelets, may decrease reocclusion of unstable arteries. The underlying coronary artery remains unstable during the following year, evidenced by angiographic reocclusion in 30% and recurrence of ischaemia in 20%.[80] Coronary arteries that have been dilated or stented, may similarly remain unstable. Immediate (early) adjunctive therapies are directed at platelet aggregation and coagulation pathways. Further therapies are directed at 'plaque stabilisation', myocardial ischaemia, and arrhythmias. Advances in adjunctive reperfusion therapies have been a major driver of outcome improvements.

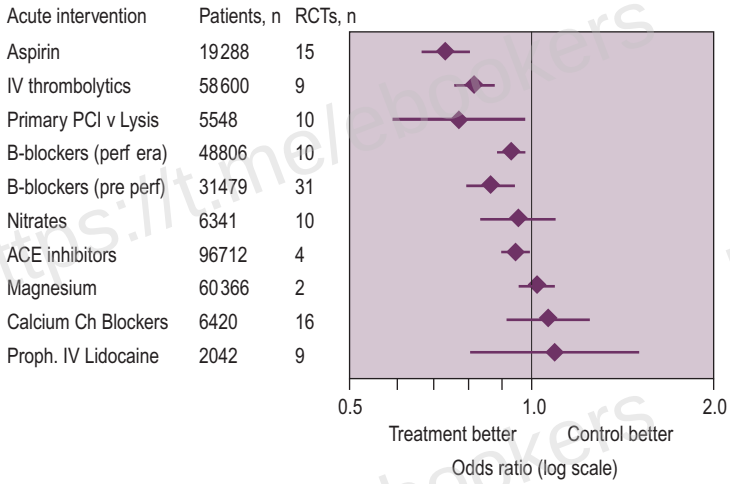

Figure 20.11 Effect of acute (early) adjunctive interventions upon mortality following MI. Results are from meta-analyses and various trials. Primary PCI has not been compared to placebo but offers superior results to thrombolysis when performed at centres within appropriate time frames. Beta blockers should only be used after exclusion of contraindications. Data graphing is indicative. *ACE*, Angiotensin-converting enzyme; *PCI*, percutaneous coronary intervention; *Proph.*, prophylactic; *RCT*, randomized controlled trial.

ASPIRIN[18,58,81,82]

Aspirin remains the most cost-effective short- and long-term treatment for STEMI and ACS. Unless contraindicated, aspirin should be administered to all patients with STEMI[2] and should be continued indefinitely.[2] In the Second International Study of Infarct survival (ISIS-2), aspirin reduced absolute mortality by 2.4% with ~50% RRR in re-infarction and stroke, and without an increase in cerebral haemorrhage or bleeds requiring transfusion.[55,83–85] Higher doses of aspirin do not provide better outcomes and may in fact be associated with higher event rates.[82,86]

Aspirin also benefits patients who have not, or cannot receive reperfusion therapy.[67] Aspirin allergic patients benefit from clopidogrel or prasugrel (avoid if the patient has had a previous transient ischaemic attack or cerebrovascular accident).

Despite the extreme value of aspirin there have been major advances in new agents and therapy.

DUAL ANTIPLATELET THERAPY[2,81,82,87]

The CURE (Clopidogrel in Unstable Angina to Prevent Recurrent Events) Trial[88] demonstrated the benefits of adding a second antiplatelet agent to aspirin (DAPT). The addition of clopidogrel to aspirin in USA and NSTEMI saw a 20% reduction in composite events, evident within 24 hours and continued over 12 months without prohibitive bleeding. Benefits of dual clopidogrel and aspirin have been demonstrated in STEMI patients undergoing PCI, and in thrombolysed STEMI patients, both with and without subsequent stenting.[82] The current standard of care for ACS patients includes aspirin and an ADP-receptor antagonist (subject to contraindications). Optimal agents and their duration are best chosen to balance the reduction of thrombotic and bleeding risks for individual patients.

Thus the agents used in combination with aspirin as part of DAPT may include:

A. ***Thienopyridines (e.g. clopidogrel, prasugrel, ticagrelor)***[81,87,89–91]: Oral $P2Y_{12}$ inhibitors are commonly used in DAPT, for all ACS patients during admission and for 12 months thereafter. Clopidogrel still has common use but slow onset of action (>6 hours, 3–5 days without dose loading) can be problematic if stent protection is not adequate. Prolonged half-life may increase bleeding if urgent CABG is required.[81] Prasugrel and ticagrelor have rapid and more reliable action, which favours their use in the setting of PCI; patients with high bleeding risk may need exclusion.[81,89,90]

B. ***Glycoprotein IIb/IIIa inhibitors (GPIs)***[2,5,18,60,90]: Abciximab, eptifibatide and tirofiban, developed prior to oral $P2Y_{12}$ inhibitors, were of critical importance during PCI and they still retain a role in complex lesions. Oral GPIs were disappointing with significant increases in bleeding and mortality. The safer profile of $P2Y_{12}$ inhibitors and suitability for long-term oral therapy has seen GPI use decline.

ANTITHROMBOTIC THERAPY AND NEW AGENTS[2,18,89]

Ruptured plaque activates thrombin. Antithrombin therapy is generally given in combination with fibrin-specific fibrinolytic agents. In the setting of primary or early PCI, antithrombin use is mandatory.

Four anticoagulants are currently used clinically (UFH, LMWH, bivalirudin and fondaparinux), in support of thrombolysis, PCI or their combination. Hospitals should have protocols reflecting international guidelines.

Thrombolysis[2,18] with fibrin-specific-agents requires anticoagulant therapy for at least 24–48 hours. Weight adjusted intravenous UFH may be preferred if PCI is likely. Otherwise LMWHs (e.g. enoxaparin) are preferred as reliable bioavailability removes the need for monitoring activated partial thromboplastin time. Meta-analyses suggest an advantage of enoxaparin to UFH, a lower composite end-point of death, non-fatal MI and cerebral haemorrhage, but with an increase in non-fatal bleeds.[92] Heparin-induced thrombotic thrombocytopaenia syndrome (HITTS) from previous or prolonged UFH can complicate UFH therapy.[62,92–94] LMWHs may need dose adjustment relating to age, bodyweight and renal function. Fondaparinux (pentasaccharide Factor Xa inhibitor) should not be used with PCI. Guideline recommendations and licencing for use can vary.

Primary PCI[2,18] requires 'heparin' (IV infusion or bolus dosing) prior to commencement. Agents and doses depend upon concurrent antiplatelet therapies (including GPIs), renal function, bleeding risk and stent. Intravenous loaded enoxaparin is superior to UFH in primary PCI,[18,95,96] but requires dosing adjustment for age and renal function. Bivalirudin (direct antithrombin inhibitor), is an alternative in primary PCI.[18,95] Fondaparinux is not recommended for primary PCI because of a peculiar problem of end-catheter thrombosis.[18,95]

BETA-BLOCKERS[2,18,58,97–100]

Pre-thrombolysis era trials demonstrated major benefit from early beta-blocker therapy (IV and oral), leading to their continued aggressive use. Post-thrombolysis trials of early use have demonstrated less benefit, and even harm.[2,33,58,97,99,100] Oral β-blockers should be started in all patients in the first 24 hours, subject to the absence of HF, impending shock, bradycardia, heart block or asthma.[2] In the Combination of Maintenance Methotrexate-Infliximab Trial (COMMIT),[97] early IV β-blocker therapy in MI had lower rates of recurrent MI and VF, but balanced higher rates of CS, especially on days 0 and 1,[2,97] STEMI patients undergoing primary PCI and without HF (echocardiography assisting) may benefit from cautious IV β-blockade.[101]

RENIN-ANGIOTENSIN ALDOSTERONE SYSTEM (RAAS) INHIBITORS[18]

RAAS inhibitors include angiotensin-converting enzyme inhibitors (ACEIs) and angiotensin II receptor blockers (ARBs). Initial ACEI doses may cause hypotension, but early introduction post-STEMI (within the first 48 hours) is generally well tolerated and is associated with a small reduction in 30-day mortality, which is evident in the first week.[18] Early benefits are additive to β-blockade and antiplatelets.

OTHER THERAPIES

Nitrates may be beneficial for the treatment of recurrent angina, LVF and hypertension, but may be harmful if hypotension deters proven therapies such as ACEIs or β-blockers. Glucose–insulin–potassium therapies have not been shown to provide 'cardio-protection'.

COMPLICATIONS OF MYOCARDIAL INFARCTION

ARRHYTHMIAS[7,18,100,102] (See Chapter 22)

Arrhythmia management is discussed in detail in Chapter 22 and in modern international guidelines.[103] Post-MI arrhythmias are minimised by:

- rapid revascularisation and treatment of HF
- correct hypoxia, hypovolaemia and acid-base disturbances.
- maintain serum potassium in normal range (3.5–4.5 mmol/L) and magnesium (0.7–1.2 mmol/L).[103,104]

Rhythm disturbance is common during acute MI, especially around onset, and during reperfusion. This can include ventricular ectopy and transient tachyarrhythmias but most do not require intervention. (Ventricular tachycardia may occur in 6% of ACS in the first 48 hours.) There has been a steady decline in the incidence of VF, from approximately 4.5% to less than 2% of MI admissions.[105,106] Early β-blockers reduce the incidence of VF and are generally first-line therapy for the management of ventricular ectopy.[103] *Routine* lignocaine and magnesium have not demonstrated benefit.[7,33,103,107] When ventricular tachyarrhythmias require treatment, amiodarone and lignocaine are preferred to the class 1 agents.[102] Ventricular arrhythmias and ventricular ectopics beyond 48 hours indicate an at-risk patients needing full reassessment and likely electrophysiological studies to determine long-term management.[100,102]

POST-INFARCTION ANGINA AND RE-INFARCTION[18,25]

Angina (STEMI or NSTEMI) may occur at rest, or with minimal exertion in the 24 hours or more after MI. It is associated with increased mortality, and the reinfarction rate and can complicate MI after thrombolysis or PCI. Ischaemia may occur in the original infarct zone, or in a distant area when there is complex vessel disease. Pathology may include recurrent thrombus or vessel spasm. Tachycardia, hypertension, anaemia and fever should be corrected and aggressive treatment with antiplatelet agents, nitrates and β-blockers is indicated. The patient should be examined, angiography reviewed and repeat angiography reconsidered to exclude vessel (or stent) reocclusion. Echocardiography will assess LV function and possible mechanical complications. Refractory pain with ECG changes is indicative of high risk and is usually an indication for revascularisation.[2] Insertion of an intra-aortic balloon pump may help improve symptoms and minimise ischaemia, and may bridge for further PCI or CABG.

Table 20.3 Mechanical complications of myocardial infarction

	CVP	PAOP	CO	OTHER FINDINGS ON PAC	ECHOCARDIOGRAPHY
MECHANICAL COMPLICATIONS					
Free wall rupture	↑	↑	↓↓	Usually tamponade physiology: RA mean, RV and PA end-diastolic, and PAOP pressures are elevated and within 5 mm Hg (0.665 kPa) of one another	Pericardial effusion with tamponade and RV diastolic collapse; may visualise pseudoaneurysm
Acute ventricular septal defect	↑	↑	↓↓	Left-to-right shunt with oxygen step-up at RV level; V waves may be seen in PAOP tracing	Visualisation of left-to-right shunting with colour Doppler, can sometimes visualise defect as well
Acute mitral regurgitation	↑↑	↑↑	↓↓	V waves in PAOP tracing	Regurgitant jet apparent on colour Doppler; can diagnose papillary muscle rupture with flail leaflet
RV infarction	↑↑	↓ or normal	↓↓		RV dysfunction
Pump failure (cardiogenic shock)	↑↑	↑↑	↓↓		Decreased overall LV performance; regional wall motion abnormalities; dyskinetic or aneurysmal segments may be seen

Echocardiography has largely replaced the need for insertion of a pulmonary artery catheter although information for a PAC shown here is useful in understanding physiology. Coronary angiography and studies may be required to determine coronary anatomy and may provide additional data.
CO, Cardiac output; *CVP,* central venous pressure; *PA,* pulmonary artery; *PAC,* pulmonary artery catheterisation; *PAOP,* pulmonary artery occlusion pressure; *RA,* right atrium; *RV,* right ventricle.

Re-infarction in the 10 days following STEMI occurs in up to 5%–10% of patients.

CARDIAC FAILURE (See Chapter 24) AND CARDIOGENIC SHOCK (Table 20.3)[18,19,33,66,108–112]

LV dysfunction is the single strongest predictor of STEMI mortality. HF complicating a patient's first ACS hospitalisation ('Index HF') complicates 15% of STEMI and NSTEMI, presence rising to perhaps 25% at 1 year. In-hospital mortality is 15% compared with 3% in STEMI without HF.[112] Rates are higher in patients with previous MI. The Killip Classification documents simple bedside findings (Table 20.4)[18,109,113–115] to allow risk evaluation. Scores correlate strongly with LV function and prognosis at the time of hospitalisation.

Standard treatment for HF should include[18,108]:

- correct hypoxia, fluid balance control
- perform chest X-ray and define left ventricular ejection fraction (LVEF [Echo])
- mild HF symptoms (Killip II) require a dose of IV loop diuretics, a regular morning oral dose if necessary. Potassium-sparing diuretics, or supplements may prevent hypokalaemia. ACEI or ARB therapy (monitor potassium) should be commenced, especially if impaired LVEF or hypertension.
- In Killip Class III patients, titrate diuretics, consider oral or IV vasodilators, and also CPAP if respiratory distress is present. Avoid negative inotropes.

Table 20.4 Killip classification of severity of infarction based on clinical assessment and its correlation with hospital mortality in 1967[113] and 30-day mortality in 1993[115]

KILLIP CLASS		CASE FATALITY (%) KILLIP & KIMBALL[113]	GUSTO[115]
Class 1	No failure	6	5
Class 2	Mild to moderate heart failure (S3, rales <50% lung fields)	17	14
Class 3	Severe heart failure (S3, rales >50% lung fields)	38	32
Class 4	Cardiogenic shock	81	58

There is a strong correlation between the degree of left ventricular dysfunction and mortality in acute coronary syndrome.
Reproduced from Thompson P. *Coronary Care Manual*. 2nd ed. Sydney: Churchill Livingstone Australia; 2011, with permission.

CARDIOGENIC SHOCK[2,18,108,110,116–119]

CS is a state of inadequate tissue perfusion resulting from severe impairment of ventricular pump function in the presence of adequate intravascular volume. It is the leading cause of in-hospital STEMI mortality (40%–50%).[117,118] It may complicate 10% of STEMI but also 2%–5% of NSTEMI. Eighty per cent of cases result

from muscle necrosis and 10%–20% from MI structural disruption.[118] Late presentation or delayed reperfusion are major risk factors [117] and emergency revascularisation with PCI or emergency CABG is critical.[2,18,66,117]

The presence of shock is usually identified by[119]:

- SBP less than 90 mm Hg (11.97 kPa) or fall in mean arterial pressure 30 mm Hg below baseline
- cardiac index: less than 1.8 L/min/m^2 despite adequate filling pressures but without vasoactive drugs, or less than 2.0–2.2 L/min/m^2 with support.

Patients with CS or severe HF, or at high risk of these, should be urgently transferred to centres of excellence, regardless of time post-MI.[2,66] Improved outcomes in CS have resulted from primary PCI replacing thrombolysis, from 'rescue' of failed thrombolysis, and from PCI in NSTEMI, late onset shock. Mortality remains very high (55%–70%) in established cases, however, which is increasingly due to co-morbid illness in aging populations.[116]

CS is characterised by the failing of the heart and hypoperfused organs, initiating a vicious cycle of deterioration. Rigorous attention to all organ function is required.

- ***Reperfusion*** with PCI or CABG should always optimised. Many patients have greater than 75% stenosis of all three coronary arteries including the LAD, and 'stunned myocardium' may recover with revascularisation and support.[66,108]
- ***Respiratory assistance*** should maintain oxygenation, but also minimise cardiac demands of the work of breathing. While early intubation and mechanical ventilation is often undertaken, non-invasive ventilation (CPAP) is vital in both support and ventilator weaning (Chapter 37). Echo may monitor afterload and RV preload changes.[120,121]
- ***Haemodynamic management*** seeks to support coronary perfusion, cardiac output and organ perfusion, without increasing myocardial ischaemia.[118,119,122] The need for inotropy, vasodilation, vasoconstriction or their combination may guide therapy, although trial data are often lacking (see also Chapters 26 and 92).
- ***Mechanical cardiac support*** is of major importance and is increasingly recognised as superior to intra-aortic balloon counterpulsation, which lacks evidence of mortality benefit (see Chapter 41).
- ***Other treatments*** include seeking to maintain sinus rhythm or to 'regularise' atrial fibrillation, to consider dual chamber pacing where pacing is required, and to consider early renal support. Decision planning should always seek to involve the patient, especially where hospital discharge with good function is unlikely.

MITRAL REGURGITATION[2,33,116,118,123]

Transient 'functional' MR is common early after MI, as LV wall dysfunction or enlargement may cause subvalvular apparatus displacement and incomplete valve closure. This may be asymptomatic and silent (identified only on echocardiography in 30%). Severe MR and papillary rupture can complicate even small, 'confined MI' (50% of cases) but may not have a classical pan-systolic murmur and its presence should be sought with echocardiography in any patient with HF or shock, especially women. Incomplete chordae rupture is better tolerated haemodynamically. Posteromedial leaflet rupture is most frequent as its blood supply arises from a single coronary artery via the posterior descending coronary artery (from the right coronary artery or the circumflex coronary artery, depending upon dominance). The anterior-lateral papillary muscle has a dual blood supply but its single body or head is prone to complete rupture. A decrescendo systolic murmur may be present rather than the typical pan-systolic murmur of chronic MR.

The incidence of catastrophic MR has fallen with the introduction of primary PCI and thrombolytic therapy (1%–5% to <0.5%). It may occur early, often at days 1–4 post MI. It is usually lethal without surgery. Chronic MR can be a late complication of MI due to a combination of papillary muscle injury and ventricular remodelling. In the first instance it is best treated medically.[2]

CARDIAC RUPTURE[2,13,18,124,125]

Cardiac ruptures have fallen significantly in the PCI era and include:

- LV free wall rupture (0.5% of MI) causing tamponade, which is usually catastrophic. Subacute rupture is less common, may mimic re-infarction and have a classic 'to-and-fro' flow on echocardiography.
- Interventricular septal rupture has an incidence 0.2% in the PCI era.[125] Anterior and inferior MI are equally represented and single-vessel disease is not uncommon.[116] Patients usually rapidly develop shock and a loud systolic murmur[2] although initially the murmur may be soft with fewer symptoms. Echocardiography will help exclude mitral valve rupture. Progressive clinical deterioration is usual (untreated, mortality can be 50% at 1 week, 90% at 1 year) and requires urgent surgery in selected patients despite high mortality.[2] Better survival with later surgery may reflect selection bias. Some cases undergo percutaneous closure, usually as a bridge.[19]

SYSTEMIC EMBOLI[13,126–130]

Embolic ischaemic stroke were historically common occurring after large anterior MI (20%–55%).[127] Mural LV thrombus was frequent, often large, and strokes usually occurred early. The incidence has fallen dramatically due to primary PCI, adjuvant supportive treatments, and routine early echocardiography. Ischaemic strokes will occur with an incidence of approximately 2% in-hospital or by day 30, and up to

4% at 1 year. In-hospital mortality of ischaemic stroke can be 10%–20%.[126,127]

The highest risk of ischaemic stroke is in the first 6 months after MI and guidelines have led to early post MI 'prophylactic' anticoagulation where there is atrial fibrillation, or anterior wall mural thrombus, or the risk factor of decreased LVEF (<40%). Anticoagulation is normally continued long term for atrial fibrillation, and for 3–6 months with echo monitoring of LV mural thrombus cases. While guidelines support an indication for anticoagulation therapy because of impaired LVEF alone and without thrombus,[33] there are concerns that this does not provide benefit because of bleeding mortality.[129,130] Control of other cardiovascular risk factors is important as perhaps 50% of ischaemic strokes may not be cardioembolic.

POST-MYOCARDIAL INFARCTION INJURY SYNDROME (DRESSLER'S SYNDROME) AND PERICARDITIS[131]

A pericardial rub may develop 24–72 hours after large, usually anterior MI. Associated pain may mimic ischaemia, and biomarkers and echocardiography may be useful in excluding post-infarction angina. Dressler's syndrome is a later-presenting pericarditis (2–3 weeks after MI) thought to be an immunopathic response to myocardial necrosis. It is characterised by fever, pleuro pericardial pain and rub, arthralgia and elevated inflammatory markers, and can occasionally be recurrent. Treatment includes NSAIDs and occasionally, steroids. It is now very uncommon (<1%); fewer incidences are perhaps due to improved and earlier reperfusion, leading to smaller MIs.[131]

MANAGEMENT OF UNSTABLE ANGINA AND NSTEMI (NSTEACS)[7,25,45]

NSTEACS are now far more frequent than STEMI. Pathology is also secondary to platelet aggregation and thrombosis upon unstable plaque with elements of obstructive ischaemia, vasospasm and mircroembolisation.[25] Much acute adjuvant therapy is similar to STEMI, and secondary prevention is common to most ACS.

General principles of treatment are:

- immediate pharmacological relief of ischaemic symptoms
- immediate introduction of antiplatelet therapy, usually in conjunction with an antithrombin agent, to stabilise plaque white thrombus and prevent complete artery occlusion
- assess benefits of early invasive (PCI, vessel reopening) versus medical therapy.

Diverse causes of NSTEAC and frequent co-morbid disease, have required large trials to determine optimal interventions. Management benefits if the patients are stratified at presentation and after, into 'high risk', 'intermediate risk' and 'low risk' groups. Treatment decisions are clinically enhanced by the use of simple, validated scoring systems correlated with mortality and major adverse cardiac events (MACEs). A common system is the TIMI Risk Score for NSTEACS.[49,132]

PERCUTANEOUS CORONARY INTERVENTION AND STENTS[68,133]

PCI involves coronary artery angiography and balloon dilatation (angioplasty), now usually followed by 'stent' placement. Thrombosis from angioplasty or the presence of coronary stents requires procedural, and often long-term, antiplatelet therapy. Following angioplasty, recurrent stenosis (processes of 'pathological remodelling') was frequent,[68] initiating the development and use of bare metal stents (BMS). Although less frequent with BMS, stenosis ('neointimal inflammatory injury') was problematic (20%–30% of lesions).[68] Newer generation 'drug-eluting stents' have significantly decreased stenotic events, but have a need for often more intense or longer duration DAPT, which is problematic in patients at a high risk of bleeding. BMS thus still maintain a significant role. The ICU, in conjunction with other acute care teams, needs an understanding of the risk of stent complications where adjuvant treatment requires interruption. These can include bleeding from antiplatelet therapy and heparins, and stent thrombosis from their withdrawal.

EARLY INVASIVE VERSUS MEDICAL THERAPY IN NSTEACS[7,25]

Although medical therapy is introduced to all patients, review of ECG, biomarker changes and instability may guide the timing of PCI. Improved adjunctive agents (principally GP inhibitors) have led to the recognition that early PCI strategies can be associated with lower recurrent MI and mortality in many groups.

Risk stratification is integral to the management of patients with ACS. Scoring systems based on simple and rapidly available clinical and laboratory tests, help to guide therapy. The GRACE[5,47] and TIMI[45,49] risk scores for UA/NSTEMI predict both in-hospital and post-discharge, 6-month mortality. Emergent PCI is demonstrated to offer clinical benefit to patients with high-risk features such as elevated troponins, recurrent chest pain and recurrent ECG changes.

ANTI-ISCHAEMIC AGENTS

Initial therapy with oxygen is started if the patient is hypoxic; reassurance and analgesia is as described for all ACS.

- ***Nitrates sublingual*** may provide immediate symptom improvement, but infusions more effectively provide control of symptoms and ST segment

changes; however, data do not suggest a mortality benefit.[5,7]

- ***β-blockers***[7,134–136] should be started orally within 24 hours in patients without contraindications, but with caution. Guideline recommendations are presumed from STEMI data.[7] Risk factors for shock are common in the NSTEMI and STEMI population, and urgent therapy may cause harm in such patients. Intravenous β-blockade with monitoring in the acute setting may target specific goals (e.g. tachycardia, hypertension, ECG changes, pain).

Calcium channel blockers non-dihydropyridine agents (e.g. diltiazem or verapamil)[7,25] may provide symptom relief when β-blockers or nitrates are not tolerated, but LVF is a contraindication as cardiogenic shock may be precipitated. Combinations of calcium channel blockers and β-blocker are generally avoided. Short-acting nifedipine given in isolation may precipitate tachycardia and can be associated with increased mortality.[2]

ASPIRIN AND DUAL ANTIPLATELET THERAPY[7]

Treatment guidelines for acute, in-hospital use of aspirin and DAPT align closely with those of STEMI, and all patients without contraindications should commence DAPT regardless of whether an invasive procedure is planned or not. ADP-receptor inhibitors are a routine component of DAPT although GPIs may be administered during PCI.

ANTITHROMBINS AND ANTICOAGULANTS[4,5,25]

- Heparins are used acutely in NSTEACS to inhibit thrombin production or activity and decrease thrombus complications.[4,5] The addition of UFH to aspirin therapy produced a significant reduction in recurrent angina and subsequent MI.[25,137] LMWHs and UFH produce similar results (less difference than in STEMI)[137] but simplicity, a lack of need for monitoring and an acceptable safety profile may favour LMWH use – except perhaps where surgery is anticipated.
- Bivalirudin is an alternate anticoagulant treatment supporting early PCI. Fondaparinux if used during PCI risks end-catheter thrombosis.

ONGOING AND DISCHARGE CARE OF ACUTE CORONARY SYNDROMES (SECONDARY PREVENTION) (Fig. 20.12)

Many therapies have been studied in the long-term (secondary) treatment of ACS and have a strong evidence base. These treatments are very similar for STEMI and NSTEACS and may offer mortality and morbidity advantages for other atherothrombotic illnesses:

1. **Antiplatelet therapy. Aspirin**[2,7,84,87,138] should be continued life-long in all types of ACS and benefit has been still present at 10 years.[139] Low-dose aspirin (75–150 mg/day) is as effective as higher doses, which show no further benefit but are associated with increased bleeding.[138] DAPT is generally recommended for all ACS patients for 12 months, unless contraindicated. Longer duration DAPT, and a change in its nature should be determined on periodic review according to perceived balancing ischaemic and bleeding risks, and in accordance with

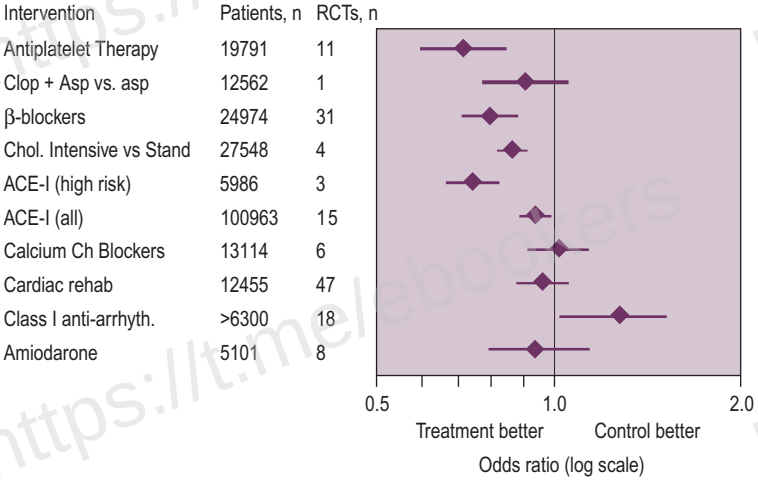

Figure 20.12 Late intervention in acute myocardial infarction. Effect of various secondary preventive treatments continued following hospital discharge. Results are from meta-analyses and various trials. Treatments may confer benefit for both STEMI and NSTEACS. DAPT benefit is dependent upon the presence and nature of stents as well as patient risk. Data graphing is indicative. *ACE-I*, Angiotensin-converting enzyme inhibitor; *Asp*, aspirin; *Calcium Ch blockers*, calcium channel blockers; *Chol Intensive*, intensive cholesterol lowering treatment; *Clop*, clopidogrel; *RCT*, randomized controlled trial.

international guidelines. Patients who discontinue aspirin despite high coronary risk, have a threefold risk of MACE, which is even higher when stents are in place.[140] Even patients who have been stable after 1 year have a high incidence of future atherothrombotic events[87] and aspirin benefits are still present at 10 years.

2. **β-blockers** historically have been recommended long term for all patients with ACS. Patients with impaired LV function (LVEF <40%) should continue long-term therapy. In asymptomatic patients with good LV function, guideline confidence levels supporting life-long therapy have fallen, perhaps due to the improvements from PCI, DAPT and ACE inhibitors. Thus such low-risk patients may derive little benefit from therapy and data suggest that where continued, lower daily doses may be as effective.[99,135,141]
3. ***Inhibitors of RAAS*** *(see Chapter 24):* Patients with anterior MI, and LVEF less than 40%, maintained on long-term ACE inhibitors may experience a sustained 20% RRR in mortality (additive to benefits of aspirin and β-blockers), and a significant reduction in the incidence of LVF.[18] Advantages may also extend to those with preserved LVEF but who are at risk of atherothrombotic disease because of concomitant hypertension, diabetes or chronic renal disease. In patients intolerant of ACE inhibitor(s), an ACE receptor blocker (ARB) may be used. Aldosterone antagonists are discussed in Chapter 24.
4. ***Lipid-lowering agents***[2,142–144]: ACS patients should commence a HMG-CoA reductase inhibitor, known as statins, in the first day after admission.[145–147] Early decreases in MACE may be due to plaque stabilisation rather than regression of stenoses. All ACS patients should continue long-term 'statin' therapy, mortality benefits being seen at 1 year. Statins reduce both vascular events and mortality, in primary and secondary settings, and benefits apply to both men and women.[143] Intensive statin therapy is superior to less-intensive lipid reduction (lower all-cause mortality)[148,149] and each 1.0 mmol/L reduction in LDL cholesterol may reduce major cardiovascular events (RRR) by 20%, major coronary events by 25%, need for coronary revascularisation by 25% and ischaemic stroke by just under 20%.[143] The benefit is maximal (and not confined only to myocardial events) in patients with elevated cholesterol and other risk factors, but the benefit is present at all cholesterol levels.

   Although statins are associated with a small risk of incidental Type 2 diabetes, this is outweighed by the reduced all-cause mortality.
5. ***Other anti-ischaemia agents*****:** Calcium channel blockers are of symptomatic use in patients intolerant of β-blockers or where there is a clinical need such as hypertension or arrhythmia but does not decrease recurrent MI or mortality.[18] Carvedilol may be of benefit in patients with ACS.
6. ***Antiarrhythmic therapy:*** Arrhythmias are discussed in Chapters 22 and 23, and in recent international guidelines.[103]
7. **Anticoagulants**[2,18,130,150]: Long-term anticoagulation is generally only indicated for specific indications. These might include atrial fibrillation, LV mural thrombus, history of embolic events, prosthetic heart valves or a prothrombotic tendency, and some with severe LV dysfunction. Increased use of DAPT has necessitated a review of INR targets, especially in the elderly. New oral anticoagulants (NOACs) have increasingly replaced warfarin, likely to continue as reversal agents improve safety.[150]
8. **Lifestyle advice:** All patients should be compliant with medication, cease smoking and receive advice on exercise and diet.[74] Tight control of blood pressure and blood sugar in diabetics is of high importance.[151] Regular medication review and confirmation of compliance are useful. A Cochrane meta-analysis found that exercise-based cardiac rehabilitation may be associated with improved outcomes.[152]

MYOCARDIAL INFARCTION IN THE INTENSIVE CARE UNIT[36,133,153–157]

MI is a common reason for admission to the ICU, often to facilitate acute management or to treat associated organ dysfunction. In patients managed acutely with STEMI or NSTEMI, primary PCI is the general treatment. Where possible, recognised guidelines should be applied.[2,5,18,60,65] However, critically ill patients are often not enrolled in clinical trials and co-morbid conditions in NSTEMI and STEMI admissions vary the risk–benefit of usual treatments. They often require continuous integrated team assessments, with further investigation and treatment on a case-by-case basis.

A difficulty in the management of 'general' ICU patients, is that cTN may be elevated in up to 40%–50%, including those with diagnoses of sepsis, pulmonary embolus and non-cardiac surgery (see Chapter 24 and Box 20.1). A presumption of ischaemic pathology ('oxygen mismatch'), would define these as Type 2 MI.[6,157] However, clinical evidence of ischaemia (voiced chest pain, ECG changes, RWMA) is often absent (perhaps in only 20% of cases) and they may now be considered as 'myocardial injury'.[156,157] Irrespective of the presence of ischaemic features, they are associated with increased early and later mortality that may often be 'non-cardiac'.[154–156] It is uncertain as to how treatment guidelines apply to such patients and how much cardiological follow-up is required. Carroll[36] indicates the value of patient team review and management with input of data from echocardiography and possible angiography. The known value of antiplatelet therapies in ACS suggests they should be introduced where possible with the support of stents following PCI on a risk–benefit judgement.

The need and nature of pre-operative investigation of high-risk surgical patients is also difficult. Data[158] in studies of major, non-cardiac surgery, found greater than 12% of patients had an elevated cTn level by post-op day 3. Mortality was 1% in patients with normal cTn but ranged from 4% to 16%, at day 30 in groups of patients in accordance with their day-3 elevation. Again, death causation was often 'non-cardiac'. Although only 50% of deaths were thought to be 'vascular', vascular investigation would seem appropriate to reduce mortality. Pre-operative exercise testing can identify patients with early positive tests, but it is unclear if revascularisation of low-risk disease patients will improve their outcomes if stent insertion requires perioperative interruption and then long-term continuation of antiplatelet therapy. Trials of perioperative beta-blockade, statin therapy or antiplatelet agents have often not shown any benefit.[159,160] Meta-analyses of statin therapy prior to CABG have not demonstrated any benefit.[161]

APICAL BALLOONING SYNDROME ('TAKOTSUBO SYNDROME')[28,29,162–165]

ABS presents with acute, reversible LV dysfunction, usually with chest pain, dyspnoea or syncope causing it to mimic an ACS (2% of such cases). Physical, pharmacological or emotional stresses may trigger 70% of cases. Up to 90% of cases occur in postmenopausal women and such cases may make up to 10% of this female demographic presenting with an initial ACS diagnosis. Biomarker or ECG changes (30% may have STE) generally necessitate coronary angiography to exclude MI, although by definition plaque rupture is absent.[28,29,164]

Echocardiography[35] reveals classical apical 'ballooning', with preserved basal contraction (the 'takotsubo' or 'Japanese octopus pot' appearance). This appearance results from a hypercontractile base of the heart with LV outflow tract obstruction, relative to a hypokinetic or akinetic apical and mid-LV ballooning myocardium; variants include a 'reverse takotsubo' appearance. The physiology of ABS is uncertain, but 'high levels of epinephrine' may paradoxically trigger cardiodepression,[166] which is most marked in apical regions because of a β_2-receptor gradient with high apical levels decreasing along the LV wall to the base.[29,165]

Major complications in severe ABS include hypotension, HF, CS, arrhythmia, LV thrombus and MR.[28] Acute mortality can be 2.4%–4.5%, and co-morbid illnesses are often the primary cause of death.[162,164] Annualised recurrence may be up to 1.5%.[164] Most cases of ABS improve with supportive treatment.[28,165] Echocardiography can help diagnose and assess response to therapy, and fluids should be administered to avoid hypovolaemia. In the presence of hypotension and shock, ideal inotropic therapy has not been defined. In severe shock, early mechanical support is often indicated as a 'bridge-to-recovery'.[28,165]

BLEEDING COMPLICATIONS AND ACUTE CORONARY SYNDROMES THERAPIES[150,167–170]

Hospital protocols and a multidisciplinary team response with skilled laboratories are required to plan major surgery and reverse major bleeding.[4,5,18,167,170,171] Treatment protocols for UFH, vitamin K antagonist and aspirin-related bleeding are generally known to clinicians.

1. **Antiplatelet agents and DAPT**[81,170]: Antiplatelet drugs have no specific reversal agents. In uncontrolled bleeding, platelets are administered and additional treatments may include DDAVP (desmopressin) and recombinant Factor VIIa (rFVIIa). The $P2Y_{12}$ oral medications have no specific 'antidotes' and treatment with these agents is also useful in this setting. The GPI abciximab can be associated with an early thrombocytopenia in 5% of patients, responsive to platelet transfusion and usually settling within a week. Tirofiban and eptifibatide have very short half-lives when renal function is normal, and antiplatelet action returns to normal 4–8 hours after discontinuation. While platelets are given, their effect is uncertain and with critical bleeding in vivo studies suggest that fresh frozen plasma (8 units) and platelets (2 units) may help reverse antiplatelet action.[171]
2. ***Antithrombins***[168]: UFH has historically been treated with dose-related protamine. Protamine treatment of LMWH is variable and incomplete, reversing perhaps only 60% of the LMWH with recommended doses. Protamine reverses 100% of the anti-IIa activity, but has far less effect on anti-Xa activity. With ongoing bleeding, rFVIIa is considered. Danaparoid, a heparinoid, is sometimes required in patients with HITTS. Its high anti-Xa/anti-IIa activity ratio168 of 20 renders it less likely to respond to protamine, and treatments have included plasmapheresis and high-dose rFVIIa. Fondaparinux has no specific antidote, but rFVIIa has been administered in severe bleeding.
3. ***Direct oral anticoagulants (DOACs)***[167,169]**:** These directly inhibit the coagulation cascade with a long-term safer profile than warfarin, but reversal of active bleeding has been extremely difficult. Dabigatran (a thrombin, Factor IIa binder) may be fully reversed by the recently licensed monoclonal antibody, idarucizumab, having been poorly responsive to cryoprecipitate, prothrombinex and rFVIIa.[150] Factor Xa inhibitors, rivaroxaban and apixaban, remain without effective reversal agents, although trials of 'decoy Factor Xa molecules' (recombinant, modified Factor Xa) that will bind to these factor agents, are encouraging.[150]
4. ***Fibrinolytic agents:*** Published studies for life-threatening bleeding have suggested large doses of cryoprecipitate (10–20 units), repletion of fibrinogen and coagulation factors (especially Factor VIII).

Fresh frozen plasma may supplement Factor V and VIII whilst platelet transfusions at high doses may replace platelets and supplement Factor V levels. ε-aminocaproic acid, loaded, followed by infusion has been suggested. Tranexamic acid might be useful.[167] Fibrinolytic reversal carries the risk of culprit coronary artery reocclusion.[171] Whilst publications may advise general advice, individual clinical scenarios and varying and multiple agents suggest considerable caution with overriding on-site multi-specialty input.

OUTCOME AFTER MYOCARDIAL INFARCTION

In-hospital mortality from MI has been steadily decreasing over the past three decades, from 15%–30% in the 1970s to approximately 10% in 1980, and now to around 8%–9% in the new millennium.[1,3–5,172] Thirty-seven per cent of the reduction of in-hospital mortality for STEMI and 21% of that for NSTEMI have been attributed to improvements in acute treatment.[1] Despite improved mortality, 60% of all deaths occur within the first hour (usually from VF) and often before reaching a medical facility.[4,5,64] Modern management of MI has undoubtedly contributed to decreased mortality. Further significant reductions in mortality must come from management strategies within the first hours of the onset of symptoms.

The most effective strategies to improve outcome are[1,18,172]:

- systems to deal with out-of-hospital VF arrest
- strategies to increase rates, and reduce time delays of PCI or thrombolysis in eligible patients
- optimise prescription and compliance with adjuvant and discharge medications.

Missed opportunities for reperfusion are a major problem. In one study, in-hospital mortality was 5.7% for those who received thrombolysis, but 14.8% for eligible patients who did not receive thrombolysis (mortality 9.3% vs. 18% in eligible women; 10.5% vs. 19% in eligible elderly). Up to 24% of eligible patients may not receive reperfusion therapy.[61,64,172,173] The role of early reperfusion and the provision of reperfusion therapy for all eligible persons, with ongoing life-long adjunctive managements, cannot be underestimated.

Cardiopulmonary resuscitation (including defibrillation)

Peter Thomas Morley

Cardiac arrest is the feared end point of the deteriorating patient. In many situations this is an anticipated and inevitable conclusion of a fatal illness. However, the appropriate management of cardiac arrest does dramatically alter its natural history. Over the past decade there have been improvements in cardiac arrest outcomes in both the in-hospital[1] and out-of-hospital settings.[2,3] There are many potential reasons for these improvements, but the most likely are related to incremental improvements in the management during and after the arrest.[3] The last decade has also seen a large number of randomised controlled trials conducted in the techniques for managing the victims of cardiac arrests, and many more are in the pipeline.[4]

PREVALENCE AND OUTCOMES OF CARDIAC ARRESTS

Cardiac arrests in the community occur at approximately 50–160/100, 000 person years.[5,6]

In-hospital cardiac arrests occur at approximately 3–13/1000 admissions,[1] with a similar inclusion/exclusion effect, as the majority of in-hospital cardiac deaths are expected and occur without attempts at resuscitation.

The majority of cardiac arrests in both pre- and in-hospital settings appear to be of cardiac origin, but the underlying causes, co-morbidities and presenting rhythms vary significantly between studies.

Outcomes of cardiac arrests are critically dependent on the inclusion/exclusion criteria.[5] The best outcomes from a cardiac arrest (near 100%) occur in the electrophysiology laboratory where ventricular fibrillation (VF) is often deliberately induced. The outcomes from in-hospital cardiac arrest are variable,[7] but surprisingly good (hospital discharge as high as 52%) and are probably related to their early detection, the early arrival of the advanced life support (ALS) team and the detection and treatment of reversible causes.[8]

INTERNATIONAL REVIEW PROCESS

The International Liaison Committee On Resuscitation (ILCOR) was formed in 1992. It has facilitated a cooperative international evaluation of the resuscitation science, which resulted in the publication of international guidelines in 2000, and international consensus documents on resuscitation science in 2005, 2010 and 2015.[9] The process for the 2015 consensus on resuscitation science involved the review of 169 topics by 250 international contributors using the Grading of Recommendations Assessment, Development and Evaluation (GRADE) methodology[10] (completed reviews available at www.ilcor.org). The major resuscitation councils throughout the world (including the American Heart Association, and the European Resuscitation Council) used this information as the basis for the development of their published guidelines. In 2016, Australasian guidelines (co-badged by the Australian Resuscitation Council and the New Zealand Resuscitation Council) were published[11] (www.resus.org.au) under the auspices of the Australian and New Zealand Council on Resuscitation (ANZCOR).

BASIC LIFE SUPPORT

The general flow of basic life support (BLS) management is outlined in the updated Basic Life Support flow chart of ANZCOR (Fig. 21.1).

COMMENCEMENT OF CARDIOPULMONARY RESUSCITATION

The current BLS guidelines recommend that cardiopulmonary resuscitation (CPR) be commenced with compressions if the victim is unresponsive and not breathing normally. An appropriately trained ALS provider can check for a central pulse (e.g. carotid) for up to 10 seconds during this period of assessment, but this should not delay CPR.

EXTERNAL CARDIAC COMPRESSION

The delivery of high-quality CPR is believed to be a key contributor to the best possible outcomes after cardiac arrest. A number of quality factors have been proposed but the best data are for chest compression rate and depth.[12]

ABSTRACT

Outcomes from in-hospital and out-of-hospital cardiac arrest have been slowly improving over the past decade. This has been the result of incremental improvements in each phase of care: the early delivery of cardiopulmonary resuscitation, more sophisticated advanced life support (including defibrillation), and attention to detail in the post-resuscitation care. The International Liaison Committee On Resuscitation (ILCOR) oversaw the creation of the 2015 consensus on science, which, in turn, was used by the international councils to develop their revised guidelines. The residual questions about the specific role of the advanced airway, epinephrine, oxygen, carbon dioxide and targeted temperature management are likely to be settled with the publication of the trials that are currently in progress.

SITE OF COMPRESSION

The desired compression point for CPR in adults remains over the lower half of the sternum. Compressions higher than this become less effective, and compressions lower than this are also less effective and have an additional risk of damage to intra-abdominal organs.

RATE OF COMPRESSION

The optimal rate of chest compressions during cardiac arrest in adults is uncertain, but observational data allow some conclusions to be drawn.[13] The international consensus recommendation is that chest compressions should be performed at a rate of 100–120/min.[9]

DEPTH OF COMPRESSION

The optimal depth of chest compressions is uncertain. The recommended compression depth for adults is 5–6 cm. To achieve this goal, ANZCOR recommends that the chest should be compressed approximately one-third of its depth (in adults, children and infants). Compressions that are too deep may be associated with an increase in complications.[14]

MINIMISE INTERRUPTIONS TO COMPRESSIONS

Interruptions to chest compressions are common, can be prolonged, and result in a decrease in coronary perfusion pressure and reduced defibrillation success.[15] These adverse effects commence within 10 seconds of stopping CPR, but appear to be at least partially reversible with the recommencement of chest compressions. The frequency and duration of interruptions in compressions for rhythm recognition or specific interventions (such as ventilations, charging the defibrillator, defibrillation or placement of devices/equipment) should be kept to a minimum.

COMPRESSION:VENTILATION RATIO

During CPR the cardiac output is reduced to approximately one-third of normal. The minute ventilation requirements are similarly decreased. A single compression:ventilation ratio of 30:2 remains recommended for adult BLS before the airway is secured (irrespective of the number of rescuers). The tidal breath should be delivered within 1 second, and the desired tidal volume to be delivered is one that results in a visible chest rise.

MONITORING THE QUALITY OF CARDIOPULMONARY RESUSCITATION

Simple techniques to monitor the quality of CPR include observation of the rate, depth and positioning of chest compressions, the rate and depth of ventilation and palpation of central pulses. Waveform capnography should be considered for all arrests (Box 21.1). Additional monitoring (e.g. defibrillators) can be used to monitor the depth and rate of compressions and ventilation. Real-time feedback from these devices offers much promise but has limitations [16] and has not been translated into improved survival,[17,18] even when supplemented with post-arrest debriefing.[18]

Box 21.1 Utility of end-tidal carbon dioxide monitoring during cardiac arrest

Cardiovascular (absolute value of $ETCO_2$)
Falls immediately at the onset of cardiac arrest
Increases immediately with chest compressions
Provides a linear correlation with cardiac index
Allows early detection of ROSC (sudden increase)
Respiratory ($ETCO_2$ waveform)
Allows assessment of endotracheal tube placement
Allows assessment of expiratory flow limitation
Prognosis (absolute value of $ETCO_2$)
Predicts successful resuscitation

$ETCO_2$, End-tidal carbon dioxide; *ROSC*, return of spontaneous circulation.

'COMPRESSION-ONLY' CARDIOPULMONARY RESUSCITATION

Increasing anxiety about the performance of mouth-to-mouth ventilation has required the consideration of an alternative approach to traditional bystander CPR. A number of animal and human studies have suggested that ventilation may not be necessary during the initial phase of resuscitation from an arrest of a cardiac cause. Despite the limited data to support 'compression-only' CPR, it is recommended that if rescuers are unable, not trained, or unwilling to perform mouth-to-mouth ventilation (rescue breathing) then they should perform 'compression-only' CPR.

DEFIBRILLATION

Defibrillation remains the definitive treatment for shockable rhythms, such as pulseless ventricular tachycardia or VF. Successful defibrillation requires an appropriate combination of defibrillator waveform and energy level.[19]

EARLY DEFIBRILLATION VERSUS CARDIOPULMONARY RESUSCITATION BEFORE DEFIBRILLATION

The traditional approach to the treatment of a shockable rhythm during cardiac arrest has been to perform defibrillation as soon as practicable. However, in situations where VF has persisted for more than a few

minutes, an initial period of CPR does not appear to be harmful.[20]

WAVEFORM FOR DEFIBRILLATION

No specific defibrillator waveform (either monophasic or biphasic) is consistently associated with a greater incidence of return of spontaneous circulation (ROSC) or increased hospital discharge rates from cardiac arrest due to VF.[19]

ENERGY LEVELS

Recommendations for energy levels to be used for defibrillation vary according to the type of defibrillator that the rescuers are using and its specific waveform. Current recommendations are based on maximising the likelihood of success for each shock. The recommended energy level for defibrillation in adults where monophasic defibrillators are used is 360 J for all shocks. When using biphasic waveforms, the energy level should be set at 200 J for all shocks unless there is relevant clinical data for the specific defibrillator suggesting that an alternative energy level provides adequate shock success (e.g. >90%). An escalation of energy levels may be considered for subsequent shocks, though there is no evidence of a survival benefit with this approach.[19]

MANUAL DEFIBRILLATION OR AUTOMATED EXTERNAL DEFIBRILLATOR

Automated external defibrillators (AEDs) provide an opportunity for BLS providers and untrained bystanders to defibrillate a shockable rhythm. Skilled health care providers should use manual defibrillation whenever possible to avoid the delays inherent in the use of an AED.[21]

SINGLE-SHOCK TECHNIQUE

A single-shock strategy is still recommended for defibrillation (i.e. deliver a single shock and then immediately commence CPR). This strategy minimises the interruptions to chest compressions that occur during defibrillation attempts.

PADS OR PADDLES

Self-adhesive defibrillation pads are safe and effective for defibrillation and pacing. If there are concerns about contact or success of defibrillation, then paddles can be used, but they require the use of conductive gel pads and the application of sufficient firm pressure to maximise electrical contact. The default position for application of electrodes is anterior-lateral, but antero-posterior or apex-posterior can also be used (www.resus.org.au).

ADVANCED LIFE SUPPORT

ALS has an established role in the management of cardiac arrests. Although it appears obvious that the provision of ALS should improve outcomes, this has not been specifically demonstrated.

ADVANCED LIFE SUPPORT FLOW CHART

The recommended sequence of treatment to be followed is outlined in the updated 2016 Advanced Life Support ANZCOR flow chart (Fig. 21.2). This flow chart has been designed to be used as an aide memoire and a teaching tool.

PRECORDIAL THUMP

The provision of a precordial thump may be considered in a monitored arrest due to pulseless ventricular tachycardia if a defibrillator is not immediately available. The technique is not without risks and should not delay defibrillation.

CHEST COMPRESSIONS

The provision of good BLS is an essential part of the ALS management of both shockable and non-shockable rhythms. Interruptions to chest compressions for definitive procedures or interventions (such as defibrillation) should be kept to a minimum. CPR also should be commenced again immediately following defibrillation (without checking the rhythm), and continued for at least 2 minutes unless signs of life return (the victim becomes responsive or starts breathing). Even if defibrillation has successfully reverted the rhythm into one that could generate a pulse, in the vast majority of cases this is not initially associated with an output. Immediate compressions in these situations avoid the detrimental effects of prolonged interruptions in compressions and maintain the coronary perfusion. After each 2 minutes of CPR[22] (or if signs of life return), the underlying rhythm should be checked. If a rhythm compatible with a return of spontaneous circulation (ROSC) is observed at that time, then a central pulse should also be checked.

AIRWAY MANAGEMENT DURING CARDIOPULMONARY RESUSCITATION

Endotracheal intubation remains the gold standard for airway maintenance and airway protection but there are conflicting data to support its use early in a cardiac arrest.[23] There appears to be some survival benefit of endotracheal intubation over supraglottic airways in the out-of-hospital setting,[24] but no advanced airway (endotracheal or supraglottic) has been shown to be consistently better than bag-valve-mask ventilation alone.[25] Attempts at securing an advanced airway

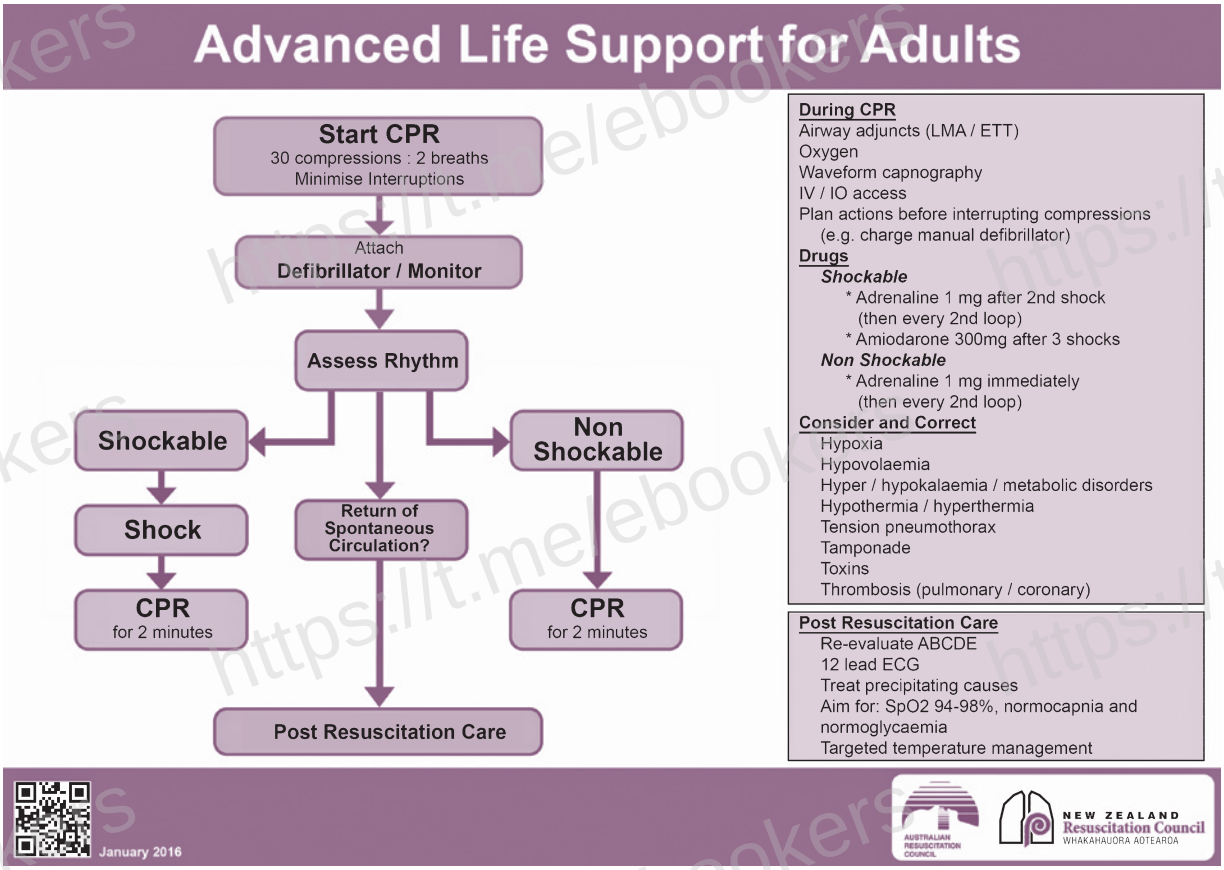

Figure 21.2 Advanced life support flow chart. *(Reproduced with permission from the Australian Resuscitation Council [www.resus.org.au]).*

should not interrupt cardiac compressions for more than 20 seconds. If an advanced airway is considered necessary, the training and experience of the resuscitation team members and the availability of devices, will determine which technique is appropriate.

VENTILATION DURING CARDIOPULMONARY RESUSCITATION

A compression:ventilation ratio of 30:2 is recommended before the airway is secured, and after the airway is secured the recommended ventilation rate is 8–10/min. One way to provide this with a secure airway, to minimise interruptions to compressions, is to use a compression:ventilation ratio of 15:1 (www.resus.org.au). The tidal volume recommended is one that results in a visible chest rise. High respiratory rates during cardiac arrest are associated with increased intrathoracic pressure, decreased coronary and cerebral perfusion, and, at least in animals, a decreased rate of ROSC.[26] If there is a concern about potential gas trapping, a period of disconnection from the ventilation circuit may be beneficial.

IDENTIFICATION OF REVERSIBLE CAUSES

Irrespective of the initial rhythm, cardiac arrests can be precipitated or perpetuated by a number of conditions that if not detected and corrected may decrease the likelihood of successful resuscitation.[8] These 'reversible causes' are categorised in the ALS algorithm as the '4Hs and 4Ts' (see Fig. 21.2). A number of techniques are available to assist in the diagnosis and exclusion of these conditions. These include a good history, a careful clinical examination and some specific investigations and interventions. Echocardiography, even in the pre-hospital setting,[27] can potentially diagnose (or help exclude) a number of cardiac and non-cardiac reversible causes (Box 21.2).[28]

MEDICATIONS DURING CARDIOPULMONARY RESUSCITATION

Although various drugs are recommended for use during the management of cardiac arrests, evidence supporting their effectiveness is quite limited. The intraosseous route should be considered for the

VF, Ventricular fibrillation.

administration of medications if venous access is not immediately available.[29]

VASOPRESSORS

The putative beneficial effect of vasopressors during cardiac arrest is to increase the perfusion pressure to the heart and brain. The use of intravenous epinephrine in randomised controlled trials (RCTs) enrolling out-of-hospital cardiac arrests has been associated with improved short-term survival, but not survival to hospital discharge.[30,31] Given these data, it is considered reasonable to continue to use epinephrine routinely in the management of cardiac arrests. The initial adult dose is 1 mg and this should be repeated approximately every 4 minutes. Vasopressin is an alternative drug, but studies have been unable to demonstrate any consistent benefits with its use.

ANTIARRHYTHMICS

Administration of amiodarone or lidocaine for shock refractory VF has been associated with an increased survival to hospital when compared with placebo.[32] In the largest RCT of anti-arrhythmic drugs, neither amiodarone nor lidocaine improved long-term survival when compared with placebo across the board,[33] though there was an increase in survival to discharge with amiodarone or lidocaine compared with placebo in the pre-specified subgroup of patients with a bystander-witnessed arrest.[34] Either amiodarone or lidocaine (but not both) should be considered in those patients still in VF after repeated attempts at defibrillation (including attempted defibrillation after the administration of epinephrine) have failed.

OTHER MEDICATIONS

Other medications that should be considered during cardiac arrest are those that address the detected underlying contributing factors. These include electrolytes (such as magnesium or potassium), atropine, sodium bicarbonate and other specific 'antidotes' (Table 21.1).[35]

Table 21.1 Cardiac arrest medications in specific circumstances

MEDICATION	POTENTIAL INDICATIONS
Atropine	Cholinergic/cardiac glycoside toxicity
Antivenom	Snake, funnel-web spider, box jellyfish venom
Benzodiazepines	Sympathomimetic toxicity
Calcium	Hypocalcaemia, hypermagnesaemia, hyperkalaemia, beta-blocker/calcium channel blocker toxicity
Digoxin-specific antibodies	Cardiac glycoside toxicity
Flumazenil	Benzodiazepine toxicity
Epinephrine (adrenaline)	Beta-blocker/calcium channel blocker toxicity
Glucagon	Beta-blocker/calcium channel blocker toxicity
High-dose insulin/dextrose	Beta-blocker/calcium channel blocker toxicity
Lipid emulsion	Local anaesthetic agents
Magnesium	Hypomagnesaemia, hypokalaemia, hypercalcaemia, tricyclic antidepressant/cardiac glycoside toxicity, torsade de pointes
Naloxone	Opioid toxicity
Potassium	Hypokalaemia
Pyridoxine	Isoniazid toxicity
Sodium bicarbonate	Hyperkalaemia, tricyclic antidepressant/sodium-channel-blocker toxicity

ADJUNCTS TO CARDIOPULMONARY RESUSCITATION

Many technologies and techniques have been evaluated as adjuncts or alternatives to CPR in an attempt to improve the management of cardiac arrests, but none have been consistently associated with improved outcomes. Mechanical CPR devices have been studied in great detail, but large RCTs have not been able to demonstrate any survival benefit with either the Lund University Cardiopulmonary Assist System (LUCAS) or AutoPulse.[36-38] The combination of active-compression decompression CPR with an impedance threshold

device was associated with improved neurological survival in an RCT in out-of-hospital cardiac arrests.[39]

However, mechanical devices (such as the LUCAS or the AutoPulse) may be useful alternatives to manual CPR in situations where traditional CPR is difficult or hazardous: during transport; during interventions (such as percutaneous coronary interventions [PCIs]); or as a bridge to extracorporeal techniques.

There has been an increased interest in extracorporeal techniques, especially as short-term rescue for refractory arrests.[40,41]

At this stage there is still insufficient supportive evidence to recommend the routine use of any of these adjunctive techniques.

POST-RESUSCITATION CARE

Survival after cardiac arrest is largely dependent on the patient's co-morbidities and the initial hypoxic insults to the heart and brain. However, survival is also influenced by subsequent complications, including secondary insults, the ensuing systemic inflammatory response[42] and differences in post-resuscitation care (Box 21.3).[1,7,43]

Box 21.3 Key factors to consider after resuscitation from cardiac arrest

Immediate tasks
- Re-evaluate Airway Breathing Circulation Disability Exposure (ABCDE)
- 12-lead electrocardiogram (ECG)
- Treat precipitating causes
- Re-evaluate oxygenation and ventilation
- Temperature control (cool)

Early goals
- Continue respiratory support
- Maintain cerebral perfusion
- Treat and prevent cardiac arrhythmias
- Determine and treat the cause of the arrest

Specific tasks
- Maintain haemodynamics (SBP >100 mm Hg [13 kPa])
- Maintain adequate oxygenation (SaO_2 94%–98%)
- Maintain normal pH and normocarbia (e.g. $PaCO_2$ 35–40 mm Hg [4.5–5.2 kPa])
- Treat hyperglycaemia (>10 mmol/L), but avoid hypoglycaemia
- Consider therapeutic hypothermia (unless contraindicated)
- Maintain appropriate sedation
- Treat seizures
- Continue search to identify underlying cause(s) and trauma related to resuscitation
- Consider specific treatment for underlying cause (e.g. percutaneous coronary intervention, thrombolytics)
- Consider prophylactic antiarrhythmics
- Consider transfer to resuscitation centre

SBP, Systolic blood pressure.

RESUSCITATION CENTRES

An increasing body of evidence suggests that there may be benefits in transporting the victims of out-of-hospital cardiac arrests to a centre that is equipped to provide all of the desired components of post-arrest care (including PCIs and therapeutic hypothermia).[1]

THERAPEUTIC HYPOTHERMIA

The international consensus recommendation is that unconscious haemodynamically stable survivors of out-of-hospital cardiac arrests due to VF should be cooled to 32–36°C for 24 hours.[44] Care should be taken if using the upper level of this range to ensure that fever is avoided.[45] A period of induced hypothermia should also be considered for cardiac arrests due to other rhythms, as well as in-hospital arrests.[44] Pre-hospital cooling with cold fluids appears not to be of benefit[44] and intra-arrest cooling with cold fluids is not indicated.[46]

ADDITIONAL FACTORS IN POST-RESUSCITATION CARE

Attention should be given to good supportive care for the patient after cardiac arrest. This includes maintenance of cerebral perfusion, provision of adequate oxygenation, ventilation, glucose control and treatment of seizures.[43]

OXYGENATION

The routine use of 100% oxygen after cardiac arrest is being questioned. Data from animal and neonatal studies have suggested that this may be associated with adverse outcomes. The adult cardiac arrest evidence regarding effects of oxygenation is accumulating, but is of low quality and remains controversial.[47] However, it seems reasonable to titrate the FiO_2 to target an acceptable SaO_2 (e.g. 94%–98%) as soon as the patient is stable.

VENTILATION

Numerous studies in animals and humans have demonstrated the potential harm of cerebral ischaemia induced by hypocapnia after cardiac arrest. Recent data suggest that mild hypercapnia may be beneficial.[48] Arterial blood gas measurements should be used to titrate ventilation in the immediate post-resuscitation period, rather than the less reliable end-tidal CO_2.

BLOOD PRESSURE CONTROL

There is limited human evidence to support specific haemodynamic goals after cardiac arrest. Hypotension appears to be detrimental,[49] but no specific target blood pressure has been identified. It is recommended to aim for a blood pressure equal to the patient's usual blood pressure or a systolic pressure greater than 100 mm Hg.

GLUCOSE CONTROL

Despite the early promise of improved outcomes with tight blood glucose control, subsequent studies have demonstrated this approach to be potentially harmful. Blood glucose should be monitored frequently after cardiac arrest. Hyperglycaemia (>10 mmol/L) should be treated with insulin, and hypoglycaemia should be avoided.

PERCUTANEOUS CORONARY INTERVENTION

The routine use of thrombolytics after cardiac arrest has not increased survival. PCIs should be considered as part of routine post-arrest care in patients with ST elevation or a new left-bundle branch block, irrespective of the neurological state. Angiography also should be considered in patients without ST-segment elevation as these patients commonly have a culprit lesion.[50]

Therapeutic hypothermia is recommended in combination with primary PCI, and should be started as early as possible, preferably prior to the initiation of PCI.

TREATMENT OF SEIZURES

Seizures are relatively common after cardiac arrest (incidence of 3%–44%), and in the post-arrest period they may be refractory to multiple medications. It is reasonable to institute prompt and aggressive treatment of seizures, but there is no definitive evidence to suggest that this approach (or preventative therapy) improves outcomes.

OTHER FACTORS

The search should be continued to identify and treat underlying causes of the arrest. Traumatic complications of resuscitation (e.g. rib fractures and sternal fractures) are relatively common, and should be identified and treated as appropriate.

It is reasonable to use an infusion of an antiarrhythmic drug that successfully restored a stable rhythm during resuscitation (e.g. lidocaine 2–4 mg/min or amiodarone 0.6 mg/kg/h for 12–24 hours). If no antiarrhythmic drug was used during resuscitation from a shockable rhythm, an antiarrhythmic drug may be considered to prevent recurrent VF.

The placement and sterility of devices inserted during the arrest should also be reviewed.

PROGNOSTICATION

It is impossible to accurately predict the potential degree of neurological recovery either during or soon after a cardiac arrest.

Accurate prediction of neurological outcome has become increasingly difficult since therapeutic hypothermia has been widely used in the post-arrest period. A number of reviews of the evidence from prognostic studies have been published.[19,51] Even the presence of myoclonus may not predict the dire outcomes it was previously associated with.[52] It is strongly recommended that decisions to limit care should not be made based on the results of a single prognostication tool, but instead the information from clinical examination, electroencephalography, neuroimaging and biochemical markers should be taken into account.

MAINTENANCE OF ALS SKILLS

Many studies have confirmed that the knowledge and skills related to ALS start to deteriorate relatively quickly after completion of ALS training (e.g. within 6 months).[53] It is recommended that ALS training includes human factors and team training, and additional simulations or education may be necessary at more frequent intervals to ensure all staff maintain their skills.

SUMMARY

Improved outcomes over the past decade are almost certainly due to a number of incremental improvements in the management of patients during and after cardiac arrests. The key to continual improvement lies with techniques to improve early delivery of good-quality BLS, as well as attention to detail in the post-resuscitation care phase and accurate prognostication. We are awaiting the publication of a number of exciting studies, and hopefully their results will inform further improvements in survival over the next decade.

Cardiac arrhythmias (combine with drugs)

Andrew William Holt

CARDIAC ELECTROPHYSIOLOGY

The electrophysiological properties of cardiac cells are important in understanding cardiac arrhythmias and their management. Cardiac cells undergo cyclical depolarisation and repolarisation to form an action potential. The shape and duration of each action potential is determined by the activity of ion channel protein complexes on the myocyte surface (Table 22.1).[1]

Ion channels are large glycoproteins that span the membrane bilayer with accessory subunits that contribute to pore structure or modulate function. The genes encoding all the major ion channels have been cloned and sequenced.

Channel activation forms pores that permit rapid transit of ions, creating ionic currents that determine the magnitude and rate of change of myocyte membrane potential.

Ion channels have two fundamental properties[2]:

ION PERMEABILITY

Channels classified on the basis of selectivity; Na^+, K^+ and Ca^{++}. Selectivity determined by size, valency and hydration energy. For example, the ration of Na^+:K^+ selectivity of Na^+ is 10:1. Channels contain multiple binding sites as ions traverse the channel and ions become dehydrated, as binding is favoured over ion-water interaction. Most have rectifying properties whereby they conduct ions more effectively in one direction.

Gating – the mechanism by which channels open and close.

Most are voltage gated and modulated by ligand binding.

Voltage-gated channels change their conductance in response to change in membrane potential. Majority of channels open in response to depolarisation, whereas pacemaker channel I_f opens in response to hyperpolarisation.

Ligand-gated channels include $I_{K\,Ach}$, the muscarinic-gated K^+ current where binding of acetylcholine mediates vagal effect by decreasing diastolic depolarisation in sinoatrial (SA) and atrioventricular (AV) pacemaker cells. $I_{K\,ATP}$ channels bind ADP activating phase 1 and 2 K^+ current to shorten the action potential matching force generation and duration to cellular energy or ADP levels. This effect is also arrhythmogenic due to shortened refractory period. The $I_{K\,ATP}$ channel is a target to break the link between ischaemia and arrhythmia. The cardioprotective effect of $I_{K\,ATP}$ plays a role in ischaemia preconditioning.

Mechanosensitive or stretch-activated channels alter action potential in response to beat-to-beat variations in pressure and volume load. Increases in load SA node pacemaker rate and action potential is increased, whereas refractory period and conduction is reduced. Sustained pressure and volume load is arrhythmogenic via these changes to the action potential.

Many of the ion channels are the molecular targets for antiarrhythmic drugs. The differential distribution of ion channel populations within the heart allows drugs to have preferential activity on different parts of the heart.

I_f 'pacemaker' channels are confined to the SA node and new drugs with specific I_f-blocking activity such as ivabradine have been shown to be beneficial in angina and heart failure by slowing the heart rate without negative effects on ventricular contractility.

I_K channels responsible for potassium ion (K^+) repolarisation currents (I_K) vary throughout the heart with the rapidly activating forms, I_{Kur}, being confined to the atrium. Vernakalant, a new K channel blocker has predominant activity on the I_{Kur} channel and therefore predominant atrial activity.

The spectrum of cardiac action potentials varies from *fast-response* cells – conducting and contractile myocytes (Fig. 22.1A) – to *slow-response* cells of pacemaker myocytes – SA and AV nodes (see Fig. 22.1B). Fast myocytes lose their characteristic action potential and behave more like slow myocytes when ischaemic. The action potential is divided into five phases and ion channel currents vary between fast- and slow-response cells (Fig. 22.2).

PHASE 0

In fast myocytes (see Fig. 22.1A), rapid depolarisation I_{Na} current occurs owing to activation of voltage-gated sodium ion (Na^+) channels. Activation is initiated in an all-or-none response once the threshold is reached. The Na^+ channels are inactivated as membrane potential

ABSTRACT

Cardiac arrhythmia is a major challenge for the critical care specialist. Cardiac electrophysiology is important to understanding arrhythmia mechanisms, accurate electrocardiographic diagnosis and guiding treatment. Acute control of arrhythmia with antiarrhythmic drugs, cardiac pacing and direct current shock are effective in avoiding haemodynamic compromise and management of cardiac arrest. Prevention and long-term control is more difficult due to lack of ideal antiarrhythmic drugs, with drug side effects outweighing antiarrhythmic benefit. Classification of antiarrhythmic drugs on the basis of their molecular targets, ion channels, receptors, ion pumps and carriers supersedes the traditional Vaughan-Williams classification. Increasingly, catheter ablation of arrhythmogenic areas of the heart is proving to be superior to antiarrhythmic drugs for long-term control. The importance of thromboembolic complications demands an evidence-based approach to anticoagulation.

Table 22.1 Characteristics of cardiac ionic channels

ION	CHANNEL	
		INWARD CURRENT/DEPOLARISATION
Sodium Na_v	I_{Na}	• Present in atria, His–Purkinje and ventricle • Absent in SA and AV node • Generates phase 0 rapid depolarisation current • Drives action potential propagation
Calcium Ca_v	$I_{Ca\text{-}L}$	• Predominate Ca^{2+} channel • Contributes to phase 2 plateau • Produces depolarisation and propagation in SA and AV nodes • Triggers Ca^{2+} release from sarcoplasmic reticulum
	$I_{Ca\text{-}T}$	• Predominates in pacemaker cells • Contributes to later stages of phase 4 in pacemaker cells
Non-selective cation	I_f	• Predominately Na • Absent in ventricular cells • Activated by polarisation • Generates phase 4 depolarisation of pacemaker function • Strongly modulated by neurotransmitters
		OUTWARD CURRENT/REPOLARISATION
Potassium K_v	I_{to}	• Activated rapidly after depolarisation • Fast I_{to1} and slow I_{to2} variants • Responsible for phase 1 rapid early repolarisation • Predominate distribution subepicardial • Distribution creates heterogeneous repolarisation
	I_K	• Delayed rectifiers • Slow activation kinetics • Major repolarising current • Variants with slow I_{Ks}, rapid I_{Kr} and ultra-rapid I_{Kur} activation • I_K populations are not characterised in the SA node • I_{Kur} are not present in the ventricle • I_{Kur} along with I_{to} contributes to earlier repolarisation and shorter action potentials of atrial cells
	I_{K1}	• Inward rectifier • Current responsible for maintaining resting potential near K^+ equilibrium • Shuts off during depolarisation • Absence in SA node enables small currents to control pacemaker rates
	I_{Ach}	• Muscarinic-gated K^+ channel • Vagal effect by decreasing phase 4 depolarisation
	I_{KATP}	• Binds ADP • Activated in ischaemia • Activates phase 1 and 2 K^+ current to shorten action potential

AV, Atrioventricular; *SA*, sinoatrial.

rises to +30 mV and remain inactivated until repolarisation occurs. Rapidity of depolarisation determines speed of conduction. In slow-response myocytes, depolarisation does not involve Na^+ channels and the slower rate of depolarisation is due to a slow inward calcium ion (Ca^{2+}) current via $I_{Ca\text{-}L}$ and $I_{Ca\text{-}T}$ voltage-dependent Ca^{2+} channels.

PHASE 1

Early rapid incomplete repolarisation to approximately 0 mV occurs owing to activation of transient outward current from I_{TO1} and I_{TO2} K^+ channels. Slow myocytes do not exhibit phase 1 or 2 characteristics (see Fig. 22.1B).

PHASE 2

The prolonged plateau repolarisation of fast myocytes is a consequence of low membrane conductance to all ions. The decreasing inward Ca^{2+} current of $I_{Ca\text{-}L}$ and $I_{Ca\text{-}T}$ Ca^{2+} channels is initially balanced and then overcome by the outward K^+ current of the delayed rectifiers or the I_k family of K^+ channels. During this phase,

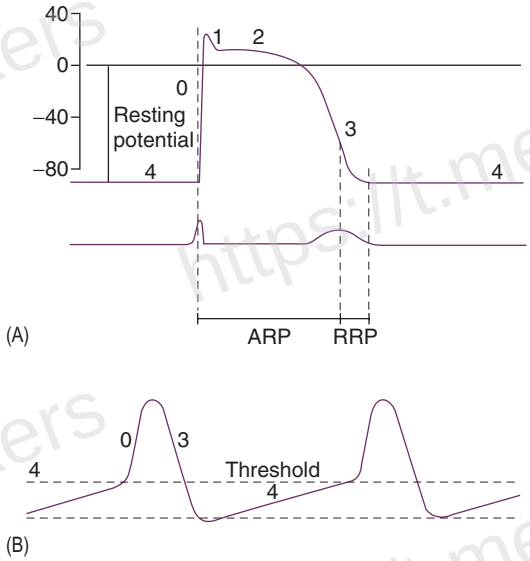

Figure 22.1 (A) Action potential in a fast-response, non-pacemaker myocyte: phases 0–4, resting membrane potential – 80 mV, absolute refractory period *(ARP)* and relative refractory period *(RRP)*. (B) Action potential in a slow-response, pacemaker myocyte. The spontaneous upward slope of phase 4, on reaching threshold potential, results in an action potential.

the rise in calcium ion concentration ($[Ca^{2+}]_i$) is the trigger to release sarcoplasmic reticulum stores of Ca^{2+} and initiate the contractile process.

PHASE 3

Relatively rapid repolarisation occurs as outward K^+ current of the delayed rectifiers increases. The I_{kr} K^+ channel, one of the I_k delayed rectifiers, is the common mechanism whereby antiarrhythmic drugs prolong the action potential and refractoriness.

PHASE 4

This is a stable electrical state in fast non-pacemaker myocytes owing to inward rectifier I_{K1} channels maintaining resting membrane potential (RMP) near K^+ equilibrium and the absence of I_f pacemaker channels. In slow pacemaker myocytes, phase 3 I_{KI} current repolarises membrane potential activating I_f channels. Subsequent pacemaker depolarisation of phase 4 to threshold occurs due to I_{K1} channel closure and I_f depolarising current (see Fig. 22.1B).

Fast-response and slow-response myocytes also have important differences in properties of refractoriness. In fast myocytes, Na^+ channels are progressively reactivated during phase 3 repolarisation as the membrane potential becomes more negative. When an extra stimulus occurs during phase 3, the magnitude of the resulting inward Na^+ current and likelihood of impulse propagation depend on the number of reactivated Na^+ channels. Refractoriness is therefore determined by the voltage-dependent recovery of Na^+ channels. The absolute refractory period (see Fig. 22.1) is that minimum time needed for recovery of sufficient Na^+ channels for a stimulus to result in impulse propagation. However, once propagation in fast myocytes occurs, conduction velocity is normal. In contrast, slow-response or Ca^{2+} channel-dependent myocytes exhibit time-dependent refractoriness. Even after full repolarisation, further time is needed before all Ca^{2+} channels are reactivated. Stimuli during this period produce reduced Ca^{2+} current and the propagation velocity of any resulting impulse is reduced. The conduction velocity independence of premature action potentials with fast-response myocytes is lost in the setting of Na^+ channel-blocking drugs or ischaemia because they behave increasingly like slow-response myocytes with resulting slowed impulse conduction.

GENETIC BASIS TO ARRHYTHMIA[1]

In the absence of structural abnormalities of the heart, primary electrical disease is associated with mutations in ion channel genes. The long-QT syndrome (LQTS) (see later), short-QT syndrome, Brugada syndrome (idiopathic ventricular fibrillation, VF), catecholaminergic polymorphic ventricular tachycardia (VT) and all causes of sudden cardiac death (SCD) in the young are examples of primary electrical disease where genetic mutations encoding for ion channel proteins have been characterised.

Inheritable forms of structural ventricular disease are associated with atrial arrhythmias and SCD. Examples include hypertrophic and dilated cardiomyopathies and arrhythmogenic right ventricular dysplasia, which are linked to mutations in sarcomeric, cytoskeletal and intercellular junction proteins, respectively.

The risk of cardiac arrhythmias and SCD in the setting of acquired structural heart disease such as ischaemic heart disease is in part genetically determined. Studies demonstrate an increased risk of SCD in patients who have a parental history of cardiac arrest.

MOLECULAR BASIS TO ARRHYTHMIA[2]

Structural and electrical remodelling in response to myocardial injury, altered haemodynamic loads and changes in neurohumoral signalling lead to alterations in:

- ion channel function
- intracellular calcium handling
- intercellular communication
- composition of intercellular matrix.

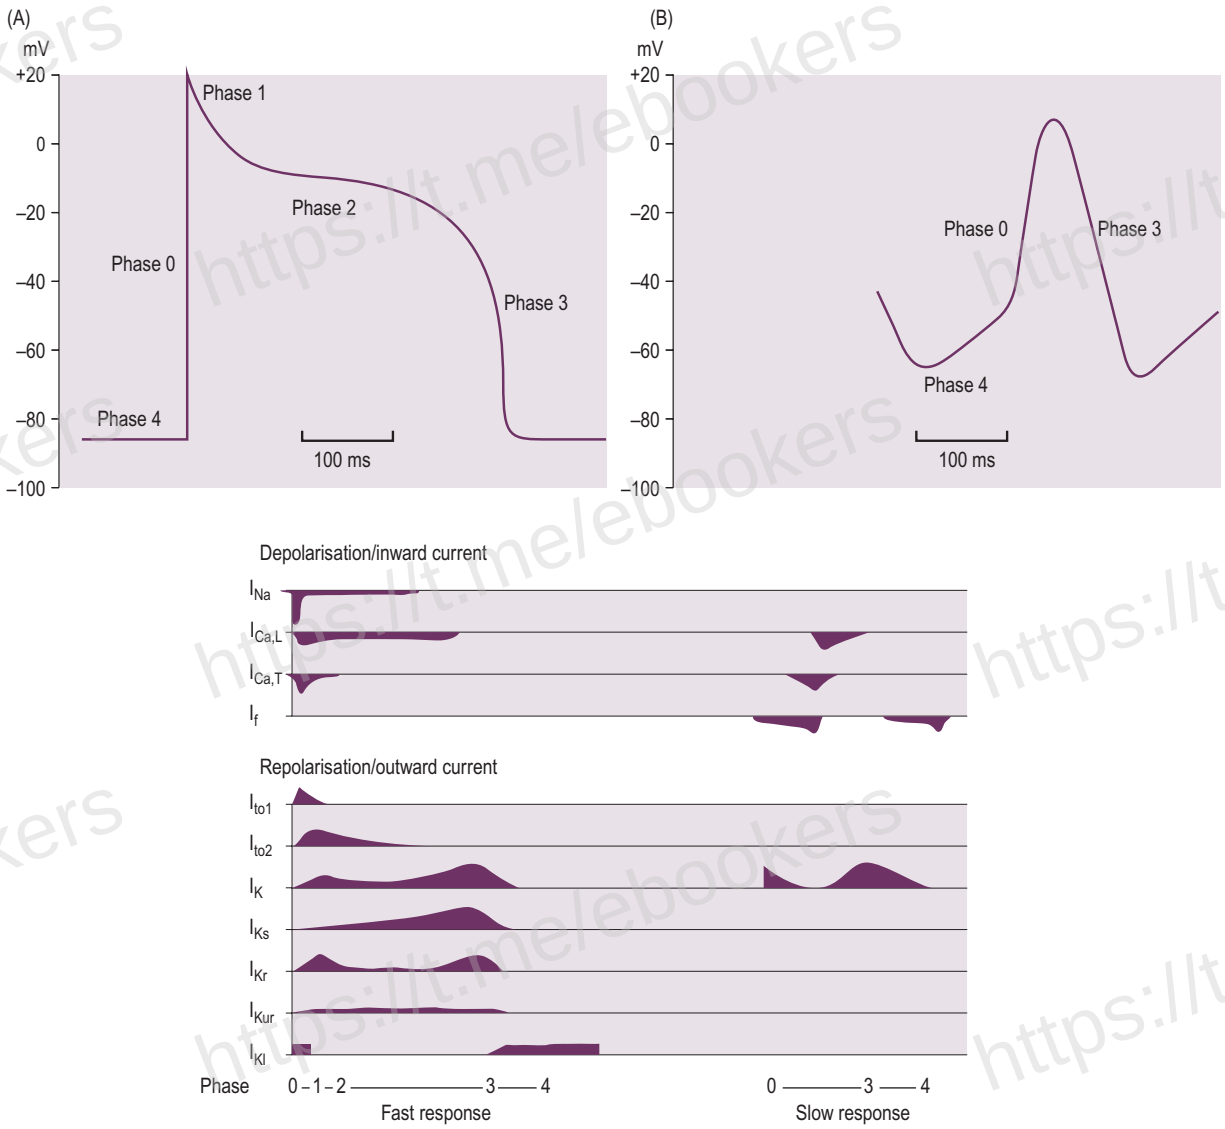

Figure 22.2 Temporal relationship between action potential and ionic channel activation for: (A) fast-response ventricular myocytes and (B) slow-response pacemaker myocytes.

All of these factors lead to heterogeneous slowing of conduction velocity and prolonged refractoriness.

Tachycardia remodelling of the atrium is associated with:

- reduced functional expression of L-type Ca^{2+} channels, intracellular Ca^{2+} overload and shortening action potential duration.

Heart failure is associated with:

- down-regulation of each of the major repolarising K^+ currents, prolonging repolarisation and resulting in susceptibility to early-after-depolarisation (EAD)-mediated arrhythmia. As these changes are heterogeneous, they also create the substrate for re-entrant arrhythmias
- reduced Na^+ channel density decreasing conduction velocity
- increased expression of Na^+–Ca^{2+} exchanger protein, leading to intracellular Ca^{2+} overload and predisposition to delayed-after-depolarisation (DAD)-mediated arrhythmia.

Intercellular ion channels or connexins at gap junctions are decreased and redistributed from the intercalated disc to lateral cell borders, slowing conduction velocity and uncoupling myocytes.

Myocardial infarction scar produces:

- heterogeneous action potential duration with zones of healing myocytes with shortened action potential and surrounding hypertrophic myocytes with prolonged action potentials
- potential anatomical circuits due to fibrous tissue separating myocyte bundles.

ARRHYTHMOGENIC MECHANISMS[4–6]

Many factors in isolation or combination give rise to the substrate of arrhythmogenesis (Fig. 22.3). Arrhythmia may arise from abnormalities of impulse generation or conduction. Table 22.2 demonstrates the relationship between mechanism and type of arrhythmia and desired antiarrhythmic effect.

ABNORMAL IMPULSE GENERATION (TABLE 22.3)

ENHANCED NORMAL AUTOMATICITY

Automaticity is the property of spontaneous impulse generation by cardiac myocytes. This results from spontaneous depolarisation during phase 4. In the SA node and subsidiary pacemaker myocytes, phase 4 spontaneous depolarisation results from an inward current, predominantly Na^+ via the non-selective cation channel I_f. SA node discharge rate is influenced by changes to channel activity. Beta-adrenergic receptor stimulation increases both I_f and $I_{Ca\text{-}T}$ conductance and rate of phase 4 depolarisation by channel phosphorylation, whereas M_2 receptor increases I_k activity during phase 3 and early phase 4 to hyperpolarise myocytes, increasing time to reach depolarisation threshold.

Enhanced normal automaticity of subsidiary atrial pacemakers, for example around pulmonary veins, is an increasingly recognised cause of atrial fibrillation (AF).

ABNORMAL AUTOMATICITY

Abnormal automaticity is the mechanism by which spontaneous impulses are generated in myocytes that are partially depolarised by a pathological process. The less negative RMP is associated with inactivation of the normal ionic currents of phase 4 depolarisation and the pacemaker current results from inward Na^+ and Ca^{2+} currents and is not readily susceptible to overdrive suppression from normal pacemaker activity. Due to this less negative membrane potential, these abnormal automatic myocytes inactivate the phase 0 fast inward Na^+ current, resulting in an impaired rate of impulse conduction (as well as contractility), which further contributes to arrhythmia. In this setting, Ca^{2+} carries the major inward current on depolarisation in these myocytes.

TRIGGERED ACTIVITY

Abnormal impulse generation from triggered activity originates from oscillations in the membrane potential that are initiated or triggered by a preceding action potential. There are two types of oscillations: EAD and DAD. EAD occurs during phase 2 or 3 of the action potential, whereas DAD occurs after the termination of depolarisation. The signal-averaged electrocardiograph (ECG) can detect after-depolarisations.

1. EADs appear as sub-threshold humps during the plateau or depolarisation phases. On reaching threshold, single or multiple action potentials can be induced. Plateau EADs are caused by an increased

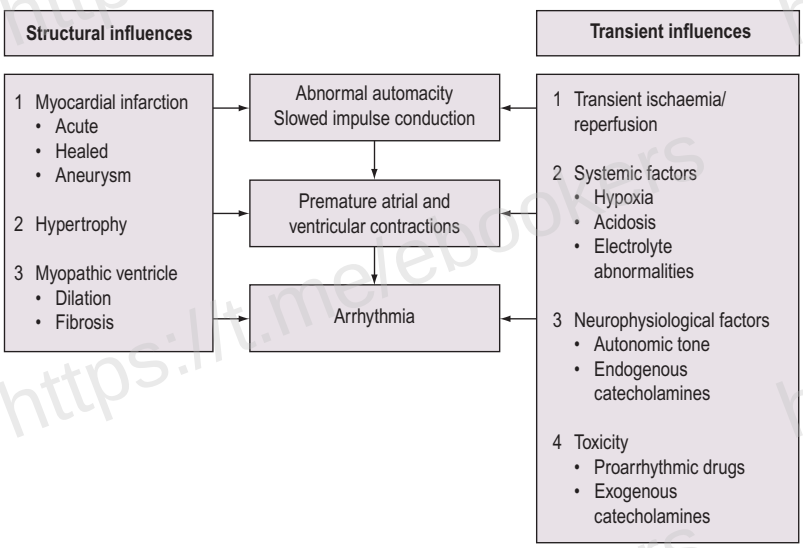

Figure 22.3 Factors that combine to form the substrate of arrhythmogenesis.

Table 22.2 Classification of mechanisms of arrhythmia and desired antiarrhythmic drug action[3]

MECHANISM OF ARRHYTHMIA	ARRHYTHMIA	ANTIARRHYTHMIC EFFECT	REPRESENTATIVE DRUGS
AUTOMATICITY ENHANCED			
Normal	Inappropriate sinus tachycardia Unifocal atrial tachycardia	Decrease phase 4 depolarisation	Beta blocker Sodium channel blockers
Abnormal	Unifocal atrial tachycardia Accelerated idioventricular rhythms VT post myocardial infarction	Hyperpolarise or decrease phase 4 depolarisation	Calcium or sodium channel blockers M_2 agonists (muscarinic receptor)
TRIGGERED ACTIVITY			
EAD	Torsade de pointes Digitalis-induced arrhythmias Some VT	Shorten action potential or suppress EAD	Increase heart rate with beta agonists or vagolytic agents, calcium channel blockers, beta blockers or magnesium
DAD		Decrease calcium overload or suppress DAD	Calcium or sodium channel blockers, beta blockers, adenosine
RE-ENTRY: SODIUM CHANNEL DEPENDENT			
Long excitable gap	Afl type 1 Circus movement tachycardia in WPW Monomorphic VT	Depress conduction and excitability	Sodium channel blockers
Short excitable gap	Afl type 2 Atrial fibrillation Circus movement tachycardia in WPW Polymorphic and monomorphic VT Bundle branch re-entry Ventricular fibrillation	Prolong refractory period	Potassium channel blockers
RE-ENTRY: CALCIUM CHANNEL DEPENDENT			
	Atrioventricular nodal re-entrant tachycardia Circus movement tachycardia in WPW VT	Depress conduction and excitability	Calcium channel blockers

DAD, Delayed after-depolarisation; *EAD*, early after-depolarisation; *VT*, ventricular tachycardia; *WPW*, Wolff–Parkinson–White syndrome.

Table 22.3 Causes of abnormal impulse generation

Enhanced normal automaticity	Adrenergic stimulation
Abnormal automaticity	Ischaemia
Early after-depolarisations	Hypoxia Hypercapnia Catecholamines Class IA antiarrhythmic drugs Class III antiarrhythmic drugs Other drugs that prolong repolarisation
Delayed after-depolarisations	Digoxin toxicity Increased intracellular Na^+ Decreased extracellular K^+ Increased intracellular Ca^{2+} Intracellular Ca^{2+} overload due to myocardial infarction or reperfusion after ischaemia

inward Ca^{2+} current (at this level of membrane potential, fast inward Na^{+} channels are inactivated) and produce slow rising and propagating action potentials. Phase 3 EADs are caused by a reduction in outward K^{+} currents and produce relatively rapidly rising and propagating action potentials. EAD amplitude and likelihood of triggered arrhythmia increase as driving rate decreases and action potential is prolonged. Tachyarrhythmia induced by EAD is more likely to occur on the background of a bradycardia.

2. DADs are produced by Na^{+}–Ca^{2+} exchanger current-induced oscillations in inward calcium current. These oscillations are caused by $[Ca^{2+}]_i$ overload saturating sarcoplasmic reticulum sequestration mechanisms, thereby leading to Ca^{2+}-induced Ca^{2+} release. Unlike EADs, DADs depend on previous rapid rhythm for their initiation.

ABNORMAL IMPULSE CONDUCTION[7]

Normal cardiac rhythm is dependent on orderly homogeneous conduction throughout atrial and ventricular tissue. This orderly homogeneity of impulse conduction can be lost by abnormal physical barriers to conduction such as infarction scars or functional disturbances in action potential leading to heterogeneity of impulse propagation. Magnitude and rate of depolarisation, presence of slow-response myocyte characteristics and rapidity of repolarisation influence speed of propagation. Functional disturbances in these properties are readily produced by channel receptor activation, ischaemia, hypertrophy and channel genetic mutation or expression.

Heterogeneity of impulse conduction may cause an arrhythmia by the phenomenon of re-entry. Re-entry describes the re-excitation of an area or entire heart by a circulating impulse. Although the classic 'bifurcating Purkinje fibre' model of Schmitt and Erlanger has given way to a much more complex picture, the essential electrophysiological requirements for re-entrant excitation remain. Requirements for re-entry are (Fig. 22.4):

- conduction block in one limb of the circuit
- slowed conduction in the other limb
- the impulse returns back along the limb initially blocked to re-enter and re-excite the pathway proximal to the block and complete the re-entry pathway.

When these properties are present, the chance of a circulating impulse producing re-entrant excitation depends on pathway geometry, the electrical properties and length of the depressed area and conduction velocity within each component. The segment of the re-entry pathway that is initially refractory and therefore blocks conduction down one limb and then recovers in time to conduct the return impulse is termed the 'excitable gap.' Therefore, the generation and subsequent maintenance of a circuit depend on this excitable gap of non-refractory tissue circulating between the advancing depolarising wave front and the repolarising tail. The resulting re-entrant impulse can be self-terminating; causing ectopic beats, or leads to atrial or ventricular tachyarrhythmia.

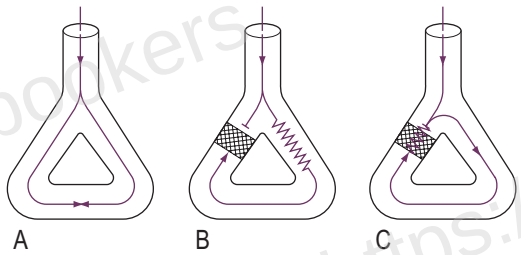

Figure 22.4 Re-entrant excitation. (A) Normal cardiac impulse conduction results in the impulse being extinguished. (B) Conduction down one limb is blocked by segment of refractory tissue (excitable gap). (C) The impulse is conducted back up the limb and arrives at the excitable gap, which has recovered from refractoriness and retrograde conduction is complete. If geometry and electrical properties are favourable, the excitable gap circulates around the re-entry loop and arrhythmia is initiated.

Risk of re-entry can be further modelled and quantified. Cardiac wavelength (λ) is the physical distance an electrical impulse travels in one refractory period; λ equals conduction velocity × refractory period (or action potential duration). Re-entry is critically dependent on the λ being shorter than the potential re-entrant pathway. If λ exceeds the path length, then the advancing impulse encroaches on the refractory tail and re-entry is terminated. Reducing λ (decreasing conduction velocity or refractory period) promotes re-entry circuits.

Re-entry may be terminated by:

- *increasing conduction velocity:* the excitable gap is abolished by the wave front arriving too early and meeting refractory tissue
- *increasing refractory period:* the excitable gap is lost
- *slowing conduction:* a unidirectional block can be converted into a complete block.

Ordered re-entry occurs along anatomical pathways which are 'macroscopic' loops (macro-re-entry), as in Wolff–Parkinson–White (WPW) syndrome. Functional circuits can be created following myocardial infarction, resulting in VT. 'Microscopic' loops (micro-re-entry) occur at the level of single fibres where antegrade and retrograde impulse propagation occurs in parallel fibres. Random re-entry refers to the generation of a circulating impulse, not from a fixed circuit but from constantly changing electrophysiologically distinct

fibres or pathways created by the circulating impulse, resulting in AF or VF.

The cellular properties that lead to impaired conduction include:

- inactivation of the phase 0 fast Na^+ channels, which reduces both the magnitude and rate of propagation of any resultant action potential
- intercellular uncoupling, which increases resistance to action potential propagation and slows conduction. Intercellular coupling is reduced by ischaemia, $[Ca^{2+}]_i$ overload, acidosis and reduced expression of intercellular ion channel connexin proteins in diseases such as chronic heart failure.

VENTRICULAR ARRHYTHMIA AND THE HIS-PURKINJE SYSTEM[8]

The Purkinje system is increasingly recognised as providing substrate for ventricular arrhythmia. Electrolyte imbalance, drugs and ischaemia during which Purkinje cells can survive in anaerobic conditions results in intracellular Ca^{++} overload, leading to enhanced automaticity and triggered arrhythmia. Triggered activity, EADs and DADs, originating in Purkinje cells during phase 2 and 3 initiate polymorphic VT and VF under these circumstances.

Recurrent ventricular arrhythmia, usually interspersed with periods of short coupling ventricular ectopics (VEs) arising from Purkinje cells allows electrical mapping of triggered activity, usually along scar borders, enabling life-saving ablation in clinical situations such as ventricular arrhythmia following acute coronary syndromes or post cardiac surgery.

The architecture of the Purkinje system in combination with areas of slowed conduction (drugs and ischaemia) can create re-entry pathways and substrate for monomorphic VT. The re-entry circuits can involve right and left bundle branches (bundle branch re-entry), single left fascicle (intrafascicle re-entry) or both left fascicles with intervening slower conducting myocardium (interfascicular re-entry). These discrete circuits can be localized by vulnerability to catheter touch and then induced or entrained by electrical pacing. The resulting VT can be terminated by programmed electrical stimulation and recurrence prevented by ablation.

ELECTROPHYSIOLOGICAL EFFECTS OF ISCHAEMIA

Both hypoxia and acidosis are implicated in the production of a less negative RMP in ischaemia. A rise in extracellular K^+ results from impairment of the adenosine triphosphate (ATP)-dependent K^+ inward channels. As $[K^+]_o/[K^+]_i$ is the major determinant of the RMP, intracellular K^+ loss results in a less negative RMP.

The consequences of this are:

- abnormal automaticity
- inactivation of the fast inward Na^+ channels, which slows the conduction velocity.

These arrhythmogenic effects of ischaemia are offset by activation of I_{KATP} K channels by ligand ADP binding, increasing phase 1 and 2 K repolarising current resulting in the antiarrhythmic action of shortening the action potential.

ELECTROLYTE ABNORMALITIES AND ARRHYTHMIA[9]

POTASSIUM

Hyper- and hypokalaemia both cause arrhythmia mediated by the resultant changes in RMP (Table 22.4). In ischaemia, hyperkalaemia at the local tissue level caused by a pathological extracellular shift of K^+ is the major factor contributing to ventricular arrhythmia in this setting. In hypokalaemia, the dispersion of pacemaker activity and the effect on repolarisation are similar to the electrophysiological effects of cardiac glycosides and beta-adrenergic agonists, and it is not surprising that a combination of these factors is associated with an increased incidence of arrhythmia. The increased risk of death in hypertensive patients treated with thiazide diuretics has been attributed

Table 22.4 Arrhythmogenic effects of potassium disturbance

	ARRHYTHMOGENIC EFFECTS	ELECTROCARDIOGRAM CHANGES	ARRHYTHMIA
HYPERKALAEMIA	Less negative RMP Inactivation of fast Na^+ channels Slowed conduction velocity	Peaked T-waves Widening of P-wave and QRS complex	Sinus node suppression Atrioventricular block Ventricular fibrillation
HYPOKALAEMIA	Prolongation of rapid repolarisation Hyperpolarisation of RMP Increased pacemaker activity in Purkinje and ventricular fibres	U-waves ST-segment and T-wave changes	Atrial and ventricular ectopy Atrial and ventricular tachyarrhythmia Ventricular fibrillation

RMP, Resting membrane potential.

to hypokalaemia (and possibly hypomagnesaemia)-induced arrhythmia (Multiple Risk Factor Intervention Trial). Thiazide-induced hypokalaemia ventricular ectopy is worsened by exercise.[10] Hypokalaemia is associated with VF and VT following acute myocardial infarction (AMI). The increased incidence of VF with a serum K^+ less than 3.5 mmol/L is clearly established and the probability of VT increases as the serum K^+ decreases. During AMI the incidence of VF/VT was 15% at 4.5 mmol/L, 38% at 3.5 mmol/L, 55% at 3.0 mmol/L and 67% at 2.5 mmol/L.[11]

MAGNESIUM

The antiarrhythmic properties of Mg^{2+} are clearly established, but a causal relationship between hypomagnesaemia and arrhythmia is largely circumstantial. Decreased extracellular Mg^{2+} by itself has little effect on the electrophysiological properties of myocytes or the ECG. Hypomagnesaemia has been implicated in the genesis of VT/VF in patients with hypertension and heart failure receiving thiazide or loop diuretics, acute alcohol intoxication or withdrawal and possibly with AMI. The product of K^+ and Mg^{2+} is the best predictor of arrhythmia in hypertensive patients taking thiazide diuretics.[12]

AUTONOMIC NERVOUS SYSTEM AND VENTRICULAR ARRHYTHMIA[13]

The parasympathetic nervous system mediates vagal effect via I_{KAch}, muscarinic-gated K channels, which hyperpolarises cell membrane and decreases phase 4 depolarisation stabilising membrane potential decreasing rate and automaticity.

The autonomic nervous system, particularly vagal tone, also has a significant effect on the occurrence of post myocardial infarction VF, as seen by the following:

- High vagal tone is associated with better outcome and less susceptibility to exercise-induced VF with new ischaemia in animal models.
- Post myocardial infarction exercise training results in an increased vagal tone, which inhibits inducible VF.
- Implantable electrical vagal stimulation and muscarinic agents, including edrophonium, are protective.
- The protection is not heart rate related, as the protection remains even when atrial pacing is used to maintain the heart rate.
- The administration of atropine increases the likelihood of developing VF.

Vagal tone can be measured by variability in the heart rate (RR interval) or blood pressure rise induced by the pressor agent phenylephrine. Heart rate variability is considered a measure of tonic vagal activity, whereas the phenylephrine method is considered a measure of magnitude of the vagal reflex in response to stimulus. A reduced vagal tone has been found post infarction in humans, which returns to normal over a 3–6-month period. There is no relationship between vagal tone and ejection fraction and the origin of reduced vagal tone post infarction appears to be due to afferent stimulation in response to necrotic tissue and impaired cardiac contractile geometry. This reduced vagal tone has also been shown to be predictive of mortality and inductility of arrhythmia at electrophysiological study (EPS).

HETEROGENEITY OF REPOLARISATION: T-WAVE ALTERNANS[14]

Regional differences in repolarisation are associated with preconditions for conduction block, re-entry and life-threatening arrhythmias. This heterogeneity is seen in settings of impaired sarcoplasmic reticulum uptake of Ca^{2+} during ischaemia, drug proarrhythmia and congenital prolonged QT syndromes. In addition to prolonged QTc, ECG changes show variability of T-waves. This variability can manifest as visible T-wave alternans (TWA), defined as a beat-to-beat alternation in the morphology and amplitude of the ST segment or T-wave (Fig. 22.5).

Computerised analytical methods for detecting non-visual TWA in the microvolt range have been developed for predicting risk of ventricular tachyarrhythmia, sudden death and need for implantable cardioverter-defibrillators. The utility of TWA appears to be better than left ventricular function. TWA can be quantified as the moving average of beat-to-beat variation in T-wave amplitude (Fig. 22.6).

TWA may find a role in guiding drug therapy as a marker of antiarrhythmic effect and proarrhythmia.

PROARRHYTHMIC EFFECTS OF ANTIARRHYTHMIC DRUGS[15,16]

Accompanying proarrhythmia with the use of antiarrhythmic drugs is increasingly recognised. The 'quinidine syncope' due to VF and polymorphic VT at therapeutic concentrations was also seen with disopyramide. The Cardiac Arrhythmia Suppression Trial (CAST) clearly defined the magnitude of this deleterious side effect in drugs that were previously perceived to be of benefit. This study, which involved flecainide, encainide and moricizine (a class IA drug), was terminated early because of adverse outcome in

Figure 22.5 Visible T-wave alternans and prolonged QT associated with heterogeneity of repolarisation.

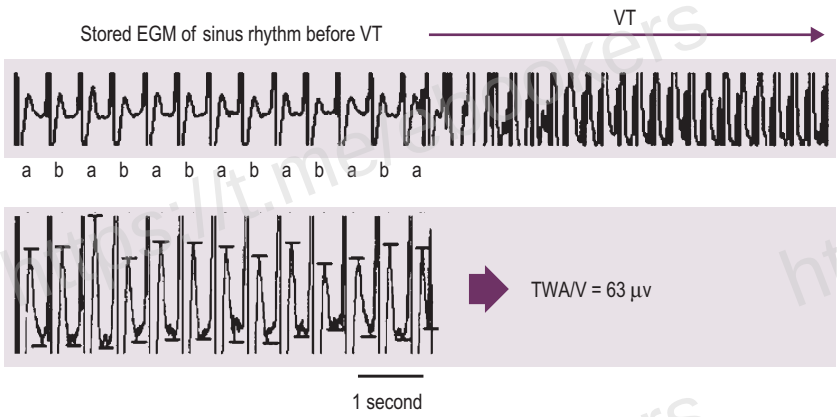

Figure 22.6 Example of heterogeneous repolarisation resulting in beat-to-beat microvolt fluctuation in T-wave amplitude measured by the Modified Moving Average method at 63 microvolts heralds the onset of ventricular tachycardia. *EGM*, Electrogram. *(From American Heart Association, with permission.)*

the flecainide and encainide groups (relative risk of arrhythmic death or non-fatal cardiac arrest of 3.6, 95% confidence interval [CI] 1.7–8.5). Proarrhythmia is reported between 5.9% and 15.8% depending on agent, clinical setting and definition of proarrhythmia, and now considered ubiquitous with all antiarrhythmic drugs.

Proarrhythmia has been defined as an increase in frequency of ventricular ectopic beat (VEB) or aggravation of the target arrhythmia on Holter monitor or exercise test. Manifestations of proarrhythmia not only include VEB, monomorphic and polymorphic VT and VF, but also bradyarrhythmias and atrial flutter (Afl) with 1:1 AV conduction. Most proarrhythmic events occur soon after starting the drug, but late arrhythmias are also a significant problem.

Proarrhythmia appears to be correlated with the degree of drug-induced QT prolongation, T-wave variability and characteristics of sodium channel blockade by the agent involved. Sodium channel-blocking agents with a long-time constant for recovery of the sodium channel blockade cause more pronounced blockade, even at slow heart rates, slow conduction to a greater extent and are associated with greater proarrhythmia. Agents with a short-time constant of sodium channel blockade, where sodium channel blockade is more pronounced at fast heart rates (e.g. class IB: lidocaine and mexiletine) are less proarrhythmic than drugs with long-time constants (e.g. class IC: flecainide and propafenone). Class III drugs and quinidine proarrhythmia correlate with degree of QT prolongation.

The mechanism of drug proarrhythmia is probably via both slowing of conduction, triggered activity and abnormal automaticity. Paradoxically, slowing conduction, which may block a re-entry circuit, may also create the very substrate needed for re-entry, unidirectional block and an excitable gap. The existence of a re-entrant circuit requires the circulating wave front of the impulse not to catch up with the refractory tissue behind the tail. Re-entry is more likely to occur with a shorter refractory period and reduced conduction velocity (Fig. 22.7).

Increasing conduction velocity is an ideal antiarrhythmic property but there are no antiarrhythmic drugs that accelerate conduction. However, antiarrhythmic drugs readily slow conduction and the degree of conduction slowing and therefore proarrhythmia tendency correlates with the potency of antiarrhythmic properties.

Prolonging the refractory period is also an ideal antiarrhythmic property, which increases the likelihood of abolishing any excitable gap by ensuring the wave front of a re-entrant circuit meets refractory tissue. The potency of class IA and III antiarrhythmic agents is dependent on the prolongation of the refractory period. This property is also protective against proarrhythmia due to re-entry mechanism. The effect of class IB agents on shortening the refractory period will contribute to proarrhythmia by this mechanism in this class.

Surface mapping of the heart has been used to quantify proarrhythmic effect. The scale of potency of proarrhythmia has been found to be:

flecainide > propafenone > quinidine > disopyramide > procainamide > mexiletine > lidocaine > sotalol

Amiodarone was not included in this study but presumably its proarrhythmic potential is similar to other class III agents and less than the class I agents.

Antiarrhythmic drugs are effective at suppressing abnormal automaticity, with the exception of triggered automaticity due to EAD. Class IA, class III and many non-antiarrhythmic drugs can produce proarrhythmia via EAD. These drugs increase not only the frequency of EAD, but also the likelihood of them leading to

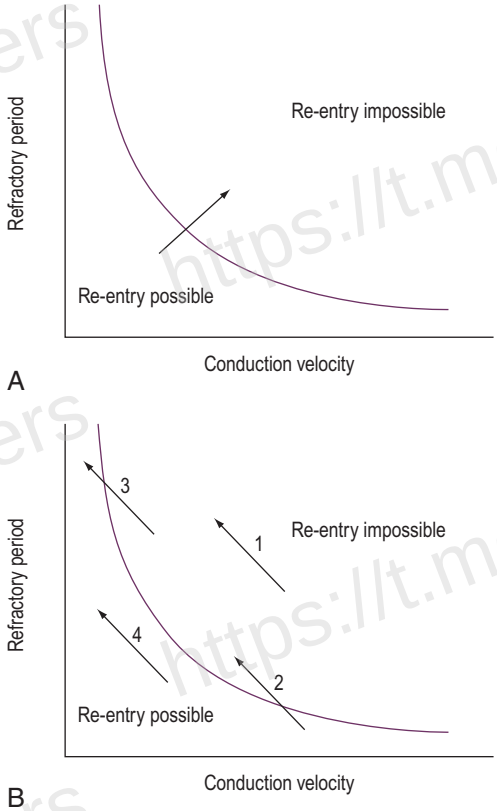

Figure 22.7 (A) Graph of refractory period of an excitable gap versus its conduction velocity around a theoretical re-entrant circuit. When conduction velocity is high enough so that refractory period of excitable gap exceeds circuit time, re-entry is impossible. *Arrow* demonstrates the action of an 'ideal' antiarrhythmic drug, which prolongs the refractory period and increases conduction velocity. (B) With antiarrhythmic drugs that increase the refractory period and slow conduction, the net effect of an antiarrhythmic drug may have no effect on proarrhythmia *(arrows 1 and 4)*, decrease proarrhythmia *(arrow 2)* or increase proarrhythmia *(arrow 3)* depending on properties of a potential re-entrant circuit. *(Adapted from Schwartz PJ, La Rovere MT, Vanoli E. Autonomic nervous system and sudden cardiac death.* Circulation. *1992;85(suppl 1): 77–91, with permission.)*

triggered tachyarrhythmia. Slowing repolarisation, which leads to QT prolongation and slower heart rate, is central to this increased frequency and sensitivity to EAD. EAD manifests as prominent and bizarre T-U waves on the ECG and, if triggered activity results, VEB and ventricular tachyarrhythmia may occur. Torsade de pointes is the classical resulting arrhythmia, although less classical polymorphic VT and VF can result. Risk of proarrhythmia via this mechanism correlates with the degree of QT prolongation.

Box 22.1 Factors facilitating antiarrhythmic drug proarrhythmia[13]

Toxic blood levels due to excessive dose or reduced clearance from old age, heart failure, renal disease or hepatic disease
Severe left ventricular dysfunction; ejection fraction less than 35%
Pre-existing arrhythmia or arrhythmia substrate
Digoxin therapy
Hypokalaemia or hypomagnesaemia
Bradycardia
Combinations of antiarrhythmic drugs and concomitant drugs with similar toxicity

All antiarrhythmic drugs are capable of producing bradyarrhythmia via decreasing normal automaticity and slowing conduction. Digoxin can be proarrhythmic via the production of triggered activity due to DAD.

Antiarrhythmic drug proarrhythmia is facilitated by several factors which are frequently found in patients on antiarrhythmic drugs or with heart disease (Box 22.1).

MANAGEMENT OF THE PATIENT WITH A CARDIAC ARRHYTHMIA

HISTORY AND PHYSICAL EXAMINATION

A careful history is important. Specific questions should confirm or exclude palpitations, syncope, chest pain, shortness of breath, ischaemic heart disease (especially previous myocardial infarction), congestive cardiac failure, valvular heart disease, thyrotoxicosis and diuretic therapy without adequate potassium supplements. A family history is helpful for arrhythmias associated with inherited disorders (e.g. LQTS and hypertrophic obstructive cardiomyopathy). The physical examination looks for underlying structural heart disease and signs to assist diagnosis, and assesses haemodynamic consequences of the arrhythmia.

VAGAL MANOEUVRES

Vagal manoeuvres may be undertaken during examination. These reflexly increase vagal tone, thereby prolonging AV node conduction and refractoriness. The effect may be:

- transient slowing of sinus tachycardia as SA nodal discharge rate is slowed
- termination of AV nodal re-entry tachycardia (AVNRT) and AV re-entry tachycardia (AVRT)
- unmasking (but not reversion) of atrial tachycardia, flutter (Fig. 22.8) and fibrillation.

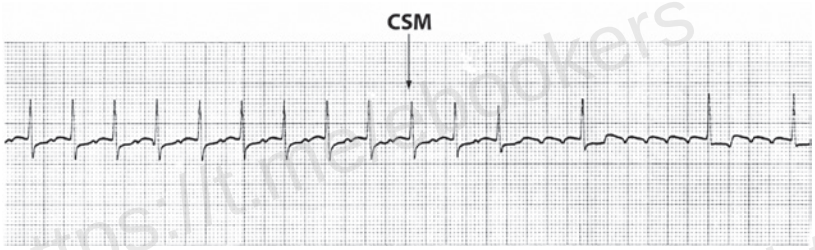

Figure 22.8 Atrial flutter with 2:1 atrioventricular (AV) block. Carotid sinus massage *(CSM)* increases AV block to 4:1, then 6:1.

VT is not affected. Carotid sinus massage has been most commonly used. Valsalva manoeuvre or iced water to the face may be useful. Eyeball pressure should be avoided as eye damage may result.

Increasingly, the Valsalva manoeuvre is recommended. Maximum vagal effect is achieved with supine positioning and a Valsalva manoeuvre of 15 seconds' duration and a pressure of 40 mm Hg (5.32 kPa) with an open glottis. An adequate Valsalva manoeuvre method can be achieved by getting the patient to blow into a 10 mL syringe in an attempt to move the plunger.

INVESTIGATIONS

A 12-lead ECG should be recorded with a longer rhythm strip (usually lead II or V_1). If P-waves are not visible, atrial activity may be recorded using an oesophageal electrode or pacing lead, or via a central venous catheter or the right atrial injectate port of a pulmonary artery catheter, using 20% saline and a bedside monitor.[17]

Holter monitoring requires prolonged (usually 24–72 hours), non-invasive, ambulatory ECG monitoring, sometimes combined with exercise testing. For infrequent symptoms suggestive of arrhythmia, implantable loop recorder can be inserted and interrogated. EPS, which involves invasive electrophysiological testing with programmed electrical stimulation, attempts to reproduce the spontaneously occurring arrhythmia.[18,19] EPS is not clearly superior to Holter monitoring in evaluating drug treatment for ventricular arrhythmias. Other investigative techniques being studied include signal-averaged ECG, heart rate variability and electrical alternans measurement.[13,20]

MANAGEMENT OF SPECIFIC ARRHYTHMIAS

Treatment has two aspects: acute termination of the arrhythmia and long-term prevention. The decision whether to treat depends on the rhythm diagnosis, haemodynamic consequences, aetiology of the arrhythmia and the prognosis (e.g. risks of sudden death or long-term complications).

ECTOPIC BEATS

These are premature impulses originating from the atria, AV junction, Purkinje system or ventricles. The coupling interval (time between the ectopic and the preceding beat) is shorter than the cycle duration of the dominant rhythm.

PREMATURE VENTRICULAR ECTOPIC BEATS

These are also known as ventricular premature beats and ventricular premature complexes. The ventricle is not activated by the normal rapidly conducting bundle branches, and a wide QRS complex results from slow ventricular conduction.

ECG

There is no preceding P-wave.

- Premature complexes occur before the next expected QRS.
- QRS is wide (>120 ms).
- T-wave of opposite polarity to the QRS (Fig. 22.9).
- VEB is not conducted retrogradely to the SA node.
- SA node is therefore not reset, and there is temporary AV dissociation with a full compensatory pause; the interval between the normal QRS complexes on either side of the VEB will usually be twice that of the dominant sinus rhythm.

Occasionally VEBs may not produce any pause, and are said to be interpolated (see Fig. 22.9). Interpolated VEBs occur when the background sinus rhythm is slow. The retrograde conduction into the AV node renders it partially refractory to the next impulse and its conduction through the AV node is slowed and the PR interval is prolonged. A VEB following each sinus beat is ventricular bigeminy. Ventricular trigeminy refers to recurring sequences of a VEB followed by two sinus beats. Two VEBs in succession are a couplet, and three, a triplet.

CLINICAL

Even when frequent, complex, or in short runs of non-sustained VT, VEBs are not associated with risk of sudden death in asymptomatic healthy adults.[21]

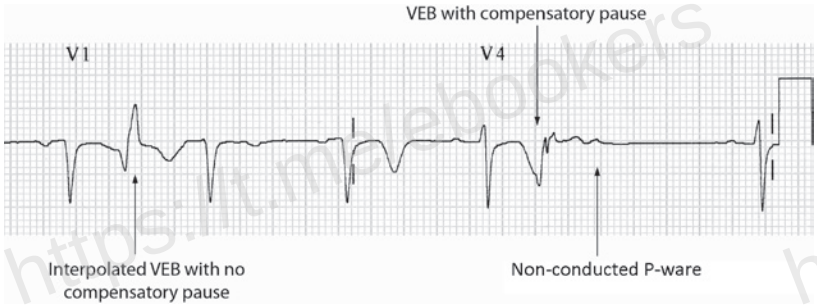

Figure 22.9 Sinus rhythm with an interpolated ventricular ectopic beat *(VEB)* without a compensatory pause and a VEB with a following non-conducted P-wave, resulting in a compensatory pause.

However, there is increased risk of cardiovascular death with:

- *exercise-induced VEB:* risk of death 2.53 (95% CI 1.65–3.88)[22]
- *AMI and VEB:* frequent and complex VEBs often precede VF or sustained VT and are a marker of risk of subsequent SCD.

Apart from ischaemic heart disease, VEB may be associated with cardiomyopathy, valvular disease, myocarditis and non-cardiac precipitating factors (e.g. electrolyte and acid-base disturbances, hypoxia and drugs such as digoxin).

TREATMENT

Drug treatment of VEB is rarely indicated and may be dangerous.

- Correct potassium and magnesium.
- Severely symptomatic patients with frequent complex VEB may benefit from judicious beta blockade.
- The underlying cause of VEB is often more clinically relevant than the arrhythmia. Following myocardial infarction, beta-adrenergic blockers, which are indicated for long-term benefit, will also likely suppress VEB.
- Prophylactic lidocaine following AMI will increase total mortality and has been abandoned.[23,24]
- Attempts at long-term VEB suppression with class IC agents (flecainide and encainide), even if successful, increase mortality.[15]

SUPRAVENTRICULAR TACHYCARDIAS (BOX 22.2)[25]

Supraventricular tachycardia (SVT) is any tachycardia that requires atrial or AV nodal tissue for initiation and maintenance.

- SVTs are usually conducted rapidly through the bundle branches so that QRS complexes are narrow.
- All narrow-complex tachycardias are SVT and wide-complex tachycardias are usually ventricular.
- However, SVT may be wide complex in the setting of bundle branch block (BBB) and pre-excitation.

Box 22.2 Classification of supraventricular tachycardia

Atrioventricular (AV) node dependent
AV nodal re-entry tachycardia: re-entry within the AV node
AV re-entry tachycardia: re-entry includes accessory pathway between atria and ventricles
Accelerated idionodal rhythm: increased automaticity of AV node
AV node independent
Afl: re-entry confined to atria
Atrial fibrillation: multiple re-entry circuits confined to atria
Unifocal atrial tachycardia: usually due to increased automaticity
Multifocal atrial tachycardia: increased automaticity or triggered activity
Others: sinus node re-entry tachycardia

Afl, Atrial flutter.

A clinically useful classification divides SVTs into AV node-dependent and AV node-independent. Distinguishing between AV node-dependent and independent SVTs can be difficult. Vagal manoeuvres or drugs that prolong AV nodal refractoriness (e.g. adenosine) may assist in diagnosis[26]:

- Temporary AV block with unchanged atrial rate indicates AV node independence.
- Slowing or reversion of the tachycardia diagnoses AV dependence.

AV NODE-DEPENDENT SVT

In these SVTs, sometimes referred to as junctional tachycardia, the re-entry circuit or ectopic focus involves the AV node or junction. Blocking the AV node with drugs such as adenosine or vagal manoeuvres will terminate these SVTs.

AV NODE-INDEPENDENT SVT

Also referred to as atrial tachycardia, the atrial tissue only is required for the initiation and maintenance of the tachycardia. Blocking the AV node will not terminate these SVTs; it will merely slow the ventricular rate.

AV NODAL RE-ENTRY TACHYCARDIA (FIG. 22.10)

Re-entry tachycardia is confined to the AV node. Antegrade conduction to the ventricles usually occurs over the slow pathway and retrograde conduction over the fast pathway.

ECG

There is regular narrow-complex tachycardia (140–220 beats/min) with abrupt onset and termination. P-waves are not usually observed as they are buried in the QRS complexes (Fig. 22.11).

CLINICAL

AVNRT is a common arrhythmia that is not usually associated with structural heart disease. The major symptom is palpitations.

TREATMENT

Vagal manoeuvres slow conduction through the AV node and may 'break' the tachycardia. If vagal manoeuvres fail, adenosine is the drug of choice and nearly all AVNRT will revert with adenosine.[24,26] Verapamil has been used in the past, but causes hypotension, which may be prolonged if cardiac function is depressed or patients are receiving beta-adrenergic blockers. Sotalol, amiodarone and flecainide may also be effective but are rarely used. Rapid atrial pacing will usually terminate AVNRT but is rarely needed.

Cardioversion is occasionally necessary when drugs are ineffective or when severe haemodynamic instability is present.

PREVENTION

Troublesome recurring episodes of AVNRT can be cured by radiofrequency ablation, using a transvenous catheter to interrupt the re-entrant circuit permanently.

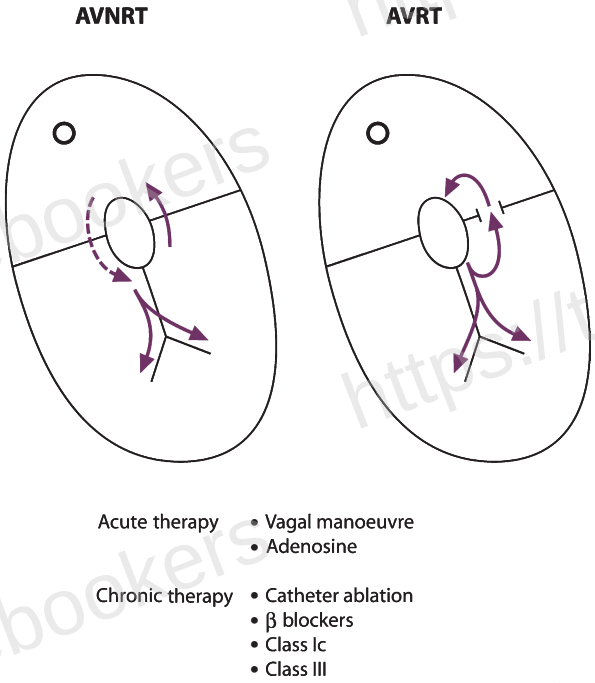

Figure 22.10 Atrioventricular nodal re-entry tachycardia *(AVNRT)* has both pathways in the AV node. The conduction occurs over the slow pathway and retrogradely over the fast pathway. AV re-entry tachycardia *(AVRT)* involves antegrade conduction through the AV node and retrograde conduction through an accessory pathway.

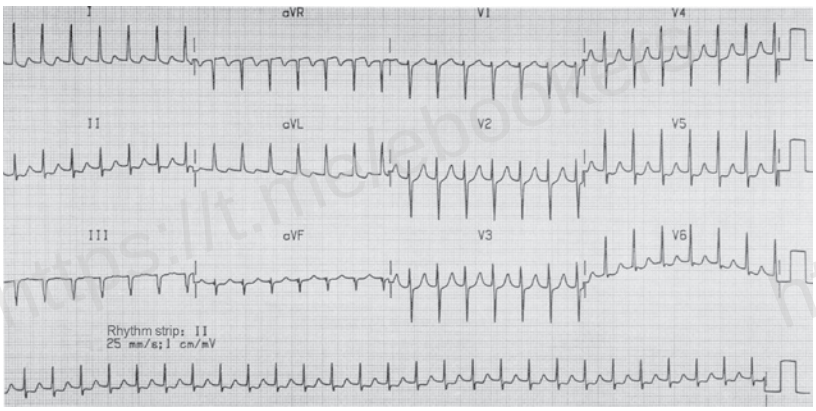

Figure 22.11 Atrioventricular nodal re-entry tachycardia. Narrow QRS tachycardia at 160 beats/min. P-waves are not apparent and are buried in the QRS complex.

AV RE-ENTRY TACHYCARDIA (SEE FIG. 22.10)

The re-entry pathway consists of the AV node and an accessory pathway, which bypasses the AV node. The accessory pathway may be evident during sinus rhythm, with the ECG showing pre-excitation: short PR interval, delta wave and widening of the QRS (see WPW, below, under Pre-excitation syndrome). However, in 25% of cases, the accessory pathway conducts only retrogradely from ventricle to atria and the ECG pre-excitation will be concealed in sinus rhythm. Orthodromic AVRT, with antegrade nodal and retrograde accessory pathway circuit, is the most common regular SVT in patients with accessory pathway.

ECG

The ECG is similar to AVNRT. The length of the re-entry circuit is, however, greater and the accessory AV pathway is some distance from the AV node. It therefore takes longer for the impulse to be conducted backwards to the atria, and so the retrograde P-wave usually occurs after the QRS, sometimes at some distance, and is inverted in leads II, III and aVF (Figs 22.12 and 22.13).

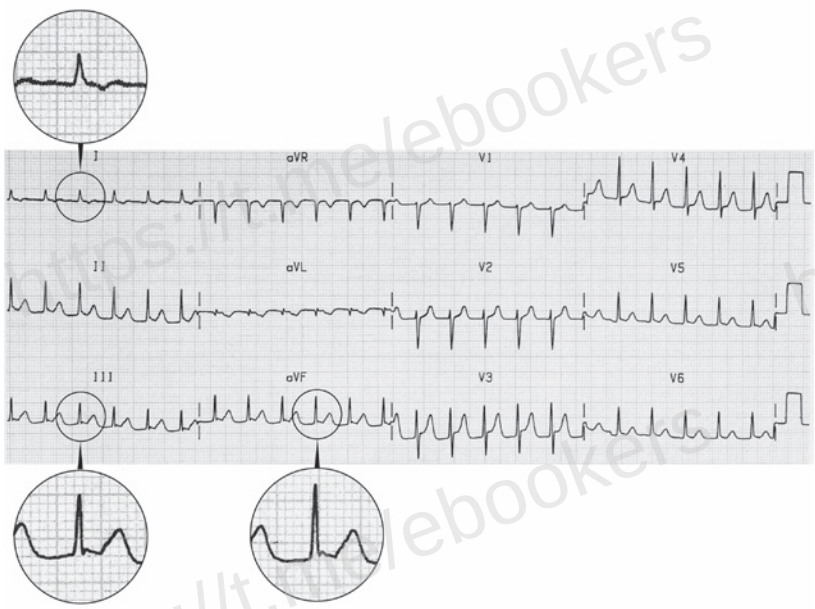

Figure 22.12 Atrioventricular re-entry tachycardia. Narrow QRS tachycardia at 135 beats/min. Inverted P-wave in leads I, II, III and aVF just following the QRS complex.

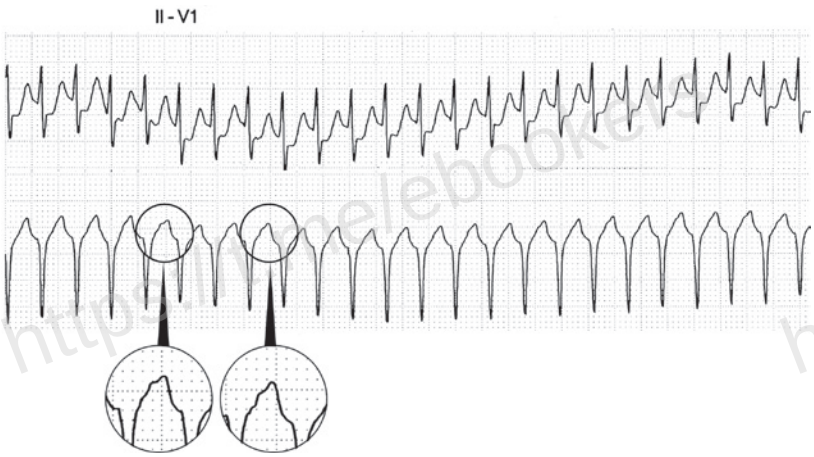

Figure 22.13 Atrioventricular re-entry tachycardia. Rate is 214 beats/min. P-wave deflection is just seen on the upslope of the T-wave in lead V_1.

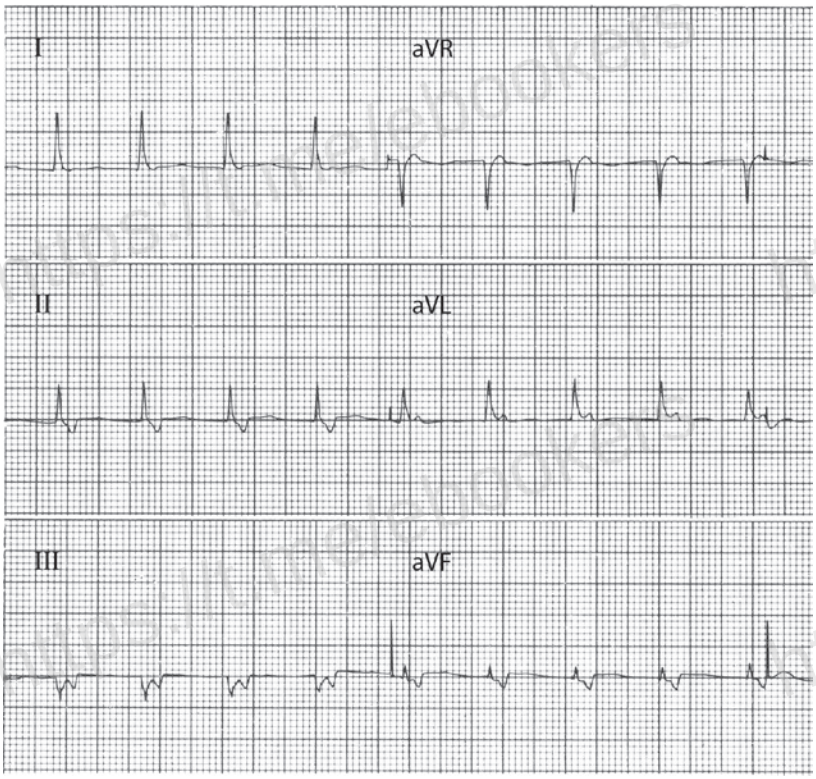

Figure 22.14 Accelerated idionodal rhythm: 105 beats/min. Inverted P-wave is immediately following the QRS complex in leads II, III and aVF.

CLINICAL
AVRT is similar to AVNRT, although antegrade conduction over the accessory pathway may be very rapid with WPW, if AF occurs.

TREATMENT[23,26]
Acute treatment is identical to AVNRT, but verapamil should be avoided in WPW syndrome, as it may block the AV node, facilitating very rapid conduction to the ventricles via the accessory pathway.[27]

PREVENTION
Drugs such as sotalol and flecainide may prevent recurrence of the tachycardia. Radiofrequency ablation of the accessory pathway is usually curative.

ACCELERATED IDIONODAL RHYTHM
Increased automaticity of the AV junction (above the inherent discharge rate of 40–60 beats/min) is the usual cause of this arrhythmia. The often-used term 'non-paroxysmal AV junctional tachycardia' is cumbersome and misleading: junctional rate is commonly 60–100 beats/min, not strictly a tachycardia. AV dissociation is often present, but there may be synchronisation of the two pacemakers – so-called isorhythmic dissociation.

ECG
There are narrow complexes on the ECG at a regular rate (60–130 beats/min) (Fig. 22.14), often with independent atrial activity. With isorhythmic dissociation, the P-wave is either fixed relative to the QRS complex (usually just after) or oscillates to and fro across the QRS in a rhythmical manner.

CLINICAL
It may be observed in normal persons, but is often associated with structural heart disease, especially following inferior myocardial infarction. Digoxin intoxication is another important cause.

TREATMENT
In most cases, the rhythm is transient and well tolerated, and no treatment is required. Treatment is otherwise directed towards the underlying cause.

UNIFOCAL ATRIAL TACHYCARDIA
This is sometimes called ectopic atrial tachycardia to distinguish it from the atrial tachycardia (referring collectively to unifocal atrial tachycardia, Afl and AF). However, it is inappropriate to call atrial tachycardia paroxysmal atrial tachycardia. Paroxysmal, by definition, indicates an abrupt onset and termination, which

Figure 22.15 Unifocal atrial tachycardia with 1:1 atrioventricular conduction; rate is 140 beats/min. Large, inverted P-waves are seen in lead II.

applies less commonly to unifocal atrial tachycardia. Vagal manoeuvres will not terminate this arrhythmia, but AV block may be induced, or increased if already present.

ECG

P-wave morphology is abnormal but monomorphic. Atrial rate is often 130–160 beats/min, and may occasionally exceed 200 beats/min. Atrial rate distinguishes unifocal atrial tachycardia from Afl, with Afl greater than 250 beats/min. The QRS complexes will usually be narrow (Fig. 22.15). AV block is common (Fig. 22.16).

CLINICAL

Digitalis intoxication is the most common cause, especially when AV block is present. Other causes include myocardial infarction, chronic lung disease and metabolic disturbances.

TREATMENT[23]

If applicable, digitalis is stopped and the toxicity treated. Otherwise, digoxin may be used to control the ventricular rate. Beta-adrenergic blockers or amiodarone are alternatives. Rapid atrial pacing may be ineffective if the arrhythmia is due to increased automaticity, although it may increase AV block, thereby slowing ventricular rate. Synchronised DC shock may be necessary, but is avoided if digitalis intoxication is suspected.

MULTIFOCAL ATRIAL TACHYCARDIA[28]

Multifocal atrial tachycardia (MAT) is defined as an atrial rhythm with a rate greater than 100 beats/min, with organised, discrete non-sinus P-waves having at least three different forms in the same ECG trace. The baseline between P-waves is isoelectric, and the PP, PR and RR intervals are irregular. This is an uncommon arrhythmia, also known as chaotic or mixed atrial tachycardia.

ECG

There are irregular atrial rates, usually 100–130 beats/min, with varying P-wave morphology (at least three

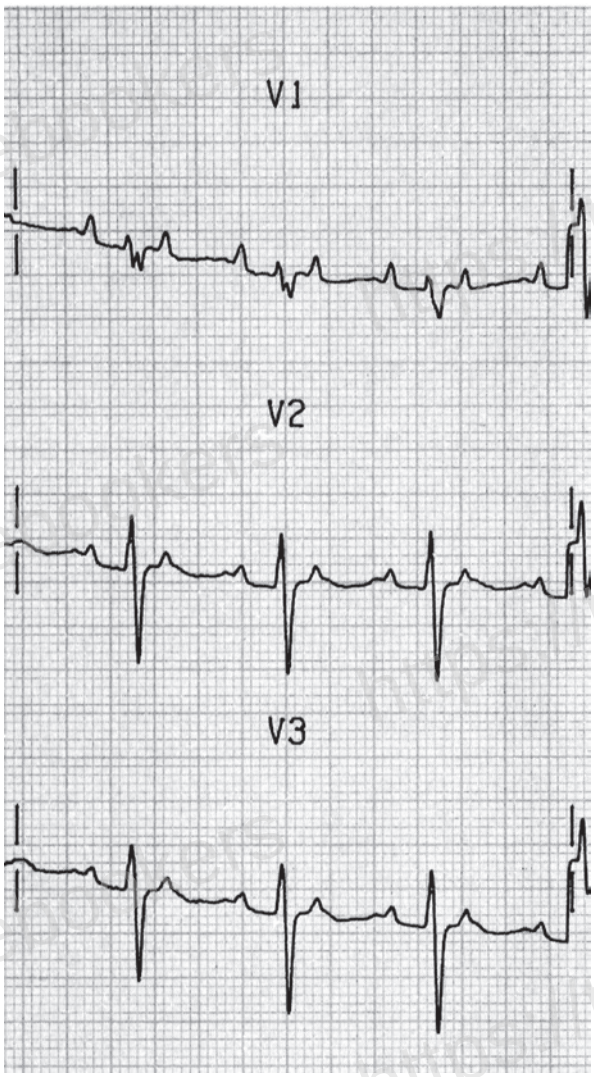

Figure 22.16 Unifocal atrial tachycardia with 2:1 atrioventricular conduction. Atrial rate is 170 beats/min.

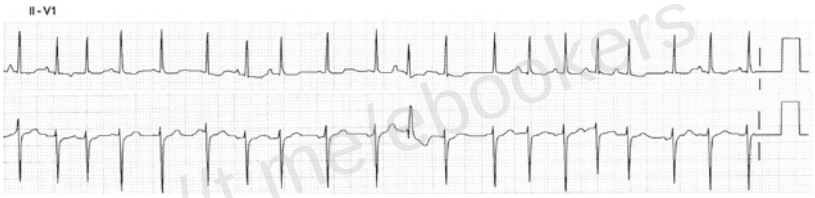

Figure 22.17 Multifocal atrial tachycardia with the rate about 130 beats/min. There is varying P-wave morphology and PR intervals. Note the wide complex preceded by a P-wave. The aberrant intraventricular conduction is related to the long-short cycle length sequence.

different P-wave morphologies and varying PR interval) and some degree of AV block (Fig. 22.17). Most P-waves are conducted to the ventricles, usually with narrow QRS complexes.

CLINICAL

MAT is often misdiagnosed and inappropriately treated as AF. This rhythm occurs most commonly in critically ill elderly patients with chronic lung disease and cor pulmonale, and is associated with a very high mortality from underlying disease. Theophylline has been implicated as a precipitating cause, and rarely, digoxin.

TREATMENT

Treatment should correct the underlying cause (e.g. treatment of cardiorespiratory failure, electrolyte and acid-base abnormalities and theophylline toxicity). Spontaneous reversion is common, and few patients require antiarrhythmic therapy. Magnesium is the drug of choice for acute control.[29] Beta blockers are probably more effective than diltiazem, but because of the common association of MAT with obstructive lung disease have limited utility. Digoxin and cardioversion are ineffective, which highlights the need to differentiate MAT from AF. Longer-term control is best achieved with diltiazem in patients with good left ventricular (LV) function and amiodarone in those without.

ATRIAL FLUTTER[30]

Afl is an intra-atrial macro-re-entrant arrhythmia with an impulse and contraction wave circulating the atrium at rates of 250–350 beats/min, and in most cases, close to 300 beats/min. Afl occurs at about one-tenth the frequency of AF, often coexisting with AF, with 56% eventually developing AF. Afl is more common in males and incidence increases with age. Conditions associated with Afl are shown in Box 22.3.

AV conduction in Afl is usually 2:1, resulting in a regular rhythm, but conduction may be irregular. Rarely 1:1 AV conduction can occur and may be lethal.

Afl is classified according to the anatomical pathway of the circuit. Right atrial cavotricuspid-isthmus-dependent flutter involving a circuit bounded by tricuspid orifice, vena cavae orifices, Eustachian and crista terminalis, is overwhelmingly most common. From a left anterior oblique view, this counterclockwise circuit makes up 90% of Afl cases and is classically referred to as 'typical.' Circuits can also be clockwise, involve the right atrium but with different circuits relating to scars or be located in the left atrium.

Box 22.3 Conditions associated with atrial flutter

- Valvular heart disease
- Myocardial infarction
- Pericardial disease
- Cardiac tumours
- Hypertrophic cardiomyopathy
- Congenital heart disease
- Post surgical repair of congenital heart disease
- Post cardiothoracic surgery
- Post major non-cardiac surgery
- Severe pulmonary disease
- Pulmonary embolus
- Thyrotoxicosis
- Acute alcohol intoxication

ECG

'Typical' Afl waves (characteristic sawtooth appearance with no isoelectric baseline) are best seen in V_1, and are negative in inferior leads with positive waves in V_1 that transition to negative in V_6 (Fig. 22.18). Rapid QRS waves may obscure typical flutter waves, and vagal manoeuvres may unmask them (see Fig. 22.8). AV conduction block (usually 2:1) is usually present, so that alternate flutter waves are conducted to the ventricles, with a ventricular rate close to 150 beats/min. Frequently flutter waves are not obvious and a ventricular rate of 150 beats/min leads to the presumption of Afl (Fig. 22.19). 'Non-typical' Afl (Type II), normally associated with scar or structural abnormalities, often results in greater atrial and ventricular rates (Fig. 22.20). Treatment with drugs that affect AV node conduction may lead to higher degrees of AV block (Fig. 22.21) and/or variable AV block with irregular QRS duration. Afl with 1:1 conduction is associated with sympathetic overactivity, class I antiarrhythmic drugs (which slow atrial discharge rate to around 200

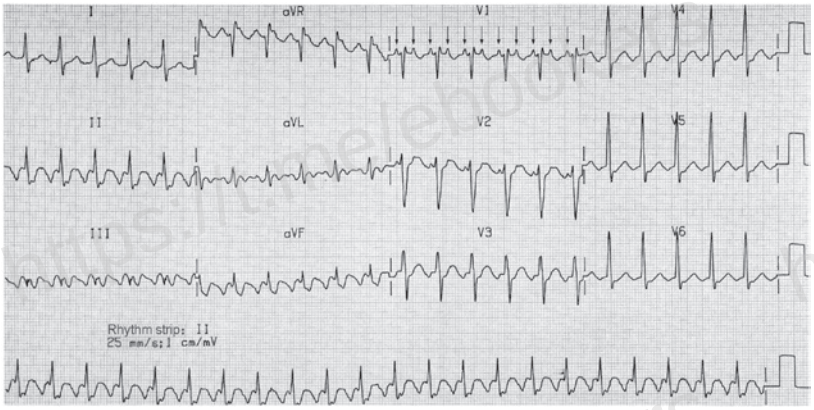

Figure 22.18 Atrial flutter with 2:1 atrioventricular conduction. Atrial rate is 270 beats/min (*arrows* V_1) and ventricular 135 beats/min. Characteristic 'sawtooth' inverted flutter waves are evident in leads II, III and aVF.

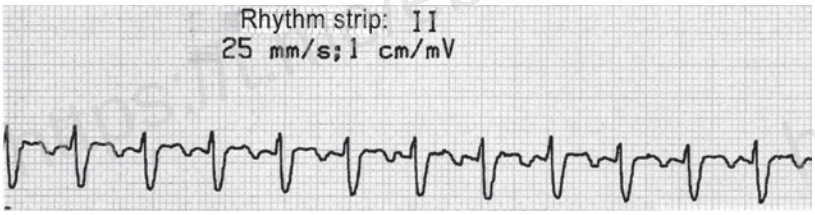

Figure 22.19 Atrial flutter (Afl) with 2:1 atrioventricular (AV) conduction. Inverted flutter waves are difficult to differentiate from T-waves. Rate of 144 beats/min confirms Afl with 2:1 AV conduction.

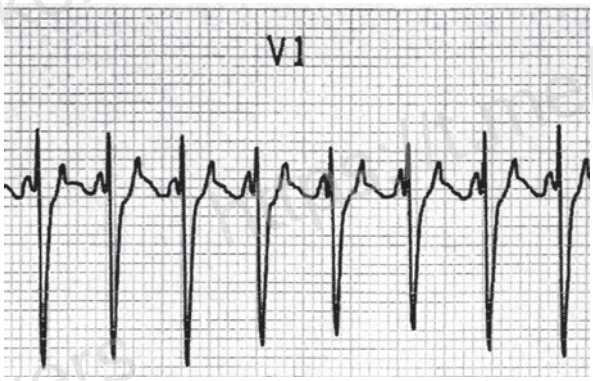

Figure 22.20 Atrial flutter (Afl) with 2:1 atrioventricular conduction. Type II Afl is confirmed by the rapid atrial rate of 380 beats/min.

beats/min, thereby allowing each atrial impulse to be conducted) or WPW syndrome and a short antegrade refractory period of the accessory pathway (Fig. 22.22). QRS complexes are usually narrow, as conduction through the bundle branches is normal.

TREATMENT[24,30]

Drug therapy has proven to be notoriously unsuccessful for Afl and large doses of AV blockers are often needed for rate control. Although no drug will reliably terminate Afl, ibutilide and dofetilide have been shown to be most likely to result in pharmacological reversion. Flecainide and procainamide may also occasionally be effective at terminating Afl. Initial attempts at slowing ventricular rate by drugs that will increase the degree of AV block are worthwhile in the first instance. Drugs such as digoxin, diltiazem, beta-adrenergic blockers, sotalol and amiodarone may be tried; the choice depends on LV function. It is important to remember class IA and IC drugs may lead to 1:1 AV conduction. Class I drugs should probably be avoided unless ventricular response has been slowed with calcium channel or beta-adrenergic blocking drugs.

Synchronised DC cardioversion, often with low energies (25–50 J), is a reliable treatment option and is often required. Rapid atrial pacing faster than the flutter rate will terminate 'typical' Afl in most patients.

Anticoagulation guidelines are the same as those for AF, although there are less supporting data.

PREVENTION

Prevention is difficult. Drugs used include sotalol and amiodarone at low doses. Class IC agents (e.g. flecainide) may be used in patients without significant structural heart disease. Increasingly, recurrent or refractory Afl may be cured by radiofrequency

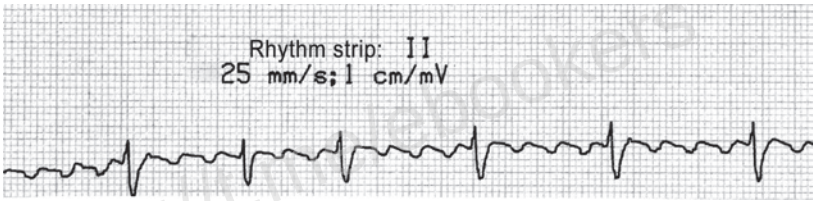

Figure 22.21 Atrial flutter varying between 3:1 and 4:1 atrioventricular (AV) conduction due to drug effect slowing AV node conduction.

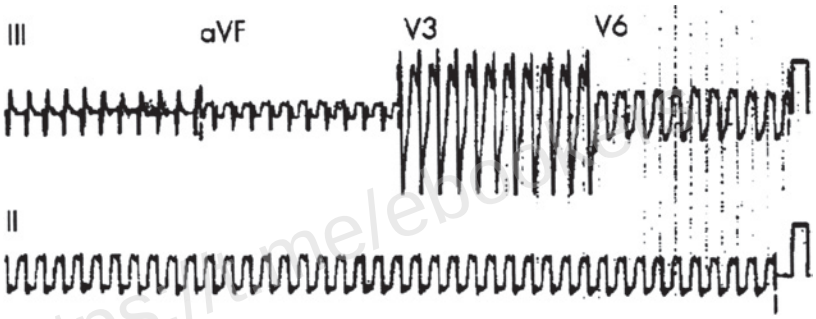

Figure 22.22 Atrial flutter with 1:1 conduction with a rate of 240 beats/min. Up-sloping of ST segment is easily mistaken as part of the QRS complex, giving the appearance of a broad QRS tachycardia in some leads. Lead III shows true narrow width of QRS complex.

Figure 22.23 Atrial fibrillation. Irregular fibrillation waves with varying amplitude and morphology.

ablation, which creates a linear lesion between the inferior tricuspid annulus and the Eustachian ridge at the anterior margin of the inferior vena cava to interrupt the re-entry circuit.[27] 'Typical' Afl is most amendable to circuit ablation.

ATRIAL FIBRILLATION[31,32]

AF is the most common arrhythmia requiring treatment and/or hospital admission. The incidence increases with age: 5% of individuals over 70 years have this arrhythmia. There is also an age-independent increase in frequency owing to increasing obesity and obstructive sleep apnoea. LV dysfunction increases risk of AF (4.5-fold in men and 5.9 in women) with atrial stretch and fibrosis causing electrical and atrial ionic channel remodelling.

AF is common in:

- congestive cardiac failure (40%)
- coronary artery bypass grafting (CABG) (25%–50%)
- critically ill patients (15%).

Idiopathic or lone AF (i.e. with no structural heart disease or precipitating factor) in someone aged less than 60 years has an excellent prognosis; however, AF developing after cardiac surgery, for instance, is associated with increased stroke, life-threatening arrhythmias and longer hospital stays.

ECG

Atrial activity is chaotic with rapid (350–600 beats/min) and irregular depolarisation varying in amplitude and morphology (fibrillation waves). Ventricular response is irregularly irregular (Fig. 22.23). Most atrial impulses are not conducted to the ventricles, resulting in an untreated ventricular rate of 100–180 beats/min. QRS complexes will usually be narrow. When the ventricular rate is very rapid or very slow, ventricular irregularity may be missed (Fig. 22.24).

CLINICAL

The variable terminology applied to AF has been clarified by American Heart Association/American College of Cardiology/Heart Rhythm Society (AHA/ACC/

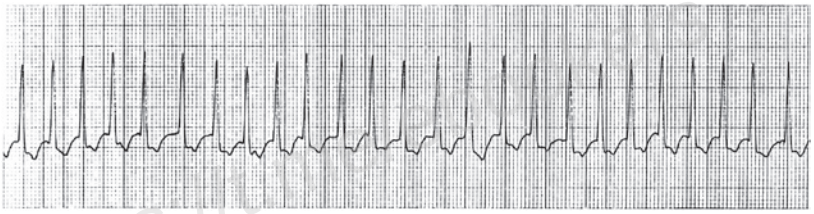

Figure 22.24 Atrial fibrillation with rapid ventricular rate. Ventricular irregularity and fibrillation waves are less evident when the rate is rapid.

Box 22.4 Definitions of atrial fibrillation

Paroxysmal AF	AF that terminates with or without treatment within 7 days of onset
Persistent AF	Continuous AF sustained for greater than 7 days
Longstanding AF	Continuous AF for greater than 12 months' duration
Permanent AF	This term is used when the patient and clinician decide to stop further attempts to restore or maintain sinus rhythm

AF, Atrial fibrillation.

Adapted from January CT, Wann LS, Alpert JS. 2014 AHA/ACC/HRS Guideline for the management of patients with atrial fibrillation: executive summary: a report of the American College of Cardiology/American Heart Association Task Force on practice guidelines and the Heart Rhythm Society. *Circulation* 2014;130:2071–2104.

Box 22.5 Summary of atrial fibrillation management

- Ventricular rate control with beta blocker or non-dihydropyridine calcium channel antagonist is not inferior to pharmacological attempts to restore sinus rhythm.
- Rhythm control with antiarrhythmic agents and serial cardioversion in heart failure is not superior to rate control.
- Cardioversion is recommended to restore sinus rhythm especially if poor rate control, haemodynamic instability or pre-excitation.
- Multiple attempts at cardioversion are indicated if initial failure or meaningful periods of sinus rhythm are achieved.
- Attempts at pharmacological cardioversion with Flecainide, Dofetilide, Propafenone, intravenous Ibutilide or Amiodarone is reasonable.
- Propafenone or Flecainide ("Pill in the Pocket") to terminate AF out of hospital is reasonable once observed to be safe in a monitored setting.
- Pharmacological maintenance of sinus rhythm needs to balance risks associated with underlying heart disease, co-morbidities and antiarrhythmic drug proarrhythmia and adverse effects.
- Pharmacological maintenance of sinus rhythm is not superior to rate control.
- AF catheter ablation is indicated for symptomatic paroxysmal AF refractory or intolerant of at least one Class I or Class II agent.
- Wider application of AF ablation, prior to therapeutic trials of antiarrhythmic agents is reasonable.
- AF ablation is superior to Amiodarone in patients with NYHA Class II or III heart failure.
- AF ablation is superior to AV node ablation and bi-ventricular pacing in patients with NYHA Class II or III heart failure.

AF, Atrial fibrillation.

HRS) Guidelines (Box 22.4).[32] AF is more common in patients with underlying heart disease (particularly those with a dilated left atrium) and abnormal atrial electrophysiology. Causes include ischaemic and valvular heart disease, pericarditis, hypertension, cardiac failure, thyrotoxicosis and alcohol abuse. AF may also occur after cardiac surgery and thoracotomy. AF can be chronic, or intermittent with paroxysmal attacks. Chronic AF has a poorer prognosis.

AF is associated with:

- *adverse haemodynamic effects:* rapid ventricular rate and loss of atrial systole may increase pulmonary capillary wedge pressure, while stroke volume and cardiac output decline
- systemic embolism and stroke
- *tachycardiomyopathy:* reversible global cardiomyopathy secondary to rapid heart rate. Assessing LV function with echocardiogram before and after AV node ablation for AF refractory to medical therapy suggests that 10% of patients with AF have AF-induced tachycardiomyopathy.[33]

TREATMENT[24,34]

The goals of treatment include ventricular rate control, conversion to sinus rhythm, maintenance of sinus rhythm and anticoagulation where appropriate. Guidelines for the management of AF are multiple and extensive (Box 22.5).[32] There is increasing evidence available on the 'rate versus rhythm' control debate. Results from several recent major studies have challenged the previous belief that achievement

Table 22.5 Atrial fibrillation rate versus rhythm control debate

STUDY	NUMBER	FOLLOW-UP (MONTHS)	AGE (YEARS)	AMIODARONE USE (%)	SINUS RHYTHM (%)	WARFARIN (%)	THROMBOEMBOLISM (%)	MORTALITY (%)

of sinus rhythm is important in the long term (Table 22.5). When comparing control of ventricular rate versus reversion to sinus rhythm, no clear survival benefit is apparent. However, composite end-points of death, stroke and recurrent hospitalisation favour rate control only.[35–38]

The possible reasons why rhythm control has not been shown to be superior include:

- trials have included predominantly elderly high-risk patients
- sinus rhythm is difficult to achieve (39%–63%)
- rate control strategies can result in sinus rhythm in up to 35% of patients
- underlying heart disease that initiates the AF persists
- there may be antiarrhythmic drug side effects
- anticoagulation is still required even if rhythm control is successful.

However, rhythm control (if possible) appears superior in patients with LV dysfunction, with both amiodarone and dofetilide reducing mortality when sinus rhythm is achieved.[35,36,39] The paucity of data in younger patients (less than 60 years) favours initial attempts at rhythm control, particularly in those with structurally normal hearts, in the hope that progressive atrial electrical and anatomical remodelling is prevented.

RECENT ONSET OR PAROXYSMAL AF

VENTRICULAR RATE CONTROL (TABLE 22.6)

The urgency of ventricular rate control depends on the clinical situation and spontaneous reversion of AF is common. Treatment may not be necessary, and a reasonable strategy is based on clinical status:

- Haemodynamically unstable with rapid ventricular rate requires immediate synchronised DC shock (in addition to drug therapy) to control rate urgently.
- Haemodynamically stable, symptomatic with depressed LV function: semi-urgent synchronised DC shock or drug therapy, digoxin or amiodarone to control ventricular rate.
- Haemodynamically stable, symptomatic, normal LV function: control of ventricular response with beta-adrenergic blockers, diltiazem, digoxin (digoxin has poor control with exertion and other settings with increased sympathetic tone), magnesium (short term), amiodarone or sotalol.
- Haemodynamically stable, with no structural heart disease and minimal or no symptoms: no immediate treatment is an option. Most cases will revert spontaneously within 24 hours. Single-dose flecainide for paroxysmal AF has been recommended (contraindicated in patients with structural heart disease).[32]

Table 22.6 Drugs for ventricular rate control in atrial fibrillation

	ACUTE	CHRONIC
STABLE	BETA BLOCKERS Metoprolol 2.5–5 mg IV bolus over 2 min – up to 3 doses Esmolol 50–200 µg/kg/min IV *NON*-DIHYDROPYRIDINE CALCIUM CHANNEL ANTAGONISTS Verapamil 0.0375–0.15 mg/kg IV over 2 min	Metoprolol ER 100–200 mg oral daily Atenolol 25–100 mg oral daily Bisoprolol 2.5–10 mg oral daily Verapamil 40 mg oral b.d. up to 360 mg ER oral daily Diltiazem 60 mg oral t.i.d. up to 360 mg ER oral daily
UNSTABLE: HYPOTENSION HEART FAILURE	Digoxin 0.5–1.0 mg IV Amiodarone 5 mg/kg IV over 1 h	Digoxin 0.125–0.50 mg oral daily Amiodarone 100–200 mg oral daily Dronedarone 400 mg oral b.d.

Table 22.7 Drugs for pharmacological conversion of recent-onset atrial fibrillation

DRUG	DOSE	FEATURES
Amiodarone	5 mg/kg IV over 1 h	Will slow ventricular rate Conversion delayed Amiodarone 80%–90%, placebo 40%–60% at 24 h Suitable structural heart disease and heart failure
Flecainide	2 mg/kg IV over 10 min 200–300 mg oral	Not suitable for structural heart disease or heart failure 67%–92% conversion at 6 h Majority within 1 h of IV dose May prolong QT Risk of Afl and 1:1 conduction
Ibutilide	1 mg IV over 10 min Further dose after 10 min	50% conversion within 90 min Risk of QT prolongation and torsades de points high
Propafenone	2 mg/kg IV over 10 min	Not suitable for structural heart disease or heart failure 41%–91% conversion within 3 h May prolong QT Risk of Afl and 1:1 conduction
Vernakalant	3 mg/kg IV over 10 min Further 2 mg/kg if required	Suitable for structural heart disease and heart failure Rapid in approximately 10 min in responders 50% conversion rate 99% of responders remain in sinus rhythm at 24 h after single dose Well tolerated

Afl, Atrial flutter.

- If pre-excitation is suspected, beta-adrenergic blockers, non-dihydropyridine calcium channel antagonists, digoxin and adenosine are contraindicated. Class I drugs are indicated. Amiodarone is no longer recommended (see Pre-excitation syndrome).

Ideal rate control can be defined as a resting heart rate of ≤80 beats/min, peak rate of ≤110 beats/min with 6-minute walk and an average of 100 beats/min.

CONVERSION TO SINUS RHYTHM

Antiarrhythmic drugs or DC shock cardioversion can be used. The likelihood of short- and long-term success depends on the clinical situation. Conversion to sinus rhythm is more important in young patients and those with heart failure. Maintenance of sinus rhythm is problematic: sinus rhythm at 1 year is 60% with amiodarone and 40% with sotalol, and associated with significant drug cardiac and extracardiac toxicities. The risk of stroke and need for antithrombotic therapy due to frequent AF recurrences, which may be asymptomatic, remain. Achieving sinus rhythm (especially greater than 60 years) is less important than previously thought.

Pharmacological conversion of recent-onset AF is variously successful depending on the clinical setting and agent used (Table 22.7). Ibutilide, propafenone and vernakalant have rapid conversion rates, compared with flecainide and amiodarone the slowest. Amiodarone, ilbutilide and vernakalent are suitable

Table 22.8 Drugs for long-term rhythm control in atrial fibrillation

DRUGS	DOSE	CONTRAINDICATIONS AND PRECAUTIONS	ECG CRITERIA FOR LOWERING DOSE OR DISCONTINUATION	AV NODE SLOWING OF PAROXYSMAL AF
Disopyramide	100–250 mg t.i.d.	Systolic heart failure QT-prolonging drugs	QT >500 ms	None
Flecainide Flecainide XL	100–200 mg b.d. 200 mg daily	Creatinine clearance <50 mL/min Coronary artery disease Reduced LV ejection fraction Conduction delay	QRS duration increase >25% over baseline	None
Propafenone Propafenone SR	150–300 mg t.i.d. 225–425 mg b.d.	Coronary artery disease Reduced LV ejection fraction Conduction delay Creatinine clearance <50 mL/min	QRS duration increase >25% over baseline	Slight
Sotalol	80–160 mg b.d.	LV hypertrophy Systolic heart failure Pre-existing QT prolongation Hypokalaemia Creatinine clearance <50 mL/min	QT >500 ms	Yes
Amiodarone	600 mg daily, 4 weeks, 400 mg daily, 4 weeks then 200 mg daily	QT prolonging drugs Warfarin dose adjustment	QT >500 ms	Yes
Dronedarone	400 mg b.d.	Heart failure NYHA Class III–IV QT prolonging drugs CYP3A4 inhibitors Creatinine clearance <30 mL/min	QT >500 ms	Yes

in heart failure. All have risk of QT prolongation and proarrhythmia, with ibutilide being the worst and vernakalant the best, although there are anecdotal case reports of ventricular arrhythmias with the latter.[40–42]

Although long-term treatment goals increasingly favour chronic rate control (see Table 22.6), antiarrhythmic drugs are still used to promote long-term rhythm control (Table 22.8). All have many contraindications and precautions, with amiodarone the best from a cardiac perspective and worst from an extracardiac point of view. The dilemma of long-term antiarrhythmic treatment in AF is highlighted by the diametrically opposite effects that dronedarone has been shown to produce in this setting.[43] In ATHENA, dronedarone decreased all cause, cardiovascular and presumed arrhythmia mortality, stroke and heart failure, whereas in PALLAS all these outcomes were worse. In PALLAS, all patients had 'permanent' AF and there was twice the baseline incidence of heart failure. Benefit would appear to be crucially dependent upon securing sinus rhythm, absence of structural substrate for proarrhythmia and cardiac reserve to tolerate the drug.

DC SHOCK CARDIOVERSION

DC shock cardioversion is indicated either before 24–48 hours or after appropriate anticoagulation protocol. Combining DC shock with antiarrhythmic drugs to promote maintenance of sinus rhythm is favoured, especially if risk factors for relapse exist. Cardioversion is less likely to be successful if:

- AF has been present for over 1 year
- left atrial size is greater than 45 mm
- untreated conditions are present (e.g. thyrotoxicosis, valvular heart disease and heart failure).

Critically ill patients who are septic, postoperative or on drugs such as catecholamines are likely to relapse.

ANTICOAGULATION AND CARDIOVERSION[44,45]

Loss of atrial contraction with AF is associated with stasis of blood flow and formation of blood clots in the left atrium, particularly the atrial appendage. Reversion to sinus rhythm and return of more effective atrial contraction may cause expulsion of any atrial clots and systemic emboli. Once AF has been present for more than 48 hours – some authors stipulate 24 hours – the risk of systemic emboli is significant and anticoagulation is required prior to DC shock cardioversion. The current recommended period of anticoagulation prior to DC shock cardioversion is 3 weeks. This 3-week period can be shortened to 1 day for heparin and 5 days for warfarin if the left atrium can be demonstrated free of clot using transoesophageal echocardiography. With this accelerated approach, heparin dose should be

titrated to an activated partial thromboplastin time 2–3 times control or warfarin to produce an international normalised ratio (INR) of 2.0–3.0. In many clinical situations such as recent surgery or other bleeding risks, anticoagulation is contraindicated and elective cardioversion should be delayed until recommended anticoagulation cover is safe. Following successful cardioversion to sinus rhythm, the risk of systemic embolism continues as the propensity to form atrial clot remains owing to atrial contractile stunning and anticoagulation should be continued for 4–6 weeks.

ATRIAL FIBRILLATION ABLATION THERAPY

Ablation techniques for AF have been continuously refined since the original Maze III surgical procedure, which involved numerous atrial incisions to form a maze-like pattern of scarring, blocking propagation of arrhythmia. The utility of this procedure was limited because it was surgical, with longer bypass times, postoperative bleeding and impaired atrial contractility. The magnitude of this original procedure was based on the belief that the entire atrium was involved in the initiation and maintenance of the fibrillatory conduction. This may be true for long-standing AF but paroxysmal AF appears to originate primarily at the junction of the left atrium and pulmonary veins. AF in 94% of patients is initiated by rapid discharges from one or more foci at or near the pulmonary vein orifices.[46] Atrial tissue in this area has heterogeneous electrophysiological properties and there is also clustering of vagal inputs, which creates substrate for rapid discharges that initiate micro-re-entrant circuits or 'rotors.' These high-frequency periodic rotors send spiral wave fronts of activation into surrounding atria. Localised ablation of a single dominant focus and rotor is inadequate, as there are usually multiple foci. Surgical excision of left atrial appendage may also be considered.

Left atrial catheter (transatrial septum) AF ablation isolating all four pulmonary veins using radiofrequency is being heralded as the possible AF cure. Results are improving, as all pulmonary veins are now isolated and the encircling lesion is clear of the pulmonary vein antrum (reducing pulmonary vein stenosis). Recently, more extensive ablation is advocated and in addition to pulmonary vein isolation, the entire left atrial posterior wall and superior vena cava is isolated as well, especially if pulmonary vein-like potentials are found. Success rates of 81% (75%–88%) free of AF and off drugs are reported. Success appears long term as any recurrence occurs early. A further 10%–20% may become responsive to antiarrhythmic drugs which were previously ineffective. Repeating the procedure can increase success to >90%, with failure only in patients found to have extensive atrial scarring (predicting and excluding patients with this extensive atrial scarring is a major future challenge). Although not yet the universal cure, the results are two- to threefold better than antiarrhythmic drugs alone. Low procedural complications are crucial to ablation having superior outcomes. While radiofrequency current ablation is the most common technique, cryoballoon ablation has been shown to be non-inferior with failure rates, recurrence of AF, occurrence of AFl or atrial tachycardia, use of antiarrhythmic drugs or repeat ablation occurring in 35% of both ablation techniques.[47] In summary:

Rhythm control is superior with ablation compared with antiarrhythmic drugs.
Ablation is indicated when rhythm control fails with antiarrhythmic drugs.
Patient outcome is superior with ablation in the setting of heart failure.[48,49]

Complication rates are falling associated with:

- intracardiac echocardiography ensuring safer transseptal puncture and positioning of isolating lesions clear of the pulmonary vein antra
- higher levels of procedural anticoagulation
- strict limitations on radiofrequency energy output.

Complications include:

- TIA, stroke
- Perforation – tamponade, oesophageal injury
- Pulmonary oedema – early from high rates of saline administration, late from pulmonary vein stenosis
- Recurrent AF
- Difficult to treat AFl

Proarrhythmia resulting from re-entrant tachycardia from incomplete ablative lesions is more common. Some are advocating ablation as first-line treatment, whereas most are selecting younger patients (less than 70 years) with paroxysmal AF for whom antiarrhythmic therapy has failed, left atrial diameter is less than 5 cm and ejection fraction is greater than 40%. Head-to-head studies comparing ablation and antiarrhythmic drugs are appearing with suggested survival benefit, improved quality of life, reduced adverse effects and cost-effectiveness after approximately 3 years with catheter AF ablation therapy.[50,51] There is renewed interest in surgical AF ablation therapy in conjunction with cardiac surgery. Complications have been reduced with energy (cryotherapy, radiofrequency) rather than incisions and the extent of lesions reduced. The minimum lesion set is now considered to be encirclement of pulmonary veins, linear lesion from the inferior pulmonary vein to mitral annulus and from the coronary sinus to the inferior vena cava.

AF and structural heart disease

The onset of AF, especially with rapid ventricular rates, often precipitates haemodynamic collapse requiring immediate control with DC shock in structural heart disease. Valvular and myopathic heart disease demands prompt preventive ablation or antiarrhythmic drugs to secure sinus rhythm.

AF in hypertrophic cardiomyopathy (HCM).[52]

AF incidence is 4–6 times greater (18%–28%) due to left atrial dilation and remodelling due to diastolic dysfunction, increase in left ventricular end diastolic pressure, primary sarcomeric atrial myopathy, left ventricular outflow tract obstruction (LVOTO) and mitral regurgitation.

AF results in four fold increase in HCM all cause mortality.

Significance mandates 24–48 hours of ambulatory monitoring every 6–12 months, especially if left atrium is greater than 45 mm. Highly sensitive troponin T predicts death and AF.

Stroke and systemic emboli are eight fold more likely than in general population AF – risk so high that CHA_2DS_2-VAScscore is not used. All are anticoagulated after one episode.

While in many settings of superiority of rhythm versus rate control continues. However with significant LVOTO, AF is so poorly tolerated that rhythm control is superior. Amiodarone is most effective to maintain sinus rhythm but long-term side effects. Disopyramide is recommended as negative inotropic action relieves symptomatic LVOTO. Must be used with AV blocking agent (beta-blocker, diltiazem or verapamil) to prevent rapid ventricular rates during AF episodes. Disopyramide dose must be decreased or ceased if QTc is greater than 480 ms. Otherwise monotherapy with Sotalol.

AF ablation is indicated for failed medical treatment although less successful than with lone AF.

If surgical myectomy is required, a MAZE procedure and left atrial appendage excision should be performed.

ANTICOAGULATION FOR CHRONIC ATRIAL FIBRILLATION[32]

VALVULAR ATRIAL FIBRILLATION

A 17-fold increased risk of embolic stroke with rheumatic mitral valve disease requires warfarin (INR 2–3). With prosthetic valves there is a similar target range of INR, though the exact level is dependent on the type of valve.

NON-VALVULAR ATRIAL FIBRILLATION

The risk of stroke has been determined by the $CHADS_2$ score (assign 1 point for congestive heart failure, hypertension, age = 75 years and diabetes mellitus, and 2 points for stroke/TIA).[53] The $CHADS_2$ score has been further developed to the CHA_2DS_2VASc score to improve risk stratification of patients at moderate risk by doubling points to 2 for age ≥75 and including vascular disease (prior myocardial infarction, peripheral artery disease determined by prior revascularisation, amputation or angiographic evidence and aortic plaque, age 65–74 and female sex) (Table 22.9).

The treatment options are discussed below.

Table 22.9 CHA_2DS_2VASc score and stroke risk stratification

RISK FACTOR	$CHA_2DS_2VAS_C$ SCORE	SCORE
Congestive heart failure Left ventricular dysfunction ejection fraction ≤40%	C	1
Hypertension	H	1
Age ≥75	A_2	2
Diabetes mellitus	D	1
Previous stroke, TIA or systemic embolism	S_2	2
Vascular disease – myocardial infarction, complex aortic plaque, prior peripheral revascularisation, amputation or angiographic evidence	V	1
Age 65–74	A	1
Female sex	S	1
Maximum score		**9**

	ADJUSTED STROKE RATE ACCORDING TO $CHA_2DS_2VAS_C$ SCORE
$CHA_2DS_2VAS_C$ SCORE	ADJUSTED STROKE RATE %/YEAR*
0	0
1	1.3
2	2.2
3	3.2
4	4.1
5	6.7
6	9.8
7	9.6
8	6.7
9	15.2

*Based on Lip GY, Frison L, Halperin JL, Lane DA. Identifying patients at high risk for stroke despite anticoagulation: a comparison of contemporary stroke risk stratification schemes in an anticoagulated atrial fibrillation cohort. *Stroke* 2010;41(12):2731–2738.
TIA, Transient ischaemic attack.

WARFARIN

Adjusted-dose warfarin reduces relative risk of stroke by 62%. The absolute risk reduction is 2.8% per year for primary and 8.4% per year for secondary prevention, although intracranial haemorrhage occurs (0.3% per year). Low-dose warfarin (INR 1.5–2.0) is less

effective than an INR of 2.0–3.0 but has fewer haemorrhagic complications. Embolic stroke rate doubles as INR falls from 2.0 to 1.7, and is markedly higher at an INR of 1.3 compared with 2.0.[44,54]

ASPIRIN

Aspirin has reduced efficacy when compared with warfarin, with a 22% relative risk reduction and an absolute risk reduction of 1.5% and 2.5% per year for primary and secondary prevention. Warfarin compared with aspirin for AF will prevent 23 strokes and result in nine additional major bleeds per 1000 patients per year.

CLOPIDOGREL PLUS ASPIRIN

Although warfarin is better under ideal circumstances, poor INR control will readily erode this benefit.

WARFARIN COMBINED WITH ANTIPLATELET THERAPY

There is no benefit over warfarin alone.

NEW ORAL ANTICOAGULANTS (NOACs) (BOX 22.6)

NOACs have an increasing role in AF anticoagulation with the benefit of fixed dosing not requiring monitoring. The evidence for superiority in non-valvular AF is oldest for dabigatran; however, other NOACs have the benefit of once-daily dosing, Rivaroxaban, and use in moderate renal failure, Apixaban. In non-valvular AF, dabigatran 150 mg b.d. had a 35% reduction in stroke and systemic embolism compared with warfarin. There was a similar rate of major bleeding, although intracranial haemorrhage was reduced by 59%. The lower dose of 110 mg b.d. had similar embolic efficacy to warfarin but with reduced bleeding. Dabigatran clearance is importantly influenced by creatinine clearance of less than 50 mL/min and rapid reversal is problematic. Apixaban (ARISTOTLE) was superior to warfarin due to reduction in haemorrhagic strokes and ischaemic strokes with haemorrhagic conversion. Rivaroxaban was non-inferior to warfarin (ROCKET-AF).

Box 22.6 New oral anticoagulants

Dabigatran
- Direct thrombin inhibitor
- 150 mg oral b.d.
- Creatinine clearance <50 mL/min decrease dose 110 mg oral b.d.
- CrCl <30 mL/min contraindicated

Rivaroxaban
- Factor Xa inhibitor
- 20 mg oral daily
- CrCl <50 mL/min decrease dose 15 mg oral daily

Apixaban
- CrCl <30 mL/min contraindicated
- Factor Xa inhibitor
- 5 mg oral b.d.
- Age >80 years, <60 kg or CrCl <50 mL/min decrease dose 2.5 mg oral b.d.
- Recommended in renal dysfunction

RECOMMENDATIONS FOR ANTICOAGULATION IN PATIENTS WITH ATRIAL FIBRILLATION

Non-valvular atrial fibrillation

INR adjusted warfarin (2.0–3.0 target 2.5) or aspirin according to CHA_2DS_2VASc score and HAS-BLED score (Tables 22.10 and 22.11).

NOACs may be substituted for warfarin, depending on risk of bleeding. Risk of bleeding can be determined by the HAS-BLED score. With a HAS-BLED score of 0–2, dabigatran 150 mg b.d. gives superior embolic prevention with reduced intracranial haemorrhage. With a HAS-BLED score of ≥3, 110 mg b.d. gives similar efficacy to warfarin, but reduced haemorrhagic complications.

Valvular atrial fibrillation

Warfarin is indicated. Direct thrombin inhibitors or Factor Xa inhibitors are yet to be studied in this situation.

Risk of haemorrhage is reduced by keeping INR = 3, systolic blood pressure <135 mm Hg (17.95 kPa) and avoiding antiplatelet drugs.

Temporary cessation of anticoagulation for AF with surgery is a common problem. Valvular AF requires

Table 22.10 Approach to thromboprophylaxis in patients with atrial fibrillation

CHA_2DS_2VASc SCORE	RECOMMENDED ANTITHROMBOTIC THERAPY
≥2	Oral anticoagulation –warfarin international normalised ratio (INR) 2.0–3.0 Target 2.5 –dabigatran –HAS-BLED score 0–2: dabigatran 150 mg b.d. <2: dabigatran 110 mg b.d.
1	Either oral anticoagulant –warfarin INR 2.0–3.0 Target 2.5 –dabigatran 110 mg b.d., *or* –aspirin 75–325 mg daily Prefer oral anticoagulation rather than aspirin
0	Either aspirin 75–325 mg daily, *or* No antithrombotic therapy Prefer no antithrombotic therapy rather than aspirin

Table 22.11 HAS-BLED bleeding risk score

L	Labile INRs Unstable or high INRs, poor time in therapeutic range <60%	1
E	Elderly >65 years	1
D	Drugs or alcohol • antiplatelet agents, non-steroid anti-inflammatory drugs • alcohol abuse	1 or 2
	Maximum score	9

INRs, International normalised ratios.

heparin or enoxaparin until surgery and recommencement of heparin/enoxiparin, then warfarin as soon as safely possible. Non-valvular CHA_2DS_2VASc score <2 can have anticoagulation withheld with minimal risk. Non-valvular CHA_2DS_2VASc score of ≥2 is increasingly managed as valvular AF.

Angioplasty and stenting of coronary arteries require aspirin and clopidogrel to maintain stent patency. Stenting in patients already on warfarin for AF is a common problem.

RECOMMENDATIONS FOR ATRIAL FIBRILLATION PATIENTS REQUIRING CORONARY ARTERY STENTING

- Non-valvular CHA_2DS_2VASc score <2: cease warfarin as aspirin and clopidogrel are started.
- Valvular AF and non-valvular with CHA_2DS_2VASc score ≥2: add aspirin and clopidogrel to continued warfarin treatment.

PRE-EXCITATION SYNDROME

Pre-excitation syndromes have an additional or accessory AV pathway. The term 'WPW syndrome' is usually applied when tachyarrhythmia is present.

ECG

During sinus rhythm, an atrial impulse will reach the ventricles via both the AV node and the accessory AV pathway. The latter conducts the atrial impulse to the ventricles before the AV node, resulting in ventricular pre-excitation and a short PR interval. On reaching the ventricles, the pre-excitation impulse is not conducted via the specialised conducting system. Hence, early ventricular activation will be slowed, resulting in a slurred upstroke of the QRS complex, the so-called delta (δ) wave (Fig. 22.25). The abnormal ventricular activation also gives rise to secondary S-T segment and T-wave abnormalities; δ-wave polarity in a 12-lead ECG may help localise the anatomical position of the accessory pathway. Type A WPW is characterised by upright QRS deflections in the right precordial leads (tall R-waves in V_1 and V_2) (Fig. 22.26). In type A WPW, the accessory pathway is usually situated on the left with pre-excitation of the left ventricle. Type B WPW has a dominantly negative QRS complex in V_1 and the accessory pathway tends to be on the right with pre-excitation of the right ventricle (Fig. 22.27).

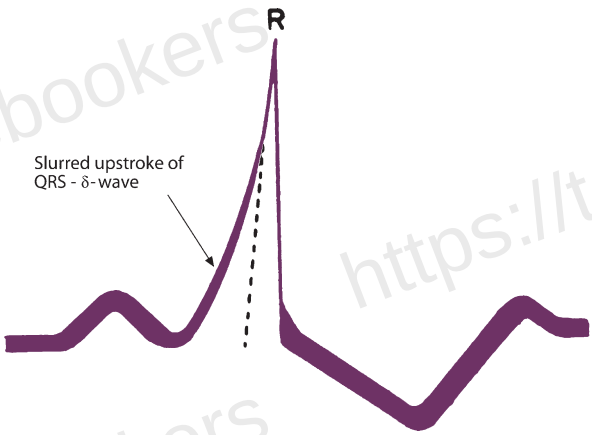

Figure 22.25 Ventricular pre-excitation via accessory pathway giving rise to a slurred upstroke and widened QRS complex.

CLINICAL

AVRT or AF can occur with WPW. During AVRT, the re-entry impulse usually travels down the AV node and back up the accessory pathway. Ventricular activation is via the normal conducting pathways and the QRS will be narrow. Occasionally, the re-entry impulse may pass in the opposite direction (down the accessory pathway and up the AV node), resulting in a wide QRS-complex tachycardia due to abnormal slow ventricular activation. Treatment is the same as for AVRT (i.e. intravenous [IV] adenosine). AF is uncommon in WPW, but may be life threatening. Most impulses are conducted via the accessory pathway, leading to wide QRS complexes. The ECG of WPW with AF usually shows rapid, irregular QRS complexes with variable QRS width (Fig. 22.28).

Ventricular response is very rapid, leading to hypotension or cardiogenic shock. This arrhythmia may degenerate to VF.

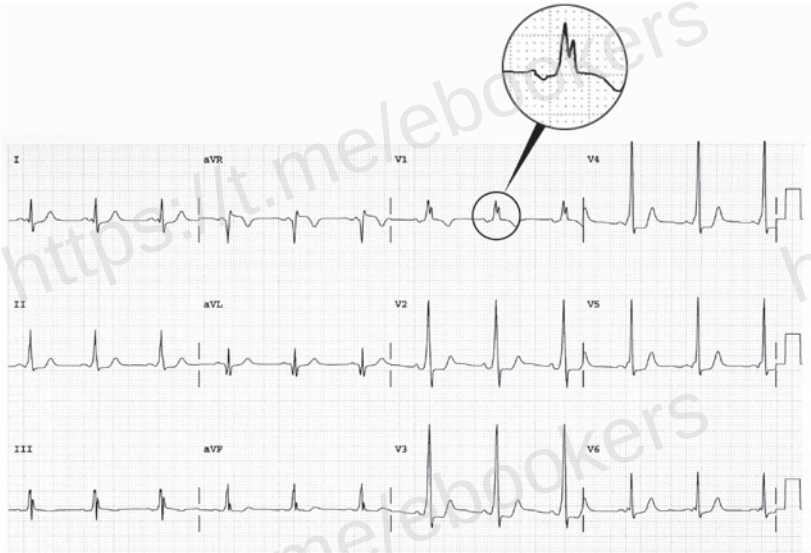

Figure 22.26 Type A Wolff–Parkinson–White syndrome with positive R-waves in the right precordial leads, short PR interval and δ-wave giving rise to a wide QRS complex.

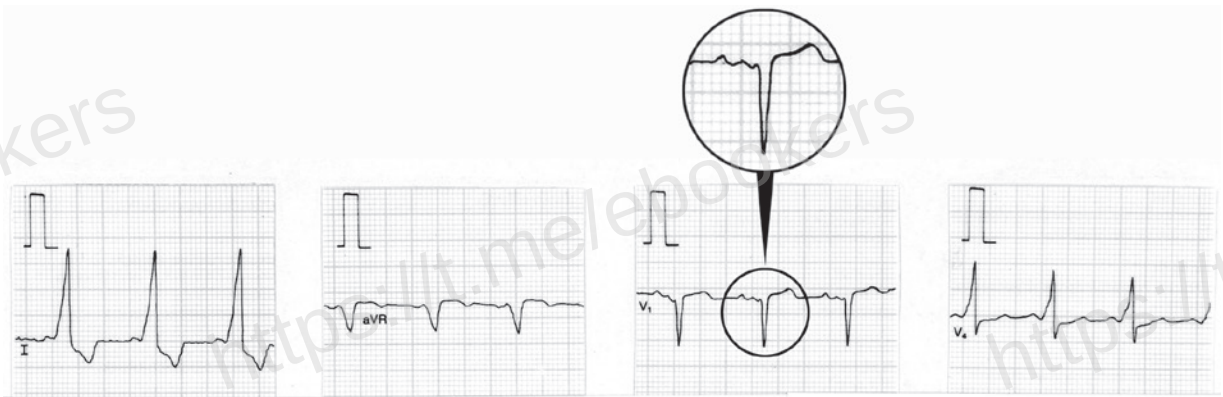

Figure 22.27 Type B Wolff–Parkinson–White syndrome with a negative QRS deflection in V_1.

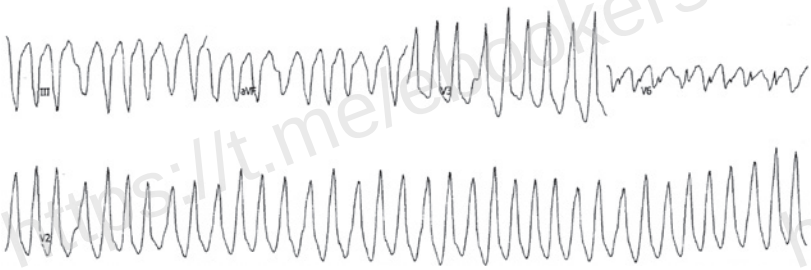

Figure 22.28 Wolff–Parkinson–White syndrome with atrial fibrillation. Rapid rate and irregularity of the broad QRS complexes help to distinguish from ventricular tachycardia.

TREATMENT[24]

Treatment usually involves synchronised DC shock if haemodynamically compromised. Antiarrhythmic drugs may be used when patients are haemodynamically stable and the ventricular rate is not excessively rapid.

- Ideal agent needs predominant action of prolonging refractory period of accessory pathway.

Agents with predominant action of slowing AV node can increase conduction rate through the accessory pathway and cause life-threatening rapid ventricular rates in the setting of AF.

Intravenous Procainamide or Ibutilide have best profile.

Amiodarone and Flecainide have been used but are not ideal due to strong AV blocking action even though they slow accessory pathway conduction.

Digoxin contraindicated as blocks AV node and increases accessory pathway conduction by shortening refractory period.

Non-dihydropyridine calcium channel blockers and adenosine may be harmful by increasing ventricular rate by blocking the AV node.

Long-term management by radiofrequency ablation of the accessory pathway is effective in selected patients.

VENTRICULAR TACHYCARDIA

VT is defined as three or more VEBs at a rate greater than 130 beats/min, and may exceed 300 beats/min. VT lasting over 30 seconds is considered to be sustained. Non-sustained VT may not cause symptoms, but is associated with increased mortality in certain patients (e.g. after myocardial infarction). VT may be monomorphic (i.e. the same QRS morphology) (Fig. 22.29) or polymorphic (varying QRS morphology).

MONOMORPHIC VENTRICULAR TACHYCARDIA

This is the most common form of VT. It is commonly associated with previous myocardial infarction, and often causes symptoms (e.g. palpitations, shortness of breath, chest pain or syncope). It may result in cardiac arrest due to the tachycardia itself or degeneration into VF. The most common mechanism is re-entry secondary to inhomogeneous activation of the myocardium and slow conduction through scar tissue from a previous myocardial infarction. AV dissociation (i.e. independent atrial and ventricular activity) (Fig. 22.30) is present in about 75% of instances, whereas retrograde ventricle-to-atrial conduction occurs in about 25%. AV dissociation is virtually diagnostic for VT during a wide-complex tachycardia, but ECG recognition of independent (and slower) atrial activity can be difficult (Fig. 22.31). VT is the most common cause of a wide-complex tachycardia (QRS >120 ms) and any such tachycardia should be considered VT until proven otherwise. Mistakes in diagnosis are common: SVT with aberrant conduction is often mistaken for VT. Inappropriate treatment based on incorrect diagnosis can have disastrous consequences.

ECG

Older criteria (e.g. QRS >140 ms and extreme electrical axis changes) are unhelpful in rhythm diagnosis.[55] ECG criteria initially proposed by Wellens and revised by Brugada et al. permit accurate diagnosis in four sequential steps (Fig. 22.32).[56–58]

The sensitivity of these four consecutive steps was 0.987, with a specificity of 0.965.

- *Step 1:* Is an RS complex present in any precordial lead? (QR, QRS, QS, monophasic R and rSR are not considered RS complexes.) If not (Fig. 22.33), the diagnosis is VT.

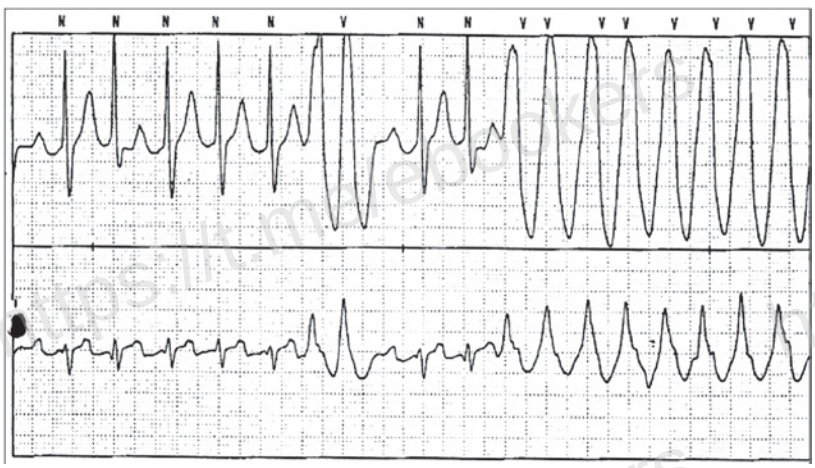

Figure 22.29 Monomorphic ventricular tachycardia preceded by a ventricular couplet.

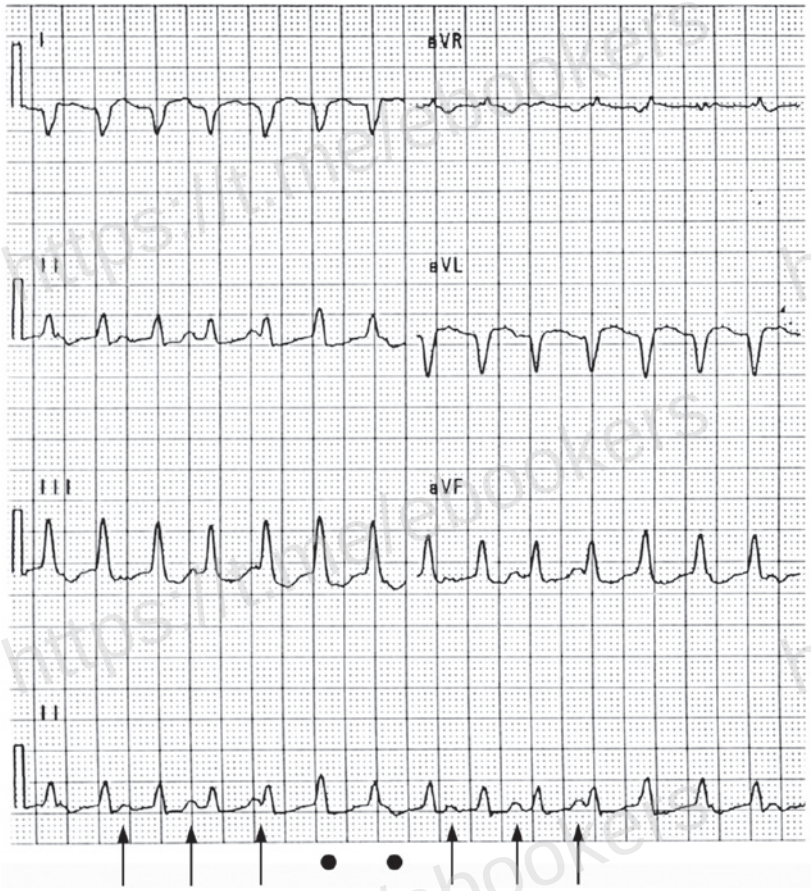

Figure 22.30 Ventricular tachycardia with obvious arteriovenous dissociation and independent P-waves are highlighted with *arrows* in lead II.

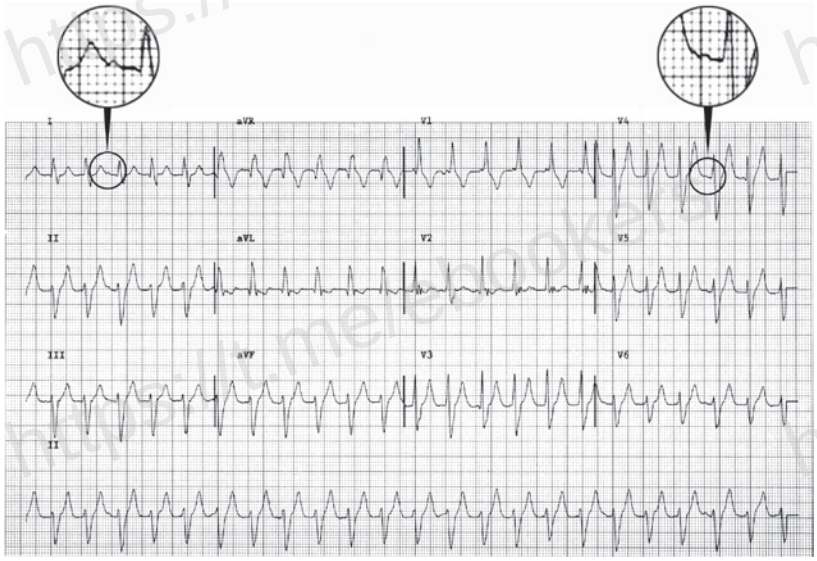

Figure 22.31 Ventricular tachycardia. Independent atrial activity can be difficult to see. Dissociated P-waves can just be seen in leads I and V_4.

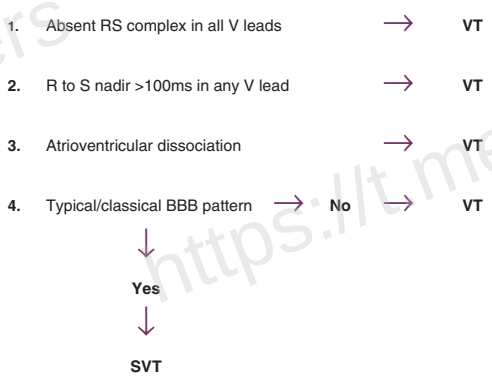

Figure 22.32 Algorithm proposed by Brugada et al.[56] to diagnose ventricular tachycardia in the setting of a broad QRS-complex tachycardia.

- *Step 2:* If an RS is present, then measure the duration of the R-to-S nadir (lowest part of the S-wave). If this duration is >100 ms in any V lead (Fig. 22.34), the rhythm is VT.
- *Step 3:* If RS <100 ms, then AV dissociation is searched for (more QRS complexes than P-waves; see Figs 22.30 and 22.31). Indirect evidence of AV dissociation such as capture or fusion beats may be present. Capture beats occur when atrial sinus impulses reach the AV node when it is no longer refractory from retrograde conduction of ventricular discharges: the AV node and ventricle are then 'captured' by the sinus impulse. The resultant QRS will occur earlier than the next expected VT complex and the QRS morphology will be that of the 'normal' underlying complexes for that patient. Similarly, a sinus impulse can penetrate the AV and 'fuse' with an

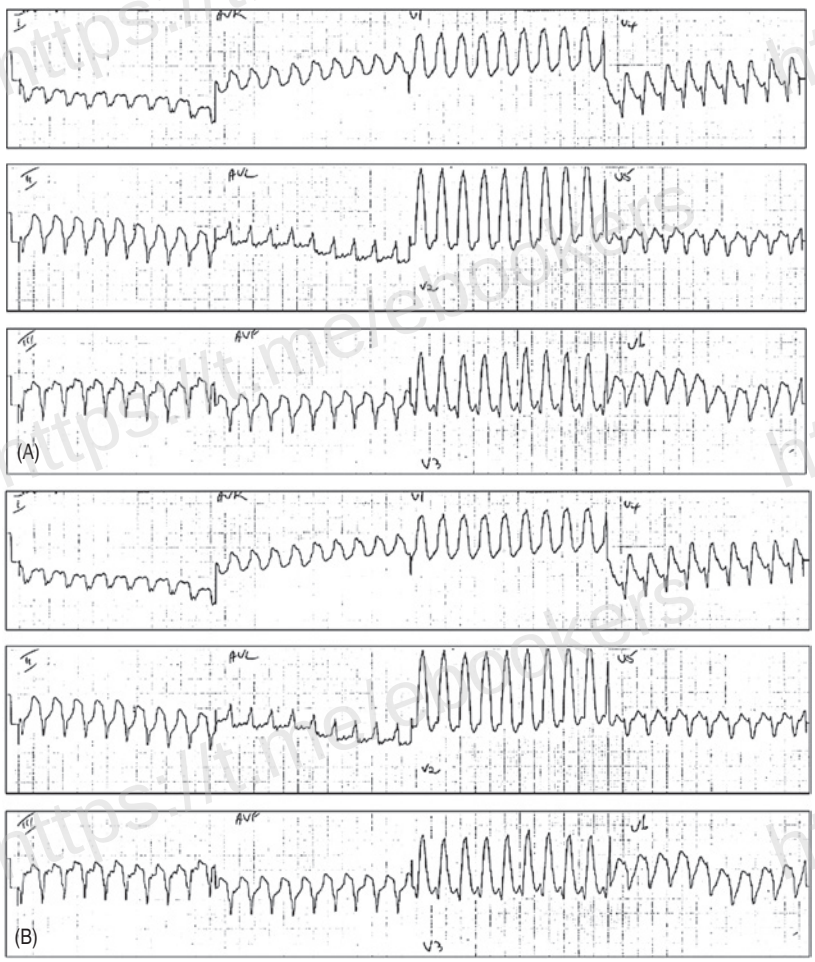

Figure 22.33 (A and B) Ventricular tachycardia. Broad QRS-complex tachycardia with absence of RS complex in all precordial leads.

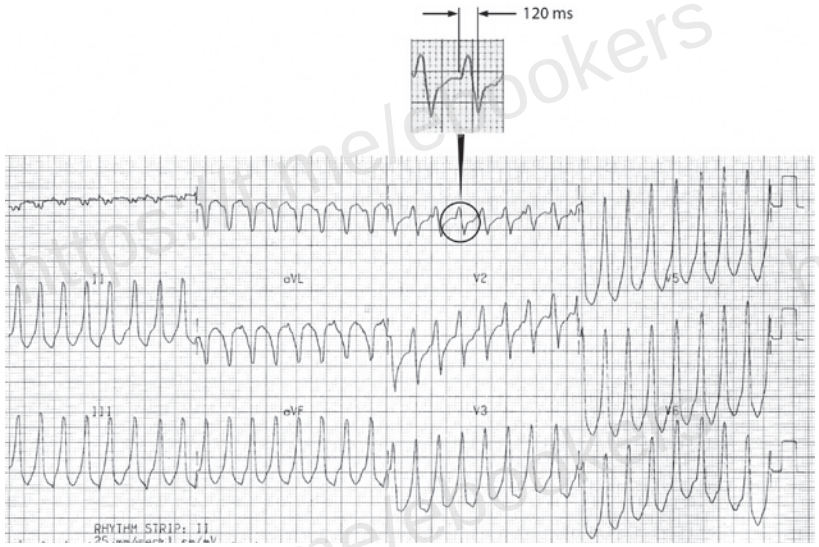

Figure 22.34 Ventricular tachycardia. Time duration of R to the nadir of the negative S-wave is 120 ms. Note also independent P-waves in lead V_1.

already depolarising ventricle from the ectopic focus initiating the VT. The resulting QRS morphology of a fusion beat will be variable and depend on the relative contribution of the supraventricular and ventricular impulses to ventricular activation. Even a single capture or fusion beat confirms AV dissociation and VT (Fig. 22.35).

- *Step 4:* If AV dissociation is not present, then decide whether the wide QRS has a right or left BBB (LBBB) pattern. If the BBB is typical in both V_1 and V_6 leads, the rhythm is supraventricular in origin (see the section on BBB). If there are any atypical features, the rhythm is considered to be VT (see Figs 22.39 and 22.40).

Termination of a wide-complex tachycardia by IV adenosine strongly suggests the arrhythmia as SVT. However, adenosine in this setting has the risk of destabilising VT when blood pressure is barely compensated by vasodilatation or acceleration of accessory pathway conduction, and is not recommended by International Liaison Committee on Resuscitation (ILCOR) as a diagnostic strategy in wide-complex tachycardia.[24] Demonstration of AV dissociation by intracardiac ECG from a central venous catheter or a transvenous pacing lead signifies VT.

CLINICAL

The major cause of VT is significant coronary artery disease. Other causes include cardiomyopathy, myocarditis and valvular heart disease. Symptoms will depend on the ventricular rate, duration of tachycardia and underlying cardiac function. There are not necessarily any haemodynamic differences between VT and SVT with aberrant conduction but haemodynamic instability mandates management as for VT.

TREATMENT[24]

DC shock is indicated if a patient is haemodynamically unstable. Antiarrhythmic drug trial is indicated in haemodynamically stable VT.

- Amiodarone may terminate VT; there is less negative inotropic action but delayed effect.
- Sotalol and procainamide are more effective than lidocaine but are associated with significant myocardial depression.
- Although traditionally indicated, there are now doubts about the efficacy of lidocaine.

If drugs are ineffective, synchronised DC shock is indicated. Rapid right ventricular pacing may also be effective.

Long-term prevention of VT and sudden death is difficult. Sotalol guided by Holter ECG or electrophysiological testing, and empirical (i.e. non-guided) amiodarone are superior to other drugs in preventing arrhythmia recurrences. Empirical beta-adrenergic blockers also have a role. Implantable defibrillators can recognise and automatically terminate VT by rapid ventricular pacing or, if this fails, by internal DC cardioversion, which may be life saving.

Catheter ablation is being increasingly used in the acute setting for VT storm. Patients with ICD and recurrent VT not controlled with amiodarone or another Class I or III agent had improved outcome with ablation compared with escalation of antiarrhythmic drugs (VANISH)[(f)][59].

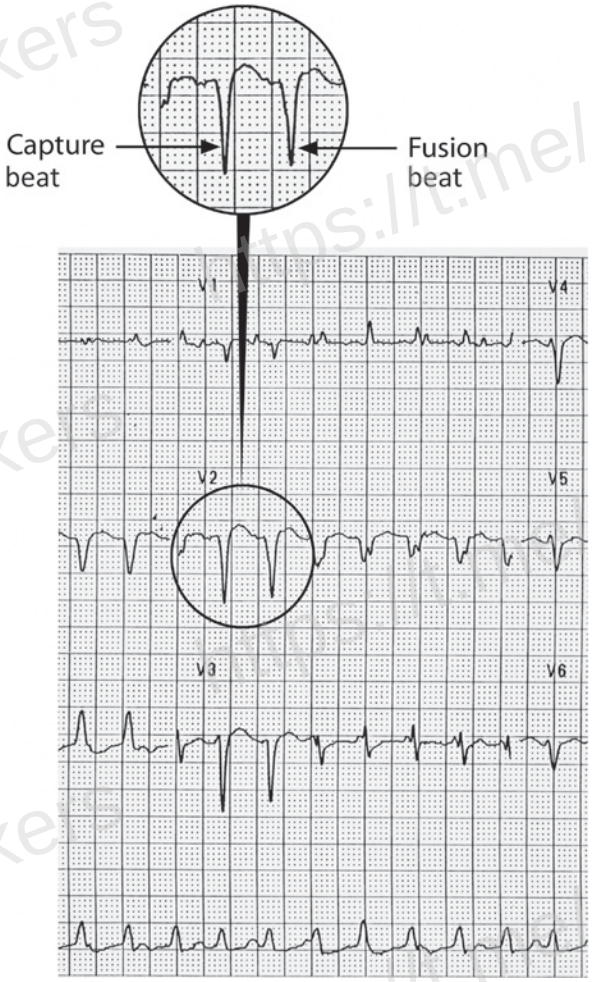

Figure 22.35 Ventricular tachycardia with a highlighted premature capture beat followed by a fusion beat showing transitional QRS morphology between the underlying normal QRS and VT complex. Note also independent P-waves.

POLYMORPHIC VENTRICULAR TACHYCARDIA AND TORSADE DE POINTES

This arrhythmia has QRS complexes at 200 beats/min or greater, which change in amplitude and axis so that they appear to twist around the baseline (Fig. 22.36). Torsade de pointes usually has prolonged QT during sinus rhythm, and U-waves are often present (see section on long-QT syndrome). However, polymorphic VT may be associated with a normal QT interval in settings such as myocardial ischaemia, infarction or post cardiac surgery.

TREATMENT

Polymorphic VT associated with a normal QT interval during sinus rhythm (e.g. following AMI) should be treated in the same way as monomorphic VT. (See section on treatment of long-QT and polymorphic VT.)

ACCELERATED IDIOVENTRICULAR RHYTHM (AIVR)

This is often inappropriately called slow VT. Increased automaticity is probably the mechanism responsible for this relatively benign arrhythmia.

ECG

There is a wide QRS with a rate of 60–110 beats/min (Fig. 22.37). Sinus rate is often only slightly slower than the arrhythmia, so the dominant rhythm may be intermittent AIVR and sinus rhythm. Fusion beats are therefore common.

CLINICAL

The rhythm is commonly encountered in inferior myocardial infarction. AIVR may be misdiagnosed as VT. Occasionally, AIVR causes haemodynamic deterioration, usually due to loss of atrial systole. Increasing the atrial rate with either atropine or atrial pacing may then be necessary.

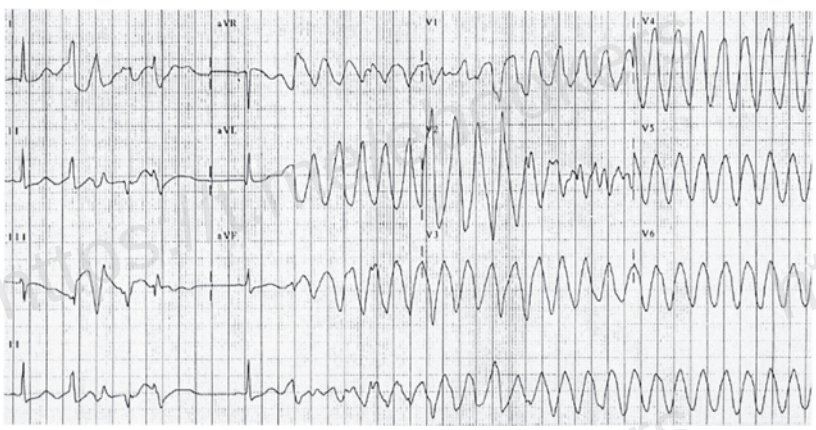

Figure 22.36 Torsade de pointes preceded by multifocal ventricular ectopic beats.

Figure 22.37 Sinus rhythm with short runs of accelerated idioventricular rhythm. Note frequent fusion beats as sinus rate is similar to the accelerated idioventricular rate.

Figure 22.38 Ventricular fibrillation with waves of varying morphology and amplitude.

VENTRICULAR FIBRILLATION

VF always causes haemodynamic collapse, loss of consciousness and death if not immediately treated. Of patients resuscitated from VF, 20%–30% have sustained an AMI, and 75% have coronary artery disease. VF (and VT) unassociated with AMI is likely to be recurrent; 50% die within 3 years.

ECG

The ECG shows irregular waves of varying morphology and amplitude (Fig. 22.38).

CLINICAL

VF is usually associated with ischaemic heart disease, although other causes include cardiomyopathy, antiarrhythmic drugs, severe hypoxia and non-synchronised DC cardioversion.

TREATMENT

Give an immediate asynchronised biphasic DC shock at 200 J. Time should not be wasted with basic life support if immediate defibrillation can be delivered.

If DC shock sequence fails, basic and advanced life support aiming to maximise coronary blood flow with chest compressions and vasopressors is crucial to cardiac success. Until recently, any role of antiarrhythmic drugs in DC shock-resistant VF has been traditional rather than proven. Recommendations have varied from lidocaine and bretylium to amiodarone. The ILCOR currently recommends consideration of a range of antiarrhythmic drugs, including amiodarone, lidocaine, magnesium and procainamide. Recent studies indicate amiodarone as the drug of choice for DC shock-resistant VF. Amiodarone (300 mg) was superior to lidocaine and, in another study, 5 mg/kg followed by 2.5 mg/kg if required was superior to lidocaine. There is an incidence of bradycardia and hypotension but no difference in adverse effect profile between lidocaine and this sizeable amiodarone dose.[60,61] After return of circulation, appropriate antiarrhythmic therapy is less clear but the role of lidocaine continues to disappear. Precipitating factors should be sought and treated (for long-term management issues, see the section on sudden cardiac death).

RIGHT BUNDLE BRANCH BLOCK (FIG. 22.39)

In right BBB (RBBB) the normal rapid coordinated depolarisation of the right ventricle is lost due to conduction block in the right branch of the bundle of His. There is normal rapid depolarisation of the septum and the initial deflection of the QRS is not altered. The activation of the free wall of the left ventricle is also normal. However, the final activation of the free wall of the right ventricle is slow and anomalous, leading to a broad QRS.

ECG

The ECG shows wide QRS (>120 ms) and the QRS morphology in the right ventricular leads V_1 and V_2 is often M shaped. This results in two R-waves, with the smaller of the R-waves being designated 'r' and the larger 'R.' The classical pattern is the M-shaped rSR in V_1 or V_2 and a broad S-wave in LV leads, especially I and V_6. In V_1 the R-wave is greater in amplitude than the R-wave. In V_6 the R-wave is greater than any S-wave present. Partial RBBB is identical, except the QRS duration is 110–120 ms.

CLINICAL

RBBB may be a normal variant, but may occur with massive pulmonary embolism, right ventricular hypertrophy, ischaemic heart disease and congenital heart disease (note that myocardial infarction can be diagnosed in the presence of RBBB).

LEFT BUNDLE BRANCH BLOCK (FIG. 22.40)

In LBBB, there is delayed and anomalous activation of the interventricular septum from right to left (i.e. in the opposite direction to normal) and the free wall of the left ventricle.

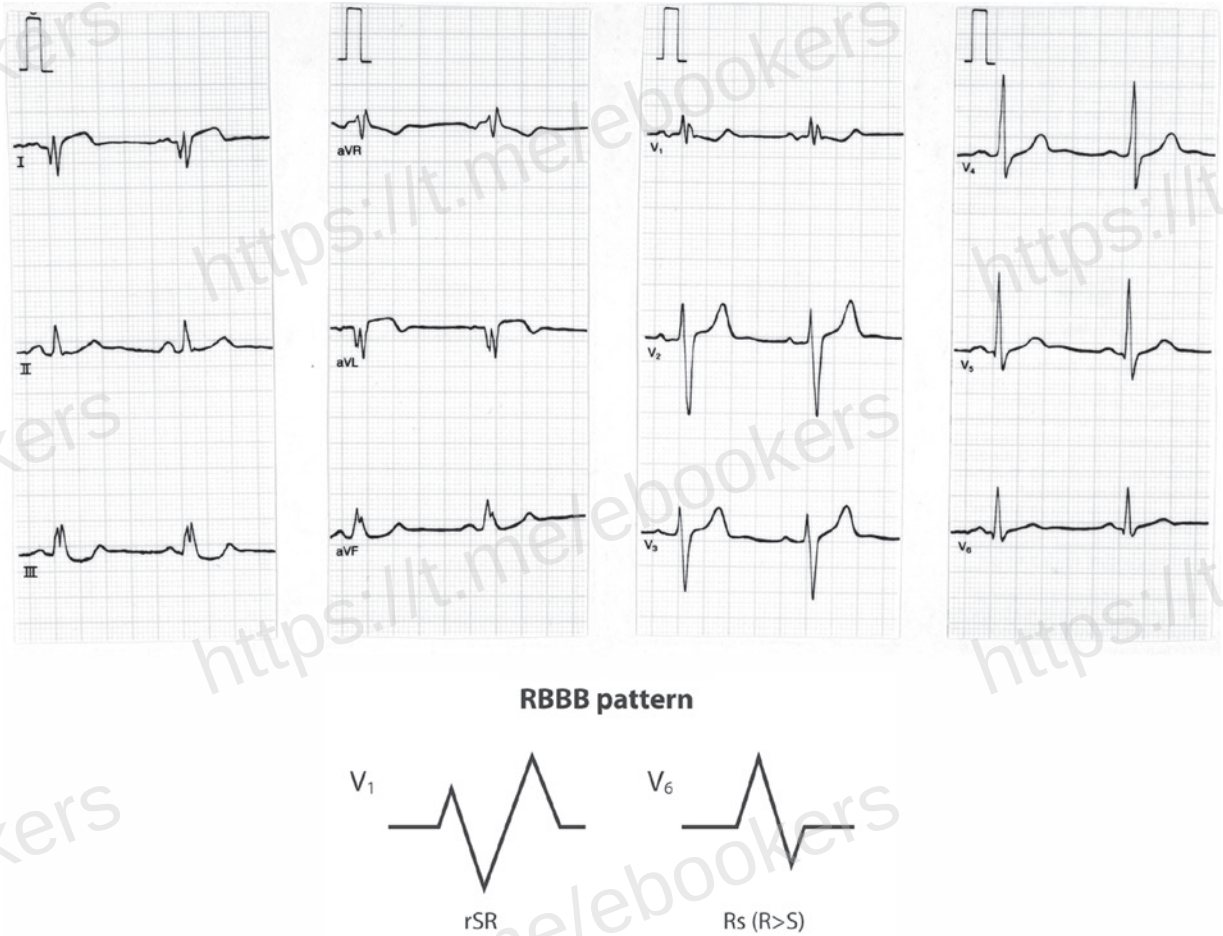

Figure 22.39 Right bundle branch block *(RBBB)* with characteristic M-shaped rSR complex in lead V_1 and Rs complex in V_6.

ECG

There is a wide QRS (>120 ms) and in V_1 the characteristic morphology shows an rS or QS. In V_6 there are primary and secondary R-waves (RR'), often resulting in M-shaped or plateau morphology. Q-waves are never seen in LV leads (V_4–V_6) (note that myocardial infarction cannot usually be diagnosed in the presence of LBBB). Partial LBBB is similar, except that the QRS duration is 110–120 ms.

CLINICAL

LBBB is often associated with heart disease such as coronary artery disease, cardiomyopathy or LV hypertrophy. LBBB makes diagnosis of myocardial infarction difficult and the development of a new LBBB fulfils ECG criteria of acute infarction.

HEMIBLOCKS

The left branch of the bundle of His divides into the left anterosuperior division supplying the anterior superior lateral wall of the left ventricle and the posteroinferior division supplying the posterior inferior diaphragmatic surface of the left ventricle. Although block can occur in either division, it is more common in the anterosuperior division, as it is more vulnerable to disease processes due to its longer course and thinner dimension. The anterosuperior division runs close to the aortic valve and tends to be involved in degenerative processes affecting this valve. The posteroinferior division is shorter and thicker and, unlike the anterosuperior division, has a double blood supply.

LEFT ANTERIOR HEMIBLOCK

There is left-axis deviation (usually lead I predominantly positive, leads II and III predominantly negative) with initial R-wave in inferior leads (II, III, aVF).

LEFT POSTERIOR HEMIBLOCK

There is usually right-axis deviation (lead I predominantly negative and lead III predominantly positive).

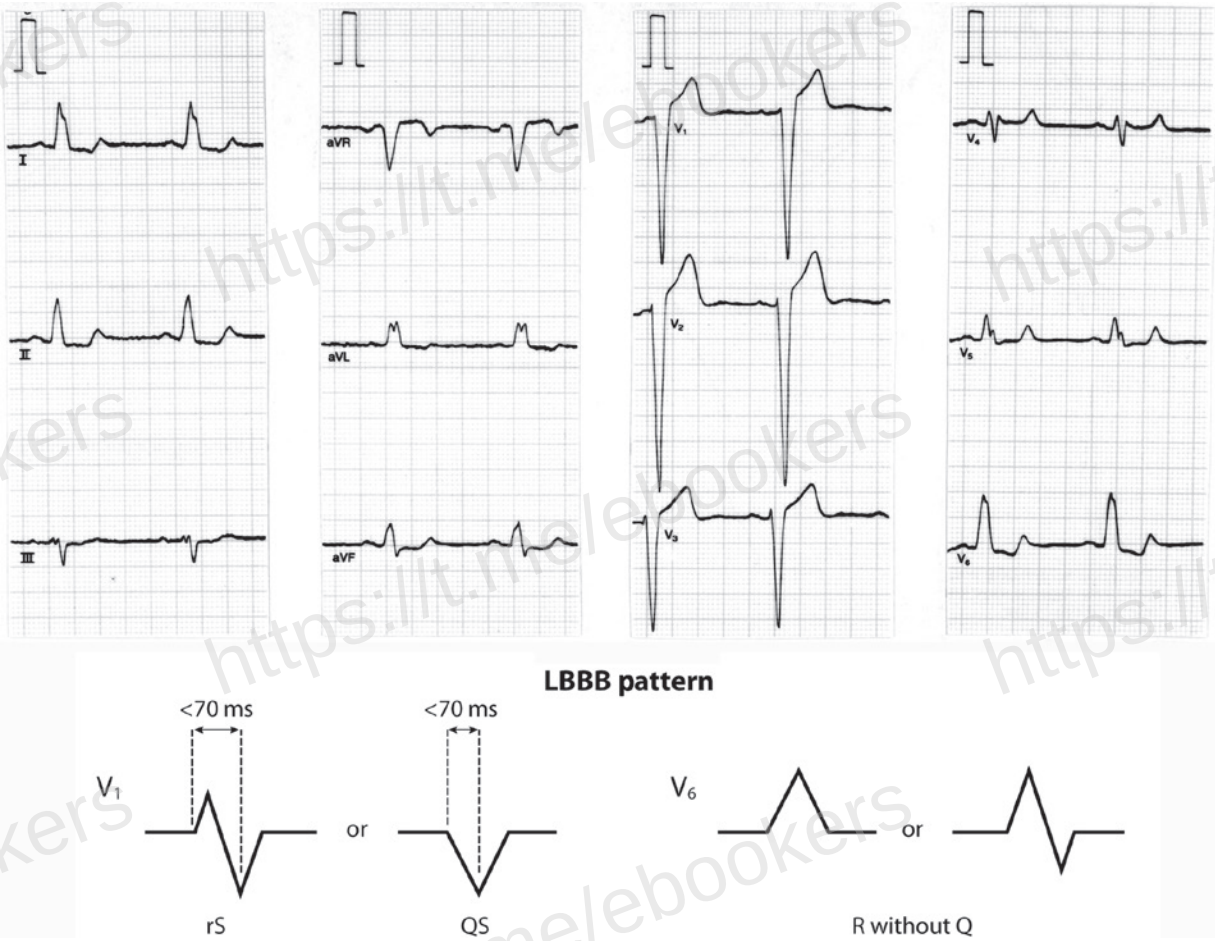

Figure 22.40 Left bundle branch block *(LBBB)*.

Other causes of right-axis deviation (e.g. right ventricular hypertrophy) need to be excluded.

CLINICAL

RBBB with either left anterior hemiblock (Fig. 22.41) or left posterior hemiblock indicates an extensive conduction defect and a poor prognosis (high risk of complete heart block), especially in AMI.

HYPERKALAEMIA

A high serum K^+ can produce ECG changes (Fig. 22.42). Early changes consist of tall peaked T-waves with reduced P-wave amplitude. Progressive widening of the QRS may be confused with BBB. Cardiac arrest may eventually occur.

ATRIOVENTRICULAR BLOCK

AV block is a delay or failure of impulse conduction from the atria to the ventricles. AV block is classified according to whether conduction of atrial impulses is delayed (first degree), blocked intermittently (second degree) or blocked completely (third degree).

FIRST-DEGREE AV BLOCK

ECG

PR interval (measured from the onset of the P-wave to the onset of the QRS) exceeds 200 ms (Fig. 22.43). Each P-wave is followed by a QRS. PR intervals may be prolonged to such a degree that the P-wave is buried in the previous T-wave or even QRS.

CLINICAL

First-degree AV block is commonly associated with increased vagal tone, and occasionally with drugs (especially digoxin), ischaemic heart disease (particularly inferior myocardial infarction) and rheumatic fever. It usually causes no symptoms and requires no treatment. If associated with digoxin, the drug should be ceased or the dose decreased.

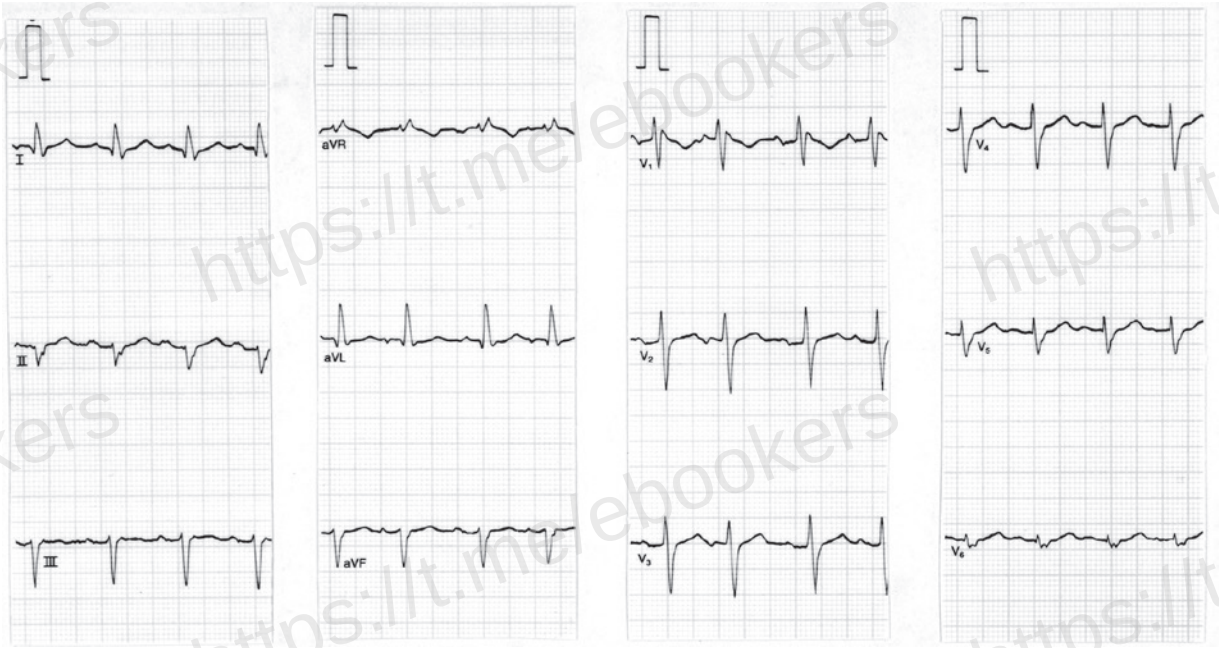

Figure 22.41 Right bundle branch block with left anterior hemiblock. There is left-axis deviation (mean frontal axis of –75°) and small R-waves in II, III and aVF.

Figure 22.42 Sinus rhythm with peaked 'tent-shaped' T-waves in a patient with a serum potassium of 7.6 mmol/L.

SECOND-DEGREE AV BLOCK

Second-degree AV block is characterised by intermittent failure of AV conduction and is classified into Mobitz types I and II. Second-degree AV block can occur in SVTs; however, the conduction block is a physiological 'protective' mechanism in the setting of rapid atrial impulses.

MOBITZ TYPE I (WENCKEBACH)

Delay in AV conduction increases with each atrial impulse until an atrial impulse fails to conduct. This is usually a repetitive pattern, which may or may not begin with first-degree AV block. The level of AV block in type 1 is usually in the AV node itself and can be physiological (increased vagal tone) as well as pathological.

ECG

There is progressive lengthening of the PR interval over successive cardiac cycles, culminating in a non-conducted P-wave, resulting in a missed beat (Fig. 22.44). Type 1 is common in fit healthy people in the presence of high levels of resting vagal tone (Fig. 22.45).

CLINICAL

The condition is generally benign and does not carry the adverse likelihood of progression to complete AV block, although it may occur with inferior infarction. Treatment is rarely necessary.

MOBITZ TYPE II

There is intermittent failure of conduction of atrial impulses to the ventricles without preceding increases

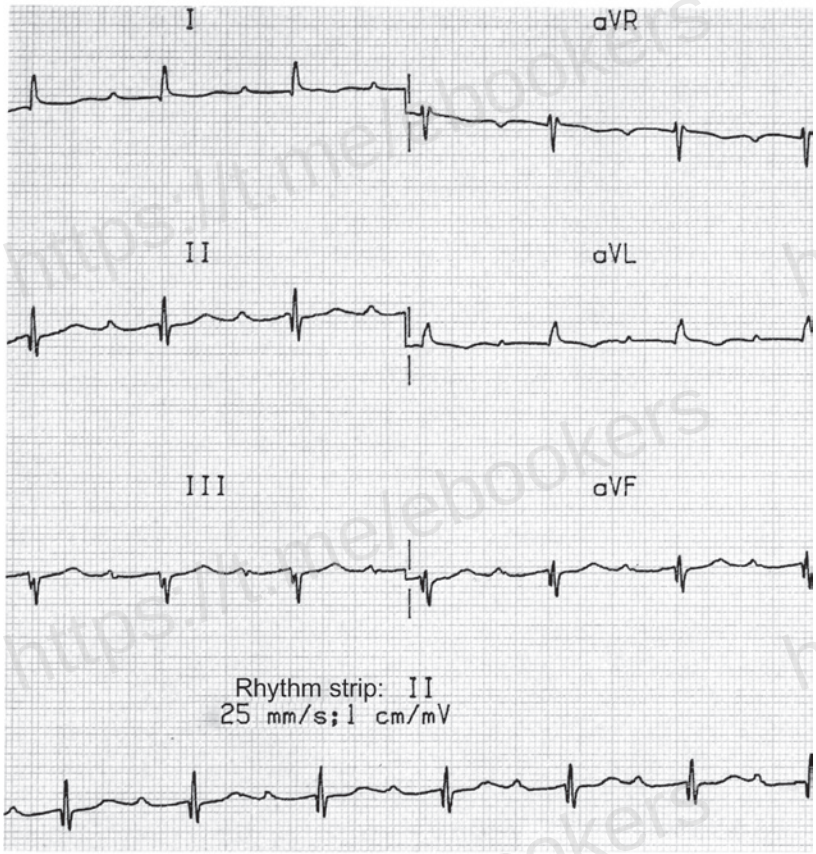

Figure 22.43 Sinus rhythm with first-degree AV block. The PR interval is 360 ms. Note inferior-wall myocardial infarction with Q-waves in II, III and aVF.

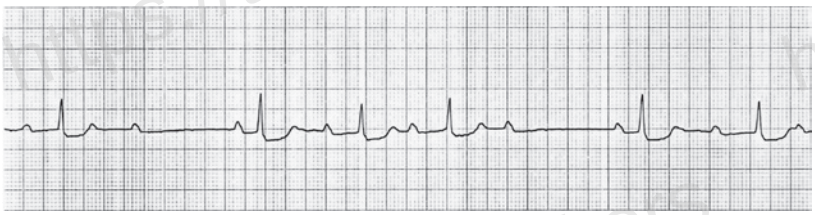

Figure 22.44 Mobitz type I (Wenckebach) second-degree arteriovenous block. Progressive lengthening of PR interval results in the failure of the second and sixth P-wave to be conducted.

Figure 22.45 Intermittent type I second-degree arteriovenous block in a healthy male with obvious background sinus arrhythmia. Constant PR interval of 0.14 second suddenly increases to 0.22 second and next P-wave is not conducted.

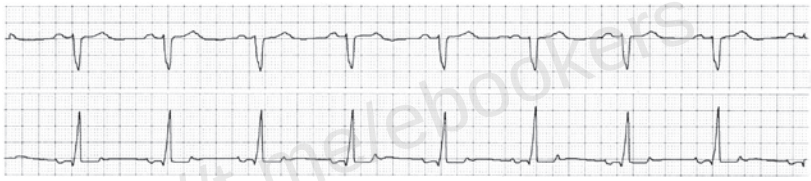

Figure 22.46 Mobitz type II second-degree arteriovenous (AV) block. Persistent 2:1 AV block with the atrial rate at 108 beats/min and the ventricular rate 54 beats/min.

Figure 22.47 Leads I, aVR, V_1 and V_4 showing third-degree arteriovenous block. Complete dissociation of atrial activity at a rate of 107 beats/min and the ventricular rate at 46 beats/min. The escape rhythm is junctional (high up in the bundle of His) with a narrow QRS morphology.

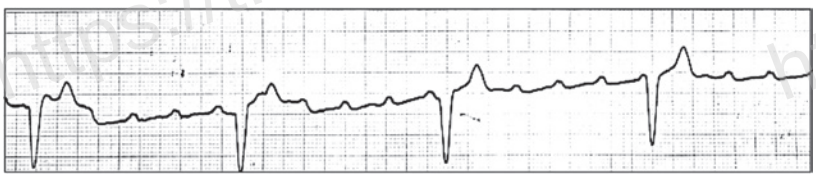

Figure 22.48 Third-degree arteriovenous block with an atrial rhythm at 135 beats/min and a broad distal ventricular escape rhythm which is unstable at a rate of 30 beats/min.

in the PR interval. The ratio of conducted to non-conducted atrial impulses varies; for example, every second or fourth atrial impulse may be conducted (i.e. 2:1 or 4:1 second-degree AV block). The lesion causing type II is usually situated in the bundle of His and is always pathological.

ECG

PR interval remains constant prior to the blocked P-wave. There is always a constant P-QRS-wave ratio: the P-waves are two (Fig. 22.46), three (rare) or four times more frequent than QRS-waves.

CLINICAL

It is likely to be associated with structural heart disease. Slower symptomatic ventricular rates may require pacing. The AV block may be intermittent or persistent. The adverse prognosis relates to the frequency of progression to complete AV block.

THIRD-DEGREE (COMPLETE) AV BLOCK

This rhythm occurs when no atrial impulses are conducted to the ventricles; atrial and ventricular contractions are dissociated. The SA node usually continues to depolarise the atria, whereas ventricular activation depends on a standby escape pacemaker located below the block. The escape pacemaker may be close to the His bundle (narrow QRS, stable pacemaker usually 40–60 beats/min) (Fig. 22.47), or more distal in ventricular tissue (wide QRS, relatively unstable pacemaker with a rate of 20–40 beats/min) (Fig. 22.48). If no ectopic escape pacemaker emerges, ventricular asystole will occur, resulting in a Stokes–Adams attack, or death if the episode is prolonged. Torsade de pointes may also occur associated with the bradycardia.

ECG

The ECG shows normal regular P-waves completely dissociated from QRS complexes. The QRS rate is always significantly slower than the P-wave rate and may be very slow at times.

CLINICAL

Idiopathic fibrosis of the conduction system is the most common cause. Other causes include myocardial infarction, valvular heart disease, cardiac surgery and a congenital form of complete heart block. Cardiac pacing is usually required to increase heart rate and cardiac output. Congenital forms often have a relatively fast escape ventricular rate, and patients may remain asymptomatic for many years.

SINUS NODE DYSFUNCTION[62]

Sinus node dysfunction (SND) results in sick sinus syndrome and or atrial arrhythmias. The incidence increases from 1 per 1000 at 45 years to 1 per 600 at 65 years. Time from development of bradycardia to SA block and sinus arrest is 13 years (range 7–29 years). SND is associated with 4.2-fold increase in AF. SND presents as AF in 40%–70% of cases. SND also presents with syncope, heart failure, other atrial tachyarrhythmia and thromboembolic events.

SND is secondary to decreased impulse generation or defective conduction out of the node resulting in bradyarrhythmia and atrial tachyarrhythmia.

Causes of SND

Intrinsic
- Interstitial fibrosis
  - Ischaemia
  - Infiltration: Amyloid
  - Inflammation: Rheumatic fever
  - Genetic mutation channellopathy: Decreased Ina propagation causing exit block

Extrinsic
- Autonomic tone
  - Drugs
  - Hypothyroid
  - Hypothermia

Sick sinus syndrome occurs in the setting of chronic SND.

Results in
- Severe sinus bradycardia
- Sinus pauses
- Sinus arrest
- SA nodal exit block

Chronotropic incompetence. Inappropriate responses to physiological demands such as exercise and stress.

Tachybradycardia. AF (most common), Afl and sinus tachycardia.

Most AF originates from left atrium and in SND the propensity of AF is explained by loss of overdrive modulation of pulmonary vein sleeves where increases in If current results in increased spontaneous activity. Impaired non-uniform conduction out of the SN also creates substrate for re-entry.

Atrial tachycardia and AF results in significant SND within 2 weeks due to down regulation of If and SND increases propensity of atrial tachyarrhythmia further.

SND recovers following AF reversion, either ablation or cardioversion.

Drug therapy is difficult in SND and tachybrady arrhythmia. If adequate chronotropic response to exercise can be demonstrated, then beta-blocker with intrinsic sympathomimetic activity can be trialled. Otherwise, all agents have negative chronotropic action and concurrent pacemaker is indicated.

Permanent pacemaker (PPM) with AAI or DDD mode reduces AF, stroke and pacemaker syndrome compared with VVI.

AF ablation improves SND, decreases bradycardia and need for pacemaker when compared to PPM and antiarrhythmic drug (Fig. 22.49).

CRITICALLY ILL PATIENTS AND ARRHYTHMIA[63]

In the general population of critically ill patients, excluding acute coronary syndromes and cardiac surgical patients, arrhythmia is common. The documented incidence is as high as 78%; however, the incidence of arrhythmia that requires treatment is much lower, at 15%–30%. SVT is by far the most common arrhythmia that requires treatment. AF, Afl and unifocal atrial tachycardias are the most frequent, in descending order. These SVTs are rarely the cause of admission but develop early in the admission, the majority by day 2. In critically ill patients, SVTs often result in:

- adverse myocardial oxygen supply–demand balance
- compromised blood pressure, cardiac output and systemic oxygen delivery
- impaired end-organ function such as oliguria and worsening gas exchange.

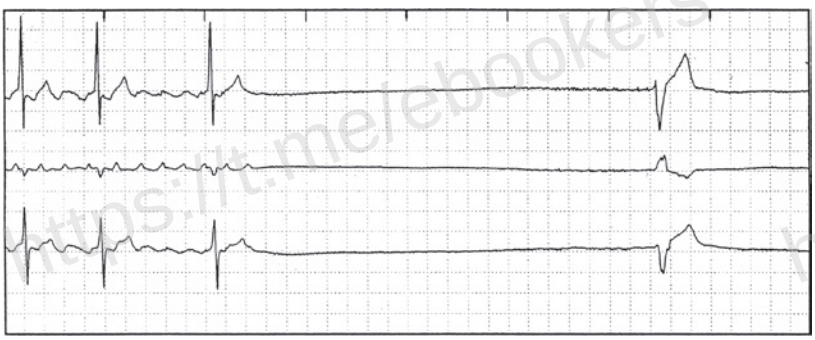

Figure 22.49 Characteristic findings in sick sinus syndrome. Episodic atrial tachycardias (atrial flutter with variable block in this instance) with periods of sinus arrest and very slow ventricular escape rhythm upon spontaneous termination in this case following carotid sinus massage.

The development of SVT in a critically ill patient is associated with a significant increase in mortality, especially in patients with sepsis and respiratory failure. Incidence of SVT is increased with:

- elderly patients
- evidence or past history of heart disease
- haemodynamic features of diastolic failure with elevated pulmonary artery occlusion pressure
- catecholamine infusion
- severe sepsis.

The actual dose of the catecholamine infusion does not appear to be important and, although electrolyte disturbances are common in critically ill patients, low plasma potassium and magnesium levels do not appear to be important predictors of SVT development. The incidence of SVT, particularly AF, is so high in elderly patients with heart disease on a catecholamine infusion that consideration of prophylactic strategies is worthwhile.

Risk of in-hospital stroke is increased in critically ill patients with new-onset AF, odds ratio 2.70 and greater focus on the need for embolic prophylaxis is needed.[64]

TREATMENT OF SUPRAVENTRICULAR TACHYCARDIA IN CRITICALLY ILL PATIENTS

Continuing arrhythmogenic and chronotropic factors make rate control difficult.

- Digoxin often results in poor rate control due to persisting endogenous and exogenous sympathomimetic tone. The inotropic and vasopressor effects of acute digitalisation are beneficial. Digoxin (10 µg/kg) has been shown to provide superior circulatory support to dopamine at 8 µg/kg per min in septic patients.[65]
- Irrespective of plasma levels, magnesium has been shown to be effective at rate control; however, hypotension due to vasodilatation can be seen.
- Amiodarone is particularly effective and has allowed reliable acute rate control over a period of days in critically ill patients with circulatory shock requiring catecholamine infusions.[66] It can cause hypotension if patients are rapidly loaded. In another study, magnesium was at least as effective as amiodarone in rate control and time to reversion to sinus rhythm.[67]
- Other agents, such as diltiazem, sotalol and procainamide, are associated with prohibitive myocardial depression and hypotension.

Urgent cardioversion is indicated in unstable patients. The likelihood of remaining in sinus rhythm in the setting of high endogenous and exogenous sympathomimetic tone is low without concomitant use of an antiarrhythmic drug. Cardioversion is best reserved for hastening onset of sinus rhythm once a drug like amiodarone has controlled rate. Cardioversion should at least be attempted within 24–48 hours of onset in the hope that embolic and anticoagulation issues are avoided.

MYOCARDIAL INFARCTION AND ARRHYTHMIA

Arrhythmia is common following AMI. While early arrhythmia contributes significantly to mortality, treatment is largely expectant and secondary to re-establishing coronary blood flow, minimising infarct size and treating ongoing ischaemia and heart failure. Late ventricular arrhythmia is particularly challenging, as selecting patients at risk is difficult and treatment options are limited.

MANAGEMENT OF ACUTE MYOCARDIAL INFARCTION AND ARRHYTHMIA CONTROL

Modern management of AMI, although targeted to prevent or reduce infarct size, has also been very effective in reducing arrhythmia incidence and sequelae. Numerous studies have documented transient ventricular arrhythmias at the time of reperfusion resulting from thrombolysis and acute angioplasty. However, the most common arrhythmias seen in this setting are VEB, AIVR and non-sustained VT, rather than VF or sustained VT.

Meta-analysis of thrombolytic trials has shown no increase in early VF following thrombolytic therapy in the first 24 hours. The likelihood of developing VF at any time during a hospital episode is reduced following thrombolytic therapy but the risk of developing VT is increased. The mechanism of reperfusion arrhythmia is believed to be related to intracellular calcium overload and the resulting triggered activity in the form of DAD. Dipyridamole, which inhibits the cellular uptake of adenosine, has been shown to be effective in preventing and treating reperfusion ventricular arrhythmia.

Prior to the introduction of thrombolytic therapy, beta-adrenergic receptor blockers significantly reduced the incidence of early VEB and VF. However, following routine use of thrombolytic therapy, the benefit of beta blockers relates to a reduction in post-infarction ischaemia and subsequent infarction.

The early work demonstrating survival benefit of magnesium was initially thought to be due to the prevention of arrhythmia.[68] However, the Leicester Intravenous Magnesium Intervention Trial (LIMIT-2) found the improved survival not to be related to a reduction in arrhythmia.[69] Subsequent studies in the thrombolytic era have failed to show any benefit at all with magnesium, although debate regarding optimal time of administration persists. Magnesium may have a role in patients in whom beta-adrenergic blockers or thrombolytic therapy are contraindicated.

ELECTROLYTE CONCENTRATIONS AND ARRHYTHMIA FOLLOWING ACUTE MYOCARDIAL INFARCTION

Serum potassium following AMI is negatively correlated with the incidence of VEB and VT, with the probability of VT falling until serum potassium exceeds 4.5 mmol/L.[11] There is no evidence that magnesium levels in this setting have any effect on ventricular arrhythmia. Nonetheless, ILCOR recommendations not only include the maintenance of serum potassium greater than 4.0 mmol/L, but also serum magnesium levels greater than 1.0 mmol/L.

BRADYARRHYTHMIAS POST ACUTE MYOCARDIAL INFARCTION

One-third of patients with AMI develop sinus bradycardia because of increased vagal tone. In inferior infarcts due to occlusion of the right coronary artery, bradyarrhythmia is due to ischaemia of the SA and AV nodes. Reperfusion of the right coronary artery can also lead to sinus bradycardia and heart block that is due to accumulation of adenosine in nodal tissue. Bradycardia in this setting is resistant to atropine.

Second- or third-degree AV block occurs in approximately 20% of AMI patients. High-degree AV block occurs early when present, with 42% presenting with AV block and most, 66%, developing in the first 24 hours. Similar to all post-AMI arrhythmias, thrombolytic therapy has reduced the incidence down to 12%. When present, high-degree AV block is associated with an increased mortality. However, high-degree AV block is not an independent predictor, but rather a marker of extensive infarction and LV dysfunction.

Treatment is only indicated for sinus bradycardia associated with symptoms, hypotension or signs of poor cardiac output. Most often, first- and second-degree block also do not need treatment. Mobitz type I second-degree block may require treatment and atropine is indicated. However, in Mobitz type II, atropine usually has no effect on infranodal block and may precipitate third-degree block by increasing sinus rate and enhancing block. Atropine may improve heart rate with AV block occurring at the AV node, as demonstrated by a narrow QRS complex, by improving AV conduction or accelerating escape rhythm. Atropine is not indicated for infranodal third-degree block, which is diagnosed by the presence of a new wide QRS complex. When required, atropine is administered, 0.5–1.0 mg every 3 minutes until signs or symptoms are resolved, up to a maximum of 0.03–0.04 mg/kg. If atropine is not indicated or effective, cardiac pacing is required (Box 22.7). Transcutaneous pacing is indicated for initial management as a bridge until a transvenous temporary pacing wire can be inserted safely and with appropriate sterile technique. With the ready availability of transcutaneous pacing, IV catecholamines for bradyarrhythmias are to be avoided in the setting of AMI.

Box 22.7 Indications for pacing following myocardial infarction

- Haemodynamically unstable bradycardia (<50 beats/min)
- Mobitz type II second-degree atrioventricular block
- Third-degree heart block
- Bilateral bundle branch block
- Left anterior fascicular block
- New left bundle branch block
- Bundle branch block and first-degree atrioventricular block

ATRIAL FIBRILLATION POST ACUTE MYOCARDIAL INFARCTION

New-onset AF occurs in 10%–15% of AMI. The incidence increases with age, large infarcts, LV hypertrophy and congestive cardiac failure. It is also related to atrial infarction with occlusion of the right coronary artery proximal to the sinus node branch or circumflex proximal to the left atrial circumflex branch. Later in the course of myocardial infarction, AF is related to postinfarct pericarditis.

Thrombolytic therapy has reduced the incidence of AF. In the setting of AMI, AF is usually self-limiting and requires no treatment. If rapid ventricular rates are associated with further ischaemic symptoms or haemodynamic compromise, cardioversion is indicated. Beta blockers, which are indicated in the treatment of AMI anyway, are the initial treatment of choice. Digoxin is not indicated in the setting of acute ischaemia as the likelihood of triggered activity associated with intracellular calcium overload is increased. AF following AMI is associated with an increase in mortality. Systemic emboli following AMI are three times more likely with AF and 50% occur in the first 24 hours of onset of AF. For this reason, sustained AF is an indication for anticoagulation prior to the normal 48-hour period following AMI.

VENTRICULAR ARRHYTHMIA POST ACUTE MYOCARDIAL INFARCTION[70,71]

VF/VT is the leading cause of mortality following AMI. Fifty per cent of patients dying from AMI do so pre-hospital due to VF/VT. Pre-hospital mortality is being reduced by improved community education, wider application of basic life support and availability of an automated external defibrillator (AED). Following admission to hospital, LV failure is the most common cause of death.

The major risk period for VF is the first 4 hours following onset of symptoms, with 4%–18% of patients

having VF in this period. Once admitted to hospital, 5% develop VF, mostly in this first 4-hour period. VF in this early 4-hour period is termed 'primary VF'. VF later in the course of an AMI, usually associated with LV failure or cardiogenic shock, is called 'secondary VF.'

Thrombolytic therapy has reduced VF incidence. The Gruppo Italiano per lo Studio della Streptochinasi nell'infarto miocardico (GISSI) study[70] found an incidence of primary VF of 3.6% and secondary VF of 0.6%. The overall incidence of ventricular arrhythmia in the Global Utilization of Streptokinase and Tissue plasminogen activator to treat Occluded arteries (GUSTO-1) report was VF, 4.1%, VT, 3.5% and both, 2.7%.

Primary VF increases in-hospital mortality and complications but not long-term mortality. Complex ventricular arrhythmias, defined as multiform VEB, couplets and non-sustained VT, occur in 35%–40% of patients during hospital stay. They occur equally with Q-wave and non-Q-wave infarction. Complex ventricular arrhythmia is a risk factor for subsequent VF/VT and SCD, particularly in non-Q-wave infarction. Polymorphous VT is less common after AMI and does not appear to be related to QT prolongation or electrolyte disturbances in the reported cases.

Lidocaine reduces primary VF by 33% but mortality is increased by a similar amount such that there is no net benefit and the third International Study of Infarct Survival (ISIS-3) reported an overall trend to increased mortality. Being more selective as to which patients receive lidocaine has not been possible, as only 50% of patients who develop VF have 'warning' ventricular arrhythmia. In the 'percutaneous coronary intervention or thrombolytic and beta-blocker' era of treatment of AMI, the use of prophylactic lidocaine, or any other antiarrhythmic drug, to prevent VF will have even less benefit. There are no conclusive data to support the use of lidocaine to prevent recurrent VF in those patients who have already suffered an episode of VF. Despite this, a short period of 6–24 hours of lidocaine has been advocated.

Patients who survive a late or secondary episode of VF/VT following myocardial infarction require full evaluation for preventive strategies, as do survivors of SCD. All survivors of a myocardial infarction are at an increased risk for SCD but accurate prediction is not feasible. Risk factors that have been shown to be associated with increased risk of a subsequent episode of VF/VT after myocardial infarction include:

- age
- Holter monitoring and demonstration of non-sustained VT, couplets and frequent VEB (i.e. >10 beats/min)
- impaired LV function (i.e. ejection fraction less than 30%–40%)
- signal-average ECG and detection of delayed afterpotentials. In patients presenting with SCD after myocardial infarction, 68%–87% have an abnormal signal-average ECG. However, the positive predictive value is poor, at 15%–25%
- demonstrated inducibility of VT postinfarction is associated with increased risk of SCD. However, the positive predictive value is again poor, at 20%–30%.

Combinations of these risk factors have been evaluated to predict risk after infarction. The combination of delayed potentials on signal-average ECG, LV ejection fraction of less than 40% and non-sustained VT on Holter monitor has been shown to be associated with up to 50% risk of SCD. Currently, there is no agreement on which patients require primary preventive strategies for VF/VT following myocardial infarction.

Using frequent VEB to identify patients at risk following myocardial infarction has been extensively used. There have been 54 randomised trials reported involving more than 20,000 patients using 11 different class I agents.

Class I agents showed no overall benefit on all-cause mortality and class IC agents have excess mortality despite arrhythmia suppression.

Class II antiarrhythmics, beta blockers, have an established and broadening role, with recent evidence showing significant benefit.[72]

Class III agents lack a consistent class effect. Sotalol (Survival with oral D-sotalol: SWORD) was found to increase all-cause mortality and arrhythmia deaths.[73] Amiodarone (Canadian Amiodarone Myocardial Infarction Arrhythmia Trial: CAMIAT) reduces all-cause mortality in patients with frequent VEB post myocardial infarction,[74] but another study (European Myocardial Infarction Amiodarone Trial: EMIAT) evaluated amiodarone in patients with ejection fraction less than 40% and found no effect on all-cause mortality but a 35% reduction in arrhythmia deaths.[75] Subsequent analysis of combined CAMIAT and EMIAT data has emphasised the importance of beta blockers. The combination of amiodarone and beta blockers in these post-infarct patients was better than either drug alone.[76]

CARDIOTHORACIC SURGERY AND ARRHYTHMIA

SVT AFTER CARDIOTHORACIC SURGERY[77]

AF predominates, with Afl and unifocal atrial tachyarrhythmia also commonly occurring after CABG, with an incidence of 11%–40% and in over 50% following valvular surgery. In addition to mechanisms found in non-surgical patients, pericardial inflammation or effusion, increased catecholamine production and postoperative autonomic changes are implicated. Major risk factors include:

- previous history of AF
- increasing age
- postoperative withdrawal of beta-blocker therapy.

Extent of coronary artery disease, postoperative ischaemia, duration of aortic cross-clamping or cardiopulmonary bypass and method of myocardial protection do not influence incidence. SVT post cardiothoracic surgery is not a benign event, with the major consequence being thromboembolic complications. Stroke occurs following CABG in 1%–6% of patients and postoperative atrial tachyarrhythmia increases the incidence threefold. Other adverse effects include:

- haemodynamic instability
- prolonged inotropic support
- need for intra-aortic balloon pump
- reoperation for bleeding
- longer and more expensive critical care unit and hospital episodes.

PREVENTION OF SUPRAVENTRICULAR TACHYCARDIA[78,79]

Preoperative beta-blocker treatment should be continued postoperatively. Beta blockers consistently reduce SVT across many studies with differing agents.

Amiodarone prophylaxis after elective cardiac surgery reduced postoperative AF from 53% to 25%. Diltiazem has also been shown to be effective at SVT prevention and there was associated improvement in haemodynamic variables and rates of myocardial ischaemia. Verapamil is not effective. Esmolol was found to be more effective than diltiazem. Sotalol is also effective but problematic bradycardia and hypotension are greater.[80] Atorvastatin is also effective.[81]

There is no relation between SVT incidence and serum magnesium levels and there are conflicting data relating to the efficacy of prophylactic magnesium. Digoxin has no role in prevention.

Incidence of postoperative AF are still high despite preventive strategies. In a large cohort of patients, overall AF incidence was 33% (28.1% CABG only, 33.7% valve only and 47.3% combined) despite 80% preventive beta blocker or calcium channel blocker (Cardiothoracic Surgical Trials Network[(h)]). Average onset of AF was 2.4 days (range 0–7).

TREATMENT OF SUPRAVENTRICULAR TACHYCARDIA

Treatment is aimed at control of ventricular rate, prevention of thromboembolism and cardioversion.

Similar to other settings, rhythm control not superior to rate control. Amiodarone, AV blocker and electrical cardioversion compared to AV blocker only (resting rate <100) had similar hospital length of stay, rates of anticoagulation and stable sinus rhythm at discharge, complications, including thromboembolic, stable sinus rhythm at 30 and 60 days and readmission rates.[82]

Digoxin, atenolol/metoprolol, diltiazem and magnesium are appropriate choices to control rate.

In persisting AF, the timing of electrical cardioversion is debatable. Early electrical cardioversion, inside 24–48 hours, avoids the need for anticoagulation but is associated with a significant recurrence rate as postoperative arrhythmogenic factors remain. In persistent or recurrent AF, sotalol and amiodarone, depending on myocardial function, are suitable antiarrhythmic drugs and should be continued for 6–12 weeks following cardioversion.

Timing of safe anticoagulation following cardiac surgery is also debatable. Many advocate delaying anticoagulation till 72 hours post surgery, which may be greater than 24–48 hours after onset of SVT. Most cardiac surgical patients receive aspirin and low-dose heparin in the early postoperative period, which is likely to reduce risk. However, it is worth noting that, in other AF settings, 325 mg of aspirin decreased thromboembolic events but 75 mg did not.

VENTRICULAR ARRHYTHMIA FOLLOWING CARDIAC SURGERY

Ventricular arrhythmia requiring treatment, DC shock or drug therapy is common following cardiac surgery and occurs in 23% of patients.[83] Arrhythmias requiring DC shock occur in the first 36 hours and are associated with:

- advanced age
- failure to use an internal mammary artery conduit (which is likely to reflect preoperative assessment of high risk)
- SVT.

The incidence was not related to previous myocardial infarction, ejection fraction of less than 50%, prolonged operative time, perioperative myocardial infarction or reduced number of vessels bypassed. In patients undergoing coronary artery bypass, grafting patients at high risk for sudden death, LV ejection fraction less than 36% and abnormalities on signal-averaged ECG had a 6.3% incidence of sustained VT and 4.3% VF.

VEBs are common early on return from surgery, with frequent or complex ectopy associated with adrenergic effects of emerging from anaesthesia and hypokalaemia. The threshold to treat these arrhythmias varies with clinicians. Potassium must be regularly checked and maintained above 4 mmol/L.

If there is accompanying emergent hypertension, in addition to the antiarrhythmic action, the vasodilating properties of magnesium provide an ideal profile at this stage. Patients with VT/VF reverting with DC shock who are haemodynamically stable should have prophylactic antiarrhythmic cover until adrenergic stimulation associated with awakening and weaning from mechanical ventilation is past. Lidocaine has been the agent of choice, but magnesium, amiodarone and sotalol are all more effective. Maintaining

antiarrhythmic levels of magnesium may not be conducive to weaning from ventilation. Extrapolating from post myocardial infarct data would support the conversion to beta blockers if there were no contraindications.

A smaller proportion of patients develop malignant VF/VT, most often in association with poor LV function and a postoperative low-cardiac-output state requiring catecholamine infusions. In this setting, ventricular arrhythmia is common, often initiated by short-coupling polymorphous VT (normal QT_c), due to ongoing ischaemia or reperfusion of ischaemic heart.

- High-dose amiodarone may work best in combination with antiarrhythmic levels of magnesium (1.8–2.0 mmol/L) or lidocaine.
- Many of these patients need an intra-aortic balloon pump to defend coronary artery perfusion pressure not only because of the likely poor LV function and low-output state, but also to minimise the adverse effects of antiarrhythmic drugs and recurrent DC shocks.
- Pacing may be required to counteract bradyarrhythmia associated with escalating doses of antiarrhythmic drugs. Pacing at faster rates (90–110 beats/min, which may not be ideal from a cardiac-output point of view) may be protective against recurrent episodes by promoting homogeneity of depolarisation and suppression of abnormal automaticity. The presence of epicardial or transvenous pacing wires also enables bedside-programmed stimulation and overdrive pacing for termination of recurrent VT, which has fewer deleterious effects than recurrent DC shocks.

Arrhythmia during pregnancy[84]

Cardiac arrhythmia is the most common cardiac complication during pregnancy.

Mechanism thought to result from increased plasma volume and stroke volume. Activation of stretch-activated ion channels (see above) results in EADs, shortened refractoriness and slowed conduction with spatial dispersion.

The majority of antiarrhythmic drugs are Category C (www.fda.gov). Risk cannot be ruled out. Amiodarone is teratogenic and associated with foetal hypothyroidism, growth retardation and prematurity and therefore is reserved for life-threatening arrhythmia. Dronedarone is also teratogenic and contraindicated. With other drugs, avoid use during organogenesis of first trimester. Monitor foetal growth, cardiac rhythm and uterine contractility during second and third trimesters.

Electrical cardioversion indicated for haemodynamic instability and drug refractory arrhythmia, and does not compromise blood flow to foetus and risk of foetal arrhythmia is small. Premature labour is theoretical risk only. There are rare cases of emergency caesarean section due to foetal arrhythmia and therefore foetal monitoring is advisable.

Catheter ablation is not indicated due to radiation exposure and potential haemodynamic instability.

Frequent atrial and ventricular ectopics can be intolerable. Metoprolol (Cat C), not Atenolol (Cat D), positive evidence of risk. Can be used after first trimester.

SVT is the most common sustained arrhythmia during pregnancy and 20% of patients with pre-existing SVT will have exacerbation during pregnancy. If vagal manoeuvres fail, Adenosine is safe (Cat C), with Metoprolol or Verapamil (Cat C) next in line. For SVT associated with accessory pathway (pre-excitation, stable wide-complex tachycardia) Procainamide (Cat C) indicated and Flecainide (Cat C) for prevention.

AF and AFL are less common than SVT. In new AF, pulmonary embolus and cardiomyopathy should be excluded. If unstable cardioversion is suggested, otherwise Metoprolol and or Digoxin (Cat C) for rate control. Sotalol (Cat B) or Flecainide for failure of rate control. Anticoagulation with Enoxaparin is indicated.

VT with structural heart disease, usually in the setting of acute or chronic cardiomyopathy, should be terminated with DC shock. Lidocaine (Cat C) or Procainamide if DC shock resistant. Prevention with Metoprolol or Sotalol. For VT without structural heart disease, prevention with Flecainide is indicated.

For foetal SVT, Flecainide, sotalol and Digoxin are indicated.

LONG-QT SYNDROME[85,86]

The traditional criteria of prolonged QT need to be corrected for heart rate (QT_c, Bazett's formula, QT divided by the square root of the RR interval) and a QT_c greater than 0.44 ms. Borderline QT_c is common and stems from miscalculation in the setting of atypical T-waves and prominent U-waves.[107] The recommended method to determine the end of the T-wave is by intersecting the tangent to the steepest slope of the last limb of the T-wave and the baseline (Fig. 22.50). The diagnosis of

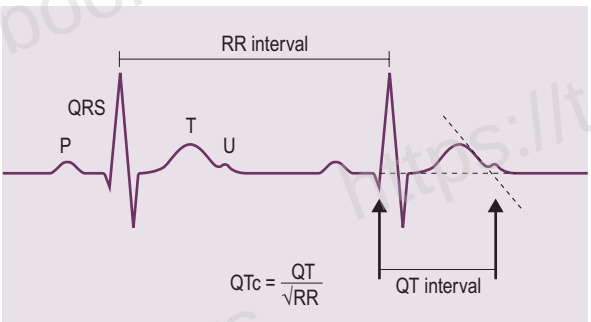

Figure 22.50 Determining QTc using the 'tangent method.'

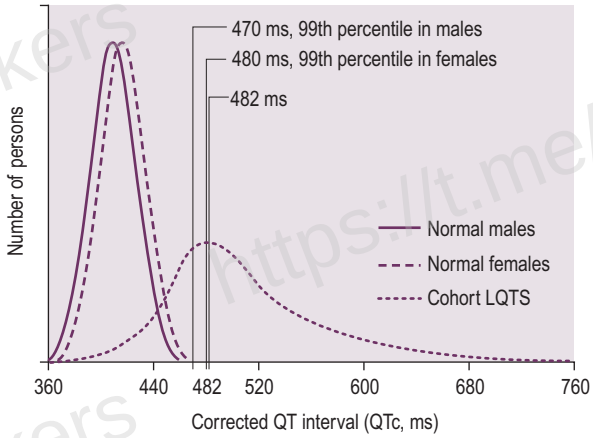

Figure 22.51 Distribution of QTc values. 99th percentile males 470 ms. 99th percentile females 480 ms. There is significant overlap of these 'normal' QTc persons and a cohort of mutation-positive patients, mean QTc 482 ms. *(Adapted from Johnson JN, Ackerman M. QTc: how long is too long?* Br J Sports Med. *2009;43:657–662; Taggart NW, Haglund CM, Tester DJ, et al. Diagnostic miscues in congenital long-QT syndrome.* Circulation. *2007;115:2613–2620, with permission.)*

'borderline LQTS' is common with QT_c in the range of 440–470 ms. QT_c should also be adjusted for age and gender with females an average 10 ms longer. There is significant overlap between the normal population and patients with congenital LQTS; 25%–35% of congenital LQTS have a QT_c <440 ms (Fig. 22.51).

The causes of LQTS can be divided into acquired and congenital (Box 22.8). Most drugs that cause LQTS do so by binding to the hERG or alpha subunit of the I_{Kr} potassium channel and reducing repolarisation current. Unlike other I_K potassium channels, the hERG subunit of I_{Kr} is very sensitive to unintended drug binding owing to aromatic amino acids positioned in such a way as to block the channel. Common to all causes is a prolongation of repolarisation, which creates the substrate for random re-entry giving rise to polymorphous VT (classically of the torsade de pointes type), particularly under conditions of acute adrenergic arousal.

Action potential prolongation results from either enhancing depolarisation (sodium [Na] channel, I_{Na}) or reducing repolarisation current (delayed rectifier potassium [K] currents, I_{Kr} and I_{Ks}).

There is less capacity to respond to additional stresses that impair repolarisation such as hypokalaemia, hypomagnesaemia and drugs with class III action.

Prolonged action potential in LQTS predisposes to arrhythmia in two ways:

1. Extended plateau phase of action potential results in susceptibility to EAD-initiated arrhythmia. EADs are due to re-opening of L-type calcium channels, the activity of which is increased by adrenergic stimulation, which explains the association between SCD and exercise and excitement in LQTS.
2. Heterogeneity of prolonged action potential creates spatial dispersion of repolarisation, leading to regions of refractory block and substrate for re-entrant arrhythmia. This mechanism appears important in pharmacological LQTS.

Box 22.8 Causes of long-QT syndrome

Acquired
Drugs
- Class IA antiarrhythmic drugs
  - Quinidine, procainamide
- Class III antiarrhythmic drugs
  - Amiodarone, sotalol
- Tricyclic antidepressants
- Macrolide antibiotics
- Phenothiazines
- Antihistamines
- Cisapride

Myocardial ischaemia/infarction
Hypokalaemia
Cardiomyopathy
Acute myocarditis
Mitral valve prolapse
Acute cerebral injury
Hypothermia
Congenital
Familial
90%
Linked to a DNA marker on the short arm of chromosome 11
Autosomal-dominant in most cases
Some cases linked to congenital deafness and autosomal-recessive
Non-familial – related to new gene mutation
Sporadic: 10%

CONGENITAL LQTS[87]

Congenital LQTS is a collection of genetically distinct arrhythmogenic disorders resulting from genetic mutations in cardiac potassium and sodium ion channels giving rise to the term 'cardiac channelopathies.' As there is overlap in QT_c between the normal population and congenital LQTS patients, a LQTS clinical probability score has been developed to determine probability of diagnosis (Table 22.12).

Congenital LQTS results from mutations in genes coding for cardiac proteins including ion channels, accessory subunits and modulatory proteins (Table 22.13).

Table 22.12 LQTS clinical probability score

FINDING	POINTS

Schwarlz PJ, Moss AJ, Vincent GM, Crampton RS. Diagnostic criteria for the long QT syndrome. An update. *Circulation*. 1993; 88:782–784.

Table 22.13 Classification of congenital LQTS

TYPE	GENE MUTATION/ PROTEIN	FEATURES
LQT1	KCNQ1 α-subunit of I_{KS}	Reduced function of I_{KS} decreases repolarising current Most common at 30%–35% but less severe When homozygous associated with congenital deafness
LQT2	KCNH2/h ERG α-subunit of I_{Kr}	Reduced function of I_{Kr} decreases repolarising current 25%–30%
LQT3	SCN5A α-subunit of I_{Na}	Increased function of I_{Na} prolonging depolarising Na current Mutations in SCN5A also cause Brugada syndrome, cardiac conduction disease and dilated cardiomyopathy
LQT4	Anchor protein ankyrin B	Ankyrin B anchors ion channels in the cell
LQT5	KCNE1 β-subunit of I_{Ks}	Reduced function of I_{Ks} Homozygous leads to Jervell and Lange–Nielson syndrome Congenital deafness
LQT6	KCNE2 β-subunit of I_{Kr}	Reduced function of I_{Kr}
LQT7	K-channel I_{Kl}	Anderson–Tawil syndrome Associated skeletal deformities
LQT8	C_{AV} CACNAlc $I_{ca\text{-}L}$	Calcium channel is distributed widely Timothy's syndrome Multiple clinical manifestations

CLINICAL FEATURES[88]

Prevalence is estimated to be 1 in 2500–5000.

Thirty per cent of patients with congenital LQTS present with unexplained syncope or aborted sudden death (which is often not the first episode). The majority (60%) are identified when family members are screened after syncope or cardiac arrest in a family member. Ten per cent are detected on routine evaluation of ECG. The majority of episodes of syncope or sudden death (60%) are precipitated by emotions, physical activity or auditory stimuli causing acute adrenergic arousal. The degree of QT_c prolongation is not predictive of syncope or sudden death.

MANAGEMENT

The first line of management of polymorphous VT with shock is DC shock, with magnesium being the antiarrhythmic of choice.[89]

- Unresponsive rhythms or recurrence despite magnesium requires pharmacological intervention (isoproterenol [isoprenaline] or epinephrine [adrenaline] depending on blood pressure) or electrical pacing.
- Factors associated with acquired LQTS need to be identified and eliminated.

Strategies for prevention of recurrence in congenital LQTS depend on the presentation. Patients who present with or have a history of syncope or aborted sudden death have a high risk of recurrence (5% per year). Beta blockers are the first line of treatment with the goal of reducing the exercise heart rate to less than 130 beats/min. Symptomatic bradycardia following adequate beta blockade requires a permanent pacemaker. Patients with recurrence despite these measures and those with an early malignant course need stellate sympathetic ganglionectomy. In 5% of these high-risk patients, triple therapy fails and an implantable defibrillator is required. Asymptomatic patients with incidental LQTS (<0.5% per year) and asymptomatic family members (0.5% per year) have a very low risk of syncope or sudden death. It is also very rare for the first episode to be fatal in these two groups, so prophylactic measures are generally not required and close follow-up is sufficient.

Class IA, IC and III drugs may increase QT interval and should be avoided in polymorphous VT and torsade de pointes.

SUDDEN CARDIAC DEATH[20]

Arrhythmic causes of SCD can be divided into three categories:

1. *VT or VF:* this is most common.
2. *SVT with a very rapid ventricular rate:* this is usually associated with the development of AF or flutter in the presence of an accessory AV connection (but can occasionally be due to enhanced conduction over the normal AV conduction system).
3. *Bradycardia or asystole:* this is usually the result of an inadequate escape pacemaker mechanism associated with either a high-degree AV block or severe sinus node dysfunction. In addition, some patients with sinus node dysfunction have paroxysmal supraventricular arrhythmia (tachycardia-bradycardia syndrome) that on termination results in an exaggerated overdrive suppression of both the sinus node and escape pacemakers such that the prolonged pause evolves into asystole or VF.

The causes of these arrhythmias can be divided into three general categories:

1. *Ischaemic heart disease:* AMI or old myocardial infarction scar
2. *Non-ischaemic heart disease:* cardiomyopathy, valvular heart disease, congenital heart disease, ventricular hypertrophy and cardiac trauma
3. *No apparent structural heart disease:* primary electrical disease, electrolyte abnormalities, LQT syndromes and drugs.

Contributing factors are often multifactorial, particularly the combination of structural heart disease, proarrhythmic drugs and electrolyte abnormalities.

EVALUATION OF A SURVIVOR OF SCD

Primary prevention of SCD has been disappointing owing to difficulties in selecting patients at risk. Regardless of the aetiology of the SCD, the reported recurrence rate is high, at least 30%–40% at 1 year. Therefore, in-hospital assessment is critical to establish the underlying cause and to guide therapy.

CORONARY ARTERY DISEASE AND SUDDEN CARDIAC DEATH

Extensive atherosclerotic coronary artery disease is the most common pathological finding in survivors and non-survivors of SCD. Fewer than 30% have evidence of a recent AMI. A larger proportion (up to 50%) has evidence of coronary artery thrombosis or plaque fissuring and rupture. In those patients not having an AMI, the majority (75%) has a coronary artery stenosis (>50% of lumen), and 60% have three-vessel disease. Approximately 50% have evidence of an old myocardial infarction. The fact that the typical pathological background for SCD is severe epicardial coronary artery disease, with or without an old myocardial infarction and evidence of a new ischaemic syndrome, underlines the central role that coronary artery disease plays in SCD.

INVESTIGATIONS[18–20]

- *Chest X-ray:* cardiac size, presence of pulmonary oedema.
- *12-lead ECG:* acute ischaemia, previous infarction, ventricular aneurysm or LV hypertrophy. Abnormalities of rate, rhythm, conduction or sinus node dysfunction. PR interval, QRS complex duration or QT interval. Changes of electrolyte abnormalities.
- *Plasma electrolytes:* potassium, magnesium and calcium. Potassium levels may be difficult to interpret after a period of resuscitation.
- *Cardiac enzymes:* serial troponin T, creatinine phosphokinase with myocardial band fractionation and lactate dehydrogenase to establish the presence of a recent AMI.
- *Plasma blood levels of drugs that affect cardiac rhythm or conduction:* while proarrhythmic effects of drugs are more likely at high levels, it should be emphasised that proarrhythmia can occur at normal or low plasma drug levels.
- *Toxicology screen:* substance abuse or drug overdose (cocaine, psychotropic drugs), particularly in patients without overt structural heart disease.
- *24-hour Holter monitor ECG:* quantitative analysis of frequency of arrhythmia and to detect silent myocardial ischaemia.
- *Assessment of LV function:* LV ejection fraction. Gated pool scan gives a better estimate of global LV systolic function, but echocardiogram will give added diagnostic information such as valvular disease and myocardial hypertrophy. Both studies will detect segmental wall motion abnormalities.
- *Exercise tolerance test:* standard exercise ECG or thallium-201 scans. Echocardiogram immediately following exercise may be as informative.
- *Signal-average ECG:* averages between 100 and 400 heart beats, for identification of low-amplitude electrical signals, such as after-depolarisations. These are found in the terminal portion of the QRS complex and cannot be seen on the 12-lead ECG. Associated with an increased risk of spontaneous and inducible ventricular arrhythmia.

- *Cardiac catheterisation and coronary angiogram:* to quantify the degree of coronary artery disease.
- *EPS:* virtually always indicated to document and characterise ventricular tachyarrhythmia. The initial baseline EPS should be performed in the absence of any antiarrhythmic drugs. Inducibility of sustained ventricular arrhythmias at EPS is associated with worse outlook, with a 5-year risk of SCD of 32% versus 24% in those without inducible arrhythmia, and is an indication for an implantable defibrillator. The inducibility of VT/VF is less common in survivors of SCD (44%) than patients who present with recurrent sustained VT. In patients with sustained monomorphic haemodynamically stable VT, EPS mapping techniques are used to determine the possibility of surgical or catheter ablation. EPS is also important in other causes of SCD other than VT/VF. Patients with ventricular pre-excitation (WPW syndrome) require localisation of the accessory pathway. Propensity to develop complete heart block can be assessed by a His-bundle ECG.

PREVENTION OF RECURRENT VENTRICULAR ARRHYTHMIA IN SURVIVORS OF SUDDEN CARDIAC DEATH

MYOCARDIAL REVASCULARISATION AND SUDDEN CARDIAC DEATH

The Coronary Artery Surgery Study (CASS) registry looked at 13,476 patients with significant operable coronary artery disease and showed an incidence of SCD of 5.2% in the medical arm compared with 1.8% in those assigned to surgery.[91] The precise mechanism of the benefit of surgery in primary prevention is unclear but is probably associated with prevention of ischaemia rather than arrhythmia control. In summary, the near-universal practice of surgical coronary revascularisation in SCD survivors with critical stenoses is based upon this primary prevention data (and the central role that ischaemia and infarction are known to play in arrhythmia substrate) rather than data demonstrating arrhythmia control.

ANTIARRHYTHMIC DRUGS AND SUDDEN CARDIAC DEATH[73–76]

The CAST study has clearly demonstrated the poor results of antiarrhythmic drug therapy alone in the prevention of arrhythmic SCD. Data from studies in survivors of SCD using amiodarone are conflicting, but generally poor, even with EPS confirmation of lack of inducibility. Certainly patients with an ejection fraction less than 30% do poorly on amiodarone alone. The primary role of antiarrhythmic drugs in the secondary prevention of SCD has all but disappeared, but amiodarone may be indicated if there is demonstrable suppression of inducible VT at EPS and the patient has an ejection fraction greater than 30%–40%.

SURGICAL AND CATHETER ABLATION TECHNIQUES AND SUDDEN CARDIAC DEATH[27]

As most sustained ventricular arrhythmias arise from a scar within the myocardium, surgical attempts were made to excise these areas completely. Catheter ablation techniques for VT are suitable for the minority of patients with haemodynamically stable VT who can withstand prolonged mapping procedures. Currently, the success rates for ablative techniques are such that a significant number still need additional preventive therapies.

IMPLANTABLE CARDIOVERTER DEFIBRILLATORS AND SUDDEN CARDIAC DEATH

The reduction in SCD and overall cardiac mortality with implantable cardioverter defibrillators (ICDs) has been so spectacular and the results of previous therapies so poor that ICDs were initially introduced with little randomised controlled data. More recently controlled studies have shown:

- reduction in 3-year mortality by 31% compared to antiarrhythmic drug therapy in SCD survivors[92]
- reduced risk of death in patients with poor LV function following myocardial infarction[93]
- improved survival in patients with HCM.[94]

However, no survival benefit was shown in high-risk patients following coronary artery bypass surgery.

Representative data from several studies are shown in Table 22.14. The benefit of ICD on survival persists for at least 8 years. Current indications are expanding, but the benefit is clear in the following groups of survivors of SCD and patients with documented VT/VF outside the early post-infarct phase:

- non-inducible VT/VF at EPS
- inducible VT/VF resistant to treatment
- VT/VF in patients with LV ejection fractions less than or equal to 30% regardless of results of EPS-directed drug therapy.

Table 22.14 Mortality data for the various treatment regimens for sudden cardiac death

	SUDDEN DEATH (%)	TOTAL MORTALITY (%)
Implantable cardioverter defibrillator	3.5	13.6
Empirical amiodarone	12	34
Electrophysiological study-directed drug treatment	14	24
Surgery	3.7	37

Further developments currently taking place include:

- transvenous catheter placement and subcutaneous patch avoiding the need for thoracotomy
- dual-chamber sensing to improve discrimination between SVT and VT that can be difficult on rate criteria alone, particularly in patients with intraventricular conduction delay
- technological advances reducing size, cost and increasing battery life.

Although one of the proposed advantages of ICD is the avoidance of antiarrhythmic drug side effects, particularly the myocardial depressant effects, current practice usually combines ICD with low-dose amiodarone. This enables improved arrhythmia control by reducing atrial tachyarrhythmia and slowing VT rate, and prolonging battery life by reducing the frequency of arrhythmia. The role of ICD in the management algorithms of SCD is shown in Figs 22.52 and 22.53. Given the current lack of available ICDs, some advocate restriction to patients less than 75 years. With wider availability of ICDs, fewer patients will be managed on drug-only strategies in the future.

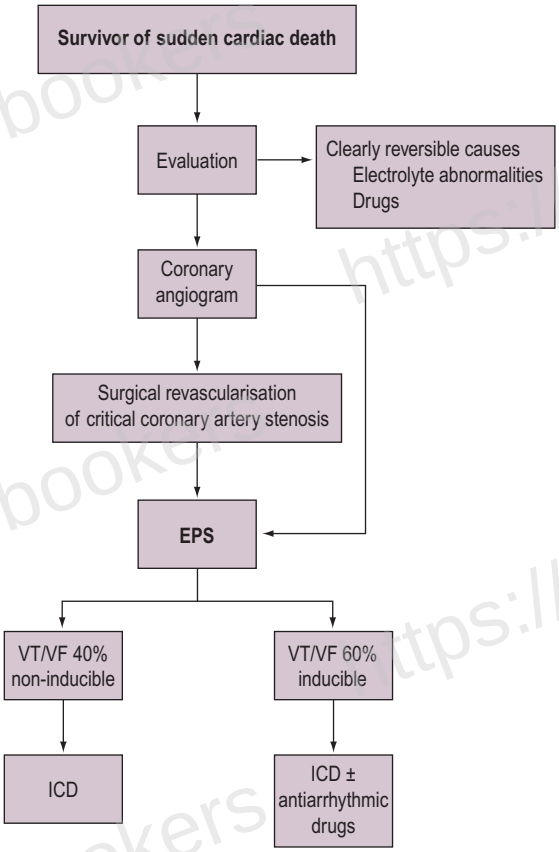

Figure 22.52 Management algorithm of a survivor of sudden cardiac death. This algorithm does not include the option of an antiarrhythmic drug alone in patients with intact left ventricular function who initially have inducible ventricular tachycardia/fibrillation *(VT/VF)* that is subsequently found to be suppressible on a drug with electrophysiological studies *(EPS)*. *ICD*, Implantable cardioverter defibrillator.

CLASSIFICATION OF ANTIARRHYTHMIC DRUGS

The time-honoured physiologically based classification of antiarrhythmic drugs is the Vaughan-Williams classification (Table 22.15), which has been modified over the years. This classification is a hybrid, with classes I and IV representing ion channel blockers, class II representing a receptor blocker and class III representing a change in an electrophysiological variable. The prolongation of repolarisation, the defining effect of class III agents, can be produced by a block of any one of several K^+ ionic channels (the delayed rectifier potassium current I_{Kr} responsible for phase 3 repolarisation is the ionic channel target of most class III agents) or from modification of Na^+ or Ca^+ channel function. This classification is also incomplete and does not include cholinergic agonists, digitalis, magnesium and adenosine. For this reason, an alternative classification has been advocated based on molecular targets for drug action that include ion channels, receptors and pumps/carriers (Table 22.16).[4]

ANTIARRHYTHMIC DRUGS

DIGOXIN

Digoxin is a muscarinic subtype 2 receptor (M_2) agonist and a highly potent Na^+/K^+-ATPase pump-blocking agent. Digoxin exerts its antiarrhythmic activity predominantly at the AV node where at lower doses conduction is slowed by the M_2 vagotonic effect. This effect is easily reversed by enhanced sympathetic tone in the setting of exercise, critical illness and postoperative state. At higher concentrations, digoxin has a direct effect on AV node conduction by the Na^+/K^+-ATPase pump blockade and is more resistant to sympathomimetic effects. The decrease in $[K^+]_i$ and increase in $[Na^+]_i$ results in hyperpolarisation, shortening of atrial action potential and an increase in AV nodal refractoriness. There is also increased availability of intracellular Na^+ for the Na^+–Ca^{2+} exchanger, increasing $[Ca^{2+}]_i$ which results in the positive inotropic effects of digoxin, making it an ideal agent in the setting of LV dysfunction. However, the positive inotropic effects of Na^+/K^+-ATPase blockade are deleterious in the setting of myocardial ischaemia and other causes of diastolic dysfunction. Digoxin also has weak vasopressor properties when administered as a slow bolus. The major

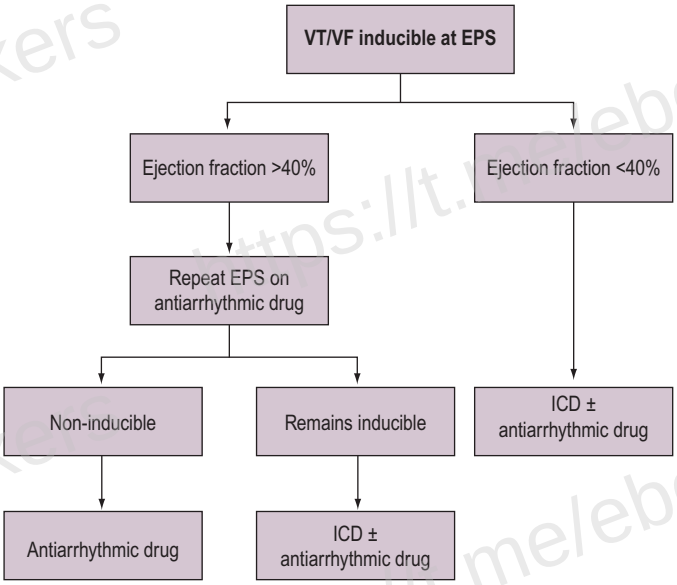

Figure 22.53 Patients found to have inducible ventricular tachycardia *(VT)* or fibrillation *(VF)* at electrophysiological studies *(EPS)*, with an ejection fraction >40% and subsequent drug suppression of their VT/VF, can be managed on antiarrhythmic drugs alone.

Table 22.15 Vaughan-Williams classification of antiarrhythmic drugs

CLASS	MECHANISM OF ACTION	EFFECT ON ACTION POTENTIAL	INDICATIVE DRUGS
Class I	Sodium channel blockers	Depresses rate of phase 0 depolarisation	
Class IA		Prolongs repolarisation	Procainamide Disopyramide Quinidine
Class IB		Shortens repolarisation	Lidocaine Mexiletine Phenytoin
Class IC		Minimal effect on repolarisation	Flecainide Encainide Propafenone
Class II	β-adrenergic receptor blockers		Propranolol Atenolol Metoprolol Esmolol
Class III	Potassium channel blockers	Prolongs repolarisation	Amiodarone Dronedarone Sotalol Ibutilide Vernakalant Bretylium
Class IV	Calcium channel blockers		Verapamil Diltiazem

ECG effects of digoxin are PR prolongation and a non-specific alteration in ventricular repolarisation with characteristic reverse-tick S-T segments.

INDICATIONS AND DOSE

- *AF:* slowing of ventricular rate only
- *Loading dose:* 15 µg/kg IV, typically administered over 30–60 minutes, but can be given faster
- *Maintenance dose:* depends on renal function.

PLASMA LEVELS

Oral bioavailability can be reduced, especially if intestinal microflora-altering antibiotics are co-administered. Therapeutic levels are 0.5–2.0 ng/mL. Plasma levels must be measured during the post-distribution phase some 6–8 hours after dose. The elimination half-life is 36 hours with normal renal function. Difference between therapeutic and toxic levels can be reduced by hypokalaemia, hypomagnesaemia, hypercalcaemia, hypoxia, cardiac surgery and myocardial ischaemia. Many drugs increase digoxin plasma levels by competing with the renal P-glycoprotein-mediated transport, or by reducing renal blood flow or function.

CONTRAINDICATIONS

Relative contraindications include myocardial ischaemia/infarction, diastolic heart failure due to hypertrophy and ischaemia, renal failure and hyperkalaemia, planned DC shock cardioversion and tachycardia–bradycardia syndromes. Co-administration with other drugs that affect AV nodal conduction, typically beta-adrenergic and calcium channel blockers, requires caution.

Table 22.16 Actions of antiarrhythmic drugs on membrane channels, receptors and ionic pumps in the heart

	CHANNELS						RECEPTORS				PUMPS
	Na^+			K^+		Ca^{2+}					
DRUG	*FAST*	*MED*	*SLOW*	I_{ks}/I_{kr}	I_{kur}		α	β	M_2	*P*	Na^+/K^+ *ATPase*
Lidocaine	+										
Mexiletine	+										
Phenytoin	+										
Procainamide		+++		++							
Disopyramide		+++		++							
Quinidine		+++		++			+		+		
Propafenone		+++						++			
Flecainide			+++	+							
Encainide			+++								
Bretylium				+++			+/–	+/–			
Sotalol				+++				+++			
Amiodarone	+			+++		+	++	++			
Dronedarone	+			+++		+	++	++			
Ibutilide				+++							
Dofetilide				+++							
Vernakalant	+				+++						
Verapamil	+					+++	++				
Diltiazem						++	+				
Propranolol	+							+++			
Metoprolol								+++			
Esmolol								+++			
Atropine									+++		
Adenosine										A	
Digoxin									A		+++
Magnesium						+					A

Sodium channel blockers are subdivided into drugs with fast-, medium- and slow-time constant for recovery from block. Receptors: α-, β-adrenoreceptors, M_2, muscarinic subtype 2; *P*, A_1 purinergic. Relative blocking potency: +, low; ++, moderate; +++, high; +/–, partial agonist/antagonist; *A*, agonist.

ADVERSE EFFECTS

The same increase in $[Ca]_i$ responsible for the positive inotropic effects of digoxin also forms the basis for toxicity arrhythmia. The increased inward calcium current is responsible for DAD-initiated arrhythmia. Digoxin toxicity can cause virtually any arrhythmia:

- DAD-related tachycardia with impairment of sinus node or AV nodal function
- unifocal atrial tachycardia with AV block is 'classic'
- ventricular bigeminy and various degrees of AV block occur.

With advanced toxicity, severe hyperkalaemia due to poisoning of Na^+/K^+-ATPase results. Profound bradycardia, which may be unresponsive to pacing, develops.

Any serious toxicity arrhythmia should be treated with antidigoxin Fab fragments. Magnesium is the drug of choice for digoxin-toxic tachyarrhythmia. Digoxin, particularly at toxic levels, increases risk of VF precipitated by DC shock. Digoxin toxicity is associated with nausea, disturbances in cognitive function and blurred or yellow vision (xanthopsia).

BETA-ADRENERGIC BLOCKERS

Beta-adrenergic blocking or class II antiarrhythmic drugs have differing properties such as relative cardioselectivity (atenolol, metoprolol), non-cardioselectivity (propranolol), intrinsic sympathomimetic activity (pindolol), lipid solubility and central activity (metoprolol, propranolol) and membrane-depressant effects (propranolol). The antiarrhythmic properties appear to be a class effect and no agent has been shown to be superior. There are data to suggest that the survival benefit of beta-adrenergic blockers post myocardial infarction may relate to some extent to the central modulation of autonomic tone of the more lipid-soluble agents. The direct membrane-stabilising or 'quinidine-like' effect of propranolol requires doses far greater than those used clinically and is of negligible clinical significance. Beta-adrenergic blockers competitively inhibit catecholamine binding at the beta-adrenergic receptor sites, which reduces the phase 4 slope of the action potential of pacemaker cells, prolongs their refractoriness and slows conduction in the AV node. Refractoriness and conduction in the His–Purkinje system are unchanged. Beta-adrenergic blockers are most effective in arrhythmia associated with increased cardiac adrenergic stimulation (postoperative states, sepsis, thyrotoxicosis, phaeochromocytoma, exercise or emotion).

INDICATIONS

Supraventricular tachycardia

Beta-adrenergic blockers may terminate SVT when the AV node is an intrinsic part of the re-entry circuit (AVNRT and AVRT); adenosine is more effective. AF and Afl do not revert with beta-adrenergic blockers, but the ventricular rate will be slowed. Beta-adrenergic blockers are effective at preventing SVT following cardiac surgery. Studies involving propranolol and atenolol have produced the best results. Beta-adrenergic blockers are effective in MAT, but, as this arrhythmia is most often seen in patients with severe chronic air-flow limitation and cor pulmonale, their utility is limited.

Ventricular arrhythmias

Beta-adrenergic blockers are ineffective for the emergency treatment of sustained VT. Empiric prophylactic administration of beta-adrenergic blockers appears to be as effective in ventricular arrhythmia prevention as electrophysiologically guided drug methods. However, ventricular arrhythmia most often occurs in the setting of poor LV dysfunction and beta-adrenergic blockers are either poorly tolerated or contraindicated.

Myocardial infarction

Survival in patients with AMI treated with thrombolytic therapy is improved by early IV beta-adrenergic blockade. Presumably this will remain the same with the current strategy of percutaneous coronary intervention. There may be other benefits such as decreased incidence of VF and relief of chest pain. Long-term beta-adrenergic blockade reduces mortality following myocardial infarction, the benefit being greatest in those at highest risk for sudden death. However, suppression of ventricular ectopy is not a requisite for benefit. Drugs with intrinsic sympathomimetic activity have not been shown to improve survival after AMI.

ATENOLOL

Atenolol does not have significant central action due to poor lipid solubility and is eliminated predominantly by the kidneys with an elimination half-life of 7–9 hours. Care is required in patients with poor or deteriorating renal function.

- *Loading dose IV:* 2.5 mg over 2.5 minutes, repeat every 5 minutes, maximum 10 mg
- *Loading dose oral:* 50–100 mg
- *Maintenance dose oral:* 50–200 mg/day
- *ISIS-1 post-MI regimen:* 5 mg IV over 5 minutes, repeated 10 minutes later if heart rate exceeds 60 beats/min. If heart rate exceeds 40 beats/min 10 minutes later, oral 50 mg atenolol and continue at 100 mg daily
- *SVT prophylaxis following cardiac surgery:* 5 mg IV within 3 hours of surgery, repeated 24 hours later, followed by oral 50 mg daily for 6 days.

METOPROLOL

Metoprolol is lipid-soluble and has significant central action. It is eliminated by the liver with an elimination half-life of 3–4 hours.

- *Loading dose IV:* 1–2 mg at 1 mg/minute, repeat every 5 minutes, maximum dose 15–20 mg
- *Loading dose oral:* 100–200 mg
- *Maintenance dose oral:* 50–100 mg/12-hourly.

PROPRANOLOL

Propranolol has been one of the most studied beta-adrenergic blockers for SVT prophylaxis following cardiac surgery.

- *Dose:* 10 mg orally 6-hourly starting the morning after surgery.

ESMOLOL

Esmolol is an ultrashort-acting cardioselective beta-adrenergic blocker, which is especially useful for rapid control of ventricular rate in AF or Afl. Esmolol has also been shown to prevent postoperative SVT. The distribution half-life is 2 minutes and the elimination half-life is 9 minutes. Esmolol is rapidly metabolised by hydrolysis of the ester linkage, chiefly by the esterases

in the cytosol of red blood cells and not by plasma cholinesterases or red cell membrane acetyl-cholinesterase:

- *Loading dose IV:* 500 µg/kg over 1 minute
- *Maintenance dose IV:* 50 µg/kg per minute for 4 minutes. If satisfactory rate control is not achieved, the loading dose should be repeated and the maintenance dose increased to 100 µg/kg per minute. If control is still not achieved after a further 4 minutes, then the procedure is repeated with 50 µg/kg per minute increments in the maintenance infusion until maximum dose of 200 µg/kg per minute is reached. Further increases in infusion rate are unlikely to be successful.

CONTRAINDICATIONS

Reversible airways disease and poor LV function are two common relative contraindications, which limit the utility of beta-adrenergic blockers in patients with cardiac disease. Beta-adrenergic blockers may also be poorly tolerated in diabetics and patients with severe peripheral vascular disease.

ADVERSE EFFECTS

Beta-adrenergic blockers, particularly those that are centrally acting, are often poorly tolerated in the long term. These effects include fatigue, hypotension, bradycardia, dry mouth, dizziness, headache and cold extremities.

CALCIUM CHANNEL BLOCKERS

Calcium channel blockers or class IV antiarrhythmic drugs block the slow calcium channels in cardiac tissue. Verapamil and diltiazem have similar electrophysiological properties. The dihydropyridine group of calcium channel blockers, which include nifedipine, does not have any significant electrophysiological properties. Calcium channel blockers depress the slope of diastolic depolarisation in the SA node cells, the rate of rise of the phase 0 and action potential amplitude in the SA and AV nodal cells. They also slow conduction and prolong the refractory period of the AV node, which results in their main antiarrhythmic actions. Refractoriness of atrial, ventricular and accessory pathway tissue is unchanged. The sinus rate does not usually change significantly because calcium channel blockers induce peripheral vasodilatation, which causes reflex sympathetic stimulation of SA node. Verapamil particularly has marked negative inotropic actions and hypotension is often seen; however, cardiac index is generally maintained because of afterload reduction. Diltiazem has a less negative inotropic effect than verapamil.

INDICATIONS

- *SVT:* calcium channel blockers are effective if the AV node is an integral part of the arrhythmia circuit. Verapamil has been superseded by adenosine for the first line of treatment for these with AVNRT and AVRT
- *AF and Afl:* slow ventricular response in AF and Afl, but termination of the arrhythmia is uncommon. Verapamil may prolong episodes of AF through a proarrhythmic effect
- *MAT:* calcium channel blockers are effective[31]
- *SVT following cardiac surgery:* diltiazem has been shown not only to reduce, but also to decrease incidence of ventricular arrhythmia and postoperative ischaemia
- *AF associated with the WPW syndrome:* calcium channel blockers may increase the ventricular response and should be avoided if this is suspected.[28]

In general, calcium channel blockers should not be given to patients with a wide-complex tachycardia not only because of the risk of accelerating accessory pathway conduction, but also because their myocardial depressant effects can result in cardiovascular collapse in the setting of VT and pre-existing myocardial dysfunction.

VERAPAMIL

Verapamil is cleared by the liver with an elimination half-life of 3–8 hours. Therapeutic plasma concentration is 0.1–0.15 mg/L. With the availability of adenosine and the better tolerance of diltiazem, the use of verapamil has fallen substantially:

- *Loading dose IV:* 5–10 mg, maximum 0.15 mg/kg over 2 minutes. If poor response after 30 minutes repeat dose of up to 10 mg, 0.15 mg/kg to a maximum of 20 mg.
- *Maintenance dose IV:* infusion up to 10 mg/hour titrated to effect.
- *Maintenance dose oral:* 80–120 mg 6–8-hourly.

DILTIAZEM

Diltiazem is cleared by the liver with an elimination half-life of 3.5 hours. There is reduced oral absorption and extensive first-pass hepatic metabolism: only 40% of oral dose is available compared with IV:

- *Loading dose IV:* 0.25 mg/kg, followed by 0.35 mg/kg if required
- *Maintenance dose IV:* infusion up to 10 mg/hour titrated to effect
- *Maintenance dose oral:* 60–120 mg 6–8-hourly
- *SVT prophylaxis following cardiac surgery:* 0.1 mg/kg per hour, starting at onset of bypass and continuing for 24 hours. The dose can be titrated up for blood pressure control.

MAGNESIUM

Magnesium is an emerging antiarrhythmic agent with a range of indications, however, as an antiarrhythmic agent, magnesium has largely defied classification. Magnesium has many reported electrophysiological effects, including blocking voltage-dependent L-type

Ca^{2+} channels. Magnesium is a necessary cofactor for the membrane enzyme Na^+/K^+-ATPase that provides energy for the membrane Na/K channels.[95] Consequences of magnesium deficiency are as follows:

- Intracellular potassium falls and intracellular sodium rises, leading to a reduction in RMP.
- Intracellular sodium is elevated, increasing the availability of sodium for the Na/Ca counter transport mechanism.
- The resulting elevation in intracellular calcium predisposes to DAD-triggered activity.

Magnesium administration reduces the availability of intracellular Na^+ and therefore this Ca^{2+} inward current. The dependency of normal membrane potassium gradients on magnesium is demonstrated by the inability to correct intracellular potassium deficiency with the administration of potassium in the setting of hypomagnesaemia. The antiarrhythmic properties of supranormal levels of magnesium associated with pharmacological doses of magnesium appear to be largely due to augmentation of this physiological role of magnesium. Therefore, magnesium may be best classified as a Na/K pump agonist.

Magnesium in pharmacological doses decreases RMP, resulting in a reduction in automaticity. However, once depolarisation occurs, the maximum rate of depolarisation and action potential amplitude is increased, thereby improving conduction. Action potential duration is increased, thereby increasing the absolute refractory period and reducing relative refractory period. The net result is a reduction in the vulnerable period and more synchronous conduction. All of these electrophysiological effects are augmented in the setting of increased extracellular potassium. It is not surprising that the utility of magnesium appears greatest in the setting of ischaemia where loss of potassium from the cell is a major consequence. A secondary effect is the reduction in the availability of intracellular sodium to contribute to inward calcium flux, producing triggered activity. Magnesium has also been shown to elevate VF and ectopy threshold.[96]

INDICATIONS

- Acute rate control of AF, and has been shown to be as effective as amiodarone in the short term[67]
- Prevent postoperative SVT following cardiac surgery with varying efficacy
- Acute control of MAT
- Ventricular arrhythmia associated with triggered activity, such as torsade de pointes and digoxin toxicity[89]
- Drug-induced polymorphous VT, particularly that caused by class I agents, can also be terminated with magnesium
- Appears very effective at controlling transient ventricular arrhythmia in the setting of ischaemia such as post-infarct and cardiac surgery.

DOSE

- *AF rate and MAT control:* magnesium sulphate, 0.15 mmol/kg, in an adult 10–20 mmol (2.5–5.0 g) over 5–10 minutes. If no response after 15 minutes dose can be repeated. Subsequent dose recommendations over 24 hours have varied from 0.1 mmol/kg/hour to a total dose of 60 mmol
- *SVT prophylaxis following cardiac surgery:* 20–25 mmol per day for 4 days
- *Transient ventricular arrhythmia:* 10 mmol as a slow IV push, repeated if required
- *LIMIT-2 post myocardial infarction dose:* 8 mmol bolus over 5 minutes, followed by 65 mmol over 24 hours. Mean plasma level 1.55 (SD 0.44) mmol/L.[69]

PLASMA LEVELS

Observational data would suggest that plasma levels of magnesium required for potent antiarrhythmic action are at least 1.8 mmol/L.

ADVERSE EFFECTS

- When administered too rapidly, magnesium can cause hypotension by excessive peripheral vasodilatation; this is associated with an unpleasant hot-flush sensation.
- Prolonged administration or excessive dosing can produce plasma levels associated with skeletal muscle weakness, which can be clinically significant in acute-on-chronic respiratory failure.
- Excessive action can be seen if magnesium is used in the setting of hyperkalaemia, resulting in bradyarrhythmia and heart block.

PROCAINAMIDE

Procainamide is a class IA antiarrhythmic drug with potent Na^+ channel-blocking activity and intermediate K^+ channel-blocking activity. The Na^+ channel-blocking action has an intermediate time constant of recovery. Procainamide has similar electrophysiological and ECG effects to quinidine but lacks vagolytic and alpha-adrenergic blocking activity:

- decreases automaticity
- increases refractory period
- slows conduction.

Procainamide is metabolised to *N*-acetyl procainamide. *N*-acetyl procainamide lacks Na^+ channel-blocking activity, but is equipotent in K^+ channel blockade and prolongation of action potential. The increasing effect of greater refractoriness and QT prolongation with chronic procainamide therapy relates to increased contribution of *N*-acetyl procainamide.

CLINICAL USE

Procainamide is used to treat both atrial and ventricular arrhythmias.

- Intravenous procainamide is more effective than lidocaine for terminating VT.

- Procainamide controls ventricular rate in AF and Afl.
- It is effective for conversion of AVNRT, AVRT and possibly AF and Afl.
- It controls rapid ventricular rate owing to accessory pathway conduction in pre-excitation syndromes and for wide-complex tachycardia that cannot be distinguished as being SVT or VT.

The need to infuse slowly to avoid hypotension is the major barrier to wider use in life-threatening arrhythmia. Maintenance therapy with procainamide is not widely used due to its side-effect profile:

- *Loading dose IV:* 15 to 18 mg/kg at 20 mg/minute until there is arrhythmia control, hypotension ensues or QRS duration increases by more than 50%. Up to 50 mg/min has been used in urgent situations
- *Maintenance dose IV:* 1–4 mg/minute. Reduce maintenance dose by 30%–60% for moderate to severe renal or cardiac impairment.
- *Plasma levels: N*-acetyl procainamide has a longer duration of action
- *Adverse effects:* as with quinidine, the ventricular response may be accelerated if given for SVT; QT-interval prolongation and torsade de pointes may also occur.

A reversible lupus-like syndrome develops in 20%–30% of patients receiving procainamide long term. Other side effects include gastrointestinal disturbances (less common than with quinidine), central nervous system manifestations and cardiac depression.

LIDOCAINE

Lidocaine, long considered an important antiarrhythmic drug for ventricular tachyarrhythmia, is now relegated to lower-choice options or missing from most treatment algorithms. Na^+ channel-blocking effect is increased in myocardial ischaemia and is unproven outside acute ischaemia settings. It has no effect on SA node automaticity, but it depresses automaticity in other pacemaker tissues. Normally, lidocaine has little or no effect on conduction. The ECG shows no changes in sinus rate, PR interval, QRS width or QT interval with lidocaine.

CLINICAL USE

Lidocaine has reducing importance.

- It is ineffective against SVT.
- Amiodarone has taken over as the antiarrhythmic of choice for DC shock-resistant VF.[62,63]
- Lidocaine increases the current required for defibrillation, increases the likelihood of post DC shock asystole and therefore is detrimental during an episode of VF.
- Prophylaxis to prevent VF in AMI can no longer be recommended.

Extensive first-pass hepatic metabolism precludes oral use of lidocaine; IV dose should be reduced by 30%–50% in severe liver disease or heart failure. The distribution half-life is about 8 minutes, and the elimination half-life is 1.5 hours in normal patients (but may be increased >10 hours in severe heart failure or shock). An initial bolus of IV lidocaine 50–100 mg (0.7–1.4 mg/kg) over 1–2 minutes. A further dose may be repeated if initial is ineffectual. Thereafter an infusion of 4 mg/min for 1 hours, then 2 mg/min for 2 hours, and thereafter 1–2 mg/min, is recommended. Increasing the maintenance infusion rate without an additional bolus requires about 6 hours (four elimination half-lives) to reach a steady state. If the initial bolus is ineffective, another bolus of 1 mg/kg may be given after 5 minutes. Another dosage regimen is 0.7–1.4 mg/kg initially, and 0.8 mg/kg at 8-minute intervals for three doses (i.e. three distribution half-lives), and thereafter 1–2 mg/min by infusion. The half-life of lidocaine increases after 24–48 hours as the drug in effect inhibits its own hepatic metabolism and dose reduction is required.

ADVERSE EFFECTS

Central nervous system toxicity with high plasma concentrations is the most common adverse effect (e.g. dizziness, paraesthesia, confusion, and coma and convulsions). Uncommonly, AV block or cardiac depression may occur. Cimetidine reduces lidocaine clearance, potentially causing toxic drug concentrations.

FLECAINIDE

Flecainide exhibits rate-dependent Na^+ channel blockade with slow-time constant of recovery, with marked slowing of conduction in all cardiac tissue, and little prolongation of refractoriness.

CLINICAL USE

- May revert AVNRT and AVRT, although adenosine and verapamil are more widely used
- Useful in SVT, including AF and possibly Afl, particularly in the setting of accessory pathway syndromes
- Flecainide has been given in life-threatening VT.

Flecainide can be administered IV or orally. If flecainide is deemed necessary for prophylaxis of ventricular arrhythmias, therapy should start with ECG monitoring. In CAST, suppression of VEBs after myocardial infarction with flecainide was associated with increased mortality:

- *Dose:* IV loading 2 mg/kg at 10 mg/min
- *Oral maintenance:* 100–200 mg 12-hourly.

ADVERSE EFFECTS

- Depression of cardiac contractility – flecainide is usually contraindicated in patients with abnormal

LV function as it can worsen or precipitate heart failure.
- Conduction block – avoid in high-degree AV block unless a pacemaker is in situ.
- Flecainide increases pacing capture threshold.
- Proarrhythmic events are common, especially in patients with depressed LV function, and may be life threatening.
- Torsade de pointes may occur, even in patients without structural heart disease.
- Incessant VT may be induced, unresponsive to any therapy, including cardioversion.
- Although flecainide depresses intracardiac conduction, a paradoxical increase in ventricular rate may occur with Afl or AF.
- Central nervous system effects include visual disturbances, dizziness and nausea.

PROPAFENONE

Propafenone is a class IC agent and has a structure similar to flecainide. The electrophysiological, haemodynamic and side-effect profile is also similar to flecainide and encainide. The I_{Na} blocking profile of propafenone has a fast time-constant resulting in greater activity at faster rates and less risk of bradycardia. In addition, propafenone has non-selective beta-blocking properties and can produce bronchoconstriction. Similar to flecainide, propafenone could be considered in both ventricular and SVT arrhythmia in the setting of normal LV function. Use of long-term propafenone should probably be limited because of its class IC profile, even though it was not included in the CAST study and contraindicated in structural heart disease because of proarrhythmia.

Propafenone is metabolised by the liver and the rate can vary significantly between patients. The short terminal half-life requires at least t.i.d. administration.

- *Dose:* Conversion of AF to SR, IV 2 mg/kg over 10 minutes, oral dose 150–600 mg stat. Oral maintenance dose 150 mg t.i.d. immediate release tablets or 225 mg b.i.d. for slow release.

AMIODARONE

Amiodarone is a potent antiarrhythmic agent with a complex electrophysiological and pharmacological profile. The appealing broad spectrum and haemodynamic stability of amiodarone have resulted in it emerging as the most frequently used antiarrhythmic in critically ill patients. In this setting short-term use predominates and the formidable side-effect profile is much less significant. Amiodarone:

- prolongs action potential duration
- increases the refractoriness of all cardiac tissue
- has Na^+ channel blockade (class I), antiadrenergic (class II), calcium channel blockade (class IV) and antifibrillatory effects. The Na^+ channel blockade of amiodarone has a fast time-constant for recovery
- QT prolongation reflects a global prolongation of repolarisation and is closely associated with its antiarrhythmic effects.

When given IV, amiodarone has little immediate class III effect: the major action is on the AV node, causing a delay in intranodal conduction and a prolongation of refractoriness. This probably explains why IV amiodarone controls the ventricular rate in recent-onset AF, but is less effective for termination of this arrhythmia. Administration IV causes some cardiac depression, the magnitude depending on rate of administration and pre-existing LV function. Cardiac index is often unchanged because of its vasodilator properties.

CLINICAL USE

It is effective in suppressing both supraventricular and ventricular tachyarrhythmia.

SUPRAVENTRICULAR TACHYCARDIA

Amiodarone is effective in terminating and suppressing recurrences of AVNRT and AVRT tachycardia, although adenosine (for acute reversion) or verapamil (acute termination and long-term prophylaxis) is superior. Amiodarone IV is less effective in reverting Afl or AF, but the ventricular rate will slow. Administration over a longer time span (days to weeks) may be more effective in reverting recent-onset AF. In preventing recurrence of AF after reversion, amiodarone is comparable in efficacy to quinidine and flecainide but superior to sotalol and propafenone.[42]

DOSE

- Lower doses than that required for ventricular arrhythmia are usually sufficient
- *AVNRT and AVRT reversion or AF and Afl rate control:* 5–7 mg/kg over 30–60 minutes depending on blood pressure and myocardial function. Alternatively for a adult, 150 mg over 10 minutes followed by 0.5–1.0 mg/minute up to maximum of 1.2–1.8 g per 24 hours. Poor rate control can be improved with additional 1–2 mg/kg boluses
- *Postoperative AF prophylaxis:* 200 mg orally 8-hourly for 5 days, followed by daily until hospital discharge
- *Long-term SVT control or AF rate control:* 100–200 mg/day orally will usually suffice.

VENTRICULAR TACHYARRHYTHMIAS

Amiodarone IV may be effective in treating life-threatening ventricular tachyarrhythmia refractory to other drugs, especially in myocardial infarction and poor LV function. Amiodarone's efficacy in DC shock-resistant VF further confirms a prominent role in this setting.[62,63] Long-term oral amiodarone is useful in controlling symptomatic VT and VF, especially when other

conventional antiarrhythmics have failed. The absence of negative inotropic effect is useful in those with severely depressed LV function, but its many adverse effects limit widespread use. The Cardiac Arrest in Seattle, Conventional versus Amiodarone Drug Evaluation (CASCADE) study demonstrated that empirical amiodarone treatment was superior to guided (non-invasive Holter or EPS) class I drugs in survivors of VF not associated with AMI. Amiodarone prevented arrhythmia recurrence and decreased the incidence of sudden death. Amiodarone, presumably because it is better tolerated in patients with poor LV function and having less proarrhythmia, can be considered as first-line drug to prevent life-threatening ventricular tachyarrhythmias.[74–76] The rate of arrhythmia control is often slower with ventricular arrhythmia and may take several days to achieve. This delay appears to be independent of dose. The pharmacodynamic basis for this relates to the fact that much of the class III or K^+ channel-blocking activity is due to the amiodarone metabolite, desethylamiodarone, whereas the predominant actions of acute administration of amiodarone are due to its class I and class II activity. The full potency of the class III activity requires several days, at least, for the effects of desethylamiodarone to appear.

DOSE

- *Haemodynamically stable VT:* 5–7 mg/kg over 30–60 minutes, followed by 0.5–1.0/minute.
- *DC shock-resistant VF:* 5 mg/kg, followed by 2.5 mg/kg if required[61]
- *Long-term prevention of ventricular arrhythmia:* oral loading with 1200 mg/day for 1–2 weeks, reducing to 400–600 mg/day and then 100–400 mg/day after 2–3 months. The dose should probably not be reduced below 400 mg/day with life-threatening ventricular arrhythmia.

MYOCARDIAL INFARCTION

Data are limited at present, but amiodarone may improve long-term survival in patients after myocardial infarction.

PHARMACOKINETICS

Oral bioavailability of amiodarone is variable at 40%–70%, with a delayed onset of action (days to weeks); however, loading doses reduce this interval. The kinetics of amiodarone has been modelled to four compartments when given acutely. Following a slow IV bolus over 15 minutes, amiodarone is rapidly distributed to the active compartment ($t_{1/2}\alpha$ = 4.2 minutes), with demonstrable prolongation of QTc and antiarrhythmic effect within 2–5 minutes. Subsequently, amiodarone is progressively redistributed to 'deeper' compartments ($t_{1/2}\beta$ = 36.6 minutes, $t_{1/2}\gamma$ = 4.5 hours and $t_{1/2}\delta$ = 33.6 hours).[97] This is in contrast to the very prolonged terminal half-life – greater than 50 days – after long-term treatment. This redistribution of amiodarone explains why repeated boluses are often required in the first 24–48 hours of treatment. Transient loading-dose hypotension due to myocardial depression or vasodilatation is dose-, rate- and patient-dependent. A loading dose of 5 mg/kg over 20 minutes resulted in significant further myocardial depression and a fall in cardiac index, whereas in patients without evidence of heart failure, 5 mg/kg over 1 minute resulted in hypotension due to systemic vasodilatation and an increase in cardiac index.[98,99]

MONITORING

Plasma amiodarone concentrations have poor correlation with arrhythmia control, and therapeutic levels, 1.0–2.5 mg/L, have the greatest utility for avoidance of adverse effects in long-term treatment.

ADVERSE EFFECTS

Adverse effects will occur in the majority of patients if they receive amiodarone for long enough. Most are reversible when the drug is discontinued. Adverse effects include:

- *Dermatological:* photosensitivity, bluish/grey skin discoloration (slate-blue skin)
- *Eye:* corneal microdeposits (almost 100%) with little or no clinical significance
- *Gastrointestinal disturbances*
- *Hypo- and hyperthyroidism*
- *Liver dysfunction:* asymptomatic increases in liver enzymes are common, and do not require amiodarone cessation unless enzymes are 2–3 times normal; hepatitis is rare
- *Neuropathy, myopathy and cerebellar abnormalities*
- *Pulmonary toxicity:* unexpected acute respiratory distress syndrome has been reported in patients on amiodarone undergoing procedures such as uncomplicated cardiopulmonary bypass surgery and pulmonary angiography. These observations suggest that amiodarone may predispose the lung to acute injury. Pulmonary toxicity is the most serious adverse effect, with a reported incidence of 10% at 3 years. Amiodarone pulmonary toxicity has been reported in one case after 13 days and 11.2 g cumulative dose and 11.2 g over 2 weeks in another. Patients on long-term amiodarone need regular respiratory function testing and decreased carbon monoxide diffusion of 15% below baseline requires dose modification or cessation. The severe syndrome of shortness of breath, cough and fever with pulmonary crepitations and widespread pulmonary infiltrates on chest X-ray has a mortality of 10%. Immediate discontinuation is necessary. Use of steroids is controversial.

Amiodarone interacts with other drugs, potentiating warfarin, digoxin and other antiarrhythmic agents. When administered concurrently, doses of these drugs should be reduced accordingly. On the positive side,

long-term amiodarone is unlikely to precipitate or worsen heart failure and proarrhythmia is uncommon.

DRONEDARONE[44,100]

Dronedarone is an amiodarone analogue designed to reduce the lipophilicity of the molecule to reduce the pharmacokinetic complexity and toxicity. The iodine moieties have also been eliminated to prevent thyroid dysfunction.

Dronedarone is a multi-channel blocker, blocking I_{Na}, I_K and $I_{Ca\text{-}L}$ channels with a predominant electrophysiological effect of prolonging repolarisation or class III. It also has antiadrenergic properties.

Dronedarone decreases the recurrence of AF, controls rate with recurrences (heart reduction of 12.3 beats/min compared with placebo), especially with exercise. Sequential major studies evaluating dronedarone highlight the importance of variable outcome in differing patient populations. In comparing dronedarone with placebo, the ATHENA study found dronedarone reduced all-cause mortality, cardiovascular admissions by 24%, death from cardiac arrhythmias, HR 0.55 (0.34–0.88) and stroke rate in addition to delaying recurrence of AF/Afl. Whereas in the PALLAS study (patients with permanent AF), all these outcomes were worse and the ANDROMEDA study (patients with poor LV function) was stopped due to increased mortality due to worsening heart failure. Meta-analysis of all placebo-controlled trials does show dronedarone has reduced mortality, but maintenance of sinus rhythm and absence of LV dysfunction is important to confer this mortality benefit. Dronedarone is currently contraindicated in patients with New York Heart Association (NYHA) class III or IV heart failure.

In comparing dronedarone to amiodarone, the picture is even less clear. In the DIONYSOS study (post electrical cardioversion) there was increased AF recurrence, dronedarone 63.5% and amiodarone 42% at 7 months, although drug discontinuation was higher with amiodarone. Meta-analysis of studies comparing the two drugs confirms greater efficacy for amiodarone maintaining sinus rhythm (HR 0.49; 0.37–0.63) but greater drug discontinuation rates and a trend to increased all-cause mortality with amiodarone. Dronedarone may have reduced torsade de pointes arrhythmia. The increased efficacy of amiodarone may relate to its lipophilicity giving higher tissue levels or the increased activity of its major metabolite, desethylamiodarone compared with *N*-debutyldronedarone.

Dronedarone has poor oral bioavailability, 15%, which can be variable, increasing by a factor of three if taken with food. It is extensively metabolised by cytochrome P450 CYP3A4 (inhibitors can result in marked elevation in plasma levels) to the metabolite *N*-debutyldronedarone, which is much less potent. The elimination half-life is 24 hours. Serum digoxin levels are increased due to inhibition of P-glycoprotein-mediated intestinal and renal excretion.

- *Dose:* 400 mg oral b.d. with steady state in 7 days.

Although long-term data are lacking, there has been no evidence of thyroid dysfunction or pulmonary toxicity.

SOTALOL

Sotalol prolongs action potential duration, thereby prolonging the effective refractory period in the atria, ventricles, AV node and accessory AV pathways. It is also a potent non-cardio-selective beta-adrenergic blocker (class II). Sotalol also has antifibrillatory actions that are superior to those of conventional beta blockers. It can worsen heart failure in patients with depressed LV function. The negative inotropic beta-blocking effect is slightly offset by a weak positive inotropic effect owing to prolongation of the action potential (resulting in more time for calcium influx into contracting myocardial cells).

CLINICAL USE

Higher doses of sotalol are required to prolong cardiac repolarisation than to cause beta blockade. Sotalol may be administered IV or orally, and is excreted by the kidneys (elimination half-life 15 hours); Should only be used if QTc is less than 450 ms. If QTc increases to greater than 500 ms during treatment, dose should be reduced or ceased. IV dose is 75 mg (0.5–1.5 mg/kg) over 5 hours. C_{max} for 75 mg IV over 5 hours equivalent to 80 mg oral. Oral therapy is initiated at 80 mg 12-hourly and increased to 160 mg 12-hourly, although doses of 320 mg 12-hourly have been administered. Maintenance dosing is dependent on renal function. If CrCl is less than 40 mL/minute long term Sotalol is contraindicated, 40–60 mL/min once daily dosing and greater than 60 mL/min b.i.d. dosing.

SUPRAVENTRICULAR TACHYCARDIA

- Effective in AVNRT and AVRT, although adenosine and verapamil are superior. Long-term sotalol will prevent recurrences of these arrhythmias
- Probably ineffective for reversion of AF/Afl, but is effective in preventing recurrence of AF after cardioversion. If AF recurs, heart rate is likely to be well controlled with sotalol
- Prevents postoperative SVT.

VENTRICULAR ARRHYTHMIAS

Sotalol is superior to lidocaine to terminate sustained VT, and should be considered a first-line drug in patients without heart failure. Oral sotalol is more effective than class I drugs for the long-term prevention of VT or VF. Guided (Holter or EPS) sotalol and empirical amiodarone are first-line drugs to prevent recurrences of VT and VF over the long term; however,

the worse outcome with sotalol in SWORD has significantly reduced the role of sotalol in this setting.[73]

ADVERSE EFFECTS

Side effects of sotalol are mainly due to beta blockade (e.g. bronchospasm, heart failure or AV conduction problems) and prolongation of QT proarrhythmia (e.g. torsade de pointes, similar 2% incidence as quinidine, which may occur early during drug titration or later during long-term treatment).

IBUTILIDE

Ibutilide is an I_{Kr} K^+ channel blocker, which prolongs action potential and increases the refractory period. This agent, with class III effect, is recommended for acute pharmacological conversion of AF and Afl, or as an adjunct to improve success of DC shock cardioversion. The success rate for ibutilide alone is higher for Afl (50%–70%) than that with AF (30%–50%) and, as expected, efficacy is greatest in short-term AF/Afl without structural heart disease. The major role of ibutilide appears to be cardioversion pretreatment to facilitate reversion to sinus rhythm from AF.[46] Ibutilide has minimal effect on blood pressure and heart rate and the major adverse effect is proarrhythmia, with torsade de pointes occurring in 3%–6% of patients. For this reason, patients should be monitored for at least 6 hours after administration. Ibutilide has a short duration of action and other antiarrhythmic drugs are required to maintain sinus rhythm.

DOSE

For patients weighing more than 60 kg, 1 mg over 10 minutes, which can be repeated 10 minutes later if unsuccessful. In patients weighing less than 60 kg, 0.01 mg/kg is given as initial dose.

DOFETILIDE

Dofetilide is one of the latest class III I_{Kr} K^+ channel blockers being investigated in the hope of finding an antiarrhythmic drug for long-term use with amiodarone's efficacy but without its side-effect profile. Dofetilide's emerging role is again in pharmacological cardioversion of AF and Afl (superior to sotalol, similar to amiodarone but inferior to ibutilide) in about 30% of patients. Prevention of recurrence is similar to amiodarone and long-term oral therapy is not associated with increased mortality in post-MI and heart failure patients. It also appears safe in patients with LV dysfunction. Early (first 3 days) proarrhythmia (3.3% of patients developed torsade de pointes) also necessitates monitoring with commencement of therapy.[42,101,102,103]

DOSE

Recommended dose is 500 mg orally 12-hourly. Dose requires adjustment for renal function and QT-interval monitoring for a minimum of 3 days. First dose is based on renal function. CrCl less than 20 mL/minute dofetilide is contraindicated. CrCl 20–40 mL/minute, 125 mg b.i.d., 40–60, 250 mg b.i.d. and greater than 60 500 mg b.i.d. Second dose is based on QTc increase. QTc increase less than 15% continue same dose. Increase greater than 15% dose is decreased. QTc interval greater than 500 ms necessitates cessation.

VERNAKALANT[104]

Vernakalant, a pyrrolidine compound, is a new multichannel blocker with I_K- and I_{Na}-blocking activity, with I_K blockade predominating (class III agent). The unique profile of vernakalant I_K blockade is the relative specificity for the atria and minimal effect on the ventricle. This specificity relates to differential activity on the various I_K channel isoforms, with I_{Kur} blockade being much greater compared with the modest activity at I_{Kr} channels. I_{Kur} channels are the 'ultra-rapid' I_K channels confined to the atria that are responsible for the fast early phase of repolarisation that results in the shorter action potential of atrial cells. Vernakalant therefore specifically prolongs atrial refractory period and slows atrial conduction with a rate-dependent profile.

Vernakalant in non-surgical, short-duration AF (ACT I and ACT III studies, duration less than 7 days) achieved sinus rhythm in 51.7% and 51.2% (placebo 4 and 3.6%) within 90 minutes, generally less than 10 minutes (median time to conversion 10 and 11 minutes). The IV dose of 3 mg/kg over 10 minutes, followed by a further 2 mg/kg over 10 minutes if conversion did not occur within 15 minutes of the first dose, produced not only rapid but durable conversion with 99% of responders remaining in sinus rhythm at 24 hours. Vernakalant was not effective in Afl, with a conversion rate of only 7%.

A similar cohort (AVRO study) comparing vernakalant (same dose as ACT I and III) with amiodarone (5 mg/kg over 1 hour followed by 50 mg over the next hour), again in recent-onset AF, found vernakalant again superior at 90 minutes with a conversion rate of 51.7 versus 5.2%. However, at 4 hours amiodarone was catching up with 21.6% versus 54.4% conversion, with amiodarone recognised to have a longer onset of action.

In post-cardiac surgical patients who developed AF, having been in sinus rhythm preoperatively (ACT II study), vernakalant was superior to placebo with rapid conversion rates (47% vs. 14%) and times (median time 12.4 minutes). However, unlike non-surgical patients, in this cohort responders were less durable with only 60% remaining in sinus rhythm at 24 hours. In all studies vernakalant had no effect on success rates with subsequent attempts at electrical cardioversion.

Vernakalant is extensively metabolised by the liver and subsequently excreted in the urine. The acute

kinetics of vernakalant is not affected by congestive cardiac failure, renal or hepatic impairment.

Vernakalant is well tolerated with serious side effects of hypotension and bradycardia during infusion infrequent (7.6%, placebo 5.1%), slightly higher than the rates of hypotension with amiodarone.

Although vernakalant may be seen as agent of choice for rapid pharmacological conversion of recent onset of AF, <7 days (the greater efficacy of ibutilide is eroded by risk of polymorphous ventricular arrhythmia), the superior conversion rate over amiodarone would appear to be lost at 24 hours and beyond, with amiodarone also likely to be a better agent to control ventricular rate in non-responders with greater AV-blocking activity.

ADENOSINE

Adenosine stimulates specific A_1 receptors present on the surface of cardiac cells, thereby influencing adenosine-sensitive K^+ channel cyclic adenosine monophosphate production. It slows the sinus rate and prolongs AV node conduction, usually causing transient high-degree AV block. The half-life of adenosine is usually less than 2 minutes as it is taken up by red blood cells and deaminated in the plasma. This ultrashort half-life is a major advantage over other antiarrhythmic drugs. The effects of adenosine, both antiarrhythmic and haemodynamic, can be antagonised by methylxanthines, especially theophylline and caffeine. Dipyridamole, an adenosine uptake blocker, potentiates the effect of adenosine. Adenosine effects are prolonged in patients on carbamazepine and in denervated transplanted hearts.

CLINICAL USE

- *AVNRT and AVRT tachycardia:* adenosine is the drug of choice. Expected reversion rates exceed 90%.[26] The AV nodal-blocking actions of adenosine may unmask atrial activity (e.g. flutter waves in Afl).
- Diagnosis of a wide-complex tachycardia may be assisted by the use of adenosine.
- SVT with intraventricular conduction block will terminate with adenosine, whereas few VTs will revert. Whether adenosine should be used routinely to discriminate between VT and SVT with aberrant conduction in haemodynamically stable wide-complex tachycardia is unclear. Potential for haemodynamic collapse in VT is real and ILCOR advises against.

Adenosine will not revert AF. Ventricular rate may transiently increase when AF is associated with the WPW syndrome.

Adenosine is given as a rapid bolus through a large peripheral or central vein followed by a saline flush, at intervals less than 60 seconds. The usual dose is 6 mg, followed by 12 mg if response is ineffective. Another 18 mg can be given if the last dose was well tolerated.

ADVERSE EFFECTS

Most patients experience transient side effects such as flushing, shortness of breath and chest discomfort. Adenosine should not be given to asthmatic patients as bronchospasm may result.

DIRECT CURRENT CARDIOVERSION[105]

DC cardioversion/defibrillation is an important treatment option in tachyarrhythmia. In addition to its emergency role in cardiac arrest from VF or VT, urgent DC cardioversion is indicated in haemodynamically unstable VT and sustained SVT that precipitate angina, heart failure or hypotension. More elective DC cardioversion is indicated in haemodynamically stable VT following a trial of antiarrhythmic drug therapy. Cardioversion is most commonly used in AF/Afl once potential precipitants have been eliminated and, again, usually after antiarrhythmic drug treatment to prevent further episodes. Digoxin toxicity is a relative contraindication to DC cardioversion, which should also be used with care in patients on digoxin.

MECHANISM OF ACTION

DC shocks need to produce a current density that depolarises a critical mass of myocardium, thereby leaving insufficient myocardium to maintain the re-entrant tachycardia and prevent recurrence. For VF and AF, the critical mass involves the entire ventricles or atria, whereas for the more organised tachyarrhythmia, VT and Afl, which involve specific re-entrant circuits, regional depolarisation in the path of their circulating wave fronts is all that is required. DC shocks also prolong the refractoriness of myocardium and this effect will contribute to the arrhythmia termination and prevention of immediate recurrence.

ELECTRICAL ENERGY

Even though the goal is to achieve a certain current through the entire heart, atria or a region depending on the arrhythmia, DC shocks are prescribed as energy measured in joules (J) or watt-seconds. Obviously it would make more sense to be able to deliver a set current. This would prevent delivering inappropriately low currents in patients with high impedance and excessive current flow causing myocardial damage in patients with low impedance. Clinical studies to determine current doses are under way for defibrillation and cardioversion. The optimal current for VF using monophasic damped sinusoidal (MDS) waveform for cardioversion waveform appears to be 30–40 A. Current dosage for biphasic waveform is not available.

CURRENT WAVEFORM

Modern defibrillators deliver a current, the magnitude of which depends on the prescribed energy and

thoracic impedance. This current can be delivered in a number of different waveforms.

MDS defibrillators deliver current that is in a single direction or polarity. They can be further characterised by the rate at which the current pulse returns to zero. MDS waveforms return to zero gradually, whereas truncated exponential waveforms return instantaneously. Biphasic waveform for cardioversion (BTE) has superseded monophasic waveforms, achieving equivalent efficacy at lower electrical energies. BTE is a sequence of two current pulses generated with the polarity of the second in the direction opposite to the first. Biphasic waveforms with lower shock energies are associated with fewer ST-segment changes and less post-resuscitation myocardial dysfunction and has an ILCOR class IIa recommendation.

THORACIC IMPEDANCE

The magnitude of current flow is dependent on the resistance to current flow or thoracic impedance. The average adult thoracic impedance is 70–80 Ω. Factors that determine thoracic impedance include:

- energy selection
- electrode size
- electrode composition
- paddle-to-skin coupling
- distance between electrodes
- number of previous shocks
- time interval between previous and present shock
- pressure on electrodes
- phase of ventilation
- patient's body build
- recent sternotomy.

Conductive gel reduces impedance, while hair trapping air between skin and paddle and self-adhesive monitor/defibrillator electrode pads may increase it. There is no clear relationship between body size and energy requirements but compensation for patient-to-patient differences in impedance can be achieved by changes in duration and voltage of shocks, or by a process called burping, which involves releasing the residual membrane charge.

PADDLE POSITION AND SIZE

ILCOR recommends standard placement of the sternum paddle just to the right of the upper sternal border below the clavicle and the apex paddle to the left of the nipple, with the centre of the paddle in the mid-axillary line. Permanent pacemakers and ICDs must be avoided as shock may cause malfunction or block current going to the heart. Inevitably, some current passes down the pacemaker lead and it is necessary to check pacing threshold post-shock. Other alternative paddle placements can enable avoidance of pacemakers and ICDs or perhaps improve current direction. Using self-adhesive electrodes, the sternum electrode can be placed posterior to the heart on the right infrascapular region and the apex on the left precordium. The use of right parasternal and left posterior infrascapula has been advocated for AF because this configuration provides an optimal vector of current delivery to the atria. Large electrodes or paddles have less impedance; however, excessively large electrodes may result in less transmyocardial current flow. The minimum recommended electrode size is 50 cm^2, with the sum of both electrodes exceeding 150 cm^2.

SYNCHRONISED CARDIOVERSION

With cardioversion of atrial tachyarrhythmia and VT, when time permits, synchronisation of DC shock with the R-wave of the QRS complex is required to reduce the possibility of inducing VF by delivering the shock during the relatively refractory portion of the T-wave of the cardiac cycle. Synchronisation in VT may be difficult and misleading because of the wide complex or polymorphous nature. Synchronisation should not delay DC shock in pulseless VT or VT associated with unconsciousness, hypotension or severe pulmonary oedema.

DIRECT CURRENT SHOCK DOSAGE

Recommendations for energy doses are changing, as biphasic waveform generators become more widely available. Where studied, BTE shocks have been consistently as effective as higher-energy MDS shocks. Recommended doses are always a balance between the energy likely to generate a critical current flow and that not likely to cause functional and morphological damage. Electrical energies greater than 400 J have been reported to cause myocardial necrosis.

- *VF and pulseless VT:* BTE shock at 200 J. Evidence for sequential escalation of the energy dose is not strong and repeated shocks at the same energy result in increasing current delivery as impedance falls. Repeated non-escalating lower-energy BTE shocks, in the range of 150–175 J, are as effective as escalating MDS recommendations.
- *VT:* energy dose for cardioversion of VT depends on morphology and rate. For monomorphic VT, synchronised 100 J BTE is the starting energy. For polymorphic VT, synchronised if possible, 200 J BTE is the starting energy and for both stepwise increases if the first shock fails.
- *AF:* initial energy is synchronised 100–200 J BTE and stepwise increases if first shock fails. Despite obvious concerns for myocardial injury, mega dose energy at 720 J MDS has been used with success in large patients with AF refractory to 360 J, without evidence of myocardial injury. Constant-current,

rectilinear biphasic waveforms, BTE appear to be more effective in cardioverting AF. This biphasic waveform at the low energy of 120 J was superior to 200 J MDS.

- *Afl, AVNRT and AVRT:* these atrial tachyarrhythmias require least energy and the initial recommended energy is synchronised 50–100 J BTE.

SEDATION

A separate doctor expert in managing the airway must perform sedation for cardioversion. The dose of the sedating agent is titrated on the basis of patient factors and type of arrhythmia. Patients with poor myocardial function not only need reduced dose but also onset time is slower because of low cardiac output. Sensitive tachyarrhythmias such as Afl require only low doses, whereas AF is likely to need higher and repeated doses as higher energy and repeated shocks may be necessary. Cardioversions should be performed with standard resuscitation equipment available and pre-oxygenation is crucial.

DIGOXIN AND CARDIOVERSION

Digoxin toxicity results in a significant reduction in the threshold for inducing ventricular arrhythmia with DC shock. If digoxin toxicity is a possibility, then reconsideration of the need for cardioversion or at least careful titration of energy is required. Clinical experience would suggest the latter procedure of starting with 10 J BTE, and a stepwise increase thereafter increases safety of DC shock in this setting.

ANTICOAGULATION FOR CARDIOVERSION[105]

Cardioversion of AF and, to a lesser extent, Afl is associated with catastrophic thromboembolism, especially stroke. Early studies suggested an incidence of up to 6.3% without anticoagulation. It is accepted that the likelihood of clots forming in the left atrium after 48 hours in AF and for these to be dislodged when sinus rhythm is restored is so high that anticoagulation is indicated prior to cardioversion in AF.

Anticoagulation for 3–4 weeks before cardioversion reduced the risk of embolism by 80%. The risk of thromboembolism following cardioversion continues for a period.

- Echocardiographic findings suggestive of atrial thrombi formation occur in up to 35% of patients post cardioversion.
- Left atrial appendage emptying velocities often decrease despite the development of coordinated electrical activity after cardioversion, presumably because of stunning of mechanical function.

Prolonged AF greater than 48 hours requires anticoagulation for 3 weeks prior to cardioversion and warfarin therapy for at least another 4 weeks depending on risk of recurrence of AF.

Transoesophageal echocardiography, which allows detection of thrombi in the left atrial appendage with much greater accuracy, has been found to be a safe means of expediting cardioversion. Anticoagulation with heparin for 1 day or warfarin for 5 days prior to demonstrating the left atrium to be free of thrombi by transoesophageal echocardiography, then 4 weeks of warfarin following cardioversion, was as effective in preventing emboli as the conventional longer anticoagulation regimen. However, there was a significant reduction in major haemorrhagic events in the transoesophageal echocardiography-guided, shorter lead-in anticoagulation strategy.

Cardiac pacing

Aaisha Opel, Oliver R Segal

Cardiac pacing has rapidly evolved since its introduction by Zoll in 1952.[1] The first pacemaker was an external device designed by John Hopps in 1950. This was followed by the insertion of an internal device in 1958 by Elmqvist and Senning. The technological knowledge gained in pacing has assisted in the even more rapidly advancing field of implantable cardioverter defibrillators (ICDs). Although implantation and follow-up of permanent pacemakers and ICDs are in the domain of appropriately trained cardiologists, intensive care physicians should be familiar with such devices, as a significant number of critically ill patients will have cardiac rhythm devices. It is also essential, when urgent pacing is required, that the intensive care physician is skilled in aspects of temporary pacing, including lead insertion and testing.

Cardiac pacing repetitively delivers very low electrical energies to the heart, initiating and maintaining cardiac rhythm. Pacing may be temporary, with an external pulse generator, or permanent, with an implanted pulse generator. More recently, a hybrid approach has been developed using a standard permanent pacemaker generator and lead but externalising the generator outside the body (see temporary-permanent systems). This is useful for patients needing long-term temporary pacing (e.g. those with systemic or device-related infection or those with long-term causes of temporary bradycardia such as Guillain-Barré syndrome or its variant Miller-Fisher syndrome). Pacing is usually used to treat bradycardia, but rapid atrial or ventricular pacing can also be used to terminate both supraventricular (SVT) and ventricular tachycardias (VT).

More recently, the indications for pacing have expanded beyond symptomatic bradycardia and include conditions such as the long QT syndrome, hypertrophic cardiomyopathy (HCM) and congestive cardiac failure.

PACING SITES

TRANSVENOUS ENDOCARDIAL PLACEMENT

Pacing leads are passed via a vein to the endocardial surface of the right atrium (RA), the right ventricle (RV) or both chambers. In patients with heart failure, an additional lead is passed to the left ventricular coronary veins via the coronary sinus (which drains into the right atrium). Balloon-flotation pacing catheters for temporary pacing are less stable and are generally reserved for emergency pacing purposes.

EPICARDIAL PLACEMENT

This is mainly used in conjunction with cardiac surgery, where electrodes are attached directly to the epicardial surface of the atrium and/or ventricle and pass out through the skin in the epigastrium. These are useful after cardiac surgery, particularly after valve surgery, but rapidly deteriorate postoperatively and are typically no longer functional after 5–10 days.

TRANSCUTANEOUS EXTERNAL PACING

Transcutaneous pacing can be instigated rapidly in an emergency by personnel unskilled in transvenous pacing. However, this is a temporary measure. Patches are applied anterolaterally or anteroposteriorly over the heart. Conscious patients can experience significant pain due to pectoral muscle contraction and may require analgesia or sedation.

Other pacing modalities such as the transoesophageal route are used rarely, except in paediatrics.

PERMANENT PACING

INDICATIONS FOR PERMANENT PACING

Guidelines for permanent pacing are published by a joint American taskforce and updated fairly regularly.[2] They recommend the following pacing indications, stratified according to the likely benefit. (Please note that the vast majority of pacing indications have only levels of evidence C [expert consensus] or B [limited non-randomised trials of small numbers of patients], as pacing predated modern randomised controlled trials.)

1. *Class I:* benefit clearly outweighs risks – treatment should be performed:
   a. in second- or third-degree atrioventricular (AV) block with:
      - *symptoms* and bradycardia
      - pauses greater than 3 seconds or rate less than 40 beats per minute whilst awake, even without symptoms

ABSTRACT

Management of pacemakers, both permanent and temporary, can cause anxiety amongst non-cardiac rhythm specialists. More and more patients undergo cardiac device implantation. This chapter provides the intensive care physician with a useful insight into permanent and temporary pacing, indications, method of placement with troubleshooting tips and complications. Pacing modes are described, together with problems that may arise. Tachyarrhythmias and the use of implantable cardioverter defibrillators are described. Management of scenarios encountered in device patients on intensive care is discussed.

KEYWORDS

Pacing
temporary
permanent
temporary-permanent
indications
technique
troubleshooting
ICD

- postoperative or post-AV node ablation
- neuromuscular disease, with or without symptoms

b. in sinus node dysfunction with documented bradycardia *and symptoms*

c. in recurrent syncope due to spontaneous carotid sinus stimulation or carotid sinus pressure and pauses greater than 3 seconds

d. in chronotropic incompetence *with symptoms*

e. in pause-dependent ventricular tachycardia.

2. *Class IIa–IIb:* benefit outweighs risks – reasonable to perform procedure or procedure can be considered:
   a. in asymptomatic complete AV block with average ventricular rate 40 beats/min in an awake patient
   b. in asymptomatic Mobitz type II second-degree AV block with narrow QRS
   c. in asymptomatic sinus bradycardia with heart rate <40 beats/min
   d. in first-degree heart block (>300 ms) in patients with depressed left ventricular function and symptoms of left ventricular failure.
3. *Class III:* risks clearly outweigh the benefits – pacing should not be performed:
   a. in asymptomatic first-degree heart block
   b. in reversible AV block secondary to drug toxicity.
4. Other indications: non-bradycardia indications for pacing include pacing to improve haemodynamics. Evolving indications include the following[2,3]:
   a. *Heart failure*: patients with heart failure, severe left ventricular impairment and left bundle branch block (LBBB) may benefit from restoring synchronous ventricular contraction through pacing the RV and left ventricle (LV) at the same time – known as biventricular pacing. Such cardiac resynchronisation therapy (CRT) improves symptoms of heart failure and survival in about two-thirds of these patients. Patients who benefit most are those in sinus rhythm, have QRS widths greater than 150 ms and New York Heart Association (NYHA) class II–IV heart failure symptoms.[4,5] Some patients with dys-synchronous LV contraction on echocardiography but narrow QRS width can also benefit. The use of CRT via a permanently implantable biventricular pacemaker (the LV lead is usually passed via a tributary of the coronary sinus to the epicardial surface of the LV) has gained widespread acceptance for treatment of heart failure, together with appropriate medications. Temporary biventricular pacing with a temporary transvenous pacemaker lead passed to a coronary vein via the coronary sinus has been used successfully in cardiogenic shock and high-degree AV block.[6] Permanent devices combining CRT and ICDs, known as CRT-D, are used in those who fulfil CRT criteria and have an indication for an ICD.
   b. *HCM*: pacing can be used in symptomatic patients with a high gradient in the left ventricle. Right ventricular apical pacing causes dys-synchronous ventricular activation and can decrease LV gradient and systolic anterior motion (SAM) of the mitral valve. However, the evidence to support this is weak (currently a class IIb indication) and is probably helpful in only a small proportion of suitable patients.

PACEMAKER MODES

The Heart Rhythm Society (HRS), previously known as the North American Society of Pacing and Electrophysiology (NASPE), and British Heart Rhythm Society, previously the British Pacing and Electrophysiology Group (BPEG) and Heart Rhythm UK, developed the North American and British Group (NBG) code[7] for pacing. This is a generic code used to identify modes of pacing (Table 23.1). The code was updated in 2002 to include multisite pacing therapy (position V)[8]:

- *Position I:* refers to the chamber(s) paced: A = atrium, V = ventricle, and D = dual chamber (i.e. both A and V).
- *Position II:* refers to chamber(s) in which sensing occurs: A = atrium, V = ventricle, and D = dual chamber (i.e. both A and V), O = no sensing.
- *Position III:* refers to the pacemaker's response to a sensed event. This may be:
  - I (inhibition) – a pacemaker's discharge is inhibited (switched off) by a sensed signal, for example VVI, where ventricular pacing is inhibited by spontaneous ventricular activity.
  - T (triggered) – a pacemaker's discharge is triggered by a sensed signal.
  - D (dual) – both T and I responses can occur. This designation is reserved for dual-chamber systems. A depolarisation sensed in the atrium inhibits the atrial output but triggers ventricular pacing. There is, however, a delay (the AV interval) between the sensed atrial depolarisation and the triggered ventricular pacing, which mimics the normal P–R interval. If a spontaneous ventricular depolarisation is sensed, ventricular pacing is inhibited.
  - O – no action.
- *Position IV:* refers to *R* or rate response and is only relevant to permanent pacing systems. An *R* indicates that the pacemaker incorporates a sensor(s) to vary the pacing rate independent of intrinsic cardiac activity. The sensor(s)[9] increases or decreases the heart rate according to the body's metabolic needs. They are useful for patients with impaired sinus node function, chronotropic incompetence (when heart rate does not increase appropriately with exercise) and patients with atrial fibrillation (AF) and complete heart block or slow ventricular rates. Two different sensors are widely used:
  1. Activity sensors with vibration detectors (accelerometer or piezoelectric crystal) increase

Table 23.1 The North American and British Group (NBG) pacemaker code

POSITION I	POSITION II	POSITION III	POSITION IV	POSITION V
Chamber(s) paced	Chamber(s) sensed	Response to sensing	Rate modulation	Multisite pacing
O = none	O = none	O = none	O = none	O = none
A = atrium	A = atrium	T = triggered	R = rate modulation	A = atrium
V = ventricle	V = ventricle	I = inhibited		V = ventricle
D = dual	D = dual	D = dual		D = dual

Note: Positions I–III are used exclusively for antibradycardia function.

Reproduced from Bernstein AD, Daubert JC, Fletcher RD, et al. North American Society of Pacing and Electrophysiology/British Pacing and Electrophysiology Group: the revised NASPE/BPEG generic code for antibradycardia, adaptive-rate, and multisite pacing. *Pacing Clin Electrophysiol*. 2002;25:260.

heart rate when movement is detected. They have the disadvantage that they may respond to non-physiological stimuli (e.g. pacing rate increase may occur when the patient is using an electrical drill).

2. Minute ventilation sensors (respiratory rate times tidal volume, which is estimated by measuring impedance differences between the pacing electrode and the pacemaker unit) rely on minute volume changes to alter the pacing rate. This sensor may occasionally inappropriately accelerate the pacing rate (e.g. in a mechanically ventilated patient requiring a large minute volume). Changing the 'upper rate' limit of the pacemaker or switching the rate-adaptive function 'off' will usually solve the problem. Other sensors, such as ventricular paced Q–T interval systems, are also used in clinical practice. Recently, rate-adaptive systems with dual sensors, where one sensor cross-checks the other and only responds if both sensors are receiving consistent data, have become available. All modern permanent pacemakers are programmable and the degree of rate response can be modified to optimise heart rate with exercise.

- *Position V:* is used to indicate whether multisite pacing is present
  O = none of the cardiac chambers
  A = atrium
  V = one or both ventricles
  D = any combination of atria and ventricles.

For example, the code for a patient with dual-chamber rate-responsive pacing (DDDR) and biventricular pacing is DDDRV.

SPECIFIC PACING MODES

The three-position code (Fig. 23.1) is adequate to describe emergency temporary pacing and most forms of permanent pacing in the intensive care unit (ICU) (Table 23.2).

Table 23.2 Examples of pacemaker modes

MODE	
VOO	Paces the ventricle, no sensing, fixed-rate, asynchronous Usually only used for pacemaker testing, during use of diathermy and 'emergency' pacing
VVI	Paces the ventricle, senses ventricular activity, ventricular activity inhibits the pacemaker Ventricular demand
AAI	Paces the atrium, senses atrial activity, atrial activity inhibits the pacemaker Atrial demand Indicated in sinus bradycardia with intact AV conduction
DDD	Paces and senses both atrium and ventricle: atrial activity triggers ventricular pacing
DDI	Paces and senses both atrium and ventricle Atrial activity not tracked; thus atrial tachyarrhythmias do not trigger rapid atrial pacing AV sequential, non-P synchronous Useful for sinus bradycardia with AV block and intermittent atrial tachyarrhythmias

AV, Atrioventricular; *DDD*, dual-chamber.

SINGLE-CHAMBER PACING

1. *AOO and VOO (asynchronous atrial and ventricular) pacing:* in this mode there is no ability to sense cardiac activity (Fig. 23.2) and it is useful during and after cardiac surgery or when a patient is exposed to external sources of noise (e.g. surgical diathermy or MRI scanning).
2. *AAI (atrial demand) pacing:* this is indicated in patients with sinus bradycardia and intact AV conduction. It is reserved for patients in whom the risk of developing AV block is thought to be low.
3. *VVI (ventricular demand) pacing (Fig. 23.3):* this is the most commonly used mode and the mode of choice

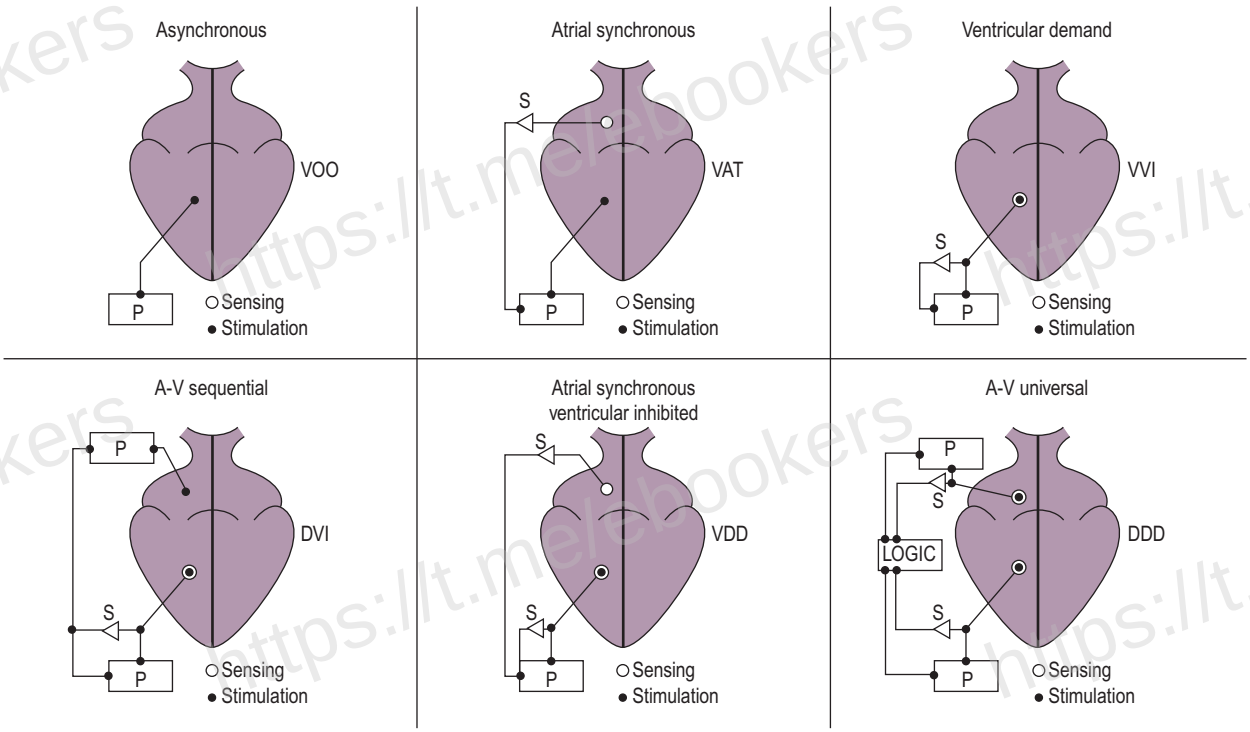

Figure 23.1 Examples of pacemaker modes and their three-position (letter) codes. *DDD*, Dual-chamber; *P*, pacemaker; *S*, sensing.

in life-threatening bradyarrhythmias. Spontaneous cardiac rhythm is sensed and a minimum ventricular rate is programmed to prevent symptoms or in the ICU setting to also optimise cardiac output. There is a low risk of pacemaker-induced ventricular tachyarrhythmia (Fig. 23.4), but AV synchrony is lost, which may depress cardiac output and blood pressure.

DUAL-CHAMBER PACING

Two sets of electrodes are required (atrial and ventricular).

1. *DDD pacing:* there is pacing and sensing in both chambers (Fig. 23.5). An atrial impulse will trigger a ventricular output if none is seen after the programmed AV delay and will simultaneously inhibit an atrial output. If the impulse is conducted normally to the ventricle, ventricular pacing is inhibited. An upper rate limit is programmed to prevent the pacemaker tracking fast atrial rates (e.g. in atrial flutter or tachycardia). The response to DDD pacing depends on the underlying cardiac rhythm:
   - **a.** atrial bradycardia with intact AV conduction – atrial pacing
   - **b.** normal sinus rhythm with high-degree AV block – tracking of P-waves and ventricular pacing
   - **c.** sinus bradycardia with AV block – sequential atrial and ventricular pacing
   - **d.** normal sinus rhythm and AV conduction – inhibition of both atrial and ventricular pacing.

   Pacemaker-mediated tachycardia (PMT), or 'endless-loop' tachycardia,[10] can occur in dual-chamber pacing systems where a ventricular premature beat (Fig. 23.6) conducted retrogradely to the atria is sensed and ventricular pacing is triggered, resulting in an endless loop: the circuit's anterograde limb is the pacemaker, and the retrograde limb is via the AV node. This can be prevented by programming a blanking period after a ventricular-paced beat so that retrograde atrial activity is not sensed. The blanking period is known as the post-ventricular atrial refractory period, or PVARP, and is found on all modern pacemakers. An alternative is to switch to an asynchronous (non-sensing) mode or programming to DDI mode.
2. *DDI pacing (AV sequential, non–P-wave synchronous):* in this mode sensing occurs in both atrium and ventricle, but sensed atrial events do not trigger ventricular pacing. Imagine it as a patient with separate VVI and AAI pacemakers that cannot talk to each other. PMT or endless-loop tachycardia cannot occur in DDI and neither will tracking of rapid atrial rates. For this reason, modern pacemakers programmed DDD will switch to DDI when an atrial tachyarrhythmia is detected (e.g. atrial fibrillation). When this happens the pacemaker will simply pace the ventricle at its back-up rate and not track the tachycardia.

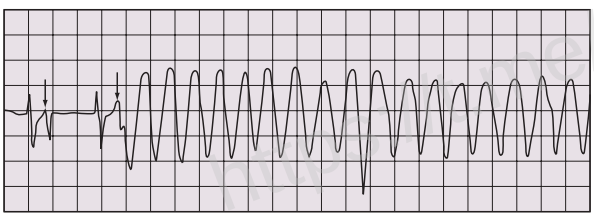

Figure 23.4 Non-sensing of QRS (see first two beats). Pacing spikes *(arrows)* fall on the T-wave with subsequent pacemaker-induced ventricular tachycardia.

HAEMODYNAMICS OF CARDIAC PACING AND THE ATRIOVENTRICULAR INTERVAL

In the normal heart, cardiac output increases three- to fourfold during exercise, mainly due to increased heart rate and stroke volume and the ability of pacemakers to increase heart rate is therefore paramount. Nevertheless, loss of AV synchrony (i.e. the normal activation sequence of atria contracting first and then the

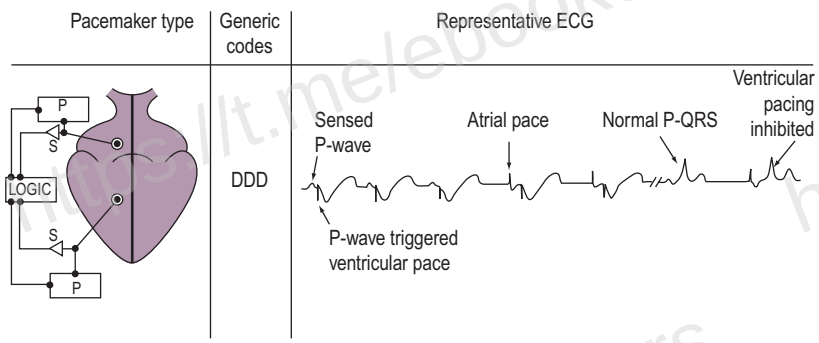

Figure 23.5 Dual-chamber *(DDD)* pacing. *ECG*, Electrocardiography; *P*, pacemaker; *S*, sensing.

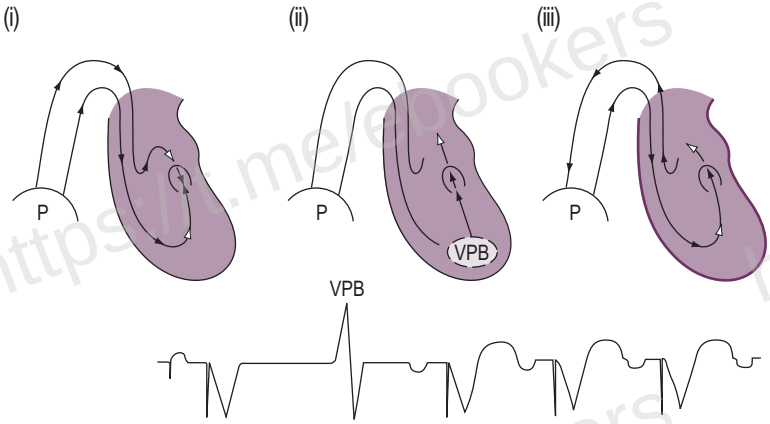

Figure 23.6 Pacemaker-mediated 'endless-loop' tachycardia: (i) under normal conditions (first beat), there is no conduction from the ventricles to the atria because of ventriculo-atrial (VA) block or because the atrial and ventricular impulses collide and extinguish each other in the atrioventricular node; (ii) if a ventricular premature beat *(VPB)* is conducted retrogradely to the atria (second beat), inducing an inverted 'p'-wave, this may be sensed by the pacemaker *(P)* which then triggers a ventricular paced beat (third beat); (iii) if the paced ventricular beat is then retrogradely conducted from the ventricle to the atria and sensed, an 'endless loop' may occur (beats 4, 5); that is, pace ventricle VA conduction 'p' wave (sensed) ventricular pace, and so forth.

ventricles) will decrease cardiac output by up to 25%,[11] most commonly in atrial fibrillation. Many permanent pacemakers are rate-adaptive. When temporary pacing is used, especially in the ICU setting, higher than normal lower rates may be needed if oxygen delivery is inadequate. For life-threatening bradyarrhythmias, increasing heart rate with VVI mode pacing is the treatment of choice and heart rate modulation with exercise is required only for permanent pacemaker patients.

During VVI and VVIR pacing, the atria and ventricles beat independently and AV synchrony is lost. This can have deleterious effects, known collectively as 'pacemaker syndrome.'[12] It can occur with any pacing mode where AV dissociation occurs and blood pressure, stroke volume and cardiac output may fall with the onset of pacing. Another feature is due to the atria contracting against closed tricuspid and mitral valves causing regurgitation of blood into the neck via the jugular veins. This is felt as uncomfortable neck pulsations. The pacemaker syndrome can be eliminated by restoring AV synchrony.

However, and somewhat counterintuitively, dual-chamber pacing has not been shown to improve mortality even though haemodynamics are usually superior to VVI pacing.[13] It does though appear to lower the incidence of AF.[3]

Changing the programmed AV interval of a dual-chamber pacemaker can affect the amount of ventricular pacing that is seen and also the haemodynamics, for the reasons outlined above. If this interval is programmed short (e.g. 80 ms), it will promote ventricular pacing. If it is programmed long (e.g. 250 ms), it will promote intrinsic ventricular activity (if present). The correct AV interval will depend on patients' clinical state and their intrinsic AV conduction and interatrial conduction (the time to conduct between the RA and LA). Promoting ventricular pacing may be a good thing if it improves haemodynamics, but promoting intrinsic conduction is often better, especially if the intrinsic AV delay is not very long. Adjusting the AV interval in the patient with poor cardiac output or low oxygen delivery can be optimised using echocardiography or thermodilution assessment of cardiac output.

TEMPORARY PACING

INDICATIONS FOR TEMPORARY PACING

Temporary cardiac pacing is indicated for:

- any sustained symptomatic bradycardia not promptly responding to medical treatment
- malignant ventricular arrhythmias secondary to bradycardia
- second- or third-degree AV block with haemodynamic compromise
- asystole.

The decision to pace is based on bradycardia causing haemodynamic deterioration, and not on the specific rhythm disturbance. For example, pacing is indicated in a patient with atrial fibrillation and a ventricular rate of 40 beats per minute associated with a blood pressure of 70/40 mm Hg (9.3/5.3 kPa), cardiac failure and oliguria, but not in an asymptomatic,

normotensive patient with the same rhythm or even a patient with an inferior myocardial infarction, complete heart block and a ventricular rate of 45 beats per minute with a narrow QRS complex.

Temporary pacing is indicated for the treatment of heart block or sinus bradycardia after cardiac surgery. In high-risk patients (e.g. aortic or mitral valve replacement), prophylactic epicardial electrodes are attached during surgery. DDD epicardial pacing has been shown to increase cardiac output at any given heart rate compared with VVI pacing.[14] Temporary perioperative cardiac-pacing strategies to increase stroke volume and cardiac output include optimisation of AV delay and rarely multisite pacing.[15] Temporary pacing may be required in patients with inferior myocardial infarction or during coronary angioplasty, particularly of the right coronary, which supplies the SA and AV nodes. Asymptomatic patients with bifascicular block do not require prophylactic pacing prior to general anaesthesia, although transcutaneous pacing should be available, but should be considered for all patients with trifascicular block (bifascicular block and prolonged PR interval). Patients with Mobitz type II or third-degree AV block should be paced prior to general anaesthesia and surgery.

Caution should be exercised in patients with acute myocardial infarction, as many will have received antiplatelet agents. Transcutaneous pacing prevents the need for transvenous pacing, but should only be used as an emergency in high-risk patients.

TEMPORARY LEADS AVAILABLE

VENTRICULAR PACING LEADS

There are different types of temporary pacing leads available with different degrees of rigidity and French size. The most common calibres will be 4–6 F. These leads are relatively stiff and can be shaped before advancing through a sheath, but are still flexible enough to be manipulated under fluoroscopic control to the correct position in the RV. Balloon-flotation leads can, in theory, float into a stable position in the RV and are useful if fluoroscopy is not available in emergent situations, or as back-up when transferring patients to centres for permanent pacing. Alternatively, softer diagnostic electrophysiology catheters can be used with a standard temporary pacing box and have the advantage of being potentially less traumatic than traditional 'temporary pacing wires,' especially if required for longer periods.

ATRIAL PACING LEADS

Leads designed specifically for placement in the right atrium have a preformed J-shaped tip designed to hook into the RA appendage. This site is often best for lead stability, low pacing thresholds and good sensing.

TECHNIQUE OF TEMPORARY TRANSVENOUS PACING

VENTRICULAR PACING

A sterile technique is mandatory in an environment with good fluoroscopic imaging, non-invasive cardiac monitoring and resuscitation facilities. In emergencies, transcutaneous pacing (VVI) can be implemented first while transvenous VVI pacing is being prepared. A bipolar lead introduced under fluoroscopic control is most commonly used.

Vascular access

The Seldinger technique is employed to access a central vein with a 5- or 6-French sheath. The sheath has a haemostatic valve, which prevents blood loss at the time of lead insertion. Percutaneous insertion via the right internal jugular vein probably offers least complications with ease of manipulation and stability of the lead. However, the subclavian vein approach is often used as it allows more freedom for arm and neck movement, but there is a slightly greater risk of pneumothorax. Patients likely to need permanent pacing later in their treatment should have the left subclavian vein saved for this purpose. Antecubital veins are associated with lead instability and thrombophlebitis. The femoral vein can be used. It is usually quick and easy to insert a ventricular pacing wire from this route, but the patient must remain lying flat. Lead stability is probably less good than superior routes and there is higher risk of infection and deep-vein thrombosis. Femoral temporary pacing is useful over a short period of time, for instance to cover a surgical procedure in a patient with trifascicular block or those who have received thrombolytic agents but should not be used for longer-term pacing if possible.

Positioning the pacing lead

The pacing lead is manipulated under fluoroscopic control in the posteroanterior (PA) position close to the apex of the RV (Fig. 23.7). This position offers the greatest stability, but the true apex should be avoided as it is thin and the risk of perforation is higher. As the lead crosses the tricuspid valve to the RV, it is usual to see ventricular ectopy (VE). However, if continuous, the lead should be pulled back to the right atrium. In the absence of VE, the lead position should be confirmed in the left anterior oblique (LAO) position to ensure it is not in the coronary sinus or a posterior vein. Manipulation of the lead is achieved by clockwise and counterclockwise torque in combination with simultaneous advancement and retraction of the lead. Temporary pacing leads are relatively stiff and perforation can occur, especially if leads are seen to buckle whilst advancing, but it is also important to ensure sufficient slack in the lead to avoid the loss of position with subsequent patient movement.

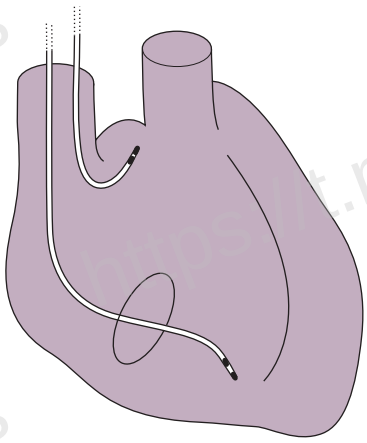

Figure 23.7 Characteristic appearance of temporary transvenous pacing leads ideally positioned in the right atrium (right atrial appendage) and apex of right ventricle.

Figure 23.8 External pacemakers. Medtronic, Inc. (i) Model 5388 (dual-chamber); (ii) model 5348 (single-chamber). Both are capable of rapid pacing for certain tachycardias.

Once in a satisfactory position, the lead should be tested electrically for sensing, pacing and diaphragmatic capture (see below). It should be sutured to the skin at two different sites: one where it exits the skin, and a second to a loop formed with the lead. A chest X-ray should be obtained to exclude pneumothorax and to confirm satisfactory positioning.

ATRIAL PACING

J-shaped atrial leads are designed to be advanced and hooked into the right atrial appendage. The appendage is an anterior structure, which is superior to the right atrium. Once the tip is advanced into the appendage orifice, retraction of the lead will hook the tip into the appendage body and a side-to-side motion of the lead tip may be seen if the patient is in sinus rhythm. The correct position is best confirmed by a lateral chest X-ray.

DUAL-CHAMBER PACING

Modern external pacing boxes are available (Fig. 23.8) that will pace in all modes. These units are small, easy to use and can fit into a small pouch suitable for mobile patients.

TEMPORARY-PERMANENT SYSTEMS

Prolonged temporary pacing is commonly associated with complications including systemic and local infection, lead displacement and even right ventricular perforation. Therefore, unless pacing with a temporary wire is extremely shortlived (i.e. for periods of <24 hours), it is no longer recommended. A temporary-permanent system or 'externalised pacemaker' is one where standard permanent pacing leads and a standard implantable generator are used in a temporary, externalised fashion. One area in which they are now very frequently used is in patients with a standard pacing indication but also concurrent infection such that a permanent system should not be implanted immediately. For example, pacing-dependent patients who undergo system extraction for cardiac device infection commonly benefit from this approach before a permanent system is implanted after treatment with antibiotics. Alternatively, patients with potentially reversible causes for bradycardia, for example acute hypothyroidism or Guillain-Barré syndrome, may also benefit from pacing using a so-called 'temporary-permanent' system until the underlying cause has either resolved or been treated.

Typically, an active fixation lead is placed in the right ventricle via an internal jugular vein or subclavian vein approach. A 'peel-away' sheath is used so that just the pacing lead remains externalised at the end of the implant procedure. Permanent pacing leads are typically 'stylet-driven' to provide support and allow positioning of the lead tip. As the proximal end of the lead is externalised, an active fixation lead mechanism is used to reduce the risk of lead displacement within the heart. Such leads can be positioned on the septum (rather than the apex) for more physiological pacing. Once positioned, the stylet is removed and the lead fixed to the skin entry point using sutures around the suture sleeve. The lead is then screwed into the generator in the normal manner, but with the generator remaining outside the body. We recommend using a chlorhexidine-impregnated dressing over the entry site of the lead through the skin to reduce the risk for infection. Any redundant lead is coiled up and this, with the generator, is placed against the patient's skin with an adhesive dressing.

After a short period of observation, the patient with a temporary-permanent system implant can be mobile

and, unlike traditional pacing wires, lead displacement and threshold rise is rare, meaning the need for the lead repositioning is also rare. This also mitigates against complications, which arise in the immobile patient, like venous thrombosis, pressure sores and pneumonia. Similarly, the risk and inconvenience associated with multiple lead repositioning procedures is avoided. In some countries, patients have even been discharged with this type of system, particularly when the reversal of a cause of bradycardia may take a long time, for example in some neurological diseases; however, in the UK, patients remain in hospital. The device can be reprogrammed just like a normal pacemaker if required and the percentage of time that the patient is pacing, or detection of intermittent arrhythmias, can be recorded so where appropriate, a decision to permanently pace or provide other treatment can be made.

Removal of the temporary-permanent system is straightforward and can be performed in a ward-based setting without needing to go to a catheter lab. The sutures are cut, the lead is removed from the generator and the active fixation component of the lead is retracted using the bespoke tool (or just a standard artery forceps). The lead can then be removed with simple traction (fluoroscopy is typically not required). Manual pressure is applied and the area dressed.

Troubleshooting

Lead does not cross the tricuspid valve Looping the lead in the right atrium and then applying counterclockwise torque will help prolapse it into the RV.

Lead cannot be advanced to the right ventricle apex Withdrawing the lead after advancing it to the RV outflow tract (RVOT) may help the tip fall towards the apex. A small amount of torque may aid the process. Alternatively, the lead may need to be shaped with a different degree of curve.

If this manoeuvre does not help, a more basal position on the inferior wall can be used. The RVOT should be used only if the patient is asystolic, as lead stability is poor here with passive leads.

Lead advances only towards the right ventricle outflow tract Ensure that this is not in the coronary sinus by checking that it does not curve posteriorly in the LAO position. If it is not, apply a slightly posteriorly facing curve to the distal tip of the lead and try again.

Testing the pacing leads

Modern temporary pacing boxes are sophisticated devices, which can perform checks of sensing as well as pacing threshold. Checking the sensitivity of a pacing lead electrogram is a very important step. Sensitivity, or sensing, is simply calculation of the amplitude of the sensed electrograms. Large electrograms are easy to sense and small ones are not and undersensing may occur. Undersensing will cause inappropriate delivery of a pacing stimulus. If this occurs on or near a T-wave, this can lead to ventricular fibrillation (VF). On most boxes, sensing is indicated by a flashing light or other digital marker. The sensitivity dial is slowly rotated from a low value to a higher one until sensing stops. This represents the sensitivity of the sensed electrograms. A higher value is better than a lower one. The sensitivity is programmed to allow continuous sensing of all intrinsic signals.

Pacing threshold The rate should be set at least 10 beats per minute faster than the intrinsic heart rate, or at 60 beats per minute if the patient has a profound bradycardia. The pacing output should be set at 5 V and sensitivity at 1 mA. The box is switched on and ventricular capture confirmed by the presence of a pacing spike immediately followed by a broad QRS of LBBB morphology at the same rate as that set on the box.

The output is slowly decreased until consistent capture is lost. It is then increased until capture returns. This is the pacing threshold and ideally should be less than 1 V. However, if another stable position cannot be found, then a higher threshold may be acceptable. In those with no underlying rhythm or profound bradycardia, loss of capture will lead to asystole – in which case the output should be rapidly increased until capture returns. The stability of the wire is checked in its position just above the pacing threshold by asking the patient to take deep breaths, cough and sniff whilst looking for loss of capture and viewing the wire fluoroscopically. Diaphragmatic capture is checked in leads on the inferior RV wall by pacing at the maximum output, usually 10 V, and feeling the abdomen or fluoroscopically screening the diaphragm. If diaphragmatic capture occurs, the lead must be repositioned.

If a threshold of less than 1 V is achieved, the pacing rate is set to the desired rate to achieve adequate cardiac output or 40 beats per minute if intermittent back-up pacing is required. The voltage is usually set to three times the pacing threshold to allow sufficient safety margin, or at least 3 V. Temporary pacing is programmed in VVI mode to allow sensing of spontaneous ventricular activity and to inhibit pacing.

Complications of temporary pacing[16]

Temporary pacing should have a low complication rate. However, it is rare nowadays for operators to gain regular experience at insertion and similarly training may also be inadequate. Several studies from the UK report complications in a third to a half of cases.[17,18] Thus, temporary transvenous pacing is best avoided where possible; rather, insertion of a permanent system at the earliest opportunity is best, and in many centres this now happens out of 'normal' working hours. Complications include:

- pneumothorax, haemothorax, arterial puncture, AV fistula and perforation of the RV or RA leading to cardiac tamponade

- undersensing, leading to inappropriate pacing and pacemaker-induced arrhythmias; oversensing (of extrinsic or intrinsic noise), with pacemaker inhibition and loss of cardiac output; failure to capture due to poor or unstable lead position, increasing pacing threshold with chronicity of lead
- diaphragmatic capture (may be associated with RV perforation)
- thrombus of the central vein and importantly infection, especially with leads older than 7 days.

How to manage abrupt failure to pace

A life-threatening situation may arise if a temporary pacemaker fails suddenly. The following is an ordered approach to such an emergency:

1. Make sure the pacemaker box is switched on and connected to the pacing lead(s).
2. The pacemaker output should be increased to its maximum setting (usually 10 V or 20 mA).
3. Asynchronous DOO/VOO mode(s) should be selected to prevent oversensing.
4. If pacing still fails, connect the pacemaker directly to the pacing lead, bypassing the connecting wire (if present), as occasionally connecting wires may be faulty.
5. Consider replacing the pacemaker box or its batteries.
6. External transcutaneous pacing should be immediately available and commenced while a new pacing system is inserted.
7. Cardiopulmonary resuscitation and positive chronotropic drugs such as atropine, isoproterenol (isoprenaline) or epinephrine (adrenaline) should be available.

PACEMAKER PROGRAMMING

Multiple parameters can be programmed on both modern temporary and permanent pacing systems. All pacing practitioners, and this includes physicians who implant temporary systems, should be familiar with programming the mode, rate, pacing output and sensitivity of a pacing system and should also be able to diagnose and troubleshoot basic pacing problems like undersensing and oversensing. If dual-chamber pacing systems are used, programming the AV delay should be performed to optimise cardiac output and cardiac function (perhaps using echocardiographic guidance). Programming permanent pacing systems is more complicated than for temporary systems and should be performed only by individuals qualified to do so. Internationally recognised pacing qualifications include the IBHRE and EHRA examinations awarded by the Heart Rhythm Society and the European Heart Rhythm Association, respectively.

NOISE AND ELECTROMAGNETIC INTERFERENCE

Any signal sensed by a pacemaker will lead to pacing being inhibited or triggered (e.g. in dual-chamber systems). These signals will include noise or electrical artefact sensed by a pacing system. Noise is characterised as intrinsic (from within the patient) or extrinsic (from outside the patient). Sources of intrinsic noise include lead fracture, fluid in the generator header and diaphragmatic and skeletal myopotentials. Extrinsic noise includes electromagnetic interference (EMI) (e.g. from a nearby electrical device or its trailing wires and surgical diathermy). Other sources include MRI scanners (patients with some modern permanent pacemakers can be safely scanned in MRI scanners) or electronic devices placed over the pacemaker generator (e.g. mobile telephones or MP3 players). Noise can be misinterpreted by ICDs as VT or VF and can result in inappropriate therapy and shocks.

MRI scanning is sometimes necessary in patients with non–MRI-safe pacing systems or ICDs. Recent studies have demonstrated that MRI scanning can be performed safely in selected patients with these types of systems,[19] but this must be performed in collaboration with a pacing expert and the risks presented by MRI must be outweighed by the diagnostic benefit of the scan on a case-by-case basis.

CARDIOVERSION/DEFIBRILLATION IN PATIENTS WITH A PERMANENT PACEMAKER (OR IMPLANTABLE CARDIOVERTER DEFIBRILLATORS)

To avoid damage to the pacemaker device, shocking pads should be placed in the anterior–posterior position and at least 10 cm from the unit. The pacemaker (or ICD) should be checked before and afterwards. In patients with a temporary transvenous pacemaker, the external unit and leads should be kept well away from the pads.

DIATHERMY

Bipolar diathermy should be used whenever possible and the pacemaker programmed to an asynchronous mode in pacing-dependent patients. In an emergency (e.g. asystole in a patient whose pacemaker is inhibited by diathermy), placing a magnet over the pacemaker generator will result in asynchronous pacing at 'magnet' rate (magnet rate varies according to pacemaker manufacturer). ICDs do not have a magnet rate; placing a magnet over an ICD will switch off its therapies (i.e. antitachycardia pacing and shocks), but ICD therapies should be switched off before using diathermy. After surgery the pacemaker or ICD should be tested and reprogrammed appropriately.

Box 23.1 Pacing versus cardioversion for the treatment of tachyarrhythmias

Pacing may assist in rhythm diagnosis
Pacing may be used (cautiously) in digitalis intoxication
Pacing does not require a general anaesthetic
Pacing avoids complications of DC shock, especially myocardial depression
Repeated reversions are easier with pacing
Standby pacing is immediately available if bradycardia or asystole occurs after electrical reversion

Box 23.2 Pacing versus drug therapy for the treatment of tachyarrhythmias

Pacing may aid in arrhythmia diagnosis
Pacing avoids drug-induced cardiac depression and other drug side effects
Pacing can be used when drug therapy has failed
Termination of the tachycardia with pacing is often immediate
Standby pacing is immediately available

Box 23.3 Indications for rapid cardiac pacing in suitable arrhythmias

Failure of drug therapy
Recurrent arrhythmias
Contraindication for cardioversion (e.g. digitalis intoxication)
Aid to arrhythmia diagnosis (e.g. wide-complex tachycardia to differentiate ventricular tachycardia from supraventricular tachycardia)

CARDIAC PACING IN TACHYARRHYTHMIAS

Although pacemakers are not usually inserted for the treatment of atrial arrhythmias, atrio-ventricular nodal reentrant tachycardia (AVNRT) or atrio-ventricular reentrant tachycardia (AVRT), these rhythms may be treated safely and effectively by rapid pacing and/or premature electrical stimulation where a device is already present. They can also be used for treatment of VT, but rapid VT should be managed with DC cardioversion. Rapid cardiac pacing has advantages over DC cardioversion (Box 23.1) and drug therapy (Box 23.2), but is of no value in sinus tachycardia, AF and VF (Box 23.3). Pacing at rates of 80–100 beats per minute can be used to try to suppress ventricular and supraventricular rhythms as well as torsade de pointes in patients with the congenital long QT syndrome.

VENTRICULAR TACHYCARDIA

Ventricular burst pacing is a simple and often effective technique to pace VT. The ventricle is paced at a rate starting at about 120% of the VT rate for 8–10 beats (Fig. 23.9). If this fails (Fig. 23.10), increasing the pacing rate and/or the number of paced beats in the train should be tried cautiously. Slow VTs particularly are very stable and often require very long pacing trains. Potential complications include accelerating the VT rate, which can precipitate VF. Trained personnel, a defibrillator and resuscitation facilities must be available to perform this safely.

Figure 23.9 Wide-complex tachycardia. Ventricular burst pacing with ventricular capture results in normal sinus rhythm on cessation of pacing.

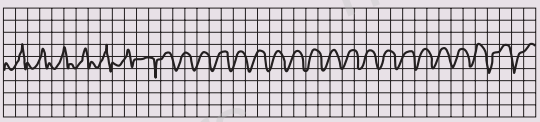

Figure 23.10 Wide-complex tachycardia is followed by ventricular burst pacing. When pacing is discontinued, a wide-complex tachycardia of opposite polarity is precipitated.

IMPLANTABLE CARDIOVERTER DEFIBRILLATORS*

This is an implantable device that recognises and tries to terminate VT and VF through antitachycardia pacing and shocks, respectively. Guidelines are published for ICD implantation.[14] ICDs are of proven survival benefit and a class I indication in patients who have survived VF or haemodynamically unstable VT not due to a transient or reversible cause (e.g. an electrolyte imbalance). ICD implantation is also indicated for patients with structural heart disease and spontaneous sustained VT, whether haemodynamically stable or unstable. ICDs are also now used prophylactically in high-risk patients (i.e. those with severely impaired LV function) and are especially efficacious in patients with previous myocardial infarction.[20]

Most ICD systems are implanted transvenously and can perform antitachycardia pacing as well as normal permanent pacing, if necessary. Single- or dual-chamber ICDs may be implanted. The addition of an atrial lead gives another piece of information for the ICD to use to diagnose a tachycardia as VT rather than an SVT, but has not conclusively been shown to do this better than single-chamber devices. ICDs continuously monitor the patient's heart rate and deliver therapy when the heart rate exceeds the programmed

detection rate. Devices are programmed with different tachycardia zones, stratified according to rate:

1. *VF zone:* for rates usually faster than 200 beats per minute. High-energy shocks are delivered if detection criteria are met, but antitachycardia pacing can be delivered while the device is charging in case it is a very fast VT. Shocks are biphasic, as these are more efficient and require lower energies than monophasic waveforms and can be programmed below the maximum output if the programmer wishes to save device battery life.
2. *Fast VT zone:* for rates between 170 and 200 beats per minute – several attempts of antitachycardia pacing are usually programmed initially, of increasing aggressiveness. This is followed by shocks if unsuccessful.
3. *Slow VT zone:* for rates between 150 and 170 beats per minute. This is similar to the fast VT zone, but even more weighted to antitachycardia pacing.

COMPLICATIONS

Occasionally, ICDs can deliver multiple discharges in short sequence and this is a clinical emergency. Shocks may be appropriate or inappropriate. Frequent malignant ventricular arrhythmias may result in multiple appropriate discharges. If the multiple shocks are successful in defibrillating the patient during an arrhythmia 'storm', the ICD device may be deactivated and antiarrhythmic drugs or even general anaesthesia initiated. This will save device battery longevity and be much more comfortable for the patient. In the absence of a programmer or whilst this is being sought, an ICD can be deactivated in an emergency by a magnet found on resuscitation trolleys. A magnet will disable shock therapy only. If shocks are inappropriate, for example for atrial fibrillation or lead fracture, the ICD needs to be reprogrammed or should be switched off.

Acute heart failure and pulmonary hypertension

Andrew Aswani, Nicholas Ioannou

ACUTE HEART FAILURE

Heart failure is a highly prevalent condition affecting 2% of the population worldwide. Most patients with heart failure have underlying coronary artery disease, hypertension, pre-existing cardiomyopathy or valvular disease.[1] Improvements in the treatment of patients with chronic heart failure (CHF) and those presenting with acute coronary syndromes (ACS) mean that the prevalence and resultant societal economic burden of this disease are projected to increase dramatically over the next 20 years.[2]

Patients may present with chest pain, palpitations, shortness of breath, fatigue and peripheral oedema. Management focuses on reducing cardiac work to relieve symptoms and prevent further myocardial damage. Heart failure encompasses a broad range of clinical syndromes and includes stable CHF and acute heart failure (AHF). AHF is estimated to account for 3 million index admissions each year in the United States alone.[1] AHF includes several different phenotypes of varying severity including de novo AHF, acute decompensated heart failure, hypertensive AHF, AHF with pulmonary oedema and cardiogenic shock (CS). It is worth noting that the improved outcomes that have been achieved over the past 30 years in reducing mortality in CHF have not been replicated in AHF, and outcomes remain very poor.[3] Notably, the improvement in outcomes in AHF with CS over this period due to aggressive revascularisation strategies for ACS[4] have lagged behind the improvements seen in septic shock.[5] This comparison points to a poorly researched field with a paucity of randomised trials showing any treatment benefit in AHF. In fact, the treatment armamentarium (comprising diuretics, vasodilators and inotropes) has remained essentially unchanged over the last 30 years.[6]

Patients with AHF may be usefully classified according to their perfusion status *(warm vs. cold)* and the presence or absence of congestion *(wet vs. dry)* (Fig. 24.1). Most patients (>95%) presenting with AHF present with symptoms and signs of congestion. Conversely, only 5% present with symptoms and signs of poor perfusion.[7] First-line management will thus be guided by this initial clinical assessment. Commonly, there is resolution of presenting signs and symptoms in most patients during the index admission. Despite this, the rates of readmission are significant, and 1 year mortality rates remain unacceptably high with figures ranging from 25% for acute decompensated heart failure[8] to as high as 50% for those presenting with CS.[5]

The situation in critical care is further complicated by the involvement of other organ systems. Management in the critical care setting focuses on both improving global and regional oxygen delivery and maintaining perfusion pressure, often with the use of drugs that stimulate rather than rest the myocardium.[9,10] The resolution of this apparent paradox requires that, for each patient, management should attempt to resolve the difficult balance between the best interests of the myocardium and the circulatory requirements of the other vital organs. The intensivist should target the minimum necessary oxygen delivery and arterial pressure to maintain other organ function at maximum cardiac efficiency (e.g. ensuring adequate fluid resuscitation before starting inotropic agents) so that cardiac work and the risk of myocardial ischaemia and necrosis from exuberant beta-agonist use are minimised, and the cardiologist should consider the wider circulation and other organ requirements when instituting strategies to protect the myocardium. Despite the known significant side-effect profile of inotropic agents,[11] they remain part of the recommended treatment for incipient or overt CS in international guidelines.[7,12,13] In practical terms, they should be utilised for hypotensive and hypoperfused patients for the shortest period possible.

The development of the cardio-renal syndrome in AHF also requires a careful balancing act in critical care. Congestion is thought to be the dominant problem causing increased venous pressure in the kidneys, which further compounds the injurious effects of the low cardiac output (CO) state found in AHF.[14] Fluid removal is therefore key to the improvement of both cardiac and renal function – sometimes at the expense of short-term renal deterioration due to diuretic-induced vasoconstriction, nephrotoxicity and other factors.[15] Judging the degree of acceptable renal injury is often challenging[16] and the presence of diuretic resistance and/or requirement for ultrafiltration for fluid removal portend a poor outcome.[17]

ABSTRACT

Acute heart failure is a common clinical condition associated with significant morbidity and mortality. Acute heart failure can present either de novo or following decompensation of chronic heart failure, and precipitating factors should be identified and promptly reversed. The diagnosis and management of the critically ill patient with acute heart failure can be challenging and the intensivist must balance the best interests of the myocardium with the circulatory requirements of the other vital organs. A sound knowledge of cardiovascular physiology and pharmacology is essential to allow safe and effective management of these patients to ensure the best possible outcomes.

Pulmonary hypertension is also frequently encountered in critically ill patients and is associated with high morbidity and mortality. Underlying pathophysiology is diverse, and the key to the management of critically ill patients with pulmonary hypertension is early diagnosis and prompt reversal of precipitating factors.

DIAGNOSIS OF ACUTE HEART FAILURE

The diagnosis of AHF in critically ill patients is more difficult than is commonly recognised. Although the underlying pathology in most patients with AHF in critical care will be a primary cardiac problem, other diagnoses must also be considered (Box 24.1). Early diagnosis and prompt management is paramount in this potentially life-threatening clinical situation. When a patient presents with suspected AHF, the 'CHAMP' acronym is a useful tool that can be used at the initial assessment to identify treatable causes (however, this is by no means an exhaustive list):

C: acute **C**oronary syndrome leading to AHF should prompt rapid consideration for percutaneous coronary revascularisation, irrespective of electrocardiogram (ECG) or biomarker changes.

H: **H**ypertensive emergency, commonly presenting as pulmonary oedema, mandates rapid blood

Box 24.1 Causes of acute heart failure in critical care

- Coronary artery disease/acute coronary syndrome (ACS)
- Cardiac arrhythmias – atrial fibrillation (AF)
- Infection – systemic sepsis, viral myocarditis
- Mechanical – endocarditis, pulmonary emboli, valve problems, septal defects, tamponade, high intrathoracic pressure with inadequate preload
- Drugs – beta-blockers, calcium antagonists, cytotoxic drugs (e.g. doxorubicin), alcohol, cocaine
- Hypoxaemia
- Metabolic – acidaemia, thiamine deficiency, thyrotoxicosis, hypocalcaemia, hypophosphataemia
- Myocardial contusion – blunt thoracic trauma
- Myocardial infiltration – tumour, sarcoidosis, amyloidosis
- Vasculitis
- Neuromuscular conditions – Duchenne muscular dystrophy, Friedrich ataxia, myotonic dystrophy

pressure reduction initially with vasodilators and diuretics.

A: **A**rrhythmias should be rapidly corrected via pharmacological, electrical or pacing device means as appropriate. However, restoration of normal sinus rhythm may be neither necessary nor achievable; the risks and benefits of each approach should be weighed carefully.

M: acute **M**echanical causes, most commonly occurring as a complication of ACS; for example, free wall rupture, ventricular septal defect and acute mitral regurgitation, and due to chest trauma, acute valve incompetence from endocarditis and aortic dissection, necessitate either surgical or percutaneous approaches for repair.

P: acute **P**ulmonary embolism (PE) leading to obstructive shock requires either systemic or localised catheter directed thrombolysis. Surgical options are rarely undertaken. The management of sub-massive PE, with echocardiographic and/or CT evidence of heart strain and elevated biomarkers, is more challenging with no convincing evidence of benefit with systemic thrombolysis[18]; catheter-directed thrombolysis trials are eagerly awaited for this cohort.

It is also important to critically reassess the patient referred with a diagnosis of AHF to decide whether this is indeed the primary problem. The history, examination and initial investigations with routine blood tests, ECG and chest radiograph may be compatible with this diagnosis, but many such patients are elderly with multiple co-morbidities, and deciding whether the patient is suffering from a primary myocardial pathology as opposed to a pulmonary problem or indeed systemic sepsis[19,20] can be difficult. Equally, patients believed to have a primary respiratory problem may fail to wean from ventilatory support because of a failure to realise that they have left ventricular (LV) failure with a high left atrial pressure (LAP) and incipient pulmonary oedema, causing a reduction in pulmonary compliance, an increased work of breathing and respiratory distress when ventilatory support is withdrawn.

Further investigations that can help to confirm or refute an initial diagnosis of AHF are echocardiography and the measurement of biomarkers, such as natriuretic peptides and cardiac troponins.

ECHOCARDIOGRAPHY

Echocardiography (see Chapter 27) is an essential investigation in the management of critically ill patients with AHF[7,21] and the modern intensivist should at least be able to perform a focused examination. Transthoracic echocardiography (TTE) is non-invasive and can be performed rapidly at the bedside. TTE may be technically challenging in mechanically ventilated critically ill patients but experienced operators can often obtain adequate images from at least one imaging window, and considerable improvement in image quality can be achieved using microbubble contrast techniques.[22] If transthoracic views are difficult to obtain or if better resolution is required (e.g. for the detection of small vegetation or intracardiac thrombi) then transoesophageal echocardiography (TOE) should be considered. TOE requires a higher level of expertise but will provide excellent views of the mitral and aortic valves, the left atrial appendage and the ascending aorta (dissection flaps); however, right heart structures and the apex of the LV are less well visualised.

Echocardiography will frequently establish the underlying cardiac pathology and can be used to monitor the response to treatment. It will:

1. Identify increased LV end-systolic and diastolic dimensions, indicating ventricular contractile failure; termed systolic dysfunction or heart failure with reduced ejection fraction (HFrEF).[7] HFrEF is defined as an ejection fraction (EF) less than 40%. However, the use of EF as an index of ventricular contractility can be misleading, especially in critically ill patients on vasopressors and inotropic drugs, as it is dependent on both preload and afterload. Therefore, EF should be interpreted in the context of LV loading conditions and any structural changes that lead to alterations in LV end-diastolic volume.[23] The typical pitfalls with sole reliance on EF are the failure to appreciate the presence of excess afterload (e.g. vasopressor use) and augmented preload (e.g. mitral regurgitation) which leads to an underestimate of true LV systolic function; conversely, the EF can overestimate true LV systolic function in concentric LVH.
2. Identify diastolic dysfunction as a consequence of impaired ventricular relaxation, also termed heart failure with preserved ejection fraction (HFpEF). HFpEF is defined as an EF greater than or equal to 50% often in the context of increased LV wall thickness and/or left atrial enlargement. Preserved EF in this context does not necessarily equate to an adequate CO,[24] and high-pressure preload measurements may fail to reflect the true volume preload and the potential need for extra fluid volume. Up to 50% of AHF patients present with HFpEF or mid-range EF (HFmrEF, with EF of 40% to 49%) and these patients tend to have a history of hypertension and/or present in a hypertensive state.[25] Outcomes for patients with HFpEF and HFmrEF are similarly poor to those with HFrEF, but the reasons for this reflect a combination of the absence of proven therapies for the former groups and the sequelae of their non-cardiovascular co-morbidities.[26] Therefore, the arbitrary cut-offs that define HFpEF, HFmrEF and HFrEF should not deter a thorough clinical assessment of the patient to allow an individualised approach to the

treatment of the particular AHF phenotype and management of other end-organ dysfunction.

3. Identify pericardial effusions and determine whether ventricular filling is impaired (tamponade) and whether drainage is indicated. However, ultimately, tamponade is a clinical diagnosis based on the full haemodynamic picture in the context of pericardial fluid demonstrated on the echocardiogram. Many of the diagnostic features related to alterations with respiration are affected by positive-pressure ventilation, and drainage may be appropriate even if such classic echocardiographic criteria are not present. Even small effusions may cause tamponade since it is the rate of accumulation of fluid rather than the amount of fluid that determines the degree of cardiac compromise.
4. Identify obstruction to cardiac filling from other intrathoracic space-occupying lesions that increase intrathoracic pressure, particularly in ventilated patients (pleural effusions, alveolar gas trapping in asthma).
5. Assess adequacy of volume preload of LV, particularly in the context of raised preload pressures; assess fluid responsiveness and monitor the effects of a fluid challenge.
6. Identify primary valvular heart disease (critical aortic stenosis, acute mitral regurgitation from papillary muscle rupture, acute endocarditis) when urgent surgery is indicated, and distinguish this from functional valvular regurgitation due to primary ventricular disease for which surgery could be lethal.
7. Identify septal defects, regional wall motion abnormalities and aneurysmal dilation from recent or previous myocardial infarction.
8. Identify the presence of intracardiac thrombus.
9. Identify pulmonary hypertension (PH) associated with tricuspid regurgitation when an estimate of pulmonary artery (PA) systolic pressure can be made.
10. Identify right ventricular (RV) size and function and discriminate between pressure and volume overload of the RV. The presence of RV dysfunction also can be used to diagnose and risk stratify patients presenting with suspected acute PE.

MEASUREMENT OF NATRIURETIC PEPTIDES AND CARDIAC TROPONINS

Myocardial injury and the development of AHF are common, but frequently unrecognised complications of critical illness occurring not only in patients with an overt ACS but also in other conditions, such as sepsis and massive PE.[27] Relying on blood tests alone to establish a diagnosis or to plan management is inadvisable but, when interpreted in conjunction with the wider clinical picture, natriuretic peptides and cardiac troponins appear to be sensitive markers of myocardial stress and necrosis.

NATRIURETIC PEPTIDES

B-type natriuretic peptide (BNP) and *N*-terminal pro B-type natriuretic peptide (NT-proBNP) are the most commonly measured natriuretic peptides in clinical practice. BNP was first isolated from porcine brain[28] and was originally termed 'brain natriuretic peptide'; however, the major source was subsequently shown to be from the ventricular myocardium. The main stimulus for natriuretic peptide synthesis and release is myocardial wall stress; cardiac myocytes release the prohormone, proBNP, which is subsequently cleaved into biologically active BNP and the inactive *N*-terminal fragment (NT-proBNP). Although natriuretic peptide release appears to be related to end-diastolic volume and pressure, it does not reliably differentiate between HFrEF and HFpEF or accurately predict EF or filling pressures.[29] Measurement of BNP and NT-proBNP in the emergency department may discriminate patients with heart failure from those with pulmonary or other non-cardiac causes for acute dyspnoea and has been shown to reduce rates of intensive care unit (ICU) admission, length of hospital stay and cost.[30] Routine measurement of natriuretic peptides is now recommended by several international heart failure guidelines.[7,12,13] Studies have demonstrated that, at a cut-off of 100 pg/mL, BNP has a sensitivity of 90% and a specificity greater than 70% as a test for excluding heart failure.[31] Similar data have also been reported for NT-proBNP with a cut-off value of 300 pg/mL.[32] BNP and NT-proBNP have high negative predictive values but lower positive predictive values; therefore their main utility is to rule out the diagnosis of heart failure in both the acute and non-acute setting. There are a number of cardiovascular and non-cardiovascular causes of raised natriuretic peptides including atrial fibrillation (AF), advanced age and renal failure. BNP has also been shown to be a marker of myocardial dysfunction and prognosis in severe sepsis.[33] Therefore, elevated levels of natriuretic peptides should prompt further cardiac investigation, specifically echocardiography. However, the use of natriuretic peptide levels to guide heart failure management has not been shown to improve outcomes.[34]

CARDIAC TROPONINS

Troponins are regulatory proteins that form part of the thin filament of the myocyte contractile apparatus (in addition to actin and tropomyosin); three subunits have been identified: (1) TnI, which binds actin to inhibit actin–myosin interaction; (2) TnT, which binds tropomyosin; and (3) TnC, which binds calcium ions resulting in a conformational change in the troponin–tropomyosin complex thus exposing myosin-binding sites. The cardiac isoforms, cTnI and cTnT, are specific to the heart and can be measured in the blood after myocyte necrosis with 50% release by 4 hours,

peaking at 12–24 hours and remaining elevated for up to 10 days. They are far more sensitive than traditional cardiac enzyme tests, such as creatine kinase, and have substantially changed the definition, diagnosis and management of acute myocardial infarction (AMI). Cardiac troponins may be released in conditions other than acute coronary ischaemia,[35] such as sepsis, and after chemotherapy, and in the absence of evidence of myocardial necrosis, as in AHF or major PE, where it is believed that the acute ventricular dilation causes increased membrane permeability. Raised troponin levels are also associated with increased morbidity and mortality in surgical ICU patients[36–38] and in patients presenting with acute decompensated heart failure.[39,40]

Elevated levels of cardiac troponins, BNP and NT-proBNP, may also be detected in the presence of RV dysfunction following an acute PE.[41] They can be used to risk stratify patients owing to their high negative predictive value for in-hospital death and adverse events. In haemodynamically stable patients, normal values indicate a lower risk of adverse outcome; therefore, less aggressive therapy may be warranted.[42–44]

Raised levels of these markers, indicating early myocardial stress, may have an important role in alerting the clinician to impending myocardial failure and the need to review the use of drugs that stimulate the myocardium, and to consider the introduction of a beta-blocker, particularly in the context of tachycardia.

It should be remembered that, for critically ill patients with AHF not resulting from primary myocardial infarction, if the precipitating cause is successfully treated without significant myocardial necrosis occurring the AHF will resolve, cardiac function will return to its premorbid state and the prognosis will be improved.

The remainder of this chapter addresses the assessment and principles of management of ventricular function in patients admitted to critical care with AHF.

CIRCULATORY FAILURE OR 'SHOCK'

The principal function of the heart is the generation of the energy necessary to perfuse the lungs with venous blood and to propel the oxygenated arterial blood through the systemic circulation at a rate and pressure that ensure that the fluctuating metabolic requirements of the various organs are met at rest and during exercise. This should be performed at maximum efficiency so that the work performed is not at the cost of unnecessarily high myocardial energy expenditure and the risk of myocardial ischaemia is minimised.

Failure to maintain an adequate oxygen supply to the tissues with the consequent development of anaerobic cellular metabolism defines circulatory failure or 'shock', a term that benefits from brevity but little else since it implies neither cause nor prognosis, but its use is now widespread and inescapable. Box 24.2 classifies circulatory 'shock'.

Box 24.2 Major categories of circulatory failure or 'shock'

- Cardiogenic – myocardial infarction, myocarditis, vasculitis, valve dysfunction (e.g. critical aortic stenosis, mitral regurgitation, acute endocarditis), post-cardiac-bypass surgery, drug overdose (beta-blockers, calcium antagonists)
- Hypovolaemic – haemorrhage, burns, gastrointestinal fluid loss
- Obstructive – pulmonary embolus, cardiac tamponade, tension pneumothorax
- Anaphylactic – drugs, blood transfusion, insect sting
- Septic – bacterial infection, non-infective inflammatory conditions (e.g. pancreatitis, burns, trauma)
- Neurogenic – intracranial haemorrhage, brainstem compression, spinal cord injury

In considering these causes of circulatory failure, several points require emphasis:

1. AHF resulting in CS is not a pathological diagnosis but a collective term that embraces all causes of myocardial failure. Treatment must focus on the underlying diagnosis.
2. Patients admitted to critical care may have AHF either as the primary reason for admission (e.g. following AMI), or develop it as part of multiple-organ failure triggered by an extra-cardiac cause, which is frequently the delayed or ineffective treatment of severe sepsis.
3. Pre-existing cardiac disease, usually ischaemic heart disease, is an important factor in determining the physiological response to critical illness. Several studies investigating the effect of manipulating oxygen delivery have demonstrated the poor prognosis associated with the inability of the heart to achieve a hyperdynamic response to critical illness either spontaneously or with volume loading and inotropic support.[9,10] Preoperative assessment with cardiopulmonary exercise testing is probably appropriate for all patients undergoing major surgery as a means of identifying those with poor physiological reserve so that the true risk of surgery can be identified and perioperative management planned accordingly.
4. Although hypotension is often considered to be the cardinal sign of circulatory failure, other global features (persistent tachycardia, confusion, tachypnoea, impaired peripheral perfusion, progressive metabolic acidaemia) occur earlier since the body has powerful homeostatic mechanisms that maintain pressure at the expense of flow.
5. The heart must provide its own blood supply, and if coronary blood flow does not match myocardial oxygen requirements coronary ischaemia develops, and cardiac and global circulatory failure may ensue.[45]

6. The primary problem in hypovolaemic, cardiogenic and obstructive shock is a progressive decline in CO and global oxygen delivery, which, if not corrected, leads to secondary failure of the peripheral circulation and progressive organ dysfunction. In septic, anaphylactic and neurogenic shock, however, the primary problem is the loss of control of the peripheral circulation resulting in systemic hypotension and disordered distribution of blood flow, although CO and global oxygen delivery are usually increased.[46]
7. Although a primary cause for the circulatory failure may be identified, other causes may contribute to the evolution of the final pathology. For example, in septic shock the initial and major derangement is peripheral; it is characterised by microcirculatory chaos triggered by cytokine release, white-cell activation, disruption of the coagulation cascade resulting in microthrombi that occlude the microvasculature and endothelial disruption resulting in interstitial oedema. This same process occurs in the coronary microvasculature impairing myocyte function. There is also widespread loss of fluid from the intravascular to the extravascular space, resulting in hypovolaemia. The primary peripheral circulatory failure may therefore be compounded by both cardiogenic and hypovolaemic shock.
8. '*Early*' and '*late*' shock are terms that reflect the association between the duration and severity of the circulatory derangement and prognosis. Early intervention in circulatory shock has a major impact on survival.[47,48] If treatment is delayed until organ failure is established, the underlying pathological processes are frequently irreversible.
9. Although not a true 'mixed' venous sample, the oxygen saturation of blood ($S_{cv}O_2$) taken from an internal jugular or subclavian central venous catheter has been shown to be valuable in assessing whether global oxygen delivery is adequate for global tissue oxygen consumption. A value less than 70% should prompt consideration of whether a fluid challenge or other strategy to increase global oxygen delivery is indicated. A value greater than 70% is not necessarily reassuring in patients with established hyperdynamic shock as this may reflect an inability of the tissues to extract and utilise oxygen. However, the use of $S_{cv}O_2$ to guide resuscitation in early shock states has more recently been shown not to improve outcomes; thus, assessing the trend of this surrogate marker may be a more sensible approach.[49–51]

ASSESSMENT OF VENTRICULAR FUNCTION

Making the considerable assumption that the circulation can be analysed as a constant-flow fixed-compliance system, six key measurements traditionally define ventricular performance:

- right and left atrial pressures (RAP, LAP) or ventricular preload
- mean systemic and pulmonary arterial pressures (MAP, PAP) or ventricular afterload
- heart rate (HR)
- CO

Table 24.1 illustrates typical values in normal subjects and in the common causes of circulatory failure with the calculation of the associated vascular resistances and oxygen delivery. The values quoted are merely examples that indicate the pattern of circulatory derangement produced by these pathologies: pre-existing cardiopulmonary disease and the severity of the condition will affect the precise figures obtained in individual cases and the response to vasoactive therapy.

Stroke volume (SV) is calculated from CO and HR:

$$SV = CO/HR \quad (24.1)$$

Three factors determine stroke volume: (1) preload, (2) afterload, and (3) myocardial contractility.

VENTRICULAR PRELOAD

Ventricular preload, traditionally assessed from atrial filling pressures, determines the end-diastolic ventricular volume, which, according to Starling's law of the heart, and depending on ventricular contractility, dictates the stroke work generated by each ventricle at the next cardiac contraction. The resulting stroke volume depends on the resistance or afterload that confronts the ventricle.[52]

On the general ward, the jugular venous pressure is measured from the sternal angle; however, in ICU, vascular pressures are measured from the mid-axillary line in the fifth intercostal space. From this reference point, in the supine position, the normal RAP is between 2 and 6 mm Hg, but it has also been shown to approximate to zero,[53] and the LAP is between 4 and 12 mm Hg. Relative changes in either the contractility of the two ventricles or the respective vascular resistances will change the relationship between the atrial pressures, which must then be independently assessed.

The predominant factor determining preload is venous return, which depends on the intravascular volume and venous tone, which is controlled by the autonomic nervous system, circulating catecholamine levels and local factors, particularly PO_2, PCO_2 and pH.

The systemic venous bed is the major intravascular capacitance or reservoir of the circulation with a compliance that can vary from 30 to over 300 mL/mm Hg and which provides a buffer against the effects of intravascular volume loss. It also explains the response observed in major haemorrhage and subsequent transfusion. As volume is lost, venous tone increases, preventing the large falls in atrial filling pressures and

Table 24.1 Measurements in a normal 75 kg adult and in various conditions causing circulatory 'shock'

	RAP (mm Hg)	LAP (mm Hg)	mPAP (mm Hg)	MAP (mm Hg)	HR (beats per minute)	CARDIAC OUTPUT (L/min)	SVR*	PVR*	STROKE WORK (g.m) LV	STROKE WORK (g.m) RV	VENOUS COMPLIANCE (mL/mm Hg)	CaO_2 (mL/100 mL)	DO_2 (mL/min)

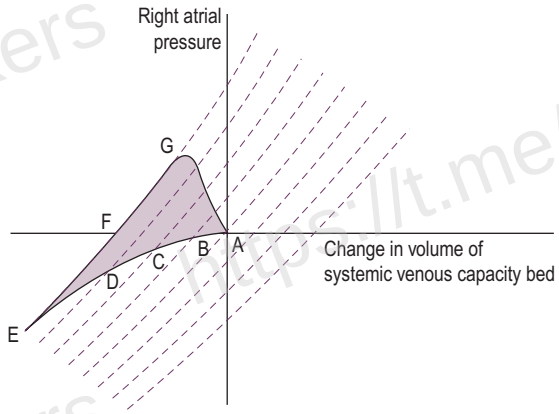

Figure 24.2 Venous compliance curves: each *dotted line* represents a line of constant venous compliance ranging from low compliance (increased tone) on the left to increased compliance (reduced tone) on the right. Line ABCDE shows the effect of progressive haemorrhage with the reduction in venous compliance limiting the fall in atrial pressure. Line EFGA shows the effect of rapid reinfusion of the same volume that was removed, but at a rate that does not allow the sympathetically mediated increase in venous tone to abate. Each dotted line represents a line of constant venous compliance ranging from minimum on the left to diminished venous tone on the right.

CO that would otherwise occur. If the equivalent volume is returned over the subsequent few hours, the RAP gradually returns to normal as the intravascular volume is restored and the reflex increase in sympathetic tone abates. However, rapid re-infusion of the same volume does not allow sufficient time for the venous and arteriolar tone to fall and may result in the LAP rising to a level that precipitates pulmonary oedema, although the intravascular volume has only been returned to the pre-haemorrhage level and LV function is normal (Fig. 24.2).

If the preload is low and either blood pressure or CO is inadequate, the priority is volume loading to restore intravascular volume and venous return.

Raised preload pressures reflect: (1) high intravascular volume, (2) impaired myocardial contractility, or (3) increased afterload.

Preload may be reduced by:

- removing volume from the circulation (diuretics, venesection, haemofiltration[54,55]) or increasing the capacity of the vascular bed with venodilator therapy (e.g. glyceryl trinitrate, morphine[56]). Caution is advised with the use of morphine in this regard as the deleterious effects on respiratory and cognitive function can offset useful vasodilation[57]
- improving contractility
- reducing afterload.[55,58]

In assessing preload, end-diastolic volume rather than pressure is relevant and when interpreting atrial

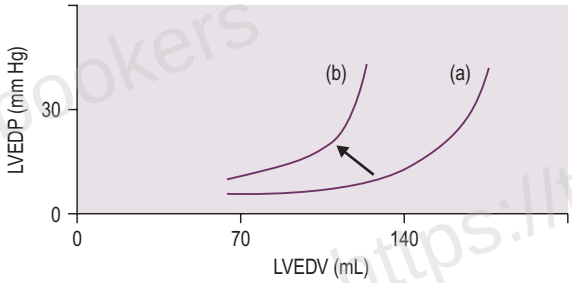

Figure 24.3 End-diastolic pressure-volume relationship (EDPVR) curves: (a) normal heart; (b) diastolic dysfunction. In the context of reduced ventricular compliance the EDPVR curve shifts upward and to the left. *LVEDP*, Left ventricular end-diastolic pressure; *LVEDV*, left ventricular end-diastolic volume. *Modified from Brandis K. The physiology viva.*

pressures as measures of preload, two points must be considered:

1. Intravascular pressure (*P*v) measurements are misleading if the intrathoracic pressure (*P*t) is raised since the true distending pressure that determines ventricular end-diastolic volume is the transmural pressure (*P*v–*P*t). This is particularly relevant if there is significant alveolar gas trapping generating intrinsic positive end-expiratory pressure (PEEP), as seen in asthma; in positive-pressure ventilation with high PEEP levels; and when an inverse inspiratory-to-expiratory time ratio is used.[59,60]
2. When the ventricle is poorly compliant, as in diastolic dysfunction, the end-diastolic pressure–volume relationship ceases to exhibit the approximately linear relationship over the normal physiological range of ventricular filling volumes (Fig. 24.3). Under these conditions, pressure will not necessarily reflect the adequacy of volume preload.

VENTRICULAR AFTERLOAD

The vascular resistance against which each ventricle works is calculated, by analogy with Ohm's law, as the pressure gradient across the vascular bed divided by the CO (Box 24.3).

Circulatory management requires a clear understanding of this relationship between pressure, flow and resistance. If ventricular work is constant, increased vascular resistances produce higher pressures but with a lower CO. A systemic dilator such as sodium nitroprusside will reduce systemic resistance and blood pressure and increase CO. Although such manipulation is attractive in increasing CO for the same cardiac work, it is important to maintain a blood pressure that ensures appropriate distribution of blood flow and a diastolic pressure sufficient to maintain coronary artery perfusion, particularly in patients

Box 24.3 Calculation of ventricular afterload and stroke work

Systemic vascular resistance (SVR) = [(MAP – RAP)/CO] × 80 dyn.s.cm^{-5}
= [(90 – 5)/5] × 80 = 1360 dyn.s.cm^{-5}
SVRI = SVR × BSA = 1360 × 1.65 = 2244 dyn.s.cm^{-5}.m^{-2}
Pulmonary vascular resistance (PVR) = [(mPAP – LAP)/CO] × 80 dyn.s.cm^{-5}
= [(15 – 10)/5] × 80 = 80 dyn.s.cm^{-5}
PVRI = PVR × BSA = 80 × 1.65 = 132 dyn.s.cm^{-5}.m^{-2}
Stroke volume (SV) = CO/HR = 72 mL
Stroke volume index (SVI) = 72/1.65 = 44 mL/m^2
Ventricular stroke work (VSW) = SV × (afterload – preload)
LVSW = SV × (MAP – LAP) × 0.0136 g.m
= 72 × (90 – 10) × 0.0136 = 78 g.m
LVSWI = 78/1.65 = 47 g.m/m^2
RVSW = SV × (mPAP – RAP) × 0.0136 g.m
= 72 × (15 – 5) × 0.0136 = 10 g.m
RVSWI = 10/1.65 = 6 g.m/m^2

Pressures are measured in mm Hg, CO in L/min. Values for resistance and stroke work are frequently indexed using the patient's BSA derived from height and weight. In calculating ventricular stroke work, 0.0136 converts to SI units of g.m. Example calculations assume a normal 75 kg individual with BSA 1.65 m^2.

with known ischaemic heart disease or pre-existing hypertension.

The effects of some of the commonly used vasoactive agents are shown in Table 24.2.

VENTRICULAR CONTRACTILITY AND EFFICIENCY

The work that the ventricle performs under given loading conditions defines contractility. For each ventricle it may be expressed mathematically as the gradient and intercept of the relationship between atrial filling pressure and stroke work (Fig. 24.4). The resulting stroke volume varies with the resistance of the vascular bed into which the ventricle is ejecting. Although the RV generates a much smaller stroke work, the afterload (pulmonary vascular resistance, PVR) against which it ejects is correspondingly lower as the RV and LV stroke volumes must necessarily be the same over time.

The work generated by each ventricle with each heart beat is the ventricular stroke work and is calculated as shown in Box 24.3.

Consideration of ventricular work is important since optimum circulatory management requires that the necessary pressures and flows to maintain satisfactory organ perfusion and oxygen delivery are achieved at maximum cardiac efficiency (i.e. for the minimum ventricular work to avoid myocardial ischaemia). Furthermore, LV efficiency is the ratio of work output to energy input and may be less than 20% in patients with AHF, with over 80% of energy lost as heat.

If circulatory failure is due to impaired myocardial contractility, as defined by a 'flattened' stroke work/filling pressure equation (see Fig. 24.4), the atrial pressures will often already be raised. Provided such pressures reflect volume preload, further increases are not helpful since the ventricle becomes increasingly distended with high wall tension, as predicted by Laplace's law:

$$(24.2)\ \text{wall tension} = (\text{intraventricular pressure} \times \text{radius}) \div (\text{wall thickness} \times 2)$$

This increase in wall tension compromises myocardial blood supply, particularly epicardial to endocardial blood flow, resulting in endocardial ischaemia, further impairment of ventricular contractility and the risk of pulmonary oedema developing.

The remaining therapeutic options are:

- *Reduce afterload* using an arteriolar dilator (nitrates, alpha-blockers, phosphodiesterase-3 [PDE-3] inhibitors, angiotensin-converting enzyme [ACE] inhibitors), although this strategy is frequently limited by the resulting fall in systemic pressure.[61]
- *Increase myocardial contractility*, either by removing negatively inotropic influences (acidaemia, hyperkalaemia, drugs; e.g. beta-blockers) or by using a positive inotropic agent, which may be defined as an agent that increases the gradient of the stroke work to filling pressure relationship, resulting in a larger stroke volume for the same preload and afterload pressures. When considering the use of an inotropic agent (see Table 24.2), the adverse effects of vasoactive agents on ventricular efficiency, metabolic rate and regional distribution of flow should be considered.

Table 24.2 Circulatory effects of commonly used vasoactive drug infusions

DRUG	RECEPTORS/ MECHANISM OF ACTION	CARDIAC CONTRACTILITY	HEART RATE	BLOOD PRESSURE	CARDIAC OUTPUT	SPLANCHNIC BLOOD FLOW	SVR	PVR

HEART RATE AND RHYTHM

In cardiac failure, the stroke volume is usually constant for rates up to 100/min and thereafter falls as restriction of diastolic filling time limits end-diastolic volume. Increasing the HR from 70 to 90/min will increase CO by almost 30%. Achieving this with a chronotrope such as the beta$_1$-agonist isoprenaline increases myocardial work and oxygen consumption and also ventricular irritability. In patients with ischaemic heart disease and particularly after an AMI, atrial or atrioventricular sequential pacing (which maintains coordinated atrial contraction in heart block) improves haemodynamics without stimulating myocardial metabolism and increasing myocardial irritability.[62]

HRs above 110/min, particularly with an irregular rhythm, should be controlled by either drugs or DC cardioversion after ensuring that plasma potassium and magnesium levels have been corrected. If the rhythm is supraventricular and unstable with intermittent periods of sinus rhythm, pharmacological control is indicated using either digoxin or amiodarone. Digoxin is appropriate for AF and has a temporary positive inotropic effect.[63] However, amiodarone is suitable for all supraventricular rhythms and is more likely to restore sinus rhythm. A meta-analysis showed that, used prophylactically, it reduced the rate of arrhythmic episodes and sudden death in patients with recent myocardial infarction or congestive cardiac failure.[64] However, it is a negative inotrope and this can be significant in the patient with severe heart failure.

A fixed rate of 150/min suggests atrial flutter and should prompt careful inspection of the ECG and a trial of adenosine. A persistent sinus tachycardia unexplained by fever may be due to hypovolaemia, pain or anxiety.

ASSESSMENT OF MYOCARDIAL FUNCTION

Of the six key circulatory variables that define ventricular function, three (RAP, MAP and HR) can be assessed clinically and are routinely monitored in ICU patients. However, additional monitoring, traditionally using the PA catheter, is required to measure the

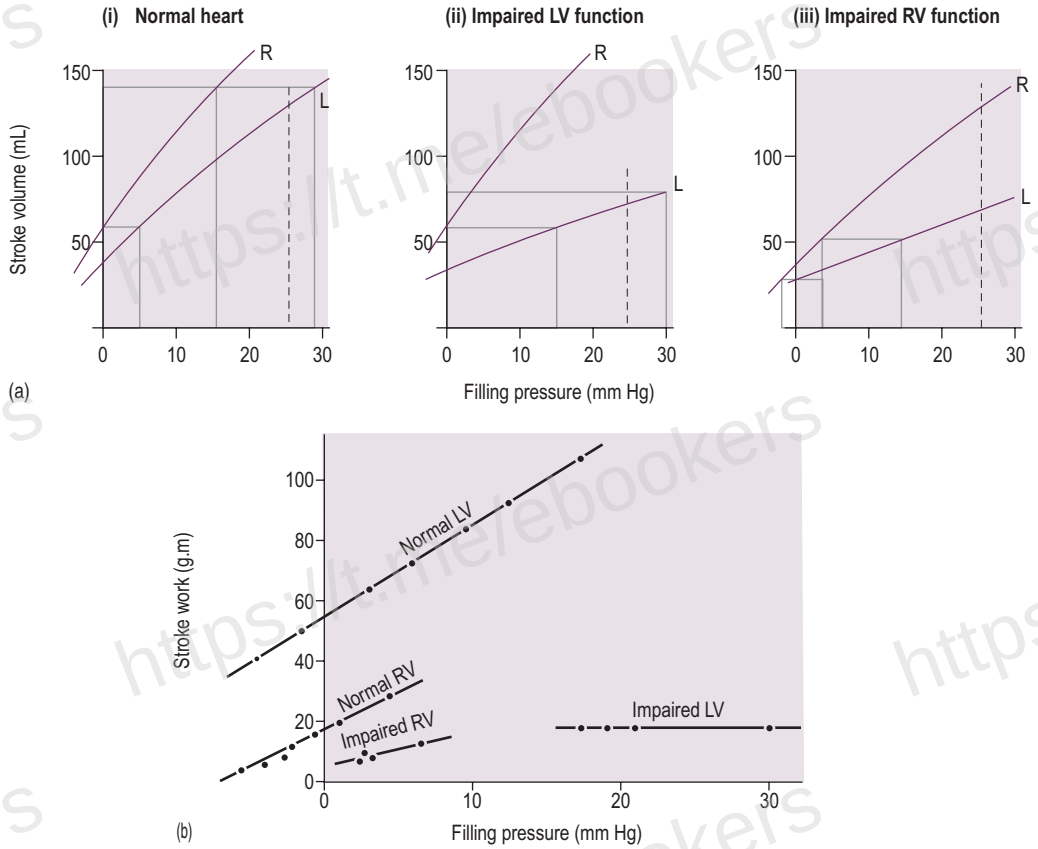

Figure 24.4 Ventricular function curves: (a) relationship between stroke volume (mL) and atrial filling pressure for left (L) and right (R) ventricles in patients with normal and impaired ventricular function; (b) relationship between stroke work (g.m.) and atrial filling pressure (in mm Hg) for the left (L) and right (R) ventricles for a normal subject and a patient with severe left and right ventricular failure.

other three variables (LAP, PAP and CO) in order to answer the following questions:

1. Is further intravascular volume indicated?
2. Is CO too low and compromising global oxygen delivery?
3. Is dilator, constrictor or inotropic therapy appropriate?

It is certainly not always necessary to use invasive monitoring. Initial management can be based on clinical assessment of intravascular volume and CO. The discipline of committing to an estimate of these key variables ensures that both the analysis of the circulation and the approach to treatment are logical. Further monitoring should be instituted if the initial management does not produce clinical improvement. Alternative, less invasive methods are available for assessing CO such as oesophageal Doppler,[65,66] lithium dilution (LiDCO),[67] transpulmonary thermodilution with pulse contour analysis,(PiCCO)[68] arterial pressure waveform analysis[69–71] and echocardiography[21,72] – techniques that can also provide data on the volume rather than pressure preload of the LV, in addition to dynamic measures of CO. Table 24.3 lists some features of the techniques available for measuring CO and whether they provide information on LV preload. Further details of circulatory monitoring and these other techniques are described in the chapter on haemodynamic monitoring (see Chapter 16). A recent international consensus produced guidelines for the diagnosis, treatment and monitoring of patients with shock.[73]

KEY POINTS WHEN ASSESSING CARDIAC FUNCTION

- Pressure is no guarantee of flow.
- Trends and changes are more important than a single observation.
- Dynamic tests (e.g. assessing stroke volume response or a change in pulse pressure or stroke volume variation to a fluid challenge) are more revealing than static tests (e.g. central venous pressure, MAP).
- Monitoring devices may be complex with many potential sources of error (e.g. 'blocked' catheters,

Table 24.3 Comparison of methods for assessing cardiac output

failure to re-level the transducer after a change in the patient's position). Readings should always be interpreted with care and in conjunction with clinical assessment.

- Invasive monitoring has its own hazards (infection, trauma, immobility) and should be removed if no longer required.

PULMONARY ARTERY CATHETERISATION

This remains a widely used method for measurement of LAP and PAP, and assessment of CO using a pulmonary thermodilution technique. Although generally viewed as the 'gold standard' for determining CO, the error is at least 10%, even with fastidious attention to technical detail.[74]

Inflation of the balloon at the end of the catheter provides a PA occlusion pressure (or pulmonary capillary wedge pressure), which reflects LAP provided there are no significant pulmonary vascular bed abnormalities, as occur in chronic obstructive pulmonary disease and long-standing mitral valve disease. Despite obtaining a good-quality wedge tracing, the measurement must be interpreted with caution since increased intrathoracic pressure and diastolic dysfunction make this pressure measurement an unreliable index of true LV volume preload.

The focus on 'goal-directed therapy' led to the widespread use of PA catheters, but their indiscriminate use was challenged by a multicentre case-controlled study, which suggested that patients managed with a PA catheter had a poorer outcome than those managed without such intervention.[75,76] This study probably reflected the enthusiasm for inappropriate goal-directed therapy prevalent at that time, poor training in the use of the catheter and an inability of clinicians to respond appropriately to the data obtained.[77] More recent evidence suggests neither harm nor benefit with the use of a PA catheter and a risk–benefit assessment should be made on an individual patient basis prior to its use.[76,78]

Box 24.4 lists the indications for PA catheterisation in heart failure.

ASSESSMENT OF INTRAVASCULAR VOLUME STATUS

CLINICAL

This is conventionally based on measurement of the right atrial filling pressure and the assumption that a normal relationship exists between the atrial filling pressures, which is not necessarily valid in the critically ill patient particularly in CS. Although values less than 12 mm Hg suggest hypovolaemia, higher levels are more difficult to interpret, particularly in the ventilated patient. The RAP should therefore be interpreted carefully and in light of other clinical evidence. However, such static tests for assessing the intravascular volume are less valuable than dynamic tests, such

Box 24.4 Indications for pulmonary arterial catheterisation in patients with heart failure

- Failure to improve with initial circulatory management and uncertainty about adequacy of cardiac output and relationship between atrial filling pressures
- Assessment of left ventricular preload when the relationship between right and left atrial pressures is uncertain owing to recent myocardial infarction, valvular abnormalities or high pulmonary vascular resistance. A low wedge pressure indicates that further volume is indicated, but a high value does not necessarily exclude the need for further volume
- Measurement of cardiac output by thermodilution to direct appropriate choice of vasoactive drug and to manipulate therapy, particularly when high doses are being used
- Need to monitor pulmonary arterial pressures and assess right ventricular function

as the fluid challenge[79,80] and the effect of positive-pressure ventilation,[81–84] which assess the circulatory response to an intervention.

Intravascular volume depletion is suggested if hypotension is precipitated by sedation, analgesia and postural change. In the patient receiving positive-pressure ventilation, respiratory fluctuation in the arterial pressure tracing also suggests relative hypovolaemia. This is confirmed if brief disconnection from the ventilator causes the blood pressure to rise and venous pressure to fall; the measurement off the ventilator more accurately reflects the ventricular end-diastolic transmural pressure. This manoeuvre is relatively contraindicated in patients with severe respiratory failure as loss of PEEP may cause widespread alveolar collapse.

FLUID CHALLENGE

If hypovolaemia is suspected, a fluid challenge should be administered and the impact on blood pressure, flow and preload observed. In the volume-depleted patient, blood pressure and flow will increase with only a small, transient increase in filling pressure. While pulmonary gas exchange and overall fluid balance remain satisfactory, there is less anxiety about giving further fluid. Sufficient volume will have been given when either the target pressures are achieved and the evidence of poor peripheral perfusion and organ dysfunction has resolved, or when there is a sustained rise in filling pressures to a level above which there is a risk of pulmonary oedema developing. An objective assessment of the effect of such a fluid challenge can also be made by looking for a ≥10% rise in stroke volume. Caution is warranted with this approach; higher rates of critical care admission, requirement for organ support and increased mortality have been shown with as little as 1 L fluid administration administered early in the course of hospital admission for AHF, compared to diuretic treatment alone.[85]

Deciding the appropriate fluid volume to give in sepsis can be difficult and frequently represents a balance between giving sufficient volume to prevent the use of excessive doses of constricting inotropes and giving excessive amounts with consequent tissue oedema and deterioration in pulmonary gas exchange.

If there is concern about administering a fluid challenge, an assessment of fluid responsiveness in critically ill patients can be made using a passive leg raising test[86,87]; this results in a 'reversible' fluid challenge, as ~300 mL venous blood from the lower body is diverted towards the right heart.

VALSALVA MANOEUVRE

The effect of changes in intrathoracic pressure can be used to assess intrathoracic blood volume and provide an estimate of true LV preload. Fig. 24.5 shows the classic Valsalva response in a normal subject and in a patient with a high intrathoracic blood volume. If a normal-type trace is observed on the monitor, further volume is indicated, whereas a square-wave response indicates an adequate LV volume preload.[88] This response can be quantified by calculating the ratio of the pulse pressure during phase 2 of the manoeuvre to the baseline value. This correlates with measurements of pulmonary capillary wedge pressure[89] and can be applied at the bedside in sedated, ventilated patients.[90] However, if the patient is breathing spontaneously, this test is difficult both to perform and to interpret.

ECHOCARDIOGRAPHY

Echocardiography is useful in identifying inadequate volume preload and the need for further fluid resuscitation, particularly when the preload pressures are high, as may occur with diastolic dysfunction. Performing serial studies to assess the response to therapy (fluid challenge, starting vasoactive therapy, changing ventilator settings) can be particularly valuable.

MANAGEMENT OF CARDIAC FUNCTION IN THE CRITICALLY ILL

Circulatory management should be regularly reviewed in the critically ill patient. Following initial assessment and with knowledge of the primary diagnosis, the need for extra monitoring should be decided, provisional targets should be set for fluid balance, central venous saturation ($S_{cv}O2$), mean and diastolic arterial pressures and a management plan agreed on how to achieve these goals. Generally, a MAP of 60–65 mm Hg with a diastolic pressure greater than 50 mm Hg is acceptable, but adequate cerebral, coronary, splanchnic and renal perfusion may require higher pressures,

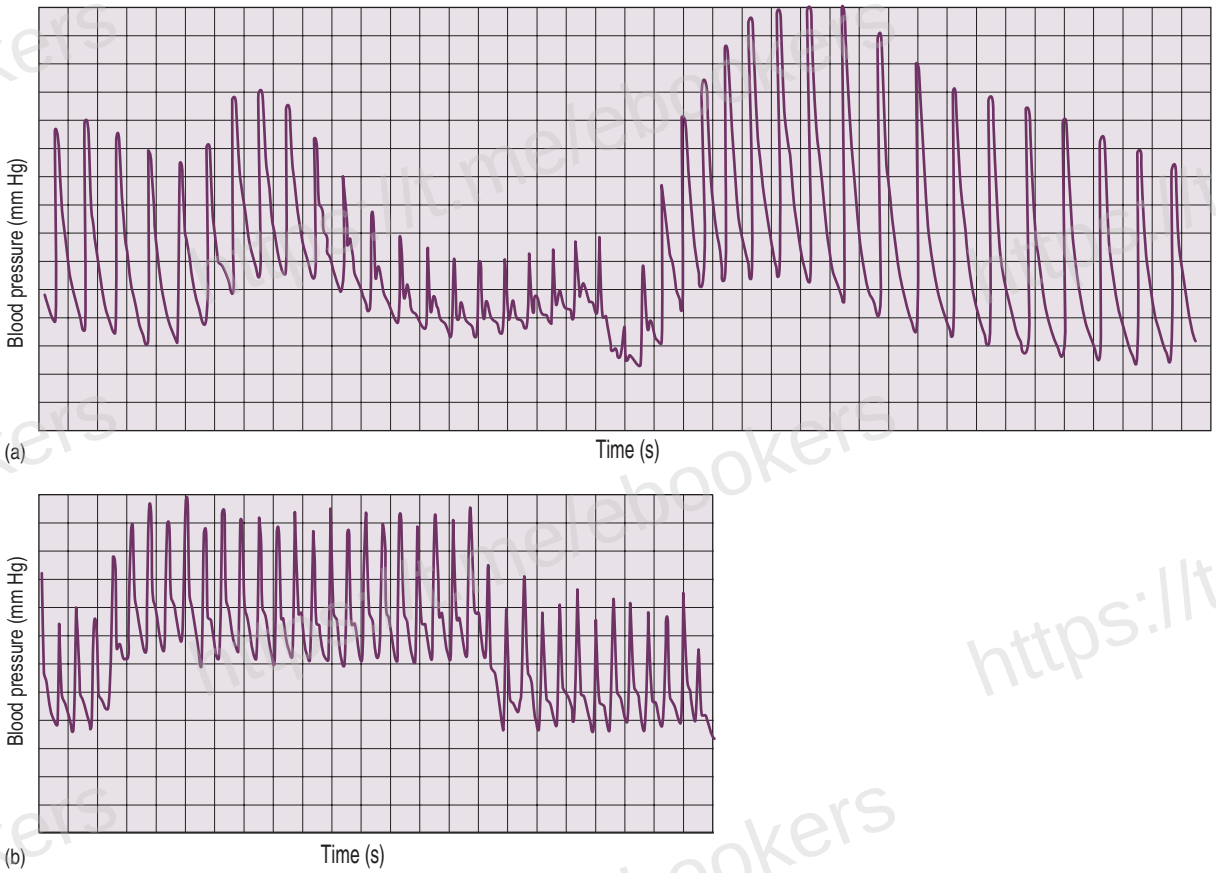

Figure 24.5 Valsalva traces (arterial waveforms): the Valsalva manoeuvre is performed by applying a pressure of at least 30 mm Hg (judged from an RA trace) for 12–15 seconds. (a) Normal pulse pressure response. (b) Square-wave pulse pressure response.

particularly in the elderly patient with pre-existing hypertension or widespread atheromatous disease.

CORRECTION OF METABOLIC FACTORS

The following metabolic factors should be promptly corrected:

- *hypoxaemia:* PO_2 <8 kPa
- *acidaemia:* pH <7.35
- *hyperkalaemia:* K^+ >5.5 mmol/L
- *hypomagnesaemia:* Mg^{2+} <0.9 mmol/L
- *hypocalcaemia:* ionised Ca^{2+} <1.0 mmol/L
- *hypophosphataemia:* PO_4^- <0.8 mmol/L
- *anaemia:* Hb <80 g/L
- *thiamine (vitamin B1) deficiency:* malnutrition, chronic alcohol use, diuretic or digoxin treatment.

A pH <7.35 and a negative base excess should be promptly corrected since myocardial contractility may be significantly reduced in the presence of a metabolic acidaemia. The suggestion that sodium bicarbonate should not be used as it produces a damaging paradoxical intracellular acidosis is misleading since the experiments demonstrating this effect were performed in vitro using non-physiological solutions, within a closed system that allowed no correction for any rise in carbon dioxide concentration and in which the sodium bicarbonate was given by bolus rather than by slow infusion.[91] The case for using bicarbonate to correct a metabolic acidaemia in the clinical setting has been recognised[92] and is supported by studies looking at the use of bicarbonate rather than lactate as the buffer solution in haemofiltration.[93] Fig. 24.6 shows the effect of correcting a severe metabolic acidaemia on CO by changing from lactate to bicarbonate haemofiltration.

Although a prospective, randomised study demonstrated an improved survival for critically patients if haemoglobin concentration was maintained at 70–90 g/L rather than at 100–120 g/L, this did not apply to the elderly and those with co-existing cardiovascular disease in whom the haemoglobin level should probably be maintained greater than 80 g/L.[94,95]

Patients with poor dietary thiamine (vitamin B1) intake, chronic alcohol use and those on chronic

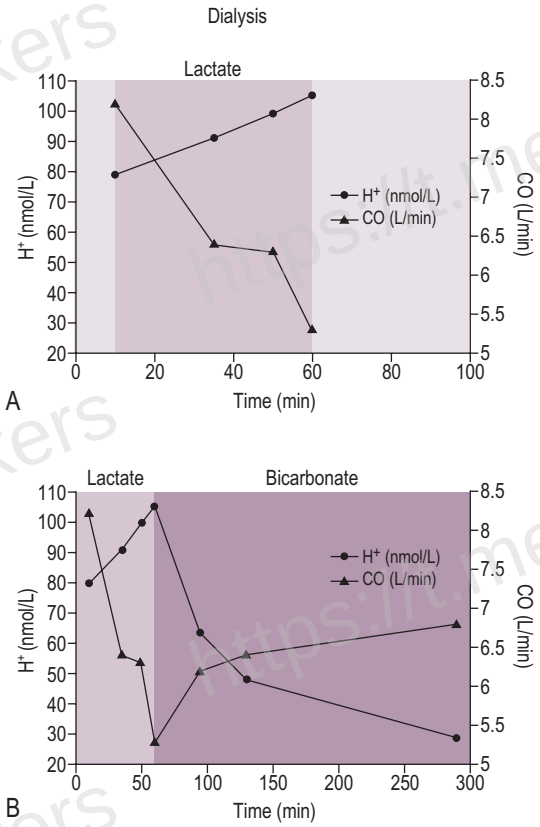

Figure 24.6 Effect of dialysis: (a) rising hydrogen ions and falling CO with lactate buffer dialysis; (b) change to bicarbonate buffer – there is falling hydrogen ion concentration and a rising CO.

furosemide or digoxin therapy are at risk of thiamine deficiency, resulting in impaired myocardial function. Oral thiamine improves LV function in these patients.[96,97]

SELECTION OF APPROPRIATE VASOACTIVE AGENTS

The choice of vasoactive agent when treating AHF represents a balance between the global circulatory requirements and those of a stressed myocardium. The properties of commonly used agents are shown in Table 24.2.

The impact of these drugs in individual patients will be influenced by the baseline state of the circulation; that is, if either intensely constricted or dilated, the same drug will potentially produce different effects on pressure, flow and its distribution. The initial choice of vasoactive agent will depend on the MAP, CO and derived systemic vascular resistance (SVR). For example:

- *CO and MAP are both low with a high SVR:* an inotropic and dilating (inodilator) effect is required and dobutamine or milrinone would be appropriate. Levosimendan would also be a suitable choice in this setting. If CO rises but MAP falls, as may happen with dobutamine, milrinone and levosimendan, and a more powerful inotropic effect is required, epinephrine may be appropriate. However, increasing doses of epinephrine risk myocardial ischaemia, ventricular irritability, splanchnic ischaemia and the development of hyperlactataemia.[98] Consequently, it may be more appropriate to use norepinephrine to maintain MAP when inodilating drugs are being administered.
- *MAP and SVR are low with high CO:* this is frequently seen in sepsis: arteriolar constriction with norepinephrine is indicated after adequate volume resuscitation.
- *MAP is at or above target but CO is low with raised SVR:* a dilating agent (e.g. glyceryl trinitrate) or an inodilator is appropriate.

When PVR and RAP are acutely raised, a pulmonary vasodilator to offload the RV and maintain CO is required but hypotension may result from concomitant systemic arteriolar dilation and hypoxaemia can develop owing to increased ventilation–perfusion mismatch.

Dopamine has been widely used in the erroneous belief that it selectively improves renal blood flow.[99] A recent randomised controlled trial demonstrated a greater number of adverse events with the use of dopamine compared with norepinephrine in patients with shock. Moreover, in a predefined subgroup of patients with CS mortality was higher in patients treated with dopamine.[100]

Dopexamine is used to improve splanchnic blood flow but, despite reported benefits when used with volume loading in perioperative patients,[101,102] there is little evidence of outcome benefit in established shock.

Patients with CHF and those receiving long-term beta-agonist infusion often develop tolerance with reduced catecholamine receptor responsiveness, resulting in less effect in raising intracellular cyclic adenosine monophosphate (cAMP) levels and increasing myocardial contractility. PDE-3 inhibitors (milrinone, enoximone) offer an alternative strategy. Milrinone competitively inhibits the PDE-3 isoenzyme, responsible for the breakdown of cAMP, thereby increasing intracellular cAMP levels and improving myocardial contractility independent of beta-receptor stimulation. There is also improvement in ventricular diastolic relaxation and a reduction in PVR. However, these agents are powerful vasodilators and hypotension frequently limits their use or requires a norepinephrine infusion.

Levosimendan is an intracellular calcium sensitiser and thus bypasses the receptors through which other inotropic agents act. It binds to and sensitises cTnC to calcium without raising intracellular calcium,

thus improving cardiac performance and contractility during systole without impairing ventricular relaxation during diastole. Administered as a continuous infusion (0.1 µg/kg per minute) over 24 hours, it has a long-lasting, pharmacologically active metabolite, which results in any improvement in myocardial contractility being sustained for several days.[103,104] Levosimendan also causes vasodilation of vascular smooth muscle due to its action on adenosine triphosphate (ATP)-sensitive potassium channels found in the myocardium, peripheral blood vessels and coronary arteries. Consequently, dose-dependent hypotension may occur, although the reduction in preload and afterload and improved coronary blood flow will be beneficial to the failing heart. Furthermore, levosimendan may also have inhibitory effects on PDE-3.[105] In the patient with severe heart failure already on inotropic drugs, treatment should start with a low-dose infusion (0.05 µg/kg per minute) and no loading dose should be given. Levosimendan may be used concomitantly with beta-blockers owing to its site of action, which does not involve beta-adrenergic receptors.[106] Its role in severe acute decompensated heart failure and CS following AMI appears promising.[106–109] However, levosimendan remains unlicensed in several countries worldwide, and the available evidence to date does not consistently confirm a significant mortality benefit.[110–113]

BETA-BLOCKADE

Several studies have demonstrated a reduction in mortality and number of hospitalisations in patients with CHF treated with beta-blockers.[114–116] Furthermore, large studies have demonstrated their benefit early after AMI.[117] Conversely, there is conflicting evidence regarding the perioperative role of beta-blockers, and their use should be limited to high-risk patients in order to minimise adverse events.[118]

Although beta-blockers are usually commenced in stable patients with heart failure, there is good evidence that they may be safely initiated in patients recovering from recent decompensation or in fact continued at a reduced dose during an episode of decompensation.[119,120]

If tachycardia develops or persists during an episode of acute decompensated heart failure, it may be appropriate to consider a trial of a beta-blocker but it is advisable to start with a small dose of a short-acting drug, such as metoprolol or a low-dose esmolol infusion. If this beta-blocker 'challenge' is successful then the beneficial effects will include an increased time for ventricular filling, improved coronary perfusion and reduced myocardial oxygen demand.

MECHANICAL SUPPORT FOR THE HEART

Continuous positive airway pressure (CPAP), non-invasive intermittent positive pressure ventilation (NIPPV) and invasive mechanical ventilation are commonly used to provide support for patients with acute cardiogenic pulmonary oedema. A systematic review concluded that non-invasive ventilation reduced hospital mortality, endotracheal intubation and ICU length of stay.[121] However, a large, randomised controlled trial did not show a mortality benefit with the use of non-invasive ventilation, although the study did show an improvement in symptoms and physiological and metabolic parameters.[122] The benefits result from improved oxygenation and reducing or eliminating the work of breathing, which may account for up to 30% of oxygen consumption.[123] This reduction in oxygen consumption reduces LV workload and alleviates myocardial ischaemia. When instituting invasive mechanical ventilation the clinician must be prepared to give volume and even inotropic or vasopressor support as the sedation and other anaesthetic agents given for intubation will reduce endogenous levels of catecholamines, producing arteriolar and venular dilation and potentially catastrophic hypotension.

Intra-aortic balloon pump (IABP) counterpulsation is physiologically attractive as it reduces afterload, improves coronary and peripheral circulatory perfusion and decreases cardiac work. This results in a more efficient cardiac performance with improvement in both CO and myocardial oxygenation.[124] A common indication for IABP insertion is CS complicating AMI; however, a recent randomised controlled trial has questioned the benefit of the IABP in this setting; the study demonstrated that there was no significant difference in 30-day mortality in the IABP and the no IABP groups.[125] Other indications for IABP support include weaning from cardiopulmonary bypass, high-risk percutaneous coronary intervention (PCI), although current evidence does not support the routine insertion of IABP in this setting,[126] and as a 'bridging therapy' to cardiac transplantation. The main absolute contraindications to IABP insertion are moderate-to-severe aortic regurgitation and aortic dissection, and complications include limb and bowel ischaemia, bleeding and infection.

Extracorporeal membrane oxygenation (ECMO) is a technology that has developed from the cardiopulmonary bypass circuit and in a venoarterial (VA) configuration can provide short-term circulatory support in refractory CS. In this circumstance, VA-ECMO will act as bridge to myocardial recovery, to a ventricular assist device (VAD) or to heart transplantation. VA-ECMO is also used peri-operatively in cardiac surgery and during cardiopulmonary arrest.[127]

VADs are mechanical systems that provide circulatory support for patients with severe AHF and CHF. Support can be provided for the LV, the RV or both. VADs can temporarily take over myocardial function and are usually indicated only if all other treatment options have been explored and an improvement in

myocardial function can be anticipated.[128] VADs are currently used as a 'bridge' to myocardial recovery in AHF following cardiac surgery or recent myocardial infarction, or when there is a realistic prospect of heart transplantation. However, with recent advances in VAD technology a role appears to be emerging for these devices as a 'destination therapy' in patients with end-stage CHF who are not eligible for heart transplantation.[129] Complications associated with VADs can be significant and include device failure, bleeding, infection, thromboembolism and stroke.

CARDIOGENIC SHOCK AFTER ACUTE MYOCARDIAL INFARCTION

The incidence of CS has remained relatively unchanged over recent years, occurring in 5%–10% of patients following AMI, and despite aggressive intervention strategies the mortality rate remains significant in patients in whom shock is present (~50%).[4,130–132] In patients admitted to critical care with CS, the following additional points should be noted:

- The effects of management on myocardial oxygenation must be considered as well as global circulatory targets.
- Although the patient may be ventilated on ICU, therapies demonstrated to improve myocardial salvage must not be overlooked or delayed. Emphasis should be placed on early revascularisation therapy, and patients should undergo urgent coronary angiography to allow PCI if appropriate. The benefits of aspirin are significant if given in the early hours after infarction; if necessary the aspirin can be given rectally. A beta-blocker[117] and an ACE inhibitor[133] should be started as soon as clinically possible but bradycardia, heart block, hypotension and impairment of renal function may cause delay. Once stable, patients with LV dysfunction and heart failure should also be started on an aldosterone receptor antagonist, such as spironolactone[134] or eplerenone.[135,136]
- In patients admitted following an out-of-hospital cardiorespiratory arrest, targeted temperature management has been shown to be beneficial,[137–139] but if planned this should not prevent other interventions, such as primary PCI being performed if appropriate.
- It is important to recognise:
  - RV infarction (ST elevation in lead V_3R and/ or V_4R in patients with inferior ST segment elevation MI (STEMI) is highly specific for RV ischaemia due to a proximal right coronary artery occlusion)[140] since further monitoring may be necessary to ensure appropriate volume loading and to direct therapy to offload the RV.[141]
  - the development of either a ventricular septal defect or mitral regurgitation from papillary rupture as urgent surgery may be indicated.[142]

PULMONARY HYPERTENSION

PH is a frequently encountered pathophysiological disorder in ICU and is associated with high mortality.[143] Box 24.5 summarises the most recent clinical classification of PH.[144,145] The classification splits PH into five diagnostic groups according to underlying cause and therefore likely to have similar treatment strategies. An important distinction to note is that group 1 PH or pulmonary arterial hypertension (PAH), previously known as primary PH, includes a set of disorders where PH is the primary problem. In contrast, all other classification groups are due to conditions that lead to PH as a result of cardiac dysfunction, abnormalities in the lung parenchyma, chest wall abnormalities, or mechanical obstruction of the pulmonary vasculature.

PH is defined as a mean pulmonary arterial pressure (mPAP) greater than or equal to 25 mm Hg on right heart catheterisation while the patient is at rest.[146] In the critical care setting, common pathological conditions leading to PH include severe respiratory failure,[147] acute respiratory distress syndrome (ARDS),[148] left-sided heart failure leading to increased LAP,[149] massive PE,[150] mechanical ventilation,[151] and following cardiac and thoracic surgery.[152] The presence of PH in many of these conditions is associated with increased mortality.[148–150,152] In addition, several factors including sepsis, cardiac arrhythmias, and treatment failure can precipitate acute exacerbations of chronic PAH leading to ICU admissions. Sepsis in these patients is associated with poor outcome.[153]

Several disorders lead to PH in ICU, yet there are no consensus or international guidelines that exist to assist with the management of these patients. Detailed reviews addressing PH[154–156] and PAH[156,157] in the critical care setting fail to make authoritative recommendations, mainly as a result of paucity of data. Therefore management of PH relies on extrapolated data from animal studies, surgical patients, local expertise and biological plausibility of interventions.

PATHOPHYSIOLOGY

An understanding of the pathophysiological changes seen in patients with PH is essential to understand the available treatment strategies and the likelihood of their success. Invariably the most crucial manifestation of PH is RV dysfunction. Under normal conditions RV outflow is to a high-compliance, low-pressure and low-resistance system. The thin-walled RV is highly sensitive to small increases in the PVR leading to ventricular dilation, an increase in end-systolic volume, and reduced RV ejection fraction and pulmonary blood flow. This in turn results in a reduction in CO. In the initial stages the RV responds by enhancing contractility in order to maintain CO.[158] Further increases in RV afterload overwhelm these compensatory mechanisms

Box 24.5 Clinical classification of pulmonary hypertension

1. Pulmonary arterial hypertension (PAH)
   - 1.1 Idiopathic
   - 1.2 Familial
     - 1.2.1 BMPR2
     - 1.2.2 ALK1, endoglin (with or without hereditary haemorrhagic telangiectasia)
     - 1.2.3 Unknown
   - 1.3 Drug and toxin induced
   - 1.4 Associated with:
     - 1.4.1 Connective tissue diseases
     - 1.4.2 HIV infection
     - 1.4.3 Portal hypertension
     - 1.4.4 Congenital heart diseases
     - 1.4.5 Schistosomiasis
     - 1.4.6 Chronic haemolytic anaemia
   - 1.5 Persistent pulmonary hypertension of the newborn

1′. Pulmonary veno-occlusive disease and/or pulmonary capillary haemangiomatosis

2. Pulmonary hypertension due to left heart disease
   - 2.1 Systolic dysfunction
   - 2.2 Diastolic dysfunction
   - 2.3 Valvular disease

3. Pulmonary hypertension due to lung diseases and/or hypoxia
   - 3.1 Chronic obstructive pulmonary disease
   - 3.2 Interstitial lung disease
   - 3.3 Other pulmonary diseases with mixed restrictive and obstructive pattern
   - 3.4 Sleep-disordered breathing
   - 3.5 Alveolar hypoventilation disorders
   - 3.6 Chronic exposure to high altitude
   - 3.7 Developmental abnormalities

4. Chronic thromboembolic pulmonary hypertension

5. Pulmonary hypertension with unclear and/or multifactorial mechanisms
   - 5.1 Haematological disorders: myeloproliferative disorders, splenectomy
   - 5.2 Systemic disorders: sarcoidosis, pulmonary Langerhans cell histiocytosis, lymphangioleiomyomatosis, neurofibromatosis, vasculitis
   - 5.3 Metabolic disorders: glycogen storage disease, Gaucher disease, thyroid disorders
   - 5.4 Others: tumoural obstruction, fibrosing mediastinitis, chronic renal failure on dialysis

ALK1, Activin receptor-like kinase 1 gene; *BMPR2*, bone morphogenetic protein receptor type 2; *HIV*, human immunodeficiency virus; *PAH*, pulmonary arterial hypertension.

Simonneau G, Gatzoulis MA, Adatia I, et al. Updated clinical classification of pulmonary hypertension. *J Am Coll Cardiol*. 2013;62(25 Suppl):D34-D41. Kiely DG, Elliot CA, Sabroe I, Condliffe R. Pulmonary hypertension: diagnosis and management. *BMJ*. 2013;346:f2028.

resulting in reduced CO and systemic circulatory failure. The intimate anatomical relationship of the two ventricles sharing a septum and both being bound by tight pericardial fibres leads to interdependence. In the setting of increased afterload the dilated RV loses its normal shape and pushes the septum towards the LV, thereby compromising LV filling and output.[159,160] RV dilation can also lead to tricuspid regurgitation further lowering CO. In addition to these anatomical considerations, a fall in systemic blood pressure can compromise RV coronary perfusion, thereby leading to ischaemia and further RV dysfunction. Unlike the LV, under normal conditions coronary perfusion to the RV is maintained throughout the cardiac cycle. As RV pressure increases there is a decrease in the perfusion pressure gradient between the aorta and the RV during systole, thereby limiting coronary perfusion mainly to diastole.[161]

ACUTE COR PULMONALE

Acute cor pulmonale (ACP) is caused by acute pressure overload of the RV due to an acute increase in PVR and thus RV afterload. The RV dilates acutely, RV systolic function is impaired and the interventricular septum becomes dyskinetic and displays paradoxical motion.[162,163] ACP is commonly seen in critically ill patients with severe ARDS and following massive PE. The incidence of ACP in severe ARDS was historically reported to be 50%–60%; however this has reduced to 20%–30% following the widespread adoption of lung protective ventilation strategies.[164] The detection of ACP is independently associated with increased mortality in patients with severe ARDS and will ultimately result in acute circulatory failure if it is not managed aggressively.

CLINICAL ASPECTS

Key to the management of patients with PH is diagnosis of the underlying cause and, if feasible, treatment should focus on prompt reversal of precipitating factors. Principles of management include optimising fluid balance (RV preload), reducing RV afterload, maintaining perfusion pressures and improving RV contractility.[154,164] The prone position, as a means to offload the RV, can also be considered.[165] Like most other disorders requiring critical care, the maxim of good ICU care is also applicable to these patients. The discussion that follows looks at treatment strategies specific to PH and the associated RV dysfunction.

MONITORING

The gold standard for diagnosing and monitoring PH in the ICU remains the PA catheter. Invasiveness of the procedure and a lack of evidence supporting a benefit in the general ICU population have meant that the use of the PA catheter has declined in the critical

care setting.[78,166] Furthermore, the use of PA catheters specifically in PH has not been studied. Echocardiography is increasingly being used in ICU and can provide clinicians with much of the information needed to manage such patients. It has the added benefit of being non-invasive and provides information on RV and LV structure and function, pericardial effusions and tricuspid incompetence.[155] However, a recent systematic review found only modest correlation between pulmonary pressures determined by echocardiography and those measured by right heart catheterisation.[167] The virtues of echocardiography in PH in ICU populations have not been studied, and ultimately local expertise is likely to dictate local practice.

MANAGEMENT

The need for adequate oxygenation applies to most critically ill patients but assumes greater importance in PH. RV myocardial oxygen demands are increased in severe PH and hypoxia may increase PVR by precipitating hypoxic pulmonary vasoconstriction. In many cases, mechanical ventilation may be unavoidable; however, it comes at a cost. Positive-pressure ventilation has adverse effects on RV afterload and along with administration of sedatives can further compromise CO. Ventilatory strategies should focus on maintaining adequate oxygenation whilst avoiding high plateau pressures.

Fluid resuscitation of patients with PH is extremely challenging. The RV predominantly relies on adequate filling to maintain CO. Conversely, RV dilation as a consequence of volume overload can lead to impaired RV function and impaired LV filling, due to ventricular interdependence, which results in a reduction in systemic CO.[168] In patients with evidence of RV volume overload and septal bowing, aggressive fluid removal, with diuretics[54] or renal replacement therapy, should be considered as it may improve CO as a consequence of improved LV filling.

The maintenance of sinus rhythm in these patients will improve RV end-diastolic volume and CO. Where possible, cardioversion should be performed in patients with tachyarrhythmias. In those patients where this cannot be achieved, the focus should be on rate control to optimise ventricular filling time.

Vasopressors and inotropes

The goal of using vasoactive drugs in patients with RV dysfunction secondary to PH is to maintain an adequate CO whilst avoiding increases in PVR and cardiac arrhythmias. In the face of systemic hypotension norepinephrine, a powerful systemic vasoconstrictor, should be considered in these patients. Improving systemic blood pressure has the additional benefit of improving coronary perfusion. However, norepinephrine also causes pulmonary vasoconstriction. In an animal model of acute PH, administration of norepinephrine restored systemic blood pressure and increased PAP.[169] Overall, the effect was to improve both RV contractility and CO. In the same study, animals treated with dobutamine showed a greater improvement in RV contractility in comparison with norepinephrine. The dobutamine-treated animals also showed a greater reduction in mPAP. In clinical studies, dobutamine has been shown to improve RV performance in ischaemic failure.[170] Evidence from these studies suggest that low-dose dobutamine may be useful in acute PH complicated by RV failure. Increases in myocardial oxygen demand and tachyarrhythmias may preclude dobutamine use in all patients with PH. Vasopressin can also be considered as an alternative to norepinephrine; in addition to powerful systemic vasoconstriction, it causes pulmonary vasodilation, which may be beneficial in PH.[171]

In another animal study the use of levosimendan and dobutamine in PH was compared. Improvement in RV contractility was similar after administration of both drugs; of the two agents, levosimendan was superior at reducing PVR.[172] Small observational studies in humans have shown a similar trend of improved RV contractility and reduced PVR following the administration of levosimendan in patients with CS.[173] In theory, levosimendan appears to be a promising alternative to dobutamine with the additional benefit of PVR reduction without increasing oxygen consumption.

PDE-3 inhibitors, such as milrinone, have inotropic and vasodilating properties. They can improve CO by reducing PVR and increasing RV contractility. PDE-3 inhibitors have been shown to successfully reduce PVR and improve RV contractility in animal models of PH[174,175] and in patients undergoing cardiac surgery.[176,177] Treatment with milrinone may require additional vasopressor support, given its propensity for systemic vasodilation. Inhaled milrinone has shown promise as a therapy to selectively reduce PVR in heart transplant patients[178] and in an animal model of PH,[179] but its use is currently experimental.[180,181]

Pulmonary vasodilators

Several pulmonary vasodilators are available and the choice of therapy and route of administration usually depend on the side effects of the drug and the condition of the patient. Intravenous agents can lead to systemic haemodynamic instability, and inhaled vasodilators may be more favourable in the ICU setting.[155]

Inhaled nitric oxide (iNO) increases production of cyclic guanosine monophosphate (cGMP) and is a potent pulmonary vasodilator. It results in the reversal of hypoxic pulmonary vasoconstriction, reduction in PVR and improved oxygenation. iNO therapy has been shown to reduce PVR and improve RV stroke work in postoperative cardiothoracic patients with PH.[182,183] When used in the context of severe ARDS and hypoxia refractory to maximal medical treatment, iNO commonly provides 48 hours improvement in

oxygenation, but fails to reduce the length of mechanical ventilation or improve mortality.[184,185] Methaemoglobinaemia and nitrogen dioxide (NO_2) production are recognised adverse effects, and rebound PH may also occur after abrupt cessation of iNO.

Inhaled and intravenous prostacyclins are also used as vasodilators in PH. Inhaled prostacyclin (epoprostenol) use is associated with significant reduction in mPAP and improvement in ICU patients with PH.[186] However, there are considerable associated side effects in this population. Inhaled iloprost, a synthetic prostacyclin analogue, has been shown to reduce mPAP and improve RV function in PH post-cardiopulmonary bypass. There was also a significant reduction in PVR to SVR ratio.[187] In a small single-centre study in post-heart-and-lung-transplant patients, inhaled prostacyclin showed similar efficacy to iNO in managing PH.[188]

Phosphodiesterase-5 (PDE-5) inhibitors stop the degradation of cGMP leading to vasodilation. In patients with chronic PAH, oral sildenafil, a selective PDE-5 inhibitor, has been shown to reduce mPAP[189] and improve CO by reducing PVR.[190] Sildenafil has also been used as a bridge to avoid rebound hypotension following iNO withdrawal in post-cardiac-surgery patients.[191] Following haemodynamic stabilisation, there may be a role for sildenafil in reducing PVR in the critical care setting.

Mechanical devices

In patients where all other treatment options have been exhausted, lung transplantation may be the only viable option. Case studies have reported the use of RV assist devices in patients with PH. Extracorporeal life support has also been described as a bridge to transplantation. VA-ECMO will help to unload the RV, reduce RV afterload and improve perfusion of vital organs and thus may provide temporary support in the acute situation.[154,164]

SUMMARY

PH and consequent RV dysfunction are frequently encountered in the ICU with a high associated mortality rate. Prompt identification of the underlying cause and its treatment should be the main focus of management. There is very little evidence for the use of specific treatments in the ICU setting and a 'one-size fits all' approach is unlikely to work given the varied aetiology. A few general principles, such as optimising fluid status, optimising HR and rhythm, avoiding high-pressure ventilation, maintaining coronary perfusion by optimising systemic pressure, inotropic support for RV dysfunction and inhaled pulmonary vasodilation may be applied where appropriate. The choice of individual therapies should be guided by an understanding of their mechanism of action and the expected physiological response in an individual patient. The response should be monitored closely to avoid adverse events and to optimise therapy.

Valvular and congenital heart disease and infective endocarditis

Steven T Galluccio

VALVULAR HEART DISEASE

Valvular heart disease (VHD) has been described as the next 'cardiac epidemic'.[1] In high-income countries, aortic stenosis (AS) is predicted to significantly increase in incidence.[2] Despite being less common than coronary artery disease, the burden of VHD is significant due to the requirement, not just for treatment, but for ongoing investigation and follow-up. Although the incidence of rheumatic heart disease has dramatically declined in high-income countries, this same reduction has not been seen in low-income countries or within low-income populations living in high-income countries.[3]

For the intensivist, VHD may pose a clinical challenge as the primary cause for haemodynamic decompensation, when manifest with an unrelated concurrent illness, or in the peri-operative period where valve replacement or repair is performed. Haemodynamic support of severe uncorrected VHD in the critical care setting can be difficult since cardiac output may remain largely independent of conventional manipulations. Nonetheless, it is important to conceptualise the underlying lesion and haemodynamic state into a model that can anticipate problems and predict responses to intervention (Table 25.1).

Recent consensus guidelines provide recommendations for the timing of intervention for VHD.[4,5] The principles of decision making involve the assessment of: patient symptoms; echocardiographic evidence of severity by standard criteria[6–8]; associated cardiac disease (e.g. coronary artery disease); co-morbidities and the risk of intervention utilising validated scoring systems. In all forms of valvular surgery, key postoperative clinical syndromes might be anticipated by the preoperative clinical information (Table 25.2).

AORTIC STENOSIS

Left ventricular (LV) hypertrophy is the adaptive response to the pressure-work brought about by AS. The initial pathophysiological hallmark is diastolic failure, but as the disease progresses, dilatation ensues and overt systolic failure becomes evident. Typically, patients remain asymptomatic for a prolonged period, but once symptoms occur the prognosis is poor if left untreated.

MEDICAL MANAGEMENT

For patients presenting with critical symptomatic AS, surgical or percutaneous intervention is required as medical management is limited. A modest heart rate is ideal and inotropic support may have a role if there is LV systolic dysfunction, but stroke volume is otherwise largely fixed. Vasodilators potentially have a temporising role but more critical is the defence of systemic pressure with vasopressors. Hypotension is an ominous sign and restoration of coronary perfusion pressure is paramount. This may require the addition of intra-aortic balloon counterpulsation (IABC).

INTERVENTION FOR AORTIC STENOSIS

Aortic valve replacement (AVR) is recommended as a Class 1 indication for severe AS with symptoms, or when it is associated with decreased left ventricular ejection fraction (LVEF) or the need for other cardiac surgery.[5] A dilemma in selecting patients for surgery occurs with so-called 'low-flow, low-gradient severe AS'.[9] Since transaortic pressure gradients (using spectral Doppler velocities) are dependent upon true valve area as well as flow rate (stroke volume), the key is to differentiate low-flow due to intrinsic poor LV function (pseudo-stenosis) versus that due to truly severe AS. The former group will have a poor outcome from intervention whereas the latter are likely to benefit. Low-flow, low-gradient severe AS can also occur in patients with normal LVEF but concentric LV hypertrophy and small chamber volumes ('paradoxical low-flow, low gradient AS').

The choice between surgical versus transcatheter intervention (transcatheter aortic valve replacement [TAVR]) is likely to evolve over the coming years as more experience and high-quality evidence is incorporated into clinical guidelines and practice.[10] Currently, surgical AVR is recommended in patients with low to intermediate surgical risk, whereas TAVR is recommended for those with prohibitive surgical risk on the condition that the predicted post-TAVR survival is greater than 12 months.[4,5] In patients with an intermediate to high surgical risk, TAVR may be a reasonable option, especially if carried out via a transfemoral approach.[4,5] In difficult cases, multidisciplinary assessment should be utilised. However, it appears that already there is drift towards the use of TAVR in lower-risk cases as well as

ABSTRACT

Seemingly disparate entities, valvular heart disease, adult congenital heart disease and infective endocarditis share several commonalities. These conditions all present challenges to the intensivist and their impact in the broader health care context is increasing. Associated haemodynamic perturbations can be complex; uncorrected structural heart disease will often render inadequate the armamentarium of critical care support. Optimal management requires integration of core clinical skills with appropriate utilisation and interpretation of laboratory, echocardiographic and radiological data. Multidisciplinary engagement is vital in determining the feasibility and timing of surgical or percutaneous interventions.

Table 25.1 Characteristics of valvular lesions

LESION	AETIOLOGY	MURMUR CHARACTERISTICS	CLINICAL FEATURES OF SEVERITY	ECHOCARDIOGRAPHIC FEATURES OF SEVERITY (13–15)	COMMENTS
AS	Degenerative (calcific), congenital (bicuspid valve), rheumatic	Mid-systolic ejection murmur Maximal over aortic area Radiation to carotid arteries Loudest sitting up in full expiration	Plateau pulse, aortic thrill, length and lateness of murmur, pressure-loaded apex beat, soft/absent A2, signs of LVF* (very late sign)	Mean aortic gradient ≥ 40 mm Hg Peak aortic velocity ≥ 4 m/s Aortic valve area ≤ 1 cm^2	Lower HR (50–60 bpm) preferable Often associated with 'post-stenotic' aortic root dilatation
AR (chronic)	Valvular (calcific, congenital bicuspid, rheumatic); Aortic root dilatation (aortitis, Marfan syndrome)	Decrescendo diastolic murmur Loudest at left third and fourth intercostal spaces	Collapsing pulse, wide pulse pressure, long decrescendo murmur, LV S3, Austin Flint murmur, signs of LVF*	Jet width ≥65% LVOT Vena contracta >6 mm Holodiastolic flow reversal in abdominal aorta RVol ≥ 60 mL EROA ≥ 0.3 cm^2 Regurgitant fraction ≥ 50% LV dilatation	IABC contraindicated
AR (acute)	Valvular (IE), aortic root dilatation, aortic dissection	Faint early diastolic murmur (may be absent)	Low-output state, soft and short diastolic murmur, no collapsing pulse (hypotension), narrow pulse pressure	As above	Surgical emergency Often associated with aortic root pathology (dilatation, abscess)
MR (chronic)	Primary (degenerative, MV prolapse); Secondary (annular dilatation, ischaemic)	Pansystolic murmur Maximal at apex Radiates to axilla	Small volume pulse, enlarged LV, loud S3, soft S1, early A2, signs of LVF*, signs of PHT† and RVF‡	Vena contracta ≥ 0.7 cm EROA ≥ 0.2 cm^2 Regurgitant fraction ≥ 50% Systolic flow reversal in pulmonary veins	Higher HR (80–100 bpm) preferable
MR (acute)	Ischaemic, IE, spontaneous chordal rupture (myxomatous degeneration)	Murmur may be absent	Low-output state, pulmonary oedema, soft systolic murmur	As above	Surgical emergency Higher HR (80–100 bpm) preferable Typically high/normal LVEF but low forward SV IABC to ↑ systemic pressure and ↓ afterload
MS	Rheumatic, degenerative	Mid to late diastolic murmur Low pitched	Small pulse pressure, soft S1, early opening snap, long diastolic murmur, diastolic thrill, signs of PHT	MV area ≤ 1.5 cm^2 Diastolic pressure half-time ≥ 220 ms	Normal LVEF Low HR preferred; AV synchrony critical High thromboembolic risk

Table 25.1 Characteristics of valvular lesions—cont'd

LESION	AETIOLOGY	MURMUR CHARACTERISTICS	CLINICAL FEATURES OF SEVERITY	ECHOCARDIOGRAPHIC FEATURES OF SEVERITY (13–15)	COMMENTS
TR	Primary (rheumatic, congenital, IE); secondary/ functional (tricuspid annular dilatation or leaflet tethering)	Pansystolic murmur at left sternal edge Louder with inspiration	Signs of PHT and RVF	Jet area ≥ 10 cm^2 Vena contracta ≥ 0.7 cm CW jet dense, triangular Hepatic vein systolic flow reversal	Mostly commonly secondary/ functional Severity of TR not always proportional to severity of PHT

*Signs of LVF: tachypnoea, Cheyne-Stokes respiration, hypotension, low pulse-pressure, LV S3, basal inspiratory crackles.

†Signs of PHT: loud P2, palpable P2, prominent A wave in JVP, left parasternal heave, RV S4.

‡Clinical features of RVF: TR murmur, PR murmur, elevated JVP, prominent V wave in JVP, RV S3, hepatomegaly, pulsatile liver, peripheral oedema, ascites, pleural effusions.

performing valve-in-valve procedures for failing bioprosthetic valves.[10] With limited magnitude and duration of benefit, percutaneous aortic balloon dilatation may be considered as a bridge to surgical AVR or TAVR in patients requiring rescue from severe symptoms or haemodynamic deterioration.

In the majority of cases, the key management concern post-AVR is diastolic LV failure. This can be exacerbated by injury related to inadequate myocardial protection associated with LV hypertrophy. Maintaining AV synchrony is crucial and this may require temporary sequential AV pacing. A particular difficulty following the correction of AS is the rapid reduction in afterload, which can produce a low-output state associated with a hypertrophic, hyperdynamic, small-cavity LV or 'suicide ventricle'. This may mimic systolic dysfunction or even pericardial tamponade, both clinically and by haemodynamic monitoring because despite the chamber size, 'filling pressures' will be elevated with low cardiac output. Inotropic agents, including vasopressors with beta-agonist activity and IABC, can exacerbate the problem, so echocardiography is critical in defining the haemodynamic state. This will confirm small cavity size with preserved systolic function, but with colour and spectral Doppler findings of flow acceleration and high-pressure gradients across the left ventricular outflow tract (LVOT) or LV cavity proper. Transoesophageal echocardiography (TOE) is usually required to ensure that local chamber compression or right-sided dysfunction is not contributing to low LV preload. Combined right ventricular (RV) dysfunction is especially challenging because this can produce a series of competing interests. For example, positive inotropes may be indicated for RV systolic dysfunction, but this may adversely affect the LV. In this situation, selective pulmonary vasodilators and early spontaneous ventilation with minimal positive end-expiratory pressure (PEEP) should be considered as this reduces RV afterload, but increases that of the left ventricle.

AORTIC REGURGITATION

Chronic aortic regurgitation (AR) generally progresses slowly with a protracted interval to development of LV dilatation, dysfunction and symptoms. However, unlike AS, once symptoms develop, LV systolic function is usually evident. The most common causes relate to the valve itself (congenital bicuspid aortic valve, degenerative calcific disease) or due to aortic root dilatation (such as occurs in Marfan syndrome). Rheumatic disease is the predominant aetiology in developing countries. Acute AR places an acute volume load on the LV, which can result in pulmonary oedema and low cardiac output, requiring urgent surgical intervention. Typical causes include infective endocarditis (IE) and aortic dissection.

MEDICAL MANAGEMENT

A generous heart rate will reduce the regurgitant volume, but medical management is essentially limited to inotropic, vasopressor and ventilatory support. Unlike other forms of cardiogenic shock, AR represents a contraindication to IABC. The main conundrum is balancing an adequate perfusion pressure, including to the coronary circulation, without worsening regurgitant volume and further LV dilatation. In acute AR, these goals may be mutually exclusive and hence the need for urgent surgery.

Table 25.2 Typical features of valvular surgery

	CONDITION	LV SIZE	LV SYSTOLIC DYSFUNCTION	LV DIASTOLIC DYSFUNCTION	PHT AND RV DYSFUNCTION	MYOCARDIAL PROTECTION*	RISK AV BLOCK	COMMENTS
AVR	AS	Hypertrophic but non-dilated	+ (usually normal LVEF unless late stage or ischaemic cardiomyopathy)	+++	+ (very late feature)	Cardioplegia less effective if LV hypertrophy is severe	+	Beware LVOT/mid-cavity obstruction ('suicide' ventricle) AVR established choice in patients with low-intermediate surgical risk
TAVR	AS	Hypertrophic but non-dilated	+ (usually normal LVEF unless late stage or ischaemic cardiomyopathy)	+++	+ (very late feature)	Risk myocardial injury due to: rapid ventricular pacing and hypotension; arterial embolisation; coronary obstruction by prosthesis	++	Beware LVOT/mid-cavity obstruction ('suicide' ventricle) TAVR established choice in patients with prohibitive surgical risk
AVR	AR	Dilated	++	++	++	Reliance on retrograde cardioplegia or direct ostial cannulation	+	LV dysfunction can potentially improve after AVR
MVR	MS	Normal	Normal	'Normal' but LV filling dependent upon HR, atrial function and AV synchrony	+++	Risk circumflex artery injury	++	Severity of pulmonary HT/RVF key considerations in postoperative management
MVR	MR	Dilated	+++ (can be underestimated by echocardiography)	++	Variable	Risk circumflex artery injury	++	LV dysfunction unmasked by valve replacement (↑ LV afterload)
MV repair	MR	Dilated	+++ (can be underestimated by echocardiography)	++	Variable	Risk circumflex artery injury	++	SAM/LVOT obstruction in 4%–10% of cases.[11,12] LV dysfunction unmasked by valve repair (↑ LV afterload)
TV replacement or repair	TR	Variable	Variable	Variable	++	Risk right coronary artery injury	+++	May unmask RV systolic dysfunction; caution if RV function severely impaired

*RV protection is worse when retrograde cardioplegia is solely used.

AR, Aortic regurgitation; *AS*, aortic stenosis; *AV*, aortic valve; *AVR*, AV replacement; *HT*, hypertension; *LV*, left ventricle; *LVEF*, left ventricular ejection fraction; *LVOT*, left ventricular outflow tract obstruction; *MR*, mitral regurgitation; *MS*, mitral stenosis; *MV*, mitral valve; *MVR*, MV replacement; *PHT*, pulmonary hypertension; *RV*, right ventricle; *RVF*, right ventricular failure; *SAM*, systolic anterior motion of the mitral valve; *TAVR*, transcatheter aortic valve replacement; *TR*, tricuspid regurgitation; *TV*, tricuspid valve.

INTERVENTION FOR AORTIC REGURGITATION

For chronic AR warranting surgical intervention, the anatomical conditions are generally less favourable towards repair, and AVR is required. Such indications include symptomatic patients with severe AR or those without symptoms, but when associated with LV dysfunction or if undergoing cardiac surgery for other indications. Whether AVR is indicated for AR or AS, it is also important to assess for dilatation of the aorta (aortopathy) as this may also warrant replacement. Due to anatomical differences, transcatheter intervention for AR is more challenging than for AS, although TAVR devices are currently in development.[10]

Survival following AVR is strongly related to preoperative symptoms, with worse outcomes once patients reach New York Heart Association class III symptoms or have reduced exercise capacity. Surgical risk is also increased as LV function deteriorates, as assessed by echocardiography. Nonetheless, even in patients with both symptoms and LV dysfunction, surgery is still recommended over medical therapy.[4,5]

Postoperatively, the course will be largely predicted by the underlying degree of systolic LV dysfunction and, if present, pulmonary hypertension (PHT) and RV failure. Inotropic and vasopressor support will be simplified with the correction of AR, and there is the potential for significant improvements in function even in patients with a poor baseline state.

MITRAL REGURGITATION

Mitral regurgitation (MR) poses a volume load on the LV with progressive left atrial (LA) and LV dilatation. Although this chamber dilatation preserves forward stroke volume, eventually systolic dysfunction occurs and cardiac output deteriorates. When evaluating significant MR, echocardiography will tend to overestimate LV systolic function, since MR represents a low-afterload state. This is often illustrated postoperatively when mitral valve repair or replacement unmasks the degree of LV dysfunction.

Understanding the mechanism of MR is important in detecting associated pathology and determining optimal treatment. MR can be broadly classified as primary, referring to intrinsic pathology of the valve apparatus (leaflets, chordae tendineae, papillary muscles) or secondary (functional) MR, referring to structurally normal leaflets but with abnormal function due to LV dilatation and remodelling. Alternatively, the Carpentier classification is determined upon leaflet motion as being normal, restricted or excessive. In high-income countries, the most common aetiologies of MR are degenerative disease with mitral valve prolapse (a primary cause) and coronary heart disease (a secondary cause).

Acute MR can present dramatically with florid pulmonary oedema and shock. In this scenario, the LA is unable to accommodate the high regurgitant volume under high pressure with subsequent pulmonary venous hypertension, acute pulmonary arterial hypertension and potentially overt RV failure. The non-dilated LV is hyperdynamic with a high ejection fraction but a low forward stroke volume. Causes include spontaneous chordal rupture with degenerative disease, leaflet perforation with IE and papillary muscle rupture due to myocardial infarction. This condition can be difficult to diagnose, sometimes mimicking severe pneumonia or ARDS, and is particularly challenging if only unilateral pulmonary oedema is present due to an eccentrically directed MR jet.

MEDICAL MANAGEMENT

Unlike stenotic lesions with relatively fixed stroke volume, there will be variable recruitment in LV function, and hence stroke volume with inotropic agents. Afterload reduction is key but often a compromise needs to be reached between acceptably low systemic arterial pressure and higher forward flow (as occurs in AR as discussed above).

Acute MR will almost always require urgent surgical intervention. Frequent communication between intensive care and surgical teams is crucial in determining the timing of surgery prior to attempts at stabilisation. Key measures are positive pressure ventilation with sufficient PEEP and the use of IABC to simultaneously reduce afterload as well as increase systemic mean arterial pressure. Further afterload reduction with vasodilators is ideal, but systemic hypotension is often a limiting factor and vasopressors are required.

INTERVENTION FOR MITRAL REGURGITATION

Based largely on observational data, MV surgery is recommended for severe chronic primary MR in symptomatic patients with LVEF greater than 30%, or in asymptomatic patients with LVEF 30%–60%.[4,5] In patients with severely depressed LV function (LVEF <30%), surgery may be reasonable but supportive data are lacking.

The preferred surgical option in all cases of primary MR is repair, especially if disease is limited to the posterior leaflet.[5,8] Repair has advantages over replacement including preservation of LV function and lower operative mortality, and it avoids the thromboembolic risk of mechanical valves and the inevitable deterioration of bioprosthetic valves. The balance swings towards MV replacement (MVR) as the chance of successful and durable repair diminish (e.g. complex anterior and posterior leaflet disease). For those with prohibitive surgical risk, but with an otherwise reasonable life expectancy, transcatheter repair may be considered.[5,8] Based on the principles of an Alfieri repair, the MitraClip tethers together the anterior and posterior leaflets. This is a feasible option if anatomical factors are favourable, but results in greater residual MR than standard open surgical approaches. Additional devices are currently in development, and will perhaps soon provide the capacity for transcatheter mitral valve replacement.

For secondary MR, the benefit of intervention on mortality or morbidity remains uncertain. Surgical

intervention is reasonable in patients undergoing simultaneous aortic valve replacement or coronary artery bypass grafting.[5] Repair or replacement can also be considered in patients with persistent symptoms despite optimal medical management.[5] Secondary MR is currently the most common indication for MitraClip use in Europe.[13]

Postoperatively, key considerations are the state of the pulmonary circulation and RV function, but previously underestimated LV systolic dysfunction can manifest as afterload is now increased. A specific complication of MV repair is LVOT obstruction with systolic anterior motion of the anterior leaflet, especially if there is excessive posterior leaflet length.[11,12] Ideally, this is identified in the operating room following the weaning of cardiopulmonary bypass as re-operation with MVR may be required.

MITRAL STENOSIS

Mitral stenosis (MS) is predominantly due to rheumatic disease. Ironically, being a left-sided valve disease, LV function is usually unaffected. The major clinical issues are left atrial hypertension with resultant PHT, RV failure, atrial arrhythmia and heightened thromboembolic risk.

MEDICAL MANAGEMENT

If severe MS is the main driver for critical care unit admission then percutaneous or surgical intervention will be required. Controlling the ventricular rate is crucial to maximise the diastolic interval with atrial fibrillation being both common (occurring in 30%–40% of patients) and poorly tolerated. Anticoagulation is recommended in the presence of atrial fibrillation (paroxysmal, persistent or permanent), a prior embolic event or LA thrombus.

INTERVENTION FOR MITRAL STENOSIS

Percutaneous mitral balloon commissurotomy (PMBC) is the preferred option in symptomatic patients with severe MS and favourable valve morphology (relatively thin, mobile leaflets and free of calcium).[5,14] Open surgery is recommended in symptomatic patients who are not candidates for PMBC, or if undergoing cardiac surgery for other indications.

Since isolated MS does not cause substantive detriment to LV function, postoperative attention is focused on the pulmonary circulation and RV function. With correction of MS, left atrial and right-sided pressures should immediately improve. However, the insults of cardiopulmonary bypass and aortic cross-clamping can be significant, and RV dysfunction can be a challenge, especially if PHT remains largely fixed and irreversible.

RIGHT-SIDED VALVULAR LESIONS

Isolated valve lesions of the right heart are rarely encountered in adult critical care practice. Occasional cases requiring surgery may relate to infective endocarditis or residual and uncorrected congenital heart disease, such as severe pulmonary regurgitation (PR) following Tetralogy of Fallot (TOF) repair.

Tricuspid regurgitation (TR) is almost ubiquitous in patients with left-sided heart disease. A common dilemma is when to perform simultaneous tricuspid valve repair or replacement in patients undergoing left-sided valvular surgery. Repair, in particular, does not add appreciably to the risks of surgery and should be performed in cases of severe TR or severe tricuspid annular dilatation. However, careful consideration is required in the presence of severe RV dysfunction or significant PHT, as such repair can provoke catastrophic RV failure.

VALVULAR HEART DISEASE IN PREGNANCY

For native VHD in pregnancy, the highest-risk lesions are those that are stenotic rather than regurgitant, and left- rather than right-sided. Pregnancy-associated haemodynamic changes include increased heart rate and decreased systemic vascular resistance (SVR), which are favourable conditions for regurgitant faults, but disadvantageous for those stenotic.[15,16] With severely stenotic lesions, cardiac output may not realise the usual 50% increase that is reached by the end of the second trimester.

Prior to pregnancy, intervention for stenotic lesions is recommended in severe AS with symptoms and for severe MS (with preference for PMBC) regardless of symptoms.[5,17] For severe regurgitant lesions, repair or replacement is indicated for symptomatic women.[5,17] In pregnant patients, severe MS is poorly tolerated. If PMBC is not feasible, surgical MVR may the safest option, but it carries significant risk of both foetal (30%–40%) and maternal (9%) mortality.[5]

ADULT CONGENITAL HEART DISEASE

Congenital heart disease (CHD) is common. Birth prevalence is 7–10 per 1000 live births, but more than 25% of CHD diagnoses are made after infancy. In high-income countries, survival in children to adulthood has improved markedly over recent decades to over 85%, with adult survivors now outnumbering twofold affected children and adolescents.[18,19] However, the same gains have not been realised in low- and middle-income countries with the burden of disease only increasing.[20,21] Although adult CHD (ACHD) is highly variable in complexity and presentation, heart failure (HF) is the leading cause of death.[22,23]

THE INTENSIVIST PERSPECTIVE

The management of ACHD patients requiring critical care presents unique challenges to the intensivist. One must appreciate the anatomical diagnosis, the history of corrective procedures, the anticipated late complications, the

Table 25.3 Considerations for the intensivist managing adult congenital heart disease

QUESTION	COMMENTS
What is the congenital diagnosis and history of corrective procedures?	Appreciate natural history, post-procedural residual abnormalities or anticipated complications (see Table 25.4)
Are there residual shunts?	Consider effect of altering PVR:SVR relationship* on shunt direction, oxygenation and cardiac output Potential paradoxical embolisation risk Cyanosis and hyperviscosity syndrome if significant R → L shunt
Which morphological ventricle is the systemic ventricle?	Look for history of transposition (morphological RV is the systemic ventricle in l-TGA or d-TGA with atrial switch)
Is pulmonary hypertension an expected feature?	May be prominent with residual shunts, but also occurs with congenital or acquired left heart and pulmonary disease RVF may be the predominant haemodynamic issue
Is PVR critically important?	Especially important with single ventricle ('Fontan' circulation) Also, consider influence of PVR on residual shunt lesions
What influence will positive pressure ventilation have on cardiopulmonary interaction?	Possibly beneficial with: left heart dysfunction (↓ LV wall stress) Possibly detrimental with: Fontan circulation, RVF, significant TR and PHT, shunts (↑ RV afterload and ↓ preload)
Is there a preload-dependent state?	Caution with Fontan circulation, Eisenmenger syndrome, LVOT obstruction
Is particular caution required with negative inotropic or vasodilatory drugs?	Beware heart failure syndromes and pulmonary hypertension With shunts, consider effect on changing ratio of SVR:PVR Caution ↓ SVR with left-sided obstructive lesions
Does IV access present any issues?	Potential difficulty if history of multiple interventions. In Fontan circulation, standard CVC approach will enter PA and transvenous ventricular pacing is not possible
Are arrhythmias a feature and is a device (PPM, AICD) in situ?	Consider device interrogation

*Factors ↑ PVR: Hypoxia, hypercarbia, high haematocrit, positive pressure ventilation, hypothermia, metabolic acidosis, alpha-adrenergic stimulation. Factors ↓ SVR: Vasodilators, general anaesthesia, hyperthermia.

AICD, Automatic implantable cardiac defibrillator; *CVC*, central venous catheter; *d-TGA*, dextro-transposition of the great arteries; *IV*, intravenous; *l-TGA*, levo-transposition of the great arteries; *LV*, left ventricle; *LVOT*, left ventricular outflow tract obstruction; *PA*, pulmonary artery; *PHT*, pulmonary hypertension; *PPM*, permanent pacemaker; *PVR*, pulmonary vascular resistance; *RV*, right ventricle; *RVF*, right ventricular failure; *SVR*, systemic vascular resistance; *TR*, tricuspid regurgitation.

associated systemic disease and the holistic consideration of cardiopulmonary interaction (Tables 25.3 and 25.4).

KEY CLINICAL SCENARIOS AND SYNDROMES

HEART FAILURE IN ADULT CONGENITAL HEART DISEASE

Major societies have recently published position statements on the treatment of HF in ACHD but these chiefly relate to the outpatient setting.[23–25] These papers highlight difficulties in diagnosis (e.g. atypical symptoms), treatment (i.e. a paucity of controlled trials with hard end points in ACHD patients) and prognosis (e.g. New York Heart Association scores are not validated for palliated ACHD).[26] Furthermore, there are no scientific trials to guide intensivists on managing ACHD patients in the critical care context. Therefore, an approach based on pathophysiological first principles and the recognition of specific syndromes (below) are paramount. Generic, acquired contributors to ventricular dysfunction (e.g. coronary artery disease) should not be discounted, especially as the incidence of these will increase as the ACHD population ages. The patients at great risk for the development of HF are those with single-ventricles palliated with a Fontan procedure, TOF patients with residual PR, and those with a systemic RV, discussed below.[27]

SHUNTS, PULMONARY VASCULAR DISEASE AND PULMONARY HYPERTENSION

ACDH results in PHT in approximately 5%–10% of patients.[28] Systemic to pulmonary shunting, with

Table 25.4 Glossary of terminology and procedures in adult congenital heart disease

NAME	DIAGNOSIS/ INDICATION	PROCEDURE	RATIONALE	COMPLICATIONS	ADULT PHYSIOLOGY AND CONSIDERATIONS
Simple shunts	Any cause of L → R shunting:		Completely correct defect; prevent long-term sequelae	Arrhythmia, residual shunt	Excellent prognosis if repaired as child
	ASD	Transcatheter repair preferred option	RV volume overload, PHT, paradoxical emboli		If unrepaired, direction and magnitude of shunt is highly variable
	VSD	Surgical patch repair preferred option	LV volume overload, PHT, paradoxical emboli		Prognosis is determined by the degree of shunt, pulmonary HT and RVF/LVF
	PDA	Transcatheter repair preferred option	LV volume overload, PHT		
Left-sided obstructive lesions	Congenital AS (bicuspid aortic valve)	Surgical repair Balloon valvuloplasty has role in selected adolescents and young adults	Relieve ↑ LV afterload and prevent complications (see across)	Residual AS or coarctation	Uncorrected lesions will result in LV hypertrophy and diastolic dysfunction Maintain preload, sinus rhythm and adequate SVR
	Aortic coarctation	Stenting preferred option over open surgery			If untreated, risks include systemic HT, stroke, aortic dissection and LVF
Right-sided obstructive lesions	Valvular PS occurs as isolated defect in ≈ 7%–12% of all CHD	Balloon valvotomy treatment of choice	Relieve ↑ RV afterload	RVOT obstruction with severe RVH when obstruction is relieved; PR (post valvotomy)	Asymptomatic valve stenosis gains more importance in adults (↓ RV compliance, ↑ filling pressures/ venous congestion)
	Subvalvular PS (rare as an isolated defect, usually associated with VSD or post TOF repair)	Surgical myomectomy ± patch repair		Residual RVOT obstruction	Can present de novo in adults as double-chambered RV
	Supravalvular PS and PA stenosis	Transcatheter intervention if anatomically feasible		Residual stenosis	RVF if untreated
Tetralogy of Fallot	Pulmonary outflow obstruction, overriding aorta, VSD, RV hypertrophy	Surgical repair	Complete intra-cardiac repair, prevent complications	Residual VSD, residual RVOT obstruction, RV aneurysm Arrhythmia Severe PR	PR most common complication in adulthood with lesions repaired in childhood

Table 25.4 Glossary of terminology and procedures in adult congenital heart disease—cont'd

NAME	DIAGNOSIS/ INDICATION	PROCEDURE	RATIONALE	COMPLICATIONS	ADULT PHYSIOLOGY AND CONSIDERATIONS
PA banding	Any cause of ACHD with excessive pulmonary blood flow (e.g. single ventricle, multiple VSDs, AVSD, double-outlet ventricle)	Encircling main PA with prosthetic band	Decrease pulmonary blood flow and increase systemic perfusion until definitive repair or as palliation	PA impingement, damage to pulmonary valve	Pulmonary stenosis; proximal main PA dilatation, PR
Blalock-Taussig-Thomas (modified) shunt	Staging procedure prior to complete repair or palliative procedure to augment pulmonary blood flow when definitive repair not possible	Subclavian artery to ipsilateral PA shunt; timing: neonate	Increase pulmonary blood flow as neonatal PA pressures transition from high to normal	Shunt thrombosis; phrenic nerve injury, steal syndrome, chylothorax, seroma	Lower BP in ipsilateral upper limb
Glenn – bidirectional shunt (BDG) or hemi-Fontan	Staging procedure for single-ventricle physiology to augment pulmonary blood flow (prior to Fontan procedure)	Anastomosis SVC to right PA; timing: usually after 2–3 months of age	Increase pulmonary blood flow after neonatal PA pressures have normalised	Permanent Pulmonary AV fistulae	Usually followed at 2–4 years of age by complete Fontan procedure
Fontan procedure (total cavopulmonary connection)	All disease types in which a two-ventricle circulation cannot be restored (e.g. hypoplastic left heart, tricuspid atresia, pulmonary atresia, double inlet ventricle)	BDG + external conduit from IVC to PA	Diversion of all systemic venous blood direct to lungs (cavo-pulmonary bypass) Circuit flow: SV > direct to PA > LV > SV	Pulmonary AVMs, thrombosis right heart chambers	Single ventricle physiology Long term: pump failure (≈40%), SV congestion (cirrhosis, protein losing enteropathy)
Norwood procedure	Hypoplastic left heart	Staged procedures to create new functional systemic circulation: create neo-aorta (from PA), atrial septectomy, PA (BT) shunt; BDG; Fontan.	End-result is modified Fontan circulation with RV as single functioning ventricle	Traditionally associated with high surgical mortality but recent outcomes are improving (≈90% early survival)	RV is the single ventricle Often associated subaortic or aortic obstruction compromising the systemic RV

Table 25.4 Glossary of terminology and procedures in adult congenital heart disease—cont'd

NAME	DIAGNOSIS/ INDICATION	PROCEDURE	RATIONALE	COMPLICATIONS	ADULT PHYSIOLOGY AND CONSIDERATIONS
Pott's shunt	Palliative procedure in TOF	Anastomosis between left PA and descending aorta	Improve pulmonary blood flow due to RVOT obstruction with L → R shunt Offloads RV with R → L shunt in severe PAH	Abandoned procedure (used prior to availability of complete repair) Also used as palliative procedure in severe PAH	Palliative procedure
d-TGA	Pulmonary and systemic circuits are parallel and independent Aorta arises from RV PA arises from LV	See below	Incompatible with life; requires surgical correction Two circuits as follows: LV > PA > PV > LV and RV > aorta > SV > RV	See below	See below
Mustard, Senning procedures ('atrial switch')	d-TGA	Intra-atrial baffle to redirect systemic venous return to LV (and PA); pulmonary venous flow to RV (and aorta)	Correction of TGA at atrial level; corrects parallel circulation; allows adequate oxygenated systemic blood flow RV is systemic ventricle Circuit flow: SV > LV > PA > RA > aorta > SV	Baffle obstruction, caval obstruction, stenosis, thromboembolism	RV remains systemic ventricle; LV is the pulmonary ventricle Variable incidence RV failure (≈22%) Now superseded by arterial switch Arrhythmia
Rastelli, Jatene procedures ('arterial switch')	d-TGA	Aorta and PA transected, reattached to the opposite AV valves; coronaries reimplanted into neoaorta. Timing as neonate	Correction of TGA at arterial level LV is systemic ventricle Circuit flow is 'normal': SV > RV > neoPA > LV > neoaorta > SV	PA stenosis, PR, neoaortic stenosis	LV becomes the systemic ventricle; near-normal adult physiology Rarely, coronary circulation issues related to reimplantation
l-TGA ('congenitally corrected TGA)	Morphological RV and LV are inverted <1% of all CHD	See below	Circulation is 'physiologically corrected' at birth with circuit flow: SV > LV > PA > RV > SV	See below	RV is the systemic ventricle; progressive RV failure and TR are key issues
Double-switch procedure	l-TGA	Atrial correction (Mustard/ Senning) + arterial switch ± PA band to 'train' LV	Complete anatomic repair; controversial if l-TGA is isolated defect	Mortality up to 7%	Limited data on long-term outcome

Table 25.4 Glossary of terminology and procedures in adult congenital heart disease—cont'd

NAME	DIAGNOSIS/ INDICATION	PROCEDURE	RATIONALE	COMPLICATIONS	ADULT PHYSIOLOGY AND CONSIDERATIONS
Ebstein's anomoly	≈1% of all CHD TV is apically displaced with 'atrialisation' of RV Commonly has an associated ASD	TV repair preferred if possible BDG may be required if RV is too small for correction	Correct TR and small RV cavity with limited stroke volume	Previously high operative mortality; current rate <6%	Arrhythmias, RVF, paradoxical embolism

See references 24, 31, 57–59.

persistent exposure of the pulmonary vasculature to increased blood flow and pressure, may lead to obstructive arteriopathy with increased pulmonary vascular resistance (PVR). At the extreme, when PVR approaches and exceeds SVR, the shunt is reversed (Eisenmenger syndrome).

For adult patients with simple shunts repaired as children, the prognosis is excellent. However, lesions are often only diagnosed once symptoms develop in adulthood. The role of shunt correction in these situations is less well defined. This requires assessment of the defect, the patient age, the PVR:SVR ratio and the ratio of pulmonary to systemic flow (Qp:Qs). Somewhat paradoxically, the left-to-right shunt has to be large enough to warrant surgery, but the risk becomes prohibitive once significant PHT is present. For atrial septal defects (ASDs), closure is recommended for large shunts with signs of RV volume overload, regardless of symptoms.[25] For ventricular septal defects (VSDs), closure is indicated for symptoms attributable to the VSD or when signs of LV volume overload are present.[25] The latter occurs as a compensatory increase in intravascular volume acts to maintain LV diastolic volume and systemic cardiac output. For secundum ASD closure, percutaneous device insertion is the preferred method, whereas for VSD, pericardial patch repair is preferred if the surgical risk is acceptable.[25] For either level of shunt, current guidelines suggest a Qp/Qs >1.5 and PVR ≤4.6 Wood units (368 dynes-sec/cm^5) as upper limits of safety.[29,30] Conversely, patients who develop PHT after shunt closure have a poor prognosis.

In the case of residual shunting, the SVR:PVR balance (see Table 25.3) will determine the magnitude and direction of the shunt, effecting systemic cardiac output, the degree of hypoxaemia and the risk of systemic embolisation. For the most severely affected patients with Eisenmenger syndrome, bosentan is recommended if World Health Organization functional class III symptoms are present.[30,31] Although lacking as strong an evidence-base, other endothelin-receptor antagonists and pulmonary vasodilators (prostanoids and phosphodiesterase type 5 inhibitors) can be considered. Secondary erythrocytosis is generally tolerated unless haematocrit is greater than 65% and is associated with hyperviscosity symptoms. For the intensivist, management can be extremely challenging. Prioritising the pulmonary circulation may warrant subtle but deliberate changes to practice to optimise PVR such as: 'earlier' use of renal replacement therapy to correct metabolic acidosis; preferential use of non-catecholamines (e.g. vasopressin) for defending systemic (coronary perfusion) pressure[32,33]; re-evaluation of haematocrit targets; cautious/selective use of sedative/hypnotic agents; use of intravenous or inhaled selective pulmonary vasodilator therapy; judicious use of non-invasive ventilation; and meticulous attention to carbon dioxide tension when controlled positive pressure ventilation is mandated.

TETRALOGY OF FALLOT

TOF is the most common cyanotic CHD in adults. For patients with lesions repaired in childhood, the prognosis is excellent. Significant PR is the most frequent complication; although well tolerated for years, PR eventually leads to RV dilatation and dysfunction, making optimal timing of valve replacement challenging. Additional long-term complications include residual VSD or right ventricular outflow tract obstruction, aortic root dilatation and

arrhythmia. Left-sided ventricular dysfunction is being increasingly recognised, largely due to interventricular interaction including abnormal septal configuration and electromechanical dyssynchrony.

THE MORPHOLOGICAL RV AS THE SYSTEMIC VENTRICLE

A systemic right ventricle is destined to fail. This group largely includes patients with dextro-transposition of the great arteries (d-TGA; palliated with atrial switch) or levo-transposition of the great arteries (l-TGA). In addition to RV systolic dysfunction, d-TGA patients who have undergone atrial switch (Mustard or Senning procedures) are often limited by fixed stroke volume due to limited flow through stiff atrial baffles. These complications do not occur with the more recent arterial switch procedures, in which normal atrioventricular and ventriculoarterial connections are restored. Patients with l-TGA (where connections are 'congenitally corrected') often develop progressive systemic AV regurgitation.

FONTAN CIRCULATION (SINGLE-VENTRICLE PHYSIOLOGY)

This group includes tricuspid atresia, double-inlet LV and hypoplastic left heart syndrome. Surgical correction bypasses systemic venous return around the subpulmonary ventricle; all systemic venous blood returns directly to the lungs via the pulmonary arteries. These patients are at high risk for HF. The lack of a subpulmonic ventricle requires a central venous pressure higher than mean pulmonary arterial and pulmonary venous pressure to maintain return to the single ventricle. The circulation is thus 'preload' dependent, but PVR is critically important (see above). Although these patients have high afterload and stroke-work, there is no clinical trial evidence to guide the use of specific afterload-reducing therapy. Pulmonary vasodilator therapies have shown mixed results.[29] Long-term complications include cirrhosis, portal hypertension and protein-losing enteropathy.

SYSTOLIC FAILURE OF THE MORPHOLOGICAL LEFT VENTRICLE

Systolic LV dysfunction may result from pressure-overload lesions, such as congenital AS, bicuspid aortic valve and coarctation of the aorta. Bicuspid valves may develop progressive insufficiency as well as aortic root dilatation and dissection. Culprit volume-overload lesions include aortic regurgitation, VSD, patent ductus arteriosis or mitral regurgitation. Although specific trials in ACHD patients with hard end-points are lacking, current treatment guidelines extrapolate data from the general HF population to include recommendations for diuretics, renin-angiotensin-aldosterone system antagonists, beta blockers and mineralocorticoid receptor antagonists.

TRANSPLANTATION

Compared to patients without CHD, adult patients with CHD undergoing heart transplantation have lower early (30-day) survival rates, but higher long-term survival rates with similar 10-year outcomes.[19,34] The timing of assessment for transplant is difficult, and patients with irreversible multisystem dysfunction may require combined multiorgan transplantation (e.g. pulmonary, hepatic or renal).

ROLE OF VENTRICULAR ASSIST DEVICES

The utilisation of ventricular assist devices (VADs) is lower in ACHD awaiting transplantation than those with acquired heart disease.[19,22] ACHD patients are more likely to have right-sided HF, pulmonary HT or residual shunts that may make them less appealing for VADs.

ARRHYTHMIA

A gamut of tachy- and bradyarrhythmias may become manifest in ACHD patients, with arrhythmias now a major cause of morbidity and mortality. Sudden cardiac death (SCD) accounts for 20%–25% of late deaths in ACHD patients with systemic ventricular dysfunction a key risk factor.[35] Selection criteria for implantable cardioverter defibrillator devices, as primary or secondary prevention of SCD are based on data extrapolated from the generalised population.[22] Catheter ablation and device implantation all may be viable options but specific planning may be required with consideration of anatomy and vascular pathways.

INFECTIVE ENDOCARDITIS

ACHD patients have a greater (15–140-fold) incidence of IE than the general population.[36] Echocardiographic diagnosis can be difficult, with disease more often involving the right side, but overall prognosis is better than other patient groups, with mortality less than 10%.

NON-CARDIAC DISEASE AND OTHER CONSIDERATIONS IN ADULT CONGENITAL HEART DISEASE

Non-cardiovascular morbidity may relate to the underlying lesion, surgical repair or medical treatment. Neurological complications include embolic stroke, intracranial haemorrhage and brain abscess. Coarctation and bicuspid aortic valve are associated with an increased risk of intracranial aneurysms.[37,38] Pulmonary abnormalities most commonly manifest as restrictive ventilatory defects, and renal dysfunction is present in ≈50% of ACHD population.[39,40] In addition to associated congenital airway abnormalities, previous prolonged intubation can result in subglottic stenosis or vocal cord paresis. Congestive hepatopathy occurs chiefly in Fontan patients and those

with RV failure. Due to radiation exposure, especially in childhood, patients with ACHD are possibly at increased cancer risk, particularly for haematological and head/neck malignancies.[24,41] Pregnancy in CHD is associated with an increased rate of maternal and neonatal adverse events.[42,43] Groups at highest risk during pregnancy include those with severe pulmonary arterial hypertension, left heart obstruction, poor systemic ventricular function and aortic root dilatation.[25,44]

INFECTIVE ENDOCARDITIS

IE can be a taxing disease for the intensivist. In critically unwell patients managed in the ICU, the short-term mortality approximates 30%–57% in those treated aggressively with surgery; whereas for patients meeting an indication but denied surgery, the prognosis is dismal with a mortality of 85%.[45–49] Common reasons for ICU admission include HF in over 60% of cases, septic shock in 20% and neurological sequelae in 15%.[48] Staphylococci have emerged as the most prevalent culprit organisms, although alternative organisms, such as fungi are proportionately more common in the ICU. Overall, the incidence of IE is static but the epidemiology is transforming: mean age at diagnosis is increasing; an increasing proportion relates to prosthetic valves, cardiac devices and other nosocomial factors; the proportion associated with rheumatic heart disease is decreasing.[50–52]

DIAGNOSIS

The modified Duke criteria, although well accepted, lack accuracy for early diagnosis, and in this context are intended as a guide and must not replace clinical judgment.[36,52,53] Diagnosis in ICU patients can be particularly challenging. This requires holding a high index of suspicion, searching meticulously for clinical features, such as fever, vascular and immunological phenomena, and arranging appropriate microbiological testing. Echocardiography is cornerstone, with major features including vegetation (defined as oscillating intracardiac masses on valve or supporting structures), abscess, new partial dehiscence of prosthetic valve and new valvular regurgitation (Table 25.5). Recent guidelines suggest additional imaging modalities may be of use. In doubtful cases, computed tomography (CT) may detect local paravalvular complications, CT and magnetic resonance imaging may detect distant embolic phenomena and 18F-fluorodeoxyglucose positron emission tomography/CT may detect prosthetic valve infection.[36]

ROLE OF TRANSOESOPHAGEAL ECHOCARDIOGRAPHY

Although transthoracic echocardiography (TTE) is the first-line imaging technique for suspected IE, TOE should be considered if clinical suspicion remains high with a negative TTE or there are concerns for local complications. Even after a negative TOE, if clinical suspicion

Table 25.5 Echocardiographic features of infective endocarditis

FEATURE	DESCRIPTION
Vegetations*	Shape: usually amorphous, shaggy, lobulated, less commonly linear or round Motion: high-frequency flutter, oscillating, chaotic, orbiting Location: typically atrial side of atrioventricular valves, ventricular side of the aortic valve
Valvular disease	New regurgitation*, leaflet perforation or destruction
Abscess*	Echolucent or echogenic-heterogeneous space or tissue thickening Usually paravalvular but may affect any myocardial region Aortic valve most commonly affected
Pseudoaneurysm	Pulsatile perivalvular echo-free space; colour-flow Doppler present
Perforation	Interruption of endocardial continuity
Fistula	Colour-Doppler communication between neighbouring cavities (e.g. aorta-ventricle or aorta-atrium)
Valve aneurysm	Saccular bulging of valvular tissue
Dehiscence of prosthetic valve*	Paravalvular regurgitation; rocking motion of prosthesis
Other findings	Altered left ventricular size or function Elevated left or right ventricular filling and pulmonary artery pressures

*Constitute the Modified Duke major echocardiographic criteria.[53]
See references 36, 60, 61.

remains high, a repeat study should be considered in 3–5 days.[52] Such an interval may allow vegetation to reach a detectable size or abscess cavities or fistulous tracts to be evident. For right-sided lesions, TOE is also more sensitive in diagnosing lead-associated and pulmonary-valve disease.

ANTIMICROBIAL THERAPY

Early antimicrobial therapy is imperative and should reflect major society guidelines in the context of local expertise and protocols. General principles include the use of prolonged, parenteral, bactericidal therapy, recognising the altered pharmacokinetics typically seen in critically ill patients. Initial empirical therapy, whilst awaiting microbiological testing, should cover staphylococci, streptococci and enterococci in native valve endocarditis (NVE). Flucloxacillin is more effective than vancomycin for methicillin-susceptible staphylococci, but the latter should be used empirically in prosthetic valve endocarditis (PVE) and healthcare-associated IE regimens to cover methicillin-resistant strains.[36]

INDICATIONS FOR AND TIMING OF SURGERY

Currently, the proportion of IE patients proceeding to surgery is ≈50%. Although the theoretical indications for surgery are clear, practical application is complex and relies largely on clinical judgement, with consideration of the real-time status of the patient, the perceived natural history and the risks of surgery. Decision making in patients requiring critical care unit admission is challenging, and multidisciplinary involvement is recommended.[36,52] It should be noted that the bulk of the evidence and guidelines relate to left-sided endocarditis.

HEART FAILURE

HF is the most common complication of IE and the most common indication for surgery. The usual mechanism of HF is new or progressive valvular regurgitation although intracardiac fistulae or valve obstruction may occur. In these circumstances, the European Society of Cardiology suggest 'urgent' surgery (within a few days), but with refractory shock or pulmonary oedema, the recommendation is for 'emergency' surgery (within 24 hours).[36] For similar indications, the American Heart Association guidelines only use the time discriminator of 'early', meaning surgery during initial hospitalisation and before completion of the antibiotic course.[52]

UNCONTROLLED INFECTION

Uncontrolled infection is described as persisting infection with ongoing positive blood cultures after an arbitrary 7–10 days of antibiotic treatment. However, recent data suggest that prognosis is worse even with only 3 days of persistently positive blood cultures.[54] Uncontrolled infection may also refer to perivalvular extension with feared complications, such as abscess formation, pseudoaneurysms and fistulae.

Although 'early' or 'urgent' surgery is recommended for patients with uncontrolled infection, surgical outcomes for patients with overt septic shock, as opposed to cardiogenic shock, are much poorer. In practice, it may be difficult to compartmentalise the haemodynamic disturbance as purely 'septic' or 'cardiogenic'. If possible, it may be preferable to attempt a period of stabilisation prior to surgical commitment. Navigating this decision-making process requires careful and repeated clinical examination, appropriate haemodynamic monitoring including serial echocardiography, and close liaison with surgical and other colleagues.

PREVENTION OF EMBOLISATION

Embolisation rates improve significantly with appropriate antibiotics, so prompt initiation is paramount. Only one randomised trial has examined the role of early surgery in this context.[55] The precise role of surgery remains unclear, with guidelines based on the size and mobility of the vegetation, the associated valve dysfunction and the presence of established embolic events. Adjunctive anticoagulation or antiplatelet therapy is not recommended.

NEUROLOGICAL EVENTS AND RISK OF SURGERY

Symptomatic neurological events develop in 15%–30% of all IE patients, and are the most common complications in patients following ICU admission.[45,56] Yet, many of these patients might otherwise warrant urgent valvular surgery, with the attendant risks of systemic heparinisation and other rheological effects of cardiopulmonary bypass. Current recommendations suggest that as long as coma and intracerebral haemorrhage are absent, ischaemic stroke should not be considered a contraindication to surgery, with an estimated neurological risk in the order of 3%–6%.[36,52,56] In the case of intracerebral haemorrhage, surgery should be delayed by at least 1 month, although patients with small lesions have been operated on safely.[36,52,56]

PROSTHETIC VALVE ENDOCARDITIS

PVE represents 10%–30% of all IE cases.[36] Antimicrobial therapy for staphylococcal PVE generally warrants more prolonged treatment often in combination with aminoglycosides and rifamycins. Surgery is more likely to be required but its precise role remains controversial, and current guidelines follow similar principles to NVE.

INFECTIVE ENDOCARDITIS ASSOCIATED WITH CARDIAC IMPLANTED ELECTRONIC DEVICES

IE associated with cardiac implanted electronic devices (CIEDs) is associated with high mortality. Diagnosis is particularly difficult and because of CIED implantation patients may inevitably have severe co-morbidity.

Coagulase-negative Staphylococci are the most common causative organisms. Management requires prolonged antibiotic therapy as well as removal of the device and leads. Transvenous explantation is preferred, but is not risk free, and should only be performed in centres with ready access to cardiac surgical rescue.

RIGHT-SIDED ENDOCARDITIS

Constituting 5%–10% of cases and despite a better prognosis, surgery for right-sided IE is less commonly employed, but can be considered reasonable for patients with right HF due to severe TR with intractable symptoms; sustained infection caused by difficult-to-treat organisms or lack of response to appropriate antimicrobial therapy; and recurrent pulmonary embolism or paradoxical emboli despite antimicrobial therapy. Valve repair may be preferred if possible rather than replacement.[36]

FUNGAL ENDOCARDITIS

Fungal IE is more commonly seen with PVE, immunocompromised patients, and in the setting of intravenous drug use. *Candida* and *Aspergillus* species are the main offenders. Surgery is more frequently required in conjunction with long-term antifungal chemotherapy.

Postoperative cardiac intensive care

Nick Fletcher, Michael Adlam

Coronary artery bypass surgery is one of the most frequently undertaken surgical procedures globally. Because of the prevalence of cardiac disease, cardiac surgery has significant health and economic implications. Intensive care may account for up to 40% of the total hospital costs for these patients and much of the short-term morbidity and mortality is based on perioperative events.

The overall mortality following cardiac surgery is low (approximately 3%). However, this ranges from less than 1% for elective coronary artery bypass grafting to more than 30% for more complex surgery in patients with significant myocardial dysfunction and significant co-morbidities. Intensive care management following cardiac surgery usually involves a short period of recovery before discharge to the ward. For a small percentage of patients, significant complications may require the complete spectrum of high acuity intensive therapy, with a profound impact on the intensive care unit (ICU) capacity, hospital budgets and resources.

ORGANISATION

TYPES OF UNIT

The co-location of large numbers of patients with similar problems in the cardiac ICU provides an ideal environment for the standardisation of care based on protocols and clinical pathways. One of the traps of postoperative cardiac care is that this apparent similarity of the patients tends to obscure their particularity. Individual patient assessment must carefully address the multisystemic manifestations of cardiovascular and other degenerative diseases. In some institutions, cardiac patients may be located with other surgical and medical intensive care patients to centralise critical care resources – staffing in particular. There is no adequate supporting evidence as to whether cardiac surgical patients have better outcomes with any particular model; rather, it is likely that high quality dedicated critical care, constructive relationships with surgeons and a multidisciplinary culture will positively impact on the results. There has been significant research into organisational factors in general ICU; however, there is less supporting information around issues such as open versus closed ICU, and surgeon-led care versus intensivist-led care in the cardiac arena.

SURGEON/INTENSIVIST RELATIONSHIP

Cardiac surgery involves a continuum of care from presentation to post-discharge management and rehabilitation. The intensive care specialist must be involved in this continuum, rather than functioning in isolation from surgeons, anaesthetists, cardiologists and even family practitioners.

The postoperative stage and outcome is largely set by the preoperative and operative phases of management, and it is the fitness of the patient to undergo surgery that is the primary determinant.[1] A component of postoperative management is active participation in patient selection and preparation, as well as in the conduct of anaesthesia and surgery. Relevant aspects include suitability and preparation for surgery, advanced care planning and more technical issues, such as temperature management, invasive monitoring, haemodynamic management and transport. Movement from the operating theatre to the ICU and on to the ward presents a potential hazard and will appear seamless only if the patient journey has been well coordinated in advance.

Joint selection and morbidity and mortality meetings may allow a forum to discuss complex cases and facilitate improvement of the institutional processes. In particular, the human factors, which are so essential to successful cardiac surgery, may be put under the microscope. Regular audit of discharge timeliness, readmission and hospital mortality allows benchmarking against other units, both internal and external, and ensures good practices are maintained and poor practice is eliminated.

OUTCOME AUDIT

In the United States and the United Kingdom, risk-adjusted cardiac surgical results are available in the public domain by individual surgeon and institution. EuroSCORE II is the predominant preoperative cardiac surgical risk score, but this performs less well as an

ABSTRACT

The worldwide volume of cardiac surgery is increasing as a result of a greater disease prevalence, surgical centre development and availability in the developing world; an ageing population in the developed world and an increasing diversity of surgical techniques. In older patients, this greater co-morbidity and increased complexity means they are sicker and are staying longer in postoperative cardiac critical care units. Organ support and rehabilitation have developed in this population in parallel to general critical care. Factors affecting the immediate postoperative care of these patients are better understood, and organisational processes have been developed in response. A good understanding of the anatomy, physiology and pharmacology that underpins this area is essential. The common complications secondary to the surgery and circulatory bypass must be recognised early and treated to minimise organ hypoperfusion and consequent failure.

ICU score. The majority of ICU scoring systems were not designed with cardiac surgery patients in mind; hence, some cardiac ICU-specific scoring systems have been more recently introduced. Currently, these are specific to different health systems.[2,3]

TYPES OF PROCEDURE

Changing patterns of practice are resulting in the management of older patients with more co-morbid pathologies. Procedures are now being offered to patients previously considered unfit for surgery, and there is a continuing growth in the use of minimally invasive forms of surgery. At the same time, patient and family expectations of surgery are increasing. This, together with greater expectation for regular and detailed communication, will increasingly impact on cardiac intensive care practice.

IMMEDIATE POSTOPERATIVE MANAGEMENT PRINCIPLES

STRUCTURED HANDOVER

The first step in the intensive care management involves a simple transfer of ventilation, monitoring and drug administration from transport to ICU systems. This should be structured to minimise disruption and maximise communication. The priorities are:

- Confirm surgical procedure and any complications
- Confirm integrity and position of the endotracheal tube
- Re-establish mechanical ventilation of both lungs
- Re-establish all patient monitoring
- Confirm venous, arterial and central access
- Heart rhythm and presence and mode of any pacing devices
- Document results of any intraoperative echocardiography regarding ventricular function.
- Intraoperative transfusion of blood or factors together with the results of any benchtop or laboratory tests of haemostasis
- An early 12-lead electrocardiograph to exclude or identify acute ischaemia.

Management is conveniently dictated by standardised protocols, which should cover investigations, fluid and electrolyte management, vasoactive and other drug administration, and weaning and withdrawal mechanical ventilation. Standardisation is probably more important than the particulars of the protocol, which might vary considerably among institutions.

HAEMODYNAMIC MONITORING

Continuous invasive blood pressure and central venous pressure monitoring are standard following surgery, and should be monitored during transfer. Patients may commonly become unstable during transfer and rapid assessment is needed to ensure the correct calibration of transducers, continuity of all infusions, evidence of hypovolaemia and haemorrhage. Cardiac output measurement by pulse contour analysis, pulse power analysis and a variety of ultrasound techniques are becoming more commonplace. Cardiac output-guided fluid boluses allow individualised treatment, and unresponsiveness can guide inotropic and vasopressor use. Of note, pulse analysis is invalid in the presence of intra-aortic counterpulsation.

In complex surgical patients, and those in which minimally invasive strategies are invalid, more invasive methods of haemodynamic monitoring are required.

Flotation pulmonary artery (PA) catheterisation has become somewhat controversial. It is now reasonably well established that PA catheterisation is safe but may not alter outcomes.[4]

- Surgery can be safely undertaken at least in low-risk patients without PA catheterisation.
- Collateral evidence supports PA catheter use in more complicated cases.
- It is essential that the known limitations and complications of PA catheters are considered in usage and interpretation.[5]

Transoesophageal echocardiography (TEE) is now almost routine in the operating theatre – at least for more complicated patients. The technique is less suitable for monitoring in the ICU, but is helpful in the diagnosis and management of cardiovascular instability in postoperative patients. Continuous TEE monitoring has been described, but the application is not widely used.[6]

Transthoracic echocardiography is of limited use postoperatively due to the poor cardiac windows. The apical window may allow some assessment of biventricular function and volume status. Inferior vena caval assessment is problematic and should not be used in this context.[7]

FLUIDS

Despite generous intraoperative fluid administration, effective hypovolaemia is common in the early postoperative period, especially as warming with associated vasodilatation occurs.

- Use of isotonic fluid is essential.
- No benefit for any specific resuscitation fluid has been established.
- Larger volumes of crystalloid than colloid solutions are required.
- An excessively positive fluid balance may increase perioperative complications.

Polyuria is frequently observed in the early postoperative period, possibly related to hypothermia,

haemodilution and the after-effects of non-pulsatile cardiopulmonary bypass on stretch and baroreceptors. This usually settles within the first 6 hours, but often necessitates considerable volume replacement in the meantime.

ELECTROLYTES

Hypomagnesaemia and hypokalaemia are frequent in the early postoperative stage and are exacerbated by polyuria. It is generally considered that levels should be maintained in the high normal range (4.5–5.0 mmols/L) although this has recently been challenged.[8]

Late hyperkalaemia may occur, especially in patients with renal impairment or prior angiotensin-converting enzyme (ACE) inhibitor administration. Treatment for hyperkalaemia is rarely required in the absence of significant renal impairment, but discontinuation of potassium-containing fluid may be required.

Calcium homeostasis is generally not disrupted by cardiopulmonary bypass. However, massive transfusion frequently causes hypocalcaemia. Ionised calcium levels are now easily monitored by point-of-care blood gas analysers.

SHIVERING

Shivering is frequent following cardiac surgery. Mechanisms are complex and not entirely related to core temperature. Shivering causes a significant increase in metabolic rate and hence cardiac workload. This is especially important in the patient with impaired cardiac function and limited reserve. Forced air warmers are the most effective treatment, but pharmacological agents may be considered; these include dexamethasone, clonidine, pethidine and high-dose morphine. Short-term neuromuscular blockade is occasionally required.

HAEMODYNAMIC COMPLICATIONS AND MANAGEMENT

HYPERTENSION

Significant postoperative hypertension is more common in patients having a history of hypertension and with cessation of beta blockade, but is reasonably common in the early postoperative period. Both absolute pressure and dp/dt are important factors in vascular injury. Complications associated with hypertension include:

- bleeding
- heart failure
- vascular (especially aortic) injury
- myocardial ischaemia.

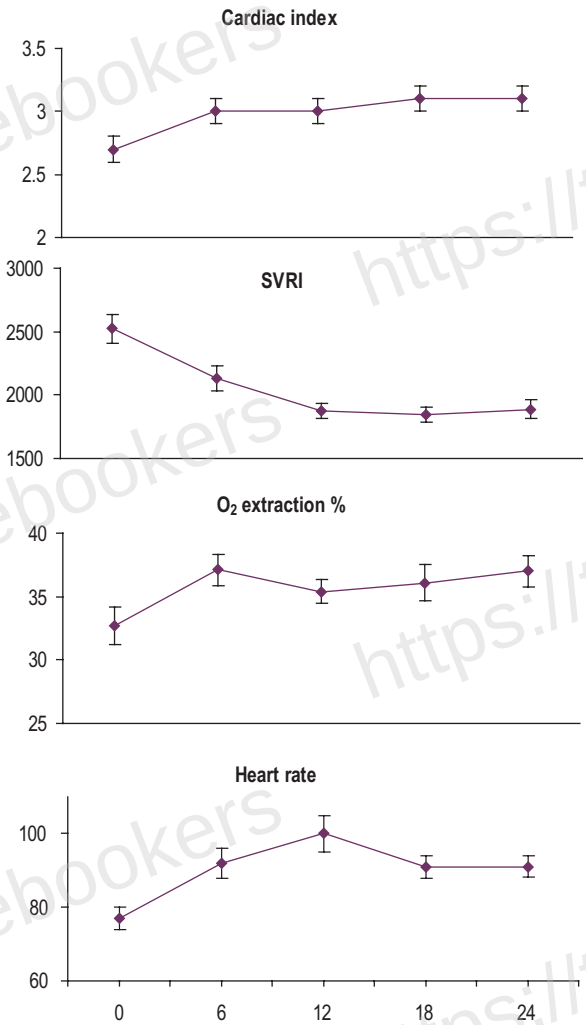

Figure 26.1 Haemodynamic changes following cardiac surgery. *SVRI*, Systemic vascular resistance index.

Vascular resistance declines over the first few hours (Fig. 26.1)[9] so that therapy during this period is best undertaken with agents with a short duration of action. Glyceryl trinitrate infusions are often useful over the first 24 hours, after which regular oral medication can be restarted. Simple measures, such as the provision of adequate analgesia and sedation, also should be considered.

The target blood pressure varies with the indication. Excessive reduction of blood pressure risks reducing myocardial oxygen supply more than demand. Under most circumstances, a mean arterial pressure between 60 and 80 mm Hg seems optimal.

HYPOTENSION

Hypotension is very common and can be a result of vasodilatation and low cardiac output (Box 26.1).

Box 26.1 Causes of postoperative hypotension

Hypovolaemia
- Haemorrhage
- Vasodilation
  - Rewarming
  - Drugs – milrinone
- Vasoplegia secondary to circulatory bypass

Low cardiac output
- Preload
  - Hypovolaemia, including haemorrhage
  - Tamponade, pericardial constriction
  - Left ventricular diastolic dysfunction
  - Right ventricular failure
- Afterload
  - Excessive vasoconstriction
  - Aortic stenosis
  - Functional left ventricular obstruction
- Myocardial function
  - Mechanical (ventricular septal defect, valve pathology)
  - Cardiomyopathy
  - Ischaemia, postischaemic stunning
  - Metabolic, electrolyte abnormalities, pharmacological depression

Whatever the cause, hypotension can cause myocardial ischaemia and consequent heart failure.

In general, all patients should have some form of cardiac output monitoring to guide fluid, vasopressor and inotropic therapy. An initial straight leg raise to assess fluid responsiveness is a safe starting point. If not fluid responsive, vasoconstrictors may be useful in breaking the cycle of hypotension–ischaemia–hypotension, but must be used cautiously in patients with impaired ventricular function, and especially in patients with major vascular or aortic pathology, for whom a hypertensive overshoot may be catastrophic.

- Norepinephrine (noradrenaline) is a potent vasoconstrictor. It is commonly used to manage vasodilation, but it should not be used alone in the presence of a low cardiac output.
- Vasopressin has an increasing role in postoperative cardiac surgery; it reduces the level of norepinephrine (noradrenaline) required, and may thus spare the myocardium from excessive beta stimulation.

Recognition of a low-output state in the absence of invasive monitoring may be difficult. Many of the usual signs of low output are also consequences of anaesthesia and surgery. Tachycardia may be obscured by drugs, hypothermia and heart disease, and even lactic acidosis may be an unreliable marker in this patient group.[9]

In the early postoperative period, a relatively low cardiac output may not warrant intervention, providing tissue oxygen delivery is adequate. Since beta blockade is beneficial in the postoperative cardiac

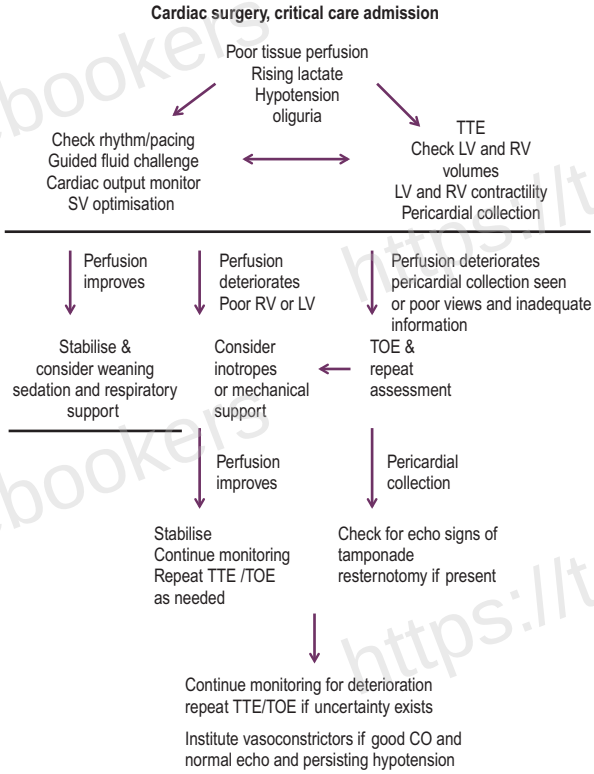

Figure 26.2 Suggested simple practical algorithm for use of echocardiography in postcardiac surgical patients. *LV*, Left ventricular; *RV*, right ventricular; *TOE*, tranoesophageal echocardiography; *TTE*, transthoracic echocardiography.

patient, beta agonists should not be used unquestioningly. Nevertheless, optimisation of cardiac function may confer some benefit[10] and intervention is clearly required when tissue oxygen delivery is inadequate.

On a specialised unit, an integrated algorithm can be used to assess and treat in sequence (Fig. 26.2).[7]

Mechanical ventilation is generally continued, reducing cardiac workload by removing the work of breathing. Positive intrathoracic pressure reduces left ventricular (LV) afterload, which is beneficial to the dilated left ventricle. Positive pressure may be detrimental; however, in the presence of diastolic ventricular dysfunction or hypovolaemia, the reduction in venous return may further reduce ventricular preload.

TAMPONADE

A high index of suspicion for tamponade in postcardiac surgery patients is paramount. Any patient with a rising central venous pressure and low cardiac output should be assumed to have tamponade unless proved otherwise. Of note, hypotension may be absent with the addition of vasopressors; thus haemodynamic monitoring is essential. Clinical assessment is difficult, and early echocardiography is required. Transthoracic

images can miss posterior thrombus, but may be diagnostic and are more readily available.[11] Early discussion with surgical teams and TEE imaging will often be required.

LEFT VENTRICULAR DYSFUNCTION

Postoperative LV dysfunction is common and can be diagnosed by echocardiography or cardiac output monitoring. Inotropic agents are frequently required, alone or in combination. Pre-emptive use of inotropic drugs may be associated with harm, so inotropes should not be used routinely without monitoring their effect.[12] Issues to consider include:

- Dobutamine is an essentially pure β_1-agonist. In the management of acute heart failure, it has been associated with an increase in mortality.[13]
- Epinephrine (adrenaline) is a potent ino-constrictor but its metabolic effects (especially lactic acidosis) and relative tachycardia make usage in cardiac surgical patients problematic.[14]
- Milrinone is a phosphodiesterase inhibitor with a long duration of action and potent vasodilating properties. These make milrinone relatively difficult to introduce and to wean. It has similar haemodynamic effects to dobutamine and is associated with increased atrial fibrillation (AF). Overall benefit is not established.[15] It may be a useful inotropic agent in patients with β-receptor down-regulation.
- Levosimendan is a calcium-sensitising agent. It offers little overall benefit in the treatment of heart failure,[16] but it may be beneficial in the perioperative period.[16,17]

Postoperative myocardial ischaemia predicts a more complicated course.[17] Recognition is enhanced by automated ECG multilead ST segment analysis with confirmatory electrocardiography, although diagnosis may be difficult in the presence of preoperative electrocardiographic abnormalities.[18]

Ischaemia may be due to graft failure. Remedial options include coronary angiography and/or reoperation. Angiography offers the potential for tailored reoperation or non-operative intervention. Management decisions may be influenced by surgical factors, such as the availability of further conduit and the state of the native arteries. Thus, close liaison among ICU personnel, cardiologists and surgeons is essential.

Delayed sternal closure has an established role in improving outcome after cardiac surgery.[19] Cardiac output is increased and inotropic requirement is reduced. Subsequent sternal closure has an acceptably low complication rate. The sternum may be left open following an initial attempt at closure, or reopened with later deterioration. Sternal retraction may be required.

RIGHT VENTRICULAR DYSFUNCTION

Right ventricular (RV) failure following cardiac surgery is reasonably common. Aetiological factors include:

- direct RV ischaemia or infarction
- poor myocardial protection
- anteriorly placed RV
- pre-existing pulmonary hypertension.

Management involves:

- careful volume resuscitation
- maintenance of RV perfusion pressure with vasoconstrictors
- intra-aortic balloon counterpulsation (IABC) as required
- inotrope administration
- RV afterload reduction.

Useful afterload-reducing agents include nitric oxide, prostaglandins and sildenafil. Conventional vasodilators tend to produce excessive systemic vasodilatation. Occasionally, RV balloon counterpulsation or an RV assist device may be required. Delayed sternal closure has an established role.

MECHANICAL SUPPORT

Intra-aortic balloon pumps (IABP) have an established role in support of cardiac surgery. Its two actions are: (1) augmentation of diastolic coronary perfusion pressure and (2) left ventricular afterload reduction. This is achieved by balloon inflation (30–50 mL capacity) within the aorta during diastole and rapid deflation of the balloon immediately before aortic valve opening. The catheter is usually inserted using a Seldinger technique, but can be placed by femoral artery cut down or directly into the descending thoracic aorta. Timing of inflation and deflation is critical to optimal function. This is best achieved using the pressure waveform (Fig. 26.3).

Inflation is timed to coincide with the dicrotic notch. Deflation is timed to occur as late as possible in diastole, ensuring that the IABP end-diastolic pressure is lower than the patient's end-diastolic pressure. IABC increases the cardiac index and coronary perfusion and reduces the left ventricular filling pressure, myocardial lactate production and oxygen extraction percentage.

Indications for IABP are summarised in Box 26.2.

IABP has an established role in the management of reversible myocardial dysfunction especially in the context of myocardial revascularisation (surgical or endovascular). There is a probable benefit in high-risk surgical patients undergoing elective revascularisation.[20] However, IABP is not helpful in the management of cardiogenic shock from irremediable causes except as a bridge to transplant. Complications include:

- limb ischaemia (6%–16%)
- vascular trauma, dissection
- infection (cut down > percutaneous)
- balloon rupture
- bleeding
- thrombocytopenia

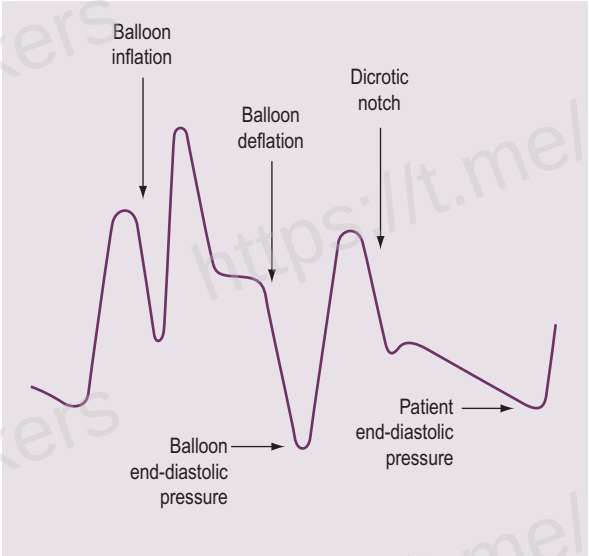

Figure 26.3 Intra-aortic balloon counterpulsation pressure waveform. Inflation is timed to coincide with the dicrotic notch. Deflation is timed to occur as late as possible in diastole, ensuring that the intra-aortic balloon counterpulsation end-diastolic pressure is lower than the patient's end-diastolic pressure.

Box 26.2 Indications for intra-aortic balloon counterpulsation

Prophylactic
- Cardiac surgery, two of:
  Left main >70%, left ventricular ejection fraction <0.4, unstable angina, reoperation
  Failure to wean from cardiopulmonary bypass
- Non-cardiac procedures in the presence of severe left ventricular impairment, unstable angina

Cardiogenic shock
- Reversible myocardial depression
- Support for reperfusion, revascularisation
- Bridge to transplant

- malposition, vascular obstruction
- malfunction, failure to unwrap.

Limb ischaemia is the most frequent complication and optimal management requires early recognition based on routine, systematic observation.

Ventricular assist devices (VAD) are expensive and technically far more demanding than IABP. The refinement of extracorporeal membrane oxygenation (ECMO) circuits has increased their use for short-term cardiac support. When instituted for failure to wean from bypass, the outlook is generally poor.[21,22] Most published VAD data relate to non-surgical patients in whom the role of heart assist devices is increasingly established both as a 'bridge to transplant' and as 'destination therapy'.

DYSRHYTHMIAS AND PACING

Ventricular and supraventricular dysrhythmias are common. Prevention and treatment of electrolyte abnormalities may be prophylactic. New occurrence of complex ventricular dysrhythmias should stimulate a search for causal ischaemia and graft malfunction.

Ventricular fibrillation and pulseless ventricular tachycardia require rapid defibrillation, preferably before external cardiac massage, which may cause mechanical injury post-sternotomy. If haemodynamic stability cannot be rapidly restored, open cardiac massage should be instituted.

Facilities for atrioventricular pacing are essential as transient heart block is common.

All units should have regular training in life support protocols focused on the post-cardiac surgical patient. AF is the most common complication of cardiac surgery.[23] Its incidence varies from 10% to 40% in patients undergoing coronary artery surgery and up to 50% with some valvular procedures. Predisposing factors include a history of AF, valvular heart disease (especially mitral valve pathology), increasing age and prolonged P-wave duration. AF can be effectively treated and its recurrence prevented with intraoperative radiofrequency ablation and left atrial reduction during cardiac surgery[24]; these may also provide a long-term survival benefit.[25] AF is probably less frequently observed following 'off-pump' surgery, and is most frequently encountered around the second and third postoperative days, but may occur weeks after surgery and hospital discharge.

AF is a potentially serious complication. Apart from discomfort, it may provoke or complicate haemodynamic instability. However, the major complication of AF is stroke, with an increased risk of approximately threefold. Based on echocardiography, there is the potential for embolic stroke within 3 days of onset of AF.

AF is also associated with:

- increase in inotrope usage
- increased use of IABP
- increased reoperation for bleeding
- prolonged ICU and hospital stay
- increased costs.

Several strategies are beneficial in preventing AF[26]:

- beta blockade
- amiodarone
- sotalol[27]
- diltiazem
- bi-atrial pacing
- dexamethasone
- colchicine[28]
- statins.[29]

Box 26.3 Management of atrial fibrillation

Rate control
- Beta blockade
- Calcium channel blockers
- Sotalol
- Digitalis

Cardioversion
- Amiodarone
- Magnesium
- Electrical cardioversion

Anticoagulation
- Always for elective cardioversion
- Consider if atrial fibrillation persists beyond 48 hours

Treatment should be tempered with an understanding that spontaneous reversion to sinus rhythm is frequent. A treatment strategy is summarised in Box 26.3.

Whether to rate control or rhythm control is unclear, with both strategies having similar complication and conversion rates.[30] Early cardioversion tends to be ineffective and potentially harmful. Although officially recommended in the presence of instability, this is not based on any empirical evidence.

EMERGENCY REOPERATION

Emergency re-sternotomy is indicated as part of resuscitation when haemodynamic stability cannot be rapidly re-established with conventional means. Advantages compared with closed-chest resuscitation include:

- establishment of the cause of instability
- correction of the cause (e.g. tamponade, kinked graft)
- more effective cardiac massage
- direct establishment of atrial and ventricular pacing.

Re-sternotomy also enables the re-establishment of cardiopulmonary bypass and regrafting or correction of mechanical abnormalities as required. Infectious complications of emergency resternotomy are probably increased, but the incidence is not prohibitive.

A protocol specific to cardiac surgical units and an internationally recognised course are available.[31]

OTHER COMPLICATIONS

COAGULATION

Excessive postoperative bleeding is a major cause of increased morbidity and mortality. Mechanisms are complex and include preoperative anticoagulation, thrombolysis and antiplatelet therapy, as well as activation of haemostatic mechanisms, including fibrinolysis.

A systematic approach to operative and postoperative blood conservation, including point-of-care testing to guide therapy, can significantly reduce bleeding, transfusion and resultant complications.[32] There is increasing evidence that transfusion is associated with excessive complications, including death, and that transfusion rates vary amongst institutions.[33]

Effective postoperative measures include reversal of residual heparin (including 'heparin rebound') and correction of coagulopathy with blood products. Retransfusion of shed blood reduces autologous transfusion requirements without apparent side effects. A restrictive transfusion strategy can reduce exposure to transfusion without increased risk[34]; restrictive transfusion to a Hb of 75 versus 90 g/L found no benefit in mortality or cost.[35]

Most studies of pharmacological strategies to minimise postoperative blood loss have involved preoperative or intraoperative intervention. Extrapolation to the postoperative phase is intuitive rather than established. Tranexamic acid reduces bleeding and exposure to blood and blood products.[36] Aprotinin has been associated with an increased risk of serious end-organ damage and was withdrawn from the market for a period, although it is now available with a license restricted to coronary surgery.[37] Desmopressin is probably less effective and has been associated with an increased risk of myocardial infarction.[38] Activated factor VII may be effective in controlling bleeding, but may result in an increased risk of stroke.[39]

'Off-pump' surgery has been associated with excessive bleeding because of the administration of anticoagulant and antiplatelet therapy out of fear of early graft closure. Controlled tamponade with discontinuation of drain suction and even clamping of drains has been reported.[40] Application of positive end-expiratory pressure (PEEP) has been shown to be effective in some studies, but not others.

RESPIRATORY

Postoperative mechanical ventilation remains routine in cardiac surgical patients. Immediate extubation appears to offer little patient benefit[41]; similarly, neither does routine prolongation of ventilation. Extubation can be safely undertaken with simple protocols. Reintubation is rarely required, but is more likely in older patients with pre-existing lung and vascular disease and impaired ventricular function. Reoperative surgery and bleeding requiring massive transfusion also increase the likelihood of early extubation failure.

Hypoxia is very common in the early postoperative period. It is mostly attributable to atelectasis as a consequence of cardiopulmonary bypass and intraoperative ventilation with high inspired oxygen and repeated disconnection from the ventilator. Treatment involves simple measures, such as appropriate PEEP and lower tidal volume selection, prolonged inspiration and simple recruitment manoeuvres.

Long-term sequelae are rare. Incentive spirometry and chest physiotherapy are commonly utilised in the postoperative period, without good supportive evidence. Early mobilisation and the use of continuous positive airway pressure (CPAP) or high flow nasal oxygen are commonly employed strategies. Adequate analgesia facilitates physiotherapy and mobilisation. Non-steroidal agents may increase the risk of complications and are rarely used.[42]

More sinister causes of hypoxia include severe heart failure and acute respiratory distress syndrome (ARDS). The aetiology of ARDS is diverse, but includes shock, massive blood product administration and cardiopulmonary bypass itself. Management is not particular to this group of patients. Occasionally, profound hypoxia accompanies minor atelectasis with moderate pulmonary hypertension. Patent foramen ovale (which is seen in 10%–15% of the normal population) with right-to-left intracardiac shunt is the likely mechanism.

Clinically detected pulmonary embolism is an uncommon complication of cardiac surgery, probably due to bypass-induced platelet dysfunction, routine postoperative antiplatelet therapy and thromboprophylaxis.[43] However, asymptomatic thromboembolism may be significantly more common.[44,45] Contrary to earlier beliefs, 'off-pump' surgery may not be associated with an increase in prothrombotic tendency or a need for a more aggressive thromboprophylaxis regimen.[46]

Pleural drains are not routinely inserted after valve surgery. When the mammary artery is harvested, the pleura is breached and thus pleural drains are placed. Once coagulation is normalised and drain output is less than 20 mL/h for 4 hours, the drains can be removed.

In patients with poor left ventricular ejection fraction, pleural effusions may accumulate and limit ventilation. This often presents after several days, and if deemed necessary new pleural drains will need to be placed.

Currently, there is much interest in oxygen, and specifically whether hyperoxia or normoxia is most beneficial. Studies in cardiac surgery of intraoperative and postoperative hyperoxia have shown no benefit – and even possible harm.[47]

Diastolic dysfunction can be exposed following surgery when trying to wean a patient from the ventilator. As a result, the heart may fail on changing from positive to negative pressure ventilation, resulting in sudden onset pulmonary oedema. The reasons for this are an increase in venous return, an increase in work of breathing and oxygen demand, and catecholamine discharge during transition. In any patient who fails extubation, an echocardiogram is needed to assess diastolic function. Treatment options include avoiding tachycardia to allow LV filling, treat AF to allow atrial synchrony, fluid removal with diuresis, and medical optimisation with ACE inhibitors.

RENAL

Depending on definition and patient groups, acute renal failure is observed in 1%–5% of patients undergoing cardiac surgery. Risk factors include increasing age, heart failure, prolonged bypass, diabetes, pre-existing renal impairment and postoperative shock. Surgery without cardiopulmonary bypass may be relatively protective and other potentially modifiable factors include anaemia, blood transfusion and re-exploration.[48] Morbidity, mortality and costs are significantly increased. Effective preventive strategies beyond careful haemodynamic management and the minimisation of associated nephrotoxic insults have not been established. Nevertheless, attention to urine output in the presence of known risk factors appears warranted.

The use of renal replacement therapy (RRT) is common to allow the normalisation of biochemistry. However, the decision on when to implement RRT is unclear. Current research shows no benefits of early initiation[49]; however, due to the large fluid load cardiac patients receive, they may benefit from early intervention if the fluid is overloaded.

NEUROLOGICAL

Neurological complications of cardiac surgery include neuropsychiatric deterioration as a consequence of cardiopulmonary bypass, delirium and a range of peripheral neuropathies – the most frequent of which is unilateral phrenic nerve palsy. Paraplegia is a recognised complication of thoracic aortic surgery.

The most devastating neurological complication is cerebral infarction. The incidence varies with patient selection, but ranges from 1% to 5%. The pathophysiology is mostly embolic. Risk factors include carotid artery stenosis, hypertension, AF, aortic atheroma, impaired ventricular function and peripheral vascular disease. 'Off-pump' and especially 'anaortic' surgery (no aortic manipulation) are protective,[50] and other operative techniques may also reduce the incidence.

Postoperative cognitive dysfunction is common, and multifactorial in nature. Standard intensive care measures include regular reorientation, minimising medications and investigating other causes, such as infection. Unless there is focal neurology, early imaging with either computed tomography or magnetic resonance imaging is not indicated.

GASTROINTESTINAL

Gastrointestinal complications after cardiac surgery are rare (<1%). However, morbidity is quite high.[51] The risk factors include increased age, complex surgery and postoperative shock. The incidence of gastrointestinal complications may be reduced with 'off-pump' surgery.

The commonest complication is mesenteric ischemia secondary to atheromatous emboli, hypoperfusion and heparin-induced thrombocytopenia. Early postoperative rises in lactate are common post-bypass; therefore distinguishing early mesenteric ischaemia is difficult, and any sign of abdominal pain should be investigated rapidly. Pseudo-obstruction and constipation are common. Perforation of the bowel or gallbladder, appendicitis and pancreatitis are rare but have been reported following cardiac surgery. Stress ulcer prophylaxis should be routine in this patient population until they are re-established on normal diets, which should happen as soon as possible following extubation.

INFECTION

Deep sternal wound infection is uncommon (0.5%–2.5%). Associated morbidity and mortality are significant. Risk factors have been variously reported but consistently include diabetes, obesity and the use of internal mammary arteries, especially if bilateral. Other contributing factors include prolonged surgery, chronic lung disease, male sex, low postoperative cardiac output, blood transfusion, sternal reopening and dialysis. Close control of blood sugar levels in diabetics[52] and preoperative nasal and oropharyngeal decontamination[53] may help prevent infection. In the last 2 years, mycobacterium chimaera has been identified as a contaminant of extracorporeal heater-cooler units and should be considered in the case of unexplained early and persistent pyrexia.

SPECIFIC PROCEDURES AND PROBLEMS

ENDOCARDITIS VALVULAR SURGERY

These patients may have acute or subacute presentation. They should be managed by a multidisciplinary endocarditis team, including cardiac surgeons, cardiologists and microbiologists. Early organism identification can aid antibiotic selection and duration. Prior undiagnosed end-organ damage may present postoperatively, and a high index of suspicion is required. If expedited surgery occurs, then there may be a massive inflammatory response with bleeding and hypotension. If it persists, a secondary source of infection must be sought through clinical and radiological examination.

AORTIC SURGERY

Aortic surgery involves a period of deep hypothermic circulatory arrest, which can be up to 30 minutes at 18°C. They should be carefully rewarmed in theatre, and the avoidance of pyrexia is a key postoperative precaution. Active cooling may be considered. High arterial pressures are avoided to minimise the risk of extending arterial intimal dissection; however, the maintenance of cerebral circulation must be considered. There is a high vascular complication rate in these patients with mortality 8%–15% and stroke rates 7%–11%.[54] Subtle long-term cognitive dysfunction is common.[55]

MITRAL AND TRICUSPID VALVE SURGERY

In the developed world, surgery for mitral incompetence is more common, whereas mitral stenosis predominates in nations with undeveloped economies. Pulmonary hypertension, right ventricular pressure overload and impairment, and tricuspid valve regurgitation may develop with longstanding disease. These conditions significantly increase the risk of cardiac surgery; therefore expert management is demanded. Tricuspid valve repair with a de Vega suture or an annuplasty ring is increasingly performed at the same time as left-sided surgery. The treatment of pulmonary hypertension with pulmonary vasodilators may be needed in addition to inotropic support of the right ventricle and appropriate ventilator settings. Monitoring with a PA catheter and phosphodiesterase inhibitors have a role here, but dose titration to avoid refractory hypotension is important.

SURGERY FOR HYPERTROPHIC OBSTRUCTIVE CARDIOMYOPATHY

Patients with symptomatic hypertrophic obstructive cardiomyopathy suffer exertion dyspnoea and fatigue. A dynamic outflow obstruction in the left ventricular outflow tract is often the underlying lesion. Surgery involves septal myectomy, which alleviates this obstruction and co-existing mitral regurgitation. Diastolic dysfunction is common in these patients and they do not tolerate AF. In addition, inotropes should be avoided. There is an increased risk of heart block and these patients may need permanent pacemakers.

TRANSCUTANEOUS AORTIC VALVE INSERTION

Transcutaneous aortic valve insertion (TAVI) allows treatment of aortic stenosis in patients felt not to be medically fit for open surgery. This is often due to advanced age, LV dysfunction, and multiple co-morbidities. Compared with medical therapy for those patients unable to have open surgery TAVI reduces mortality. However, there is an increase in stroke and vascular complications.[56] On the ICU, these patients have a high risk of delirium. Due to their premorbid state, the risks of other organ failure is raised and they may benefit from prolonged postoperative monitoring.

END OF LIFE CARE

When severe complications occur following cardiac surgery that may significantly reduce the chances of

patients making the expected postoperative recovery, this may give rise to conflict between teams. As the patient opted for surgery, consideration must be given to allowing ample time for recovery to occur; however, when severe complications, such as stroke, end-stage renal failure and failure to wean, occur, family discussions may arise around treatment limitation and withdrawal of care. It is important that the surgical team are involved in this dialogue and that the family are not given conflicting messages. Advice can be sought from palliative care teams when needed.

Echocardiography in intensive care

Ubbo F Wiersema

Echocardiography is an integral part of modern intensive care practice. A wide range of diagnostic, monitoring and procedural indications are suitable for echocardiographic evaluation in critically ill patients (Table 27.1). Image acquisition, analysis and interpretation are, however, entirely operator dependent. Therefore the clinician needs to have a clear understanding of the purpose and potential limitations each time an echocardiogram is performed.[1–5]

INTENSIVE CARE ECHOCARDIOGRAPHY

Used as an extension of the physical examination in the emergency situation, or used to supplement or replace traditional haemodynamic monitoring tools, echocardiography needs to be immediately available and may be required for repeated studies of the same patient. The information required is often more about function than structure. More robust, but less sophisticated echocardiography machines are often used where image quality may be inferior to that obtained with advanced 'high-end' machines. Furthermore, image acquisition may be challenging because of the patient's position, dressings, positive pressure ventilation and tachycardia. A clinician with expertise in echocardiography may not be readily available. To overcome these limitations and achieve satisfactory information for clinical decision making, the concept of a focused or targeted echocardiogram looking to answer a small number of specific questions in a limited number of defined clinical situations has evolved.[1,2,4,5] At other times, a more detailed study with expert interpretation is required.[6] A suggested terminology for different types of study is shown in Table 27.2.[1,2,4,5,7] Appropriate certification for different levels of expertise should be achieved through a recognised training programme that uses competency-based assessment.[1,4,5,7–9]

ULTRASOUND PHYSICS

Ultrasound consists of waves of alternating compression and rarefaction at frequencies higher than that audible to the human ear. Echocardiography involves transmission of a beam of ultrasound waves and the subsequent detection of the returning waves reflected at interfaces between tissues with differing acoustic impedance. The degree of impedance mismatch determines the amplitude of the reflected wave. The depth of the reflecting interface is determined from the time taken for the pulse of ultrasound waves to return. Ultrasound waves that are not reflected are attenuated by absorption, refraction and scattering. The machine software adjusts the detector amplifier to compensate for the loss of energy with depth penetration. Time gain compensation (TGC) control allows manual adjustment of the relative brightness of structures at different depths. For echocardiography, ultrasound frequencies of 1–5 MHz are used, which is a compromise between the higher spatial resolution achieved with higher frequencies and the greater depth penetration achieved with lower-frequency imaging.

To produce an ultrasound image, repeated pulses of ultrasound waves are transmitted and received. The number of pulses emitted per second is called the pulse repetition frequency. To build a 2D image, the ultrasound beam sweeps across the plane of interrogation, creating the image one line at a time. The frame rate is the frequency with which the 2D image is renewed (temporal resolution), which depends on the pulse repetition frequency and the image width (number of scan lines). M-mode imaging provides high temporal resolution by scanning along a single line.

DOPPLER ECHOCARDIOGRAPHY

The Doppler effect is the change in frequency (Δf) of ultrasound waves that occurs when the reflecting structure is moving relative to the wave transmitter and receiver. The velocity of the structure (v) can be calculated from the measured frequency shift by the Doppler equation: $v = c(\Delta f)/2f_T.\cos\theta$ where c is the velocity of sound in soft tissue (1540 m/s), f_T is the transmitted frequency and θ is the angle between the ultrasound beam and the direction of movement.

The four most commonly used modes of Doppler echocardiography are as follows:

Continuous wave (CW) Doppler involves continuous transmission and reception of a beam of ultrasound waves along the line of interrogation. The frequency

ABSTRACT

Echocardiography is suitable for a wide range of diagnostic, monitoring and procedural indications in intensive care. In most circumstances a focused transthoracic study is sufficient to guide management, but the clinician should be familiar with the indications for a more comprehensive study. Transoesophageal echocardiography is appropriate in intubated patients if transthoracic images are inadequate, or for a limited number of other indications. Image interpretation is operator dependent and thus requires recognition of pitfalls that may lead to misdiagnosis. Quantitative methods may be used, but are often not required.

A guide to the role of echocardiography in the diagnosis and management of different causes of circulatory failure, pericardial effusion, and complications of acute coronary syndrome and cardiac surgery is described. The role of echocardiography in pulmonary embolism, acute respiratory distress syndrome and cardiac arrest with non-shockable rhythm is also provided.

KEYWORDS

Echocardiography
Doppler
fluid responsiveness
pericardial effusion
systolic function
diastolic function
shock
pulmonary embolism
acute cor pulmonale
cardiac arrest

Table 27.1 Indications for echocardiography in intensive care

HYPOTENSION OR HAEMODYNAMIC INSTABILITY
Hypotension or haemodynamic instability of uncertain aetiology
Assessment of fluid responsiveness during controlled mechanical ventilation
Evaluation of left and right ventricular function in sepsis
MYOCARDIAL INFARCTION (MI)
Acute chest pain with suspected MI and non-diagnostic electrocardiograph
No chest pain but laboratory markers indicative of ongoing MI
Suspected complication of myocardial infarction
Evaluation of ventricular function following MI
RESPIRATORY FAILURE
Respiratory failure of uncertain aetiology
Acute respiratory distress syndrome
Failure to wean from mechanical ventilation
Suspected hepatopulmonary syndrome
PULMONARY EMBOLISM (PE)
Known acute PE to guide therapy
Re-evaluation of known PE after thrombolysis or thrombectomy for assessment of change in right ventricular function and/or pulmonary artery pressure
CARDIAC ARREST
Non-shockable cardiac arrest to identify cause
Non-shockable cardiac arrest to distinguish between pulseless electrical activity and pseudo-pulseless electrical activity
Ventricular tachycardia/fibrillation after return of spontaneous circulation to identify regional wall motion abnormalities as a surrogate for acute coronary syndrome
CARDIAC TRAUMA
Blunt trauma with haemodynamic instability (severe deceleration injury or chest trauma with suspected valve injury, pericardial effusion or cardiac injury)
Penetrating chest trauma with or without haemodynamic instability
EVALUATION OF VALVULAR FUNCTION
Suspected valvular heart disease
Re-evaluation of known valvular heart disease after a change in clinical status
Suspected prosthetic valve dysfunction
Initial evaluation of suspected infective endocarditis
Re-evaluation of infective endocarditis after a change in clinical status
EVALUATION OF INTRACARDIAC AND EXTRACARDIAC STRUCTURES AND CHAMBERS
Suspected cardiac mass, source of embolus
Suspected pericardial effusion
PROCEDURAL GUIDANCE
Percutaneous pericardial drainage
Temporary transvenous pacemaker insertion when radiographic imaging is not feasible
Cannulation for extracorporeal membrane oxygenation

See references 1, 3, 6.

shift of the reflected waves is used to calculate velocity at all points along the line. This allows measurement of high velocities, but at the expense of spatial uncertainty. Velocity is displayed against time. High-amplitude, low-velocity signals are filtered out (wall filter) so that only blood flow velocities are displayed.

Pulse wave (PW) Doppler involves alternating transmission and reception of pulses of ultrasound to interrogate the velocity of blood at the specific site (sampling volume) selected by the operator. Velocity is calculated from the phase shift of the reflected PW, thus limiting the highest velocity (Nyquist limit) that can be measured. Velocities greater than the Nyquist limit are displayed as if flow is in the opposite direction (aliasing phenomenon).

Colour Doppler is a pulse-wave Doppler method that determines the velocity at multiple points along multiple lines of interrogation. Each sampling volume is assigned a colour according to the average velocity and direction of blood flow (blue away, red towards), and displayed in a colour box superimposed on the 2D image.

Tissue Doppler imaging is a form of pulse-wave Doppler used to measure myocardial wall motion velocities by filtering out the high-velocity, low-amplitude signals of blood flow.

Measurement of blood velocity by Doppler methods makes it possible to calculate blood flow and pressure gradients. Volumetric flow is calculated from the velocity and the cross sectional area of the structure through

Table 27.2 Terminology for echocardiography in the intensive care setting

TERMINOLOGY DERIVED FROM ECHOCARDIOGRAPHY LITERATURE (see references 4, 5)
FOCUSED CARDIAC ULTRASOUND
Focused transthoracic study used by the clinician at the point of care, as an adjunct to physical examination, to recognise specific ultrasound signs that represent a narrow list of potential diagnoses in specific clinical settings
COMPREHENSIVE ECHOCARDIOGRAM
A complete transthoracic or transoesophageal study including quantitative evaluation, performed by experts in image acquisition with a fully equipped echocardiography platform and interpreted by a specialist in echocardiography
LIMITED ECHOCARDIOGRAM
A definitive study that requires the same level of expertise as a comprehensive study, but where a reduced number of images is obtained in order to address a specific clinical question
TERMINOLOGY DERIVED FROM CRITICAL CARE LITERATURE (see references 1, 2, 7, 9)
FOCUSED CRITICAL CARE ECHOCARDIOGRAM
As for focused cardiac ultrasound, but using either a transthoracic or transoesophageal probe
BASIC CRITICAL CARE ECHOCARDIOGRAM
As for focused critical care echocardiogram, but also including basic colour Doppler to identify severe valvular regurgitation
ADVANCED CRITICAL CARE ECHOCARDIOGRAM
As for comprehensive echocardiogram, but performed by an intensive care clinician, using either a transthoracic or transoesophageal probe

which the blood flows. Accuracy depends on parallel alignment of the Doppler ultrasound beam with the direction of flow, laminar flow with a flat profile, and accurate measurement of the cross sectional area. For pulsatile flow, the stroke volume is calculated from the integral of instantaneous velocity with respect to time during one pulse period (velocity time integral [VTI]), multiplied by the cross-sectional area.

The *continuity principle* states that the net forward stroke volume in one part of the heart equals the net forward flow in another part of the heart, provided that there is no shunt. The continuity principle is used to calculate valve orifice area. The *principle of conservation of energy* allows pressure gradients (ΔP) to be calculated from velocity, using the Bernoulli equation.

Table 27.3 Artefacts

TYPE OF ARTEFACT	EXAMPLES OF ERRONEOUS FINDINGS
REFLECTION AND/OR REFRACTION-RELATED ARTEFACTS	
Reverberation	Thrombus in left atrial appendage Thoracic aortic dissection Pacemaker lead reverberation
Mirror artefact	'Double barrelled' aorta or inferior vena cava Prosthetic valve pseudo-mitral regurgitation on colour Doppler
Acoustic shadowing	Obscuration of structures and colour Doppler deep to prosthetic valves
Refraction	Duplicate mitral valve leaflets or aortic root
ULTRASOUND BEAM PROPERTY-RELATED ARTEFACT	
Side-lobe artefact	Thrombi or vegetations Ascending aortic dissection flap
Beam-width artefact	Thrombi or vegetations Tricuspid regurgitation due to disturbed left ventricular outflow tract flow
Near-field clutter	Left ventricular apical thrombus

In practice, a simplified form of the Bernoulli equation is used, $\Delta P = 4v^2$, where pressure is measured in mm Hg and velocity in m/s. The simplified Bernoulli equation overestimates pressure gradients in the setting of severe anaemia (lower blood density) and if the upstream velocity is greater than 1 m/s.

IMAGE OPTIMISATION

With 2D imaging, spatial resolution is improved by using the highest frequency probe for the required depth of scanning. Temporal resolution is improved by using a higher frame rate, by decreasing imaging depth and narrowing image width. Gain should be set to show a bright myocardium but echo-free blood space.

With colour Doppler, temporal resolution is improved by reducing the width and depth of the colour box. Gain should be set just below the level at which colour speckling occurs.

ARTEFACTS

Imaging artefacts can result in false, missing or distorted structures (Table 27.3).[10] Failure to recognise artefacts may lead to misinterpretation and misdiagnosis. Artefacts may occur with 2D and Doppler imaging.

Prosthetic devices such as catheters, wires and artificial valves are particularly prone to causing artefacts.

Decreasing the gain, adjustment of focal depth and alternative imaging planes can be used to circumvent artefacts. Application of colour Doppler can sometimes help distinguish between true and artefactual structures.

COMPONENTS OF INTENSIVE CARE ECHOCARDIOGRAPHY

For a focused cardiac ultrasound, 2D images are obtained from the parasternal long-axis (PLAX) view, parasternal short-axis (PSAX) mid-papillary view, apical four-chamber view, and subcostal four-chamber and inferior vena cava (IVC) views.[2,4,5] For a more complete study, additional parasternal and apical views, and M-mode and Doppler methods are required.

LEFT VENTRICLE

Echocardiography of the left ventricle (LV) includes evaluation of dimensions, geometry and contractile function. The LV should be imaged in multiple views, even with a focused study, so that an accurate picture of LV size and function is obtained. Subjective estimation of LV cavity size (small, normal or dilated), LV wall thickness (thinned, normal or hypertrophied) and global LV systolic function (normal, mildly impaired or severely impaired) is usually sufficient to guide clinical decision making.[11] LV systolic function is assessed subjectively by observing the degree of inward (radial) movement and wall thickening during systole; this is most easily done by observing movement towards an imaginary centre point in the LV cavity in the PSAX mid-papillary view. However, longitudinal movement should also be evaluated (PLAX and apical views); impaired longitudinal shortening is an early sign of LV systolic dysfunction.

For a more complete evaluation, quantitative measurements can be made (Table 27.4).[12,13]

LV dimensions are measured at end-diastole. LV cavity size can be measured in one, two or three dimensions as follows: *LV diameter* is measured in the PLAX view, with the cursor perpendicular to the long axis of the LV at the level of the mitral valve leaflet tips (see Table 27.4). *LV cross-sectional area* is measured by tracing the endocardial border in the PSAX mid-papillary view. Monitoring of changes in LV area in the transoesophageal trans-gastric mid short-axis view is suited to intraoperative monitoring of preload (see below). *LV volume* can be measured with 3D echocardiography, or calculated from perpendicular 2D views, but is rarely applicable in intensive care.

LV wall thickness is measured at the basal inferolateral (posterior) wall. Severe hypertrophy is defined as a thickness greater than 20 mm. A wall thickness less than 2 mm represents non-viable myocardium at risk of rupture.

LV systolic function is evaluated by measuring changes in LV cavity dimensions, as follows: *Fractional shortening* measures changes in a single LV dimension and is the least accurate. *Fractional area change* measures change in mid-papillary cross-sectional area, calculated as (end-diastolic area – end-systolic area)/end-diastolic area (see Table 27.4). *Ejection fraction* (EF) measures change in LV cavity volume. With the Simpson biplane method (preferred EF method), the LV cavity volume at end-diastole and end-systole is calculated by tracing the endocardial borders of the LV in the apical four-chamber and apical two-chamber views. EF is calculated as (LV end-diastolic volume – LV end-systolic volume)/LV end-diastolic

volume. Normal EF is greater than 55%, severe dysfunction is an EF less than 30%. Measurement of EF is highly suited to comprehensive serial evaluation of systolic function in the outpatient setting, but in the intensive care environment is time consuming and prone to inaccuracies from apical foreshortening and poor endocardial definition. A simple method to quantify longitudinal systolic function is the mitral annular plane systolic excursion (MAPSE). Normal MAPSE is greater than 12 mm, severe dysfunction is a MAPSE less than 6 mm.

Caution must be exercised in interpretation of all the methods of evaluating LV systolic function because of the confounding effects of loading conditions (preload and afterload), valvular dysfunction (e.g. mitral regurgitation) and the degree of cardiorespiratory support (inotropes and mechanical ventilation).

Stroke volume is calculated as left ventricular outflow tract (LVOT) VTI (measured in the apical five-chamber view with the PW Doppler sampling volume in the LVOT) × LVOT cross-sectional area (calculated from LVOT diameter assuming a circular cross section, measured in the PLAX zoom view during mid-systole) (see Table 27.4). *Cardiac* output is stroke volume × heart rate.

Regional LV systolic function is described for each wall segment by the extent of wall thickening and inward wall motion during systole (Fig. 27.1). Regional abnormalities are usually due to coronary artery disease and thus distributed according to the pattern of coronary artery perfusion. However, septal dysfunction may also be due to right ventricular (RV) disorders and pulmonary hypertension, conduction abnormalities and pacing, or following cardiopulmonary bypass.

DIASTOLIC FUNCTION AND LEFT ATRIAL PRESSURE

The ability of the LV to fill during diastole depends on active relaxation (in early diastole), LV restoring forces

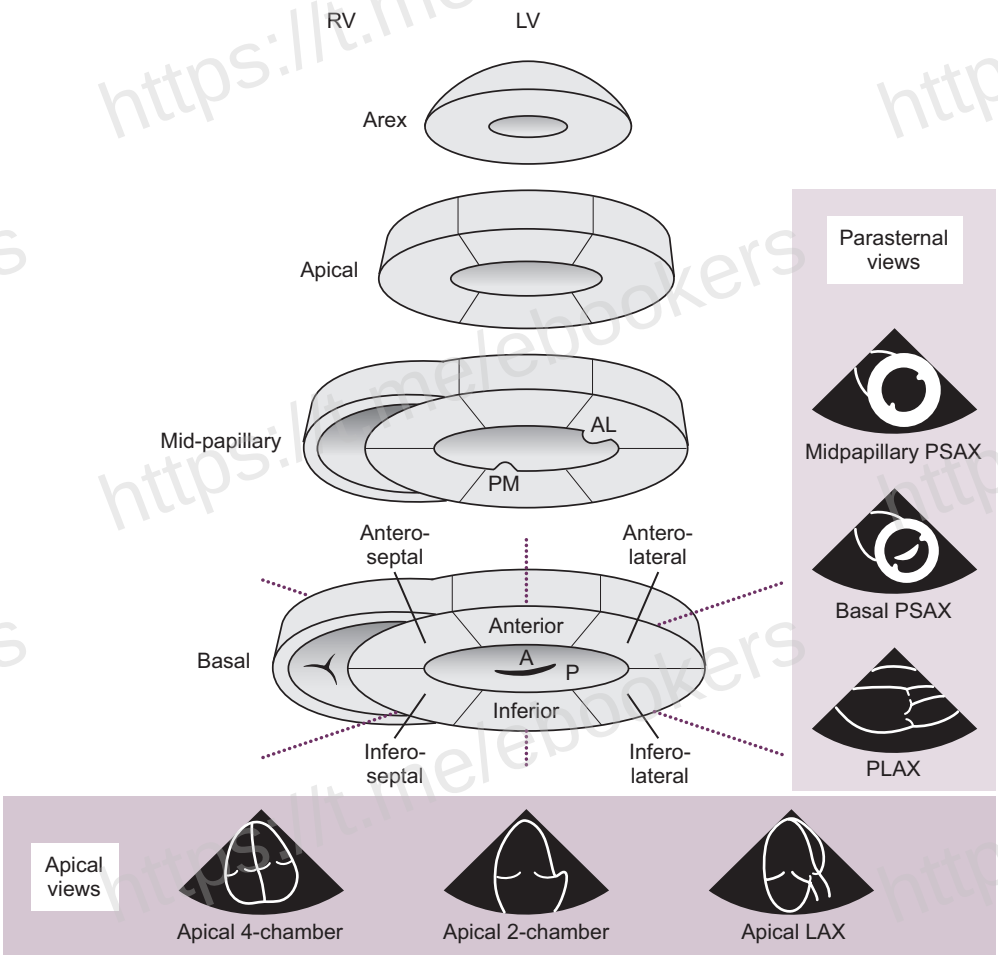

Figure 27.1 Left ventricular (LV) wall segments and standard transthoracic echocardiography views. *A*, Anterior mitral valve leaflet; *AL*, anterolateral papillary muscle; *P*, posterior mitral valve leaflet; *PLAX*, parasternal long-axis; *PM*, posteromedial papillary muscle; *PSAX*, parasternal short-axis.

and LV chamber compliance. Impaired diastolic function manifests as increased LV filling pressure, heart failure with normal ejection fraction (HFNEF) and reduced capacity of the LV to increase stroke volume in response to physiological stress. On echocardiography, diastolic dysfunction should be suspected if there is LV hypertrophy or left atrial (LA) enlargement not explained by mitral valve disease or longstanding atrial fibrillation. Further evaluation of diastolic function is largely based on Doppler methods.[13] There is significant overlap between the values of Doppler indices in subjects with and without diastolic dysfunction, and normal aging is associated with slowing of LV relaxation and increased LV chamber stiffness. Doppler indices are also affected by heart rate, rhythm, volume status, mitral valve disease, cardiomyopathy and systolic function. In the presence of systolic dysfunction, severity of diastolic dysfunction is primarily graded according to the PW Doppler mitral inflow E to A wave velocity ratio (Table 27.5). Diagnosis of

diastolic dysfunction with normal systolic function requires additional measurement of tissue Doppler mitral annular velocities, LA size (volume) and pulmonary artery pressure (see Table 27.5).[13]

Two additional methods, both suited to transoesophageal echocardiography, may be useful for estimating LA pressure[15,16]:

- PW Doppler of pulmonary vein flow normally demonstrates forward systolic (S) and early-diastolic (D) waves, and a smaller reverse atrial (A) wave. Normally the S wave VTI is greater than D wave VTI, but with a high LA pressure this ratio is reversed.[15] This method has limited accuracy in patients with normal systolic function, atrial fibrillation or mitral valve disease.
- The position of the interatrial septum is determined by the relative pressure in the left and right atrium. During positive pressure ventilation, the interatrial septum is normally bowed from left to right for most of the cardiac cycle, except transiently in mid-systole. With high LA pressure, the septum remains fixed bowed left to right.[16] With low atrial pressures, movement of the septum is increased with a buckled appearance during systole.

RIGHT VENTRICLE

The complex 3D shape of the RV makes measurement of RV size from 2D images subject to inaccuracy. RV size is thus usually determined by comparing RV cavity area to LV cavity area, and the relative position of the RV apex to the LV apex, in the apical four-chamber view (see Table 27.4).[14] Care must be taken to ensure optimal imaging planes, and appropriate adjustments made to account for abnormal LV dimensions. RV free wall thickness is measured at end-diastole by M-mode or 2D echocardiography in the subcostal four-chamber view or PLAX view. To avoid overestimation of wall thickness, care must be taken to exclude RV trabeculations, epicardial fat and visceral pericardium.[14]

The shape of the RV also limits 2D assessment of RV systolic function. Longitudinal RV systolic function may be quantified through the tricuspid annular plane systolic excursion (TAPSE) measured using M-mode with the cursor directed through the lateral tricuspid annulus in the apical four-chamber view (see Table 27.4). Alternatively, the lateral tricuspid annulus tissue Doppler systolic wave (s') can be measured from the same view (see Table 27.4). RV radial systolic function is assessed by visualisation of RV free wall thickening and inward wall excursion during systole.

Interventricular septal curvature and kinetics should be examined in the PSAX view for signs of RV volume or pressure overload. RV volume overload (e.g. tricuspid regurgitation) causes flattening (leftward shift) of the interventricular septum, with a characteristic D-shaped LV cavity in cross section, during diastole. LV pressure overload (e.g. pulmonary hypertension) causes septal flattening predominantly during systole. The degree of septal shift can be quantified by the eccentricity index, calculated as the anterior-posterior LV diameter divided by the septal-lateral LV diameter in short axis. A ratio greater than 1.0 signifies RV overload. The precise timing of septal dyskinesia is easier to appreciate with M-mode. Septal dyskinesia is also seen with intraventricular conduction disorders, septal infarction and after cardiac surgery.

Estimation of pulmonary artery pressure is an integral part of right heart evaluation. RV systolic pressure (RVSP) can be estimated from peak tricuspid regurgitant jet velocity (TRmax), using the simplified Bernoulli equation, plus the right atrial pressure (RAP): $RVSP = 4(TRmax)^2 + RAP$. In the absence of pulmonary stenosis, systolic pulmonary artery pressure is equal to RV systolic pressure. The tricuspid regurgitant jet velocity is measured using CW Doppler at a sweep speed of 100 mm/s, with the cursor aligned through the vena contracta on colour Doppler. The tricuspid regurgitant signal from multiple views should be examined and the highest velocity used in calculations. Pulmonary hypertension is likely to be present if the tricuspid regurgitant jet velocity is greater than 2.8 m/s. Underestimation of systolic pulmonary artery pressure occurs if there is poor alignment of the Doppler cursor with the tricuspid regurgitant jet, or severe tricuspid regurgitation (which causes early RV to RA pressure equalisation).[17] Advanced techniques may be used to estimate mean and diastolic pulmonary artery pressures.[14]

VALVULAR ASSESSMENT

Valvular stenosis or regurgitation can be identified with 2D imaging and simple application of colour Doppler.[1,2] Two-dimensional images are examined for abnormal chamber dimensions and geometry (the cause or consequence of valvular dysfunction), valve leaflet thickening or calcification, and excessive or restricted valve leaflet motion. Colour Doppler imaging is used to identify valvular regurgitation.

Aortic stenosis should be suspected on 2D imaging if the aortic valve leaflets appear thickened or calcified, with restricted leaflet motion, and the LV is hypertrophied.

Aortic regurgitation can be detected with colour Doppler in the PLAX, apical long-axis view or apical five-chamber view. Two-dimensional imaging may demonstrate aortic root dilatation, excessive leaflet motion (flail) or LV dilatation.

Mitral stenosis should be suspected if the mitral valve leaflets are thickened or calcified, with restricted leaflet motion. With rheumatic mitral stenosis, fusion

of the commissures causes a characteristic ice-hockey stick appearance of the valve leaflets in cross section in diastole.

Mitral regurgitation can be detected with colour Doppler in multiple echocardiography views. Two-dimensional images are examined for valve leaflet prolapse or flail, and for distorted LV geometry causing dilatation of the mitral annulus or restriction of mitral leaflet coaptation.

Tricuspid regurgitation can be detected with colour Doppler in the PSAX, right tilted PLAX and apical four-chamber views. Two-dimensional images are examined for RV or tricuspid annular dilatation.

Structurally normal valve leaflets and ventricular geometry, with a central narrow jet, is consistent with only trivial or mild regurgitation. This is a common normal finding with the mitral and tricuspid valves. A broader or eccentric jet, or involvement of the aortic valve, is abnormal.

If signs of valvular stenosis or abnormal regurgitation are identified, comprehensive evaluation is indicated to quantify the severity and determine the mechanism of dysfunction (Table 27.6). Comprehensive echocardiography is also indicated for evaluation of prosthetic valve function, or if endocarditis is suspected.

Methods of quantifying valvular stenosis are[18]:

- Peak transvalvular jet velocity, or mean transvalvular pressure gradient derived from tracing the VTI, using CW Doppler. Multiple acoustic windows should be sampled to obtain the highest velocity signal. Recordings are made with the time scale set at 100 mm/s. Velocity and pressure gradient methods are affected by the haemodynamic loading conditions.
- Effective orifice area calculated with the continuity equation.

Table 27.6 Echocardiographic signs of severe valvular heart disease

	AORTIC STENOSIS	MITRAL STENOSIS
Peak velocity (m/s)	>4	
Mean pressure gradient (mm Hg)	>40	>10
Valve area by planimetry (cm^2)		>1
Effective orifice area (cm^2)	<1	<1
Pressure half time (ms)		>220
Velocity ratio	<0.25	
Systolic pulmonary artery pressure (mm Hg)		>50
Low flow, low pressure severe aortic stenosis	Mean pressure gradient <40 mm Hg, Effective orifice area <1 cm^2, LVEF <40%	
Additional features	LV hypertrophy	LA dilatation

	AORTIC REGURGITATION	MITRAL REGURGITATION	TRICUSPID REGURGITATION
Vena contracta width (mm)	>6	>7	>7
Jet width/LVOT width (%)	>65		
Effective regurgitant orifice area (cm^2)	>0.3	>0.4	
Pressure half time (ms)	<200		
Colour Doppler regurgitant jet	Large central, or eccentric jet	Large central, or eccentric jet	Large central jet
Additional features	Dilated LV Holodiastolic flow reversal in descending aorta	Dilated LV and LA Systolic flow reversal in pulmonary veins. Flail leaflet Ruptured papillary muscle	Dilated RV, RA and IVC Systolic flow reversal in hepatic veins

See references 18, 19.

- Anatomical orifice area traced from a 2D image (planimetry).
- Pressure half time for mitral stenosis. Severe mitral stenosis is characterised by slow diastolic pressure equalisation between the LA and LV and thus a long pressure half time.

Aortic stenosis is quantified most easily by the peak jet velocity; care must be taken to avoid misdiagnosis due to LVOT obstruction or eccentric mitral regurgitation. Additional measures include mean pressure gradient and aortic valve effective orifice area by the continuity equation. Mitral stenosis is quantified by a combination of mean pressure gradient, planimetry and pressure half time.

Methods for quantifying valvular regurgitation are[19]:

- Width of the colour Doppler jet at its narrowest point through the valve (vena contracta). Zoom mode and a small colour Doppler box are used to optimise spatial and temporal resolution. Accuracy is improved if the jet origin, width of vena contracta and spatial orientation in the receiving chamber are all visualised.
- The colour Doppler jet area in the receiving chamber. The Nyquist limit is set at 50–60 cm/s. This method underestimates severity with eccentric jets as they are constrained against the wall of the receiving chamber, and is particularly unreliable with acute regurgitation because of tachycardia, rapid pressure equalisation and small size of the receiving chamber.
- Effective regurgitant orifice area, regurgitant fraction and regurgitant volume calculated with the continuity equation.
- Proximal isovelocity surface area (PISA) method, which is a form of the continuity equation using a combination of measurements from 2D, colour Doppler and CW Doppler. This is often technically challenging in the critically ill patient.
- Pressure half time for aortic regurgitation. Severe or acute aortic regurgitation results in rapid pressure equalisation between the proximal aorta and LV during diastole, and thus a short pressure half time.
- Detection of flow reversal upstream of the receiving chamber, using PW or colour Doppler.

Aortic regurgitation is quantified by the width of the colour Doppler regurgitant jet within 1 cm of the aortic valve or the vena contracta, and the pressure half time method. Mitral and tricuspid regurgitation are quantified most easily by the width of the vena contracta. Continuity equation methods should be used for a comprehensive assessment of mitral regurgitation when there is uncertainty.

Prosthetic valves are inherently stenotic compared to native valves. Thus, it may be difficult to distinguish mild obstruction due to valve design from that due to pathological changes or prosthesis-patient mismatch. Most prosthetic valves are associated with trivial or mild regurgitation. Imaging of prosthetic valves may be difficult due to shadowing artefacts; transoesophageal echocardiography may be required, particularly for a mitral prosthesis.

PRELOAD AND VOLUME RESPONSIVENESS

In the appropriate clinical context, several echocardiographic indices may be used to predict fluid responsiveness.

Static indices measure preload rather than fluid responsiveness. Direct measures of preload include LV end-diastolic area or volume. Indirect measures include estimates of LV end-diastolic pressure based on Doppler mitral and pulmonary vein inflow, or the pattern of interatrial septal movement. An LV end-diastolic area of less than 8 cm^2 likely represents hypovolaemia. Monitoring of LV end-diastolic area (with transoesophageal echocardiography in the transgastric mid-papillary view) is sometimes used to guide fluid therapy intraoperatively when large fluid shifts are anticipated (e.g. cardiopulmonary bypass, liver transplantation).

Dynamic indices apply the Frank-Starling law of the heart to examine the effect of a change in preload on stroke volume or systemic venous return. If the LV is operating on the steep ascending part of the ventricular function curve, then changes in preload induced by mechanical ventilation will be associated with variation in stroke volume or diameter of the vena cavae, and predict fluid responsiveness.[20–22] These methods are only valid in the mechanically ventilated patient with no spontaneous respiratory effort, no arrhythmia, no impairment of right or left systolic function, and no intra-abdominal hypertension. IVC distensibility with inspiration can be measured using 2D or M-mode imaging of the proximal IVC in the subcostal view. Care must be taken to ensure that the cursor remains over the widest part of the IVC throughout the respiratory cycle (Fig. 27.2). With transoesophageal echocardiography, superior vena cava collapsibility can be measured in the upper oesophageal short-axis view. The vena cava methods can be used with arrhythmia, but otherwise have the same limitations as the stroke volume variability method.[20–22] In the spontaneously breathing patient, the stroke volume response to a passive leg raise test may be used.[23]

PERICARDIAL EFFUSION AND TAMPONADE

Echocardiography is the initial imaging modality of choice to detect a pericardial effusion and is the best method for assessing the physiological effects of pericardial effusion on cardiac function.[24] In the normal subject, the pericardial space contains a minimal amount of fluid and separation of the parietal pericardial and the epicardial layers is visible only in systole. Accumulation of more than 50 mL of fluid in

Figure 27.2 Dilated inferior vena cava demonstrated in a subcostal long-axis view.

Figure 27.3 A large pericardial effusion with right ventricular free wall compression demonstrated in a parasternal short-axis view.

the pericardial space is abnormal, resulting in pericardial effusion formation with separation of the layers throughout both systole and diastole. A simple pericardial effusion manifests as an echolucent space surrounding the cardiac chambers. The size of an effusion may be quantified by measuring the maximum separation of the pericardial layers at end-diastole. A small effusion is defined as less than 0.5 cm, moderate effusion 0.5–2.0 cm and large effusion greater than 2.0 cm. In the PLAX view, pericardial effusion is distinguished from pleural effusion by its anatomical relationship to the descending aorta. Complex pericardial effusions may contain echogenic fibrinous strands with tethering to adjacent structures. Pericardial haematoma often has a heterogeneous echodensity and variable thickness around the heart, or may be localised.

Pericardial tamponade occurs when intrapericardial pressure exceeds intracardiac pressures causing cardiac chamber compression, increased ventricular interdependence, venous obstruction and ultimately haemodynamic compromise. Both the rate of accumulation and volume of a pericardial effusion determine the degree of physiological compromise. In the structurally normal heart, the lowest intracardiac pressure occurs in the right atrium during ventricular systole and then the RV during diastole. Thus, with increasing pericardial pressure, chamber compression manifests at first as systolic right atrial free wall collapse, and later also with RV free wall collapse (Fig. 27.3). Chamber collapse is best appreciated in the subcostal four-chamber view, where the right heart lies close to the probe. In the apical four-chamber view, the right atrium lies deep to other structures and the right atrial free wall may be poorly visualised if imaging conditions are difficult. In the presence of pulmonary hypertension and RV hypertrophy, right-sided free wall collapse occurs at higher pericardial pressure and left-sided compression may occur first.

In the spontaneously breathing patient, increased ventricular interdependence manifests as increased respiratory variation in mitral and tricuspid blood flow. This can be measured with CW Doppler echocardiography in the apical four-chamber view at an imaging sweep speed of 25 cm/s. An inspiratory decrease in mitral E wave velocity greater than 25% and decrease in tricuspid E wave velocity greater than 40% is consistent with tamponade physiology. However, marked respiratory variation in blood flow can also occur with acute respiratory disease, RV disease, or hypovolaemia. In the mechanically ventilated patient, respiratory variation in blood flow is decreased rather than increased. Fixed IVC dilatation is present whether the patient is spontaneously breathing or mechanically ventilated (see Fig. 27.2).

In practice, the combination of clinical features of tamponade (shock with hypotension and tachycardia) and the presence of a pericardial effusion on echocardiography confirms a diagnosis of tamponade. LV contractility may be hyperdynamic or hypodynamic.

When performing pericardiocentesis, echocardiography is used to guide the best approach (apical versus subxiphoid), confirm pericardial entry of the needle, and confirm guidewire and catheter placement.[3]

TRANSOESOPHAGEAL ECHOCARDIOGRAPHY

Transoesophageal echocardiography provides better image quality compared to transthoracic imaging because of reduced imaging depth, use of higher

Table 27.7 Indications for transoesophageal echocardiography

Inadequate visualisation of relevant structures on transthoracic echocardiography (e.g. haemodynamic assessment after cardiac surgery)
Suspected aortic dissection where computed tomography is not immediately available
Suspected native valve infective endocarditis, where transthoracic echocardiography is inconclusive
Suspected prosthetic valve endocarditis
Evaluation of left atrium (appendage) to guide decisions regarding cardioversion and anticoagulation for atrial fibrillation
Evaluation for cardiovascular source of embolus

See references 1, 3, 6.

frequency transducers and lack of intervening chest wall and lung. Posterior cardiac structures such as the left atrium, mitral valve, pulmonary veins and aorta are particularly well imaged. In mechanically ventilated patients, transthoracic views are often limited, and transoesophageal echocardiography may be required (Table 27.7). However, transoesophageal echocardiography is an invasive procedure that is contraindicated in the setting of oropharygneal or oesophageal disease and severe bleeding diathesis. Risks also include dislodgement of endotracheal and enteral tubes, and oesophageal burn from prolonged imaging in hyperthermic patients. Transoesophageal echocardiography should generally be avoided in the unintubated critically ill patient because of the risk of worsening hypoxaemia and aspiration. Limitations of transoesophageal echocardiography include inability to obtain true anatomical measurements due to oblique imaging planes, difficulty obtaining Doppler beam alignment resulting in underestimation of velocities, and inability to visualise the distal ascending aorta and proximal aortic arch.

CLINICAL SITUATIONS

Indications for echocardiography in intensive care are listed in Table 27.1.[1,6] The type of study (basic versus comprehensive and transthoracic versus transoesophageal) will depend on the clinical situation, availability of equipment and the echocardiography expertise of the attending clinician. Most often, a focused study, with basic assessment of valvular function, will suffice to address the clinical problem.[4,5,25]

Repeated studies may be indicated in patients with haemodynamic instability or acute cor pulmonale to guide fluid and vasoactive drug therapy, and monitor the haemodynamic effects of changes in ventilator settings.[11,26,27] Usually a subjective impression is sufficient to gauge the response to intervention, but quantitative parameters may also be followed, as long as meticulous care is taken with measurement technique (see Table 27.4).[3]

HAEMODYNAMIC INSTABILITY

Echocardiography may be used to augment clinical findings to characterise the basic haemodynamic state as follows[11,20–22,25–27]:

Hypovolaemia is characterised by positive indices of fluid responsiveness and reduced LV diastolic dimensions. Systolic function may appear normal or reduced.

Vasodilatation is characterised by reduced LV systolic dimensions. Systolic function appears normal or hyperdynamic. With severe hypovolaemia or vasodilatation, there is obliteration of the LV cavity during systole, so called 'kissing papillary muscles'. Obliteration is more likely to occur if the LV is hypertrophied.

LV systolic dysfunction can usually be identified by subjective assessment, but account must be taken of the loading conditions, co-existent valvular heart disease and the amount of circulatory support (inotropes, vasopressors and mechanical ventilation). The cause of LV dysfunction should be sought. A dilated, thinned LV is consistent with pre-existing dilated cardiomopathy. Regional wall motion abnormalities are consistent with coronary artery disease. LV structure appears normal in sepsis-induced LV dysfunction.[11,26] Takotsubo (stress) cardiomyopathy causes circumferential mid-wall or apical akinesia, with hyperdynamic basal function.[28]

LV diastolic dysfunction is likely if the LV wall is thickened, or LV systolic function is impaired, but requires Doppler interrogation to confirm the diagnosis.[13]

RV dysfunction is characterised by RV dilatation, with interventricular septal flattening in diastole with RV volume overload, and with interventricular septal flattening in systole with RV pressure overload.[14,26] The features of acute cor pulmonale and RV infarction are described below.

ACUTE CORONARY SYNDROME

Regional wall motion abnormalities visible on echocardiography develop within 30 minutes of an acute coronary syndrome. Wall motion abnormalities should be described in terms of the segments affected and severity of hypokinesia or akinesia; normal myocardial radial thickening is greater than 30%. The location of segments involved should be correlated with the distribution of coronary artery perfusion.

A change in clinical status following an acute coronary syndrome should prompt echocardiography to detect complications as follows:

Complete or partial papillary muscle rupture usually causes severe *mitral regurgitation*. Posterior leaflet restriction due to inferior or posterior myocardial infarction causes less severe functional mitral regurgitation, which may be dynamic, presenting as failure to wean from mechanical ventilation.

Ventricular septal rupture causes cardiogenic shock; on echocardiography one or more septal defects can be detected with colour Doppler. LV function may appear deceptively good due to offloading to the RV. *LV free wall rupture* causes very rapid accumulation of pericardial blood with severe tamponade.

RV infarction is differentiated from acute cor pulmonale by the absence of pulmonary hypertension and coexistence of LV inferior wall hypokinesia.

SEPTIC SHOCK

Basic echocardiography is well suited to provide rapid and repeated evaluation of the haemodynamic state in septic shock.[11,26] Fluid administration may be guided by indices of fluid responsiveness in the sedated, mechanically ventilated patients. Alternatively, the development of B lines on lung ultrasound after fluid loading can be used as a stopping criteria to discontinue further fluid administration (see Chapter 40). Treatment of persistent hypotension after adequate fluid loading, with either vasopressors or inotropes, is then guided by echocardiographic assessment of LV function. Impaired LV systolic function is a common finding in septic shock, but may not be evident until at least 24 hours after presentation, or is only 'unmasked' after vasopressor therapy is commenced, increasing LV afterload.[26,28] Impaired RV function may also occur, either as a part of global ventricular dysfunction, or due to acute cor pulmonale.[27-29]

INFECTIVE ENDOCARDITIS

Diagnosis of infective endocarditis by major Duke criteria requires a combination of positive microbiological culture and evidence of endocardial involvement on echocardiography: vegetations (mobile echodense masses visible on a valve or prosthetic material, e.g. pacemaker lead), abscess, or dehiscence of a prosthetic valve. Transoesophageal echocardiography may be required if transthoracic imaging is inconclusive, and is warranted if prosthetic valve involvement is suspected.

RESPIRATORY FAILURE

Echocardiography is useful for evaluating the cause and haemodynamic consequences of respiratory failure. Firstly, in patients with pulmonary infiltrates on chest radiograph, examination of the left heart is focused on findings that may predispose to cardiogenic pulmonary oedema such as LV systolic dysfunction, diastolic dysfunction or left-sided valvular heart disease.

Secondly, examination of the right heart is focused on identifying signs of acute cor pulmonale and quantifying the severity of pulmonary hypertension.[17,27] Acute cor pulmonale is the result of a sudden increase in RV afterload, caused by acute respiratory distress syndrome or pulmonary embolism. On echocardiography acute cor pulmonale is characterised by RV dilatation, and interventricular septal dyskinesia with septal flattening in late systole (D-shaped LV in short axis). Chronic pulmonary hypertension is distinguished from acute cor pulmonale by the presence of RV hypertrophy; however, hypertrophy can develop within several days of having a sustained increase in RV afterload.[27]

Thirdly, in patients with hypoxaemia disproportionate to the severity of underlying illness, a bubble study during echocardiography can be used to identify a right-to-left shunt through a patent foramen ovale, or intrapulmonary shunt (e.g. with hepatopulmonary syndrome).

PULMONARY EMBOLISM

The echocardiographic signs of high-risk pulmonary embolism are those of acute cor pulmonale.[30] In addition, the combination of RV free wall hypokinesis and relative sparing of apical systolic function (McConnell sign) has a high specificity for pulmonary embolism. Rarely, thrombus may be directly visible in transit through the right heart. Thrombus may also be visible in the main pulmonary artery on transoesophageal echocardiography.

Echocardiography is indicated in the hypotensive or shocked patient with suspected pulmonary embolism where computed tomography pulmonary angiography to confirm the diagnosis is considered too risky or impractical.[30] In this setting, echocardiography can be used to exclude other causes of haemodynamic instability. Absence of echocardiographic signs of acute cor pulmonale effectively excludes pulmonary embolism as the cause for haemodynamic compromise. Conversely, the presence of acute cor pulmonale in this setting has been used to justify thrombolysis therapy.[30]

In the patient with known pulmonary embolism, but haemodynamic instability, a normal echocardiogram can be used to justify withholding thrombolysis.

ACUTE RESPIRATORY DISTRESS SYNDROME

A quarter of patients with acute respiratory distress syndrome develop acute cor pulmonale due to a combination of pulmonary vascular dysfunction and mechanical ventilation.[27] Acute cor pulmonale usually develops over a few days, but may become severe, particularly in the setting of high ventilator driving pressures (>18 cm H_2O), severe hypoxaemia (P/F <150 mm Hg) and hypercapnia. Thus, repeated

echocardiography may be required to detect the development of acute cor pulmonale and guide optimal ventilatory strategy to protect the right heart.[27]

FAILURE TO WEAN FROM MECHANICAL VENTILATION

During the transition from mechanical ventilation to spontaneous breathing, the change in ventricular loading conditions may unmask occult systolic or diastolic dysfunction (with increased LA pressure). Echocardiography should be combined with lung ultrasound to detect signs of acute pulmonary oedema (B lines) and assess diaphragmatic function (see Chapter 40).

POSTCARDIAC SURGERY

The early postoperative period after cardiac surgery presents unique challenges to image optimisation due to mechanical ventilation, surgical dressings and drains, and to image interpretation because of diagnostic findings unusual in other clinical settings:

Pericardial haematoma can cause focal cardiac chamber compression; thus, every cardiac chamber must be clearly visualised. Rarely, massive haemothorax can cause tamponade.

Dynamic LVOT obstruction should be suspected in the patient with mitral valve repair, hypertrophic LV, or aortic valve replacement for aortic stenosis, who develops shock that fails to respond to catecholamines or intra-aortic balloon counterpulsation. Echocardiography demonstrates a high LVOT flow velocity and mitral regurgitation.

RV dysfunction may occur in isolation due to inadequate intraoperative cardioplegia.

Increased intrathoracic pressure may present with haemodynamic features similar to pericardial tamponade, but should be recognised from assessment of ventilation. On echocardiography there are features of acute cor pulmonale.

Patient prosthesis mismatch results in a high transvalvular pressure gradient and difficultly weaning from mechanical ventilation. Other causes of prosthetic valve dysfunction (e.g. leaflet entrapment or paravalvular leak) warrant expert evaluation.

CARDIAC ARREST

Echocardiography may be used during cardiac arrest with non-shockable rhythm to assess myocardial contractility and help identify potentially reversible causes such as pericardial tamponade, pulmonary embolism, hypovolaemia, or tension pneumothorax.[31] Echocardiography should not disrupt good quality chest compressions. A clearly defined approach such as the focused echocardiographic evaluation in life support (FEEL) should be followed.[31] Subxiphoid placement of the probe just before chest compressions are paused for a planned rhythm assessment allows image acquisition within 5 seconds during the pause.[31] Echocardiography findings should be clearly communicated to the resuscitation team.

With asystole, echocardiography may demonstrate myocardial activity when the electrocardiogram monitoring falsely shows no electrical activity. The absence of cardiac activity with asystole is highly predictive of death.[32] With pulseless electrical activity (PEA), the presence of myocardial activity (pseudo-PEA) confers a better prognosis.

Transoesophageal echocardiography can provide better imaging quality than transthoracic echocardiography, without interruption of chest compressions. The transoesophageal probe should not be inserted until after the airway has been secured with an endotracheal tube and satisfactory ventilation has been achieved.

Oxygen therapy

Brett Sampson, Shailesh Bihari

In humans, uptake of environmental oxygen via the lungs provides necessary substrates for energy production. This is a key ingredient to survival. Aerobic respiration is the most efficient mechanism for adenosine triphosphate (ATP) production by oxidative phosphorylation and serves as the fuel to maintain cellular homeostasis and metabolism. Absence or lack of ATP leads to loss of cellular integrity initially, followed by cellular and later organism death. Under hypoxic conditions, ATP production is inefficient (through glycolysis) and leads to production of lactic acid. A substantial part of critical care is targeted at treating and/or preventing hypoxia, yet in recent years the risks of hyperoxia leading to organ damage have become better understood. Thus an understanding of the common pathways and significance of cellular hypoxia is vital to providing appropriate and safe support and treatment to the acutely unwell patient.

PHYSIOLOGY OF OXYGEN DELIVERY

The transfer of a gas across a membrane relies on physical principles and is summarised by Fick's first law of diffusion[1]:

$$(28.1) \qquad O_2 \text{ diffusion} = K \times A/T \times \Delta P$$

where K is the diffusion constant for a particular gas, A is the surface area of a membrane; T is the membrane's thickness and ΔP the difference in partial pressure across the membrane. Because oxygen is poorly soluble in water, diffusion alone is insufficient to deliver oxygen to the cells, and novel methods of delivery have evolved, most notably the cardiovascular system.[2] This provided the means to deliver oxygen around the body.

OXYGEN DELIVERY

Transport of oxygen to the cells can thus be divided into six simple steps reliant only on the laws of physics: (1) convection of oxygen from the environment into the body via the lungs (ventilation); (2) diffusion of oxygen into the blood through the alveolar–capillary membrane (oxygen uptake); (3) reversible chemical bonding with haemoglobin; (4) convective transport of oxygen to the tissues (cardiac output [CO]); (5) diffusion into the cells and organelles; and (6) the redox state of the cell. This chain of events is oxygen delivery or more correctly oxygen flux ($\dot{D}_{O_2}$).

Step 1: convection – ventilation The first step occurs in the lung in the form of pulmonary ventilation. At sea level the partial pressure of oxygen in environmental air is approximately 160 mm Hg (21.3 kPa). On inspiration the air is humidified and mixed with exhaled carbon dioxide (CO_2) such that the partial pressure of oxygen at the alveolus (P_{AO_2}) is 100 mm Hg (13.3 kPa). P_{AO_2} varies in different environments and different conditions (Table 28.1) and can be calculated from the alveolar gas equation:

$$(28.2) \qquad P_{AO_2} = Fi_{O_2} \times (P_{atm} - P_{H_2O}) - PaCO_2/R$$

where P_{AO_2} is partial pressure of O_2 in the 'ideal' alveolus, Fi_{O_2} is the fraction of O_2 in inspired gas, P_{atm} is atmospheric pressure, P_{H_2O} is saturated vapour pressure of water (47 mm Hg), $PaCO_2$ is partial pressure of CO_2 in arterial blood, and R is the respiratory quotient (ratio of CO_2 production to O_2 consumption), which is 0.8 for a modern diet (see Chapter 18).

Much of oxygen therapy is based on increasing Fi_{O_2} during spontaneous or mechanical ventilation. However, it is important to note that the delivery of oxygen to the alveolus can still be achieved without lung ventilation. During apnoea, ongoing oxygen consumption results in a fall in P_{AO_2}, creating a pressure gradient for the mass movement (bulk flow) of oxygen into the alveoli. Clinically, this can be used to maintain oxygenation during the apnoeic period following induction of anaesthesia (apnoeic oxygenation) and during brain death testing, discussed later.

Step 2: diffusion – alveolus to blood Oxygen within the alveolus diffuses across the alveolar–capillary membrane. The average thickness of the alveolar capillary membrane is 0.3 µm, and the surface area of the respiratory membrane between 50 and 100 m^2. This leads to a partial pressure of oxygen in the pulmonary capillaries (Pa_{O_2}) of approximately 90 mm Hg (12 kPa). Herein lies many of the problems seen in the critically ill, where two mechanisms predominate: (1) the thickness and barrier effect of the space between alveolus

ABSTRACT

Although oxygen is essential for human survival and is a life-saving therapy, its injudicious use must be avoided to prevent inadvertent harm. Careful titration of oxygen therapy is essential to ensure hypoxia is safely treated and hyperoxia avoided. This requires a sound understanding of the pathophysiological perturbations in oxygen delivery and utilisation seen in the critically ill. Choosing the appropriate oxygen therapy device in the conscious self-ventilating patient can be challenging and may require a trial of different devices before a balance between patient tolerability and satisfactory oxygenation is achieved. Humidified high-flow oxygen and non-invasive ventilation have become the mainstay treatment for conscious hypoxaemic patients; however, close monitoring is required to ensure invasive ventilation is not delayed when indicated. Oxygen toxicity is to be avoided, but this may not always be possible. Hyperbaric oxygen therapy has few indications in the critically ill, including severe carbon monoxide poisoning and necrotising soft-tissue infections.

Table 28.1 Clinical significance of some Pa_{O_2} and Sa_{O_2} values

Pa_{O_2} mm Hg	Pa_{O_2} kPa	Sa_{O_2} (%)	CLINICAL SIGNIFICANCE
160	20.0	99	Inspired air at sea level
97	12.9	97	Young normal man
80	10.6	95	Young normal man asleep Old normal man awake Inspired air at 19,000 ft (5800 m)
70	9.3	93	Lower limit of normal
60	8.0	90	Respiratory failure (mild); shoulder of O_2 dissociation curve
50	6.7	85	Respiratory failure (significant); admit to hospital
40	5.3	75	Venous blood – normal Arterial blood – respiratory failure (severe) Acclimatised man at rest at 9000 ft (2750 m)
30	4.0	60	Unconscious if not acclimatised
26	3.5	50	P50 of haemoglobin
20	2.7	36	Acclimatised mountaineer exercising at 19,000 ft (5800 m); hypoxic death

P50, The partial pressure of oxygen when haemoglobin is 50% saturated with oxygen.

and capillary – usually a minor issue, and (2) the relationship between perfusion and ventilation at alveolar level (V/Q ratio). Thus any pathophysiological state that causes a diffusion defect and/or V/Q mismatch will result in an increased gradient between P_{AO_2} and Pa_{O_2}, known as the A-a gradient. The A-a gradient also increases with advancing age and right-to-left shunt and is discussed further in Chapter 18.

Step 3: haemoglobin binding Oxygen is poorly soluble in water, having a solubility of 0.003082 g/100 g H_2O. Having diffused across the alveolar capillary membrane, the oxygen binds rapidly to the respiratory pigment haemoglobin. The saturation of haemoglobin with oxygen (Sa_{O_2}): Pa_{O_2} relationship is not linear and forms a sigmoidal shape (Fig. 28.1). The P50 is the Pa_{O_2} at which 50% of the haemoglobin is saturated. Various factors are known to alter the affinity of haemoglobin for oxygen (Table 28.2). These have teleological advantages because, for example, a low pH or high CO_2 at tissue level could imply tissue hypoxia, and the reduction in oxygen-binding affinity increases oxygen availability. Similarly, hyperthermia (fever), hypercarbia and an increase in the concentration of 2,3-diphosphoglycerate (2,3 DPG) all move the curve to the right and increase oxygen availability.

Table 28.2 Factors influencing the position of the oxygen dissociation curve

FACTORS INCREASING P50 (CURVE SHIFTS TO THE RIGHT)	FACTORS DECREASING P50 (CURVE SHIFTS TO THE LEFT)
Hyperthermia	Hypothermia
Decreased pH (acidaemia)	Increased pH (alkalaemia)
Increased P_{CO_2} (Bohr effect)	Decreased P_{CO_2}
Increased 2,3 DPG	Decreased 2,3 DPG Foetal haemoglobin Carbon monoxide Methaemoglobin

DPG, Diphosphoglycerate; *P50*, the partial pressure of oxygen when haemoglobin is 50% saturated with oxygen.

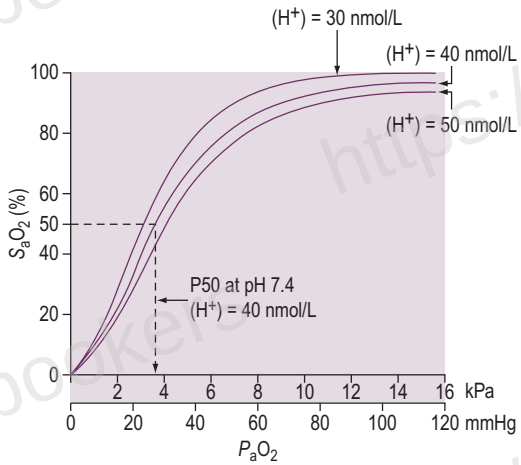

Figure 28.1 Haemoglobin oxygen dissociation curve. Normal curve at 40 nmol/L and shifts to left and right. H^+, Hydrogen ion concentration; *P50*, the partial pressure of oxygen when haemoglobin is 50% saturated with oxygen; PaO_2, arterial partial pressure of oxygen; SaO_2, arterial oxygen saturation.

2,3-DPG is a by-product of glycolysis and therefore binds haemoglobin in predominantly hypoxic tissues, facilitating a release of oxygen. Conversely, hypocarbia, alkalosis and low concentrations of 2,3-DPG result in a leftward shift of the curve and a higher affinity for binding for any given P_{O_2}. Systemic interventions such as alteration in P_{CO_2} or pH will influence the curve and therefore oxygen dissociation and availability. Exposure to carbon monoxide causes a conformational change in haemoglobin causing an increased affinity for oxygen and a left shift of the oxygen dissociation curve.

Step 4: convection – cardiovascular In humans the cardiovascular system is the solitary delivery system of oxygen to the cells. This is achieved by the convection (bulk flow) of oxygen, predominantly bound to

haemoglobin from the lungs via the heart and out into the systemic circulation by way of the arteries. These branch down to form the capillaries, where the oxygen is offloaded to the tissues. Convection of oxygen by the cardiovascular system is influenced centrally by the CO and peripherally by local control of the regional perfusion of the tissues.

Oxygen delivery also relies on its concentration in the blood (Ca_{O_2}). This is calculated by the following formula 28.3 and is approximately 20 mL O_2/dL in health[3]:

(28.3)
$$Ca_{O_2} = (\text{Hb(g/dL)} \times 1.39 \times Sa_{O_2}(\%)) + (0.003 \times Pa_{O_2})$$

Each gram of haemoglobin binds 1.39 mL of oxygen. Thus changes in Sa_{O_2} and haemoglobin concentration are important in determining the oxygen concentration. Delivery of oxygen is therefore summarised by the formula:

(28.4)
$$\text{delivery of oxygen } (\dot{D}_{O_2})\ \text{mL/min} = 10 \times \text{CO(L/min)} \times Ca_{O_2}$$

Normal resting $\dot{D}_{O_2}$ is approximately 1000 mL/min. Oxygen consumption ($\dot{V}_{O_2}$) at rest is approximately 250 mL/min:

(28.5)
$$\text{oxygen consumption } (\dot{V}_{O_2})\ \text{mL/min} = 10 \times \text{CO(L/min)} \times (Ca_{O_2} - C\bar{v}_{O_2})$$

where $C\bar{v}_{O_2}$ is calculated as $(1.39 \times [\text{Hb}] \times S\bar{v}_{O_2}) + (0.003 \times P\bar{v}_{O_2})$. It can be seen that the amount of oxygen extracted is approximately 25% of that delivered at rest and that there is a large reserve. This obviously varies between organs. This ratio is referred to as the oxygen extraction ratio (OER): $\text{OER} = \dot{V}_{O_2}/\dot{D}_{O_2}$.

During exercise this can increase by up to 70%–80% at maximum. Oxygen that is not removed by the tissues returns to the heart and lungs. Globally the difference between that delivered and that returning is the consumption. This model can also be used to look at regional consumption. Hence the saturation of mixed venous blood ($S\bar{v}_{O_2}$) which is all the returning blood, or central venous blood (most of the returning blood), can be used as an indicator of global $\dot{V}_{O_2}$ and indirectly the adequacy of $\dot{D}_{O_2}$. If oxygen delivery by the microcirculation and cellular oxygen uptake are adequate, then a $S\bar{v}_{O_2}$ value of 65% usually indicates that global $\dot{D}_{O_2}$ is appropriate. Lower values may indicate increased uptake but more often reduced or inadequate delivery. Mixed venous blood is useful for measurement of global $\dot{D}_{O_2}$, but it usually requires the presence of a pulmonary artery catheter. The use of central venous saturations has become an alternative surrogate that is usually adequate and considerably more practical. The body cannot store large amounts of oxygen (although the lungs and myoglobin can act as short-term reservoirs) so is dependent on a continuous supply. The excess ability to increase $\dot{D}_{O_2}$ to match changes in $\dot{V}_{O_2}$ is an adaptation that permits sudden changes in demand, such as exercise where $\dot{V}_{O_2}$ can sometimes exceed 1500 mL/min.

Step 5: diffusion – blood to mitochondrion Ninety per cent of cellular aerobic metabolism takes place in the mitochondria. The rate of diffusion of oxygen from bound oxyhaemoglobin to the mitochondria follows similar principles to the diffusion of oxygen into the blood from the alveoli: (1) Fick's law of diffusion, where ΔP depends on $\dot{D}_{O_2}$ and the rate of cellular uptake and utilisation; and (2) the position of the oxygen haemoglobin dissociation curve. Once delivered to the cell, oxygen generates ATP by the electron transport chain, using the reducing power of nicotinamide adenine dinucleotide (NADH) and flavin adenine dinucleotide ($FADH_2$) generated from the citric acid cycle.[4] The movement of electrons through the chain requires a terminal electron acceptor. This is molecular oxygen, which combines with the electrons and protons to form water. Without oxygen, the proton motive force generated by the electron chain would not exist and phosphorylation of adenosine diphosphate (ADP) to ATP would cease (Fig. 28.2).[4]

Starting at approximately 160 mm Hg (21.3 kPa), the partial pressure of oxygen (P_{O_2}) at the mouth can fall to as low as 1 mm Hg (0.133 kPa) (Pasteur point) in some mitochondria. Below this value, cellular demands for oxygen outweigh its delivery, and ATP production may be reduced.

Step 6: the redox state of the cell Oxygen delivery from atmosphere to cell is conventionally considered a cascade, implying that a high concentration at one end cascades down and increases oxygen in the cell. Although this will increase oxygen potentially available to the cell, the driving force for it to enter the cell and mitochondrion is the gradient between the partial pressures of oxygen within and outside the cell. Increased oxygen utilization reduces that tension and increases that gradient; conversely, adequate oxygen in the cell will reduce the gradient until oxygen will not diffuse. Hence the cell itself determines how much oxygen it uses by creating the gradient that 'sucks in' oxygen – and not a cascade. Similarly, it is the ATP/ADP ratio and probably hydrogen ion concentration that drives ATP production and modifies oxygen requirement (i.e. the cell is largely autonomous and uses what it needs).[5] Although adequate oxygen delivery is important, excess oxygen is at least theoretically of no benefit.

PATHOLOGY OF OXYGEN DELIVERY ($\dot{D}_{O_2}$)

Failure of oxygen delivery to the cells leads rapidly to cellular dysfunction and can lead to cellular death and organ dysfunction culminating in the organism's death. $\dot{V}_{O_2}$ drives the $\dot{D}_{O_2}$ requirement, and failure of $\dot{D}_{O_2}$ to match $\dot{V}_{O_2}$ results in reduction in aerobic metabolism and energy production, necessitating ATP production

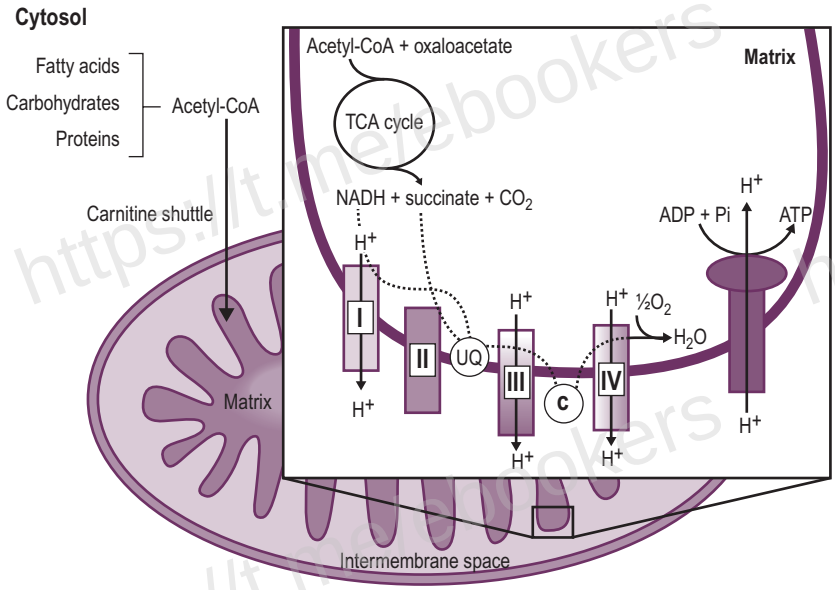

Figure 28.2 Schematic representation of the mitochondrion. Figure 28.3 The normal relationship between $\dot{V}_{O_2}$ and $\dot{D}_{O_2}$. Greater than the value of 'critical $\dot{D}_{O_2}$' $\dot{V}_{O_2}$ is independent of oxygen delivery. Less than this value and $\dot{V}_{O_2}$ becomes supply dependent and may be amenable to therapeutic interventions.

by the less-efficient glycolytic pathway. The level of $\dot{D}_{O_2}$ at which $\dot{V}_{O_2}$ begins to decline has been termed the 'critical $\dot{D}_{O_2}$' and is approximately 300 mL/min in an adult (Fig. 28.3).[6] 'Shock' is the usual term used in this situation, defined loosely as failure of oxygen delivery to match tissue demand. Commonly this refers to failure of the circulation, but low $\dot{D}_{O_2}$ can result from several pathological mechanisms that can occur singly or in combination (Table 28.3).

The impact of a low $\dot{D}_{O_2}$ can be worsened by increased oxygen demand. The metabolic rate increases with exercise, inflammation, sepsis, pyrexia, thyrotoxicosis, shivering, seizures, agitation, anxiety and pain.[7] Therapeutic interventions such as adrenergic drugs (e.g. epinephrine)[8] and certain feeding strategies can also lead to an increased $\dot{V}_{O_2}$. In critical illness, in which oxygen delivery is considered to be in jeopardy, there has been considerable interest in the relationship between $\dot{D}_{O_2}$ and $\dot{V}_{O_2}$ (see Fig. 28.3). The presence of signs or markers of tissue hypoxia such as acidosis implies inadequate tissue oxygenation. This could be from either inadequate delivery failing to meet consumption requirements or reduced ability of the tissues to extract oxygen. The former could be corrected by increasing delivery; the latter is more difficult. Historically this has led to the strategy for delivering 'supranormal' $\dot{D}_{O_2}$ to ensure adequate supply.[9,10] It is irrefutable that if delivery is inadequate it should be corrected to meet consumption; however, increasing delivery can increase consumption through mathematical linkage.[11,12] Furthermore, the inotropes used to increase delivery also increase consumption. As discussed later, hyperoxia also has directly detrimental effects.

Clinical studies clearly show that adequate resuscitation to meet oxygen requirements is sensible. In the critically ill going beyond this is not helpful.[13,14] Early reports in sepsis suggested the combined use of tissue hypoxia markers (acidosis and lactate) and surrogates of oxygen delivery (Scv_{O_2}) were beneficial when used in conjunction with standard haemodynamic

Table 28.3 Types of hypoxia

TYPE OF HYPOXIA	PATHOPHYSIOLOGY	EXAMPLES
Hypoxic hypoxia	Reduced supply of oxygen to the body leading to a low arterial oxygen tension	1. Low environmental oxygen (e.g. altitude) 2. Ventilatory failure (respiratory arrest, drug overdose, neuromuscular disease) 3. Pulmonary shunt: (a) anatomical – VSD with R–L flow (b) physiological – pneumonia, pneumothorax, pulmonary oedema, asthma
Anaemic hypoxia	The arterial oxygen tension is normal, but the circulating haemoglobin is reduced or functionally impaired	Massive haemorrhage, severe anaemia, carbon monoxide poisoning, methaemaglobinaemia
Stagnant hypoxia	Failure of transport of sufficient oxygen due to inadequate circulation	Left ventricular failure, pulmonary embolism, hypovolaemia, hypothermia
Histotoxic hypoxia	Impairment of cellular metabolism of oxygen despite adequate delivery	Cyanide poisoning, arsenic poisoning, alcohol intoxication

monitoring.[15] Although this saw the widespread adoption of 'early goal-directed therapy' in sepsis,[16] current evidence now suggests it is not superior to usual care in patients with septic shock.[17]

Oxygen delivery can be improved in a variety of ways from the ambient inspired oxygen through the lungs and cardiovascular system to the cell itself, but once at the cell, the ability to manipulate delivery ceases.

CELLULAR HYPOXIA

In environments where the $\dot{D}_{O_2}$ is reduced, human cells can tolerate hypoxia to a certain extent by adapting 'hibernation' strategies to reduce metabolic rate, increased oxygen extraction from surrounding tissues and enzyme adaptations that allow continuing metabolism at low P_{O_2}.[18] Anaerobic metabolism is actively used by some tissues. In low oxygen concentrations, both myocardial and vascular endothelium upregulate glycolytic enzymes and glucose transport proteins.[19] Experiments in humans at altitude, to mimic hypoxic stress, suggest that, although $\dot{D}_{O_2}$ is preserved, $\dot{V}_{O_2}$ is reduced.[20] This may be due to reduced oxygen uptake at a microcirculatory level, reduced cellular oxygen consumption or an improvement in the efficiency of ATP production. These theories may be evidenced by the recovery of critical illness multiorgan failure, in which function may be compromised in the short term without long-term structural damage,[21] and in vitro studies of mitochondria, which demonstrate more efficient ATP production when exposed to hypoxic environments.[22] The ability of humans to tolerate and then acclimatise to altitude mainly by a reduction in $\dot{V}_{O_2}$ may explain why many critical care strategies to increase Pa_{O_2} (e.g. inhaled nitric oxide) fail to convey any survival benefit. Indeed, accepting a Pa_{O_2}/Sa_{O_2} less than 'normal' levels does not appear to significantly reduce survival and may reduce the risk of oxygen toxicity.[22]

REGIONAL HYPOXIA

Much of what has been discussed describes effects of oxygen delivery and uptake for the body as a whole. The reality is far more complex because not only can the $\dot{D}_{O_2}$ of each organ system be manipulated to meet demand, but also, within each organ, regional demands may vary and can be varied. Few of the clinical methods commonly used for assessing $\dot{D}_{O_2}$ can identify changes in either organ or regional $\dot{D}_{O_2}$. Thus it is possible in critical illness for tissue hypoxia to exist with associated organ dysfunction despite normal global $\dot{D}_{O_2}$ and $S\bar{v}_{O_2}$ values.[23]

The effects of disordered or diverted regional blood flow can be important. For example, splanchnic blood flow is often reduced in shock, with the potential for ischaemia. Clearly, detection of gut ischaemia could be used to influence management of oxygen delivery and hopefully reduce the likelihood of multiorgan failure.[24] The control of regional blood flow is itself complex. Methods of increasing global $\dot{D}_{O_2}$ in the hope that this will optimise all tissues often necessitate the use of vasoactive drugs (vasopressors, inotropes and vasodilators). Paradoxically, although such therapy can influence regional flow, it may not necessarily be in the direction sought in individual regions.

DIAGNOSIS AND MONITORING OF $\dot{D}_{O_2}$

Early recognition and treatment of oxygen delivery failure is important for preserving organ function. Clinical assessment of $\dot{D}_{O_2}$ and $\dot{V}_{O_2}$ (e.g. heart rate, blood pressure or urine output) can be misleading. Particularly in the young patient, the ability of the OER to increase to as high as 70%–80% can mean that

such variables can change only late in the evolution of diminished $\dot{D}_{O_2}$. However, the assessment of an effective cardiac output – normal heart rate, blood pressure and peripheral perfusion with signs of organ function and normal oxygen saturation – must not be excluded in favour of more technical quantitative methods. Rather, the technical values must be considered in the clinical context. All assessments of $\dot{D}_{O_2}$, clinical or technical, require continuous reevaluation to ensure that treatments being planned or administered are appropriate for the patient's current condition.

Sa_{O_2} AND Pa_{O_2}

Both these measures are included in the Ca_{O_2} (Eq. 28.3), and their importance is clear. However, what is a 'safe' Sa_{O_2} and/or Pa_{O_2} can be difficult to define. Measured systemically, they do not alone reflect tissue oxygenation, and oxygen extraction mechanisms vary between organs. However, supplementary oxygen is generally required when Pa_{O_2} falls to less than 60 mm Hg (8 kPa) or the Sa_{O_2} is less than 88%. Table 28.1 lists the clinical significance of common Pa_{O_2} and Sa_{O_2} values.

ACID–BASE BALANCE

Many intensive care units (ICUs) use acid–base balance as a simple bedside indicator of global $\dot{D}_{O_2}$. The presence of acidosis and a base deficit of less than –2 may be used to detect evidence of inadequate $\dot{D}_{O_2}$, presuming this reflects lactate accumulation. However, plasma lactate concentration is an unreliable indicator of tissue hypoxia; it represents the balance between production and consumption so, if used in isolation or as a single value to assess $\dot{D}_{O_2}$, can easily mislead.[25] The use of lactate as a marker of $\dot{D}_{O_2}/\dot{V}_{O_2}$ balance is best used as a trend using serial measurements.

$S\bar{v}_{O_2}/Scv_{O_2}$

In critical illness, a falling $\dot{D}_{O_2}$ can be compensated for by an increase in oxygen extraction. This leads to a lower oxygen saturation of haemoglobin returning to the right side of the heart. Analysis of this saturation either in vivo (fibreoptic oximetry) or in vitro (oximetry) allows assessment of the OER. Classically, a low $S\bar{v}_{O_2}$ (<70%) in the face of a normal Sa_{O_2} implies tissue hypoperfusion secondary to a low CO, either hypovolaemia or pump failure. However, it could indicate very high $\dot{V}_{O_2}$, as may occur with hyperthermia. Conversely, a raised $S\bar{v}_{O_2}$ (>75%) will imply low demand (e.g. hypothermia, or a cellular use problem), easily explained in cyanide poisoning when the oxidative phosphorylation mechanism is inhibited but much more difficult to rationalise when seen (commonly) in sepsis. In a very low output state, it could indicate total failure of peripheral perfusion and therefore no oxygen usage. Scv_{O_2} is a reasonable surrogate for $S\bar{v}_{O_2}$ and reduces the need for the more complex pulmonary artery catheter.[26] Whichever method of venous oxygen saturation is used, it must be in conjunction with other markers of adequacy of oxygen delivery and clinical context.

MEASUREMENT OF REGIONAL $\dot{D}_{O_2}$

Most assessments of $\dot{D}_{O_2}$ are global and do not reflect regional differences between organs or even different tissues within an organ. Current methods of non-invasively assessing individual organ or tissue oxygenation are limited; measurements are difficult, require specialised techniques and are not widely available. Currently, only gastric tonometry and near-infrared spectroscopy have clinical applications in the detection of organ hypoxia.[24] Novel techniques such as palladium porphyrin phosphorescence–based techniques are being evaluated in animals but require improvement as palladium is itself cytotoxic.[27] Cellular oxygenation measurement methods are also in development.[28]

OXYGEN THERAPY APPARATUS AND DEVICES

In the hypoxic self-ventilating patient, delivery of oxygen to the alveoli is usually achieved by increasing the Fi_{O_2}. Most commonly this involves the application of one of the many varieties of oxygen mask to the face, such that it covers the nose and mouth. There are other methods (e.g. nasal cannulae), but each needs to fulfil the same basic requirements.

Most of the simpler devices (e.g. plastic masks, nasal cannulae) deliver oxygen at relatively low oxygen flow rates relative to peak inspiratory flows (25–100+ L/min). The final Fi_{O_2} delivered is heavily influenced by the entrainment of environmental air, which dilutes the set Fi_{O_2}. From a physical principle perspective, the actual concentration of oxygen delivered is determined by the interaction between the delivery system and the patient's breathing pattern. The Fi_{O_2} that reaches the alveolus is therefore unpredictable. Factors that influence this can broadly be divided up into patient factors and device factors (Box 28.1).[29,30]

Box 28.1 Factors that influence the Fi_{O_2} delivered to a patient by oxygen delivery devices

Patient factors	Device factors
Inspiratory flow rate	Oxygen flow rate
Presence of a respiratory pause	Volume of mask
Tidal volume	Air vent size
	Tightness of fit

Leigh J. Variation in performance of oxygen therapy devices. *Anaesthesia*. 1970;25(2):210–222.

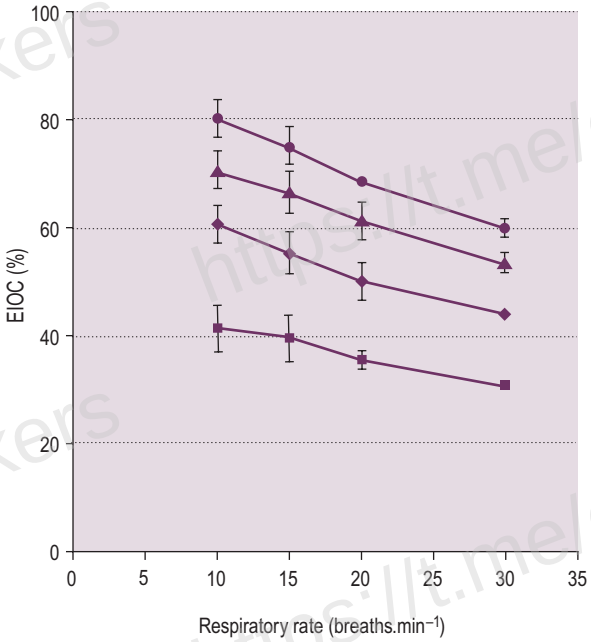

Figure 28.4 The performance of a Hudson mask on a model of human ventilation at a tidal volume of 500 mL and four oxygen flow rates (2 L/min [□], 6 L/min [◇], 10 L/min [△] and 15 L/min [○]). As the respiratory rate increases, the effective inspired oxygen concentration (EIOC) deteriorates. *From Wagstaff TAJ, Soni N. Performance of six types of oxygen delivery devices at varying respiratory rates.* Anaesthesia. *2007;62(5): 492–503.*

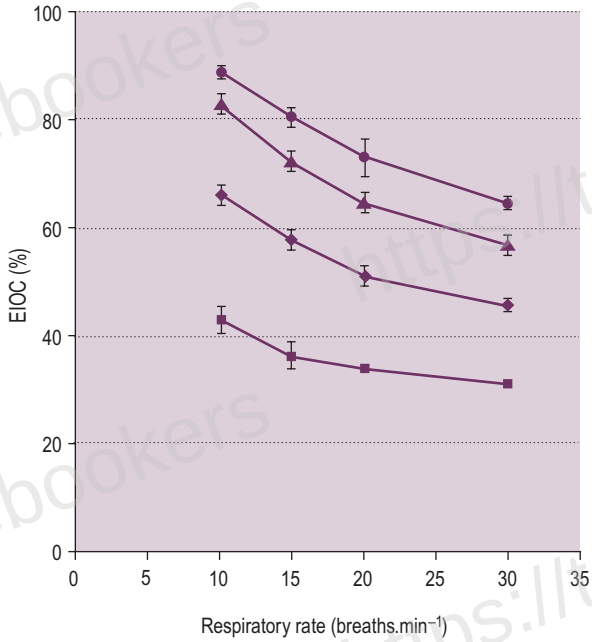

Figure 28.5 The performance of a Hudson non-rebreather mask on a model of human ventilation at a tidal volume of 500 mL and four oxygen flow rates (2 L/min [□], 6 L/min [◇], 10 L/min [△] and 15 L/min [○]). As the respiratory rate increases, the effective inspired oxygen concentration (EIOC) deteriorates. Note also how the curves of the graph are similar to the Hudson mask without the reservoir bag, implying no superiority with its addition. *From Wagstaff TAJ, Soni N. Performance of six types of oxygen delivery devices at varying respiratory rates.* Anaesthesia. *2007;62(5):492–503.*

In the hypoxic patient, it is common to find significant increases of inspiratory flow rates, as well as an absence of the respiratory pause. This can result in the actual Fi_{O_2} at the alveolus being significantly less than that thought to be delivered. This is due to a greater proportion of the inhaled gas being entrained air when the patient's inspiratory flow rate increases. The normal peak inspiratory flow rate (PIFR) is 25–35 L/min; in critical illness this can increase eightfold, greater than 200 L/min.[31] The greater the inspiratory flow rate, the lower is the alveolar Fi_{O_2}. This is particularly true for the variable performance-type masks but is seen even in the more 'reliable' Venturi-type masks, particularly when higher Fi_{O_2} inserts are used. The presence of a valve-controlled reservoir bag on a 'non-rebreather' semi-rigid plastic mask should compensate for high inspiratory flows – hence the belief that such masks can deliver 100% oxygen. However, this is not the case, and in models of human ventilation, such masks do not seem to confer significant extra oxygen delivery ability greater than that of semi-rigid plastic masks without a reservoir bag (Figs 28.4 and 28.5).[32] The failure of oxygen masks to deliver the desired Fi_{O_2} can be improved either by having a high enough oxygen flow rate and reservoir to compensate for the high inspiratory flow rate (e.g. high-flow nasal cannulae [HFNC] such as the Vapotherm) or by sealing the upper airway (nose and mouth) from the environment (e.g. the continuous positive airway pressure [CPAP] mask). Indeed, there is evidence supporting the hypothesis that some of the improvement in oxygenation seen with CPAP ventilation may be due to the eradication of entrainment of environmental air rather than the positive airway pressure exerted by the CPAP valve.[32]

In summary, the use of non-sealing oxygen masks and cannulae should be guided by the patient's requirements and response to therapy, rather than a belief that the concentration being delivered is that reaching the alveolus. This can be particularly important in the treatment of patients whose ventilatory drive is sensitive to P_{O_2} levels.

OXYGEN DELIVERY DEVICES

Methods of delivering oxygen to conscious patients with no instrumentation to their airway can broadly be divided into four categories: (1) variable performance

systems, (2) fixed performance systems, (3) high-flow systems, and (4) others. With the exception of the intravascular devices, all comprise similar component parts:

1. *Oxygen supply:* oxygen can be delivered from pressurised cylinders, hospital supply from cylinder banks or a vacuum-insulated evaporator, or an oxygen concentrator.
2. *Oxygen flow control:* oxygen supplied to the device is controlled by some sort of valve, often with an associated flow meter.
3. *Connecting tubing:* both from the supply to the flow control and from the flow control to the device, the type and size of the tubing are important. Small-bore tubing can limit oxygen flow when high flow is intended. In some systems the connecting tubing can also act as a reservoir (e.g. Ayre's T-piece). Some devices require specialised tubing with appropriate end attachments, such as the Schräeder valves required for connecting to the wall oxygen supply.
4. *Reservoir:* all oxygen delivery devices have some sort of reservoir. In a simple oxygen mask, it is the mask itself. Some low-flow CPAP circuits have a balloon reservoir. Nasal cannulae use the nasopharynx as a reservoir. An oxygen tent uses the volume of the tent as a large reservoir. The effectiveness of the reservoir in 'storing' oxygen ready for the next inspiratory effort is one of the important factors in governing its ability to deliver the desired oxygen concentration. The oxygen tent is a good example of the effectiveness of a large reservoir because it eliminates air entrainment, whatever the patient's PIFR. Thus the oxygen flow rate does not have to be high, but just enough to ensure that CO_2 re-breathing is abolished. Indeed, it is the retention of CO_2 that can be the major problem if gas is expired into the reservoir.
5. *Patient attachment:* the patient is connected to the oxygen supply and reservoir such that the device delivers oxygen to the airway – either by directly covering the upper airway (e.g. plastic mask/head box), intranasally or by increasing the oxygen concentration in the wider environment as in an oxygen tent.
6. *Expired gas facility:* expired gas from the patient needs to be allowed to dissipate into the environment and not be retained in the system to be inspired at the next inspiratory effort. Most masks achieve this by having a small reservoir capacity and holes in the plastic to allow the gas to exit. One-way valves, as in the non-rebreather type reservoir mask, aid in unidirectional flow of gas away from the patient. High-flow T-piece systems like those used in a CPAP system use the high flow to remove the gas down an expiratory limb and into the environment.
7. *Humidification:* most systems use the physiological humidification properties of the nasopharynx and trachea. However, high-flow systems may overcome this, leading to drying of the airway and secretions, which can be uncomfortable and undesirable. Artificial humidification (and warming) should be employed, using devices such as a water bath or heat and moisture exchanger (HME).
8. *Oxygen monitor:* some systems have an oxygen monitor incorporated in the apparatus (e.g. a fuel cell). This allows the much more accurate monitoring of Fi_{O_2}, but this is dependent on where in the system it is placed and also adds bulk and expense to the oxygen delivery method.

VARIABLE PERFORMANCE SYSTEMS

Typically these are non-sealed mask or nasal cannulae systems, which deliver oxygen at low gas flows (2–15 L/min). The reservoir is usually small, consisting of the volume of the mask in the case of the semi-rigid type, or the nasopharynx as in the nasal cannulae. The entrainment of environmental air is important in their delivery capability and has to be considered when being used.

Nasal cannulae The proximity of the reservoir – the nasopharynx – means that these systems are particularly sensitive to changes in inspiratory flow rate and particularly the loss of the respiratory pause. However, for mild hypoxia, they are tolerated well by patients who can eat and drink with them in situ. They can cause drying of the nasal mucosa when used at higher flow rates, and newer systems are available that can humidify and warm the inspired oxygen. They are cheap and easy to use, with no risk of CO_2 retention.

Simple semi-rigid plastic masks (e.g. Hudson) The most commonly used type of oxygen mask, these are cheap and easy to administer. The reservoir comprises the mask, and rebreathing of CO_2 can therefore occur if used at oxygen flow rates less than 4 L/min. A maximum Fi_{O_2} of only 0.6–0.7 can be achieved, which will be lower in the presence of respiratory distress.

Tracheostomy masks These semi-rigid plastic masks act in the same way as their facial counterparts. However, the delivery they achieve is very dependent on the presence of an endotracheal tube and the inflation status of its cuff. If absent, or if the cuff is deflated, then air from the nasopharynx will mix with that being delivered to the tracheostomy and further dilute the Fi_{O_2}.

T-piece system These simple systems, consisting of an inspiratory limb and expiratory limb forming the bar of the 'T', can be used with endotracheal tubes (oral, nasal or tracheostomy) or with a sealed CPAP-type mask. The oxygen flow rate needs to be high enough to match the patient's PIFR so as to prevent rebreathing of expired gas and thus potential entrainment of air from the expiratory limb. The seal of the mask or tube cuff is important also to prevent entrainment of air.

FIXED PERFORMANCE SYSTEMS

These systems are so called because their delivery of oxygen is independent of the patient factors outlined previously.

Venturi-type masks Oxygen concentration is determined by the Venturi principle: oxygen passing through a small orifice entrains air to a predictable dilution. The Fi_{O_2} is adjusted by changing the Venturi 'valve' and setting the appropriate oxygen flow rate. Although the Venturi effect can deliver 40–60 L/min, this is possible only at the lower Fi_{O_2} valves (e.g. at Fi_{O_2} of 0.24 the flow rate is approximately 53 L/min at an inflow of 2 L/min), and oxygen flow rate falls as the Fi_{O_2} increases. Thus, in respiratory distress associated with hypoxia, the reduction in oxygen flow rate can lead to failure despite a higher Fi_{O_2} setting. The larger orifice leads to the system behaving more like a simple mask.

Anaesthetic breathing circuits Non-rebreathing systems (e.g. Mapleson A, B, C, D and E) depend on the gas flows to ensure no re-breathing. No air entrainment is possible, but re-breathing occurs readily at low flows (most require flows >150 mL/kg). Delivery of oxygen to the patient with a Mapleson circuit via face mask takes considerable skill and training. Bag inflation is reliant on continuous fresh gas flow and a tight mask seal, without which the bag will not maintain adequate inflation (or will empty completely) rendering ventilation ineffective (or impossible). However, use of the Mapleson circuit is a skill worth acquiring because there is no inspiratory valve to overcome (unlike the bag valve mask [BVM] discussed later), minimising the inspiratory effort required during spontaneous breathing.

Self-inflating bag valve mask Despite the BVM being easier to use than Mapleson circuits by the non-expert, it has disadvantages. By design, self-inflating BVMs are not reliant on fresh gas flow or mask seal to deliver a hand-ventilated inspiratory volume. Therefore vigilance is required to establish a tight mask seal and to ensure the oxygen source is connected, turned on and filling the reservoir bag. In addition, a self-ventilating patient in respiratory failure may not be able to open the one-way valve to achieve effective ventilation; hence inspiratory effort often needs to be assisted by hand, which can be challenging, especially when two hands are required for a mask seal. There is also no direct feedback from the self-inflating bag itself to alert the operator to a loss of mask seal or inform them of ventilation adequacy. A blow-off valve, usually set at 60 cm H_2O, is the only means of detecting high airway pressure.

HIGH-FLOW SYSTEMS

High-flow oxygen therapy, originally developed in the neonatal and paediatric settings, is a relatively recent innovation in the critically ill adult patient.[33] It delivers warm humidified high-flow oxygen at flow rates between 15 and 60 L/min through a small nasal or face mask interface. Humidification of this high gas flow rate contributes to a remarkably high degree of tolerance, and, rather than cyclically increasing the upper airway inspired oxygen concentration which is then diluted by entrained air (standard oxygen therapy), it offers (1) a gas flow rate closer to the subjects inspiratory flow rate, (2) flow-dependent continuous positive airway pressure (CPAP) with increased end-expiratory lung volume, and (3) washout of upper airway CO_2 leading to decreased physiological dead space, with both latter mechanisms possibly contributing to reduce the work of breathing.[34–36] A number of investigators have shown that HFNC is comfortable and effective at improving oxygenation.[37] The current evidence suggests that in patients with hypoxaemic respiratory failure, high-flow oxygen therapy prevents reintubation after extubation when compared with standard oxygen therapy.[38] However, a high proportion of patients with de novo acute hypoxaemic respiratory failure require intubation when initially managed with high-flow oxygen therapy[39]; and when intubation is delayed in these patients, it is associated with increased ICU mortality.[40] This reinforces the need for an appropriate high-acuity clinical environment and appropriately trained team to manage patients with acute hypoxaemic respiratory failure with high-flow oxygen therapy.

Positive-pressure devices Non-invasive ventilation (NIV) delivers oxygen with some element of positive pressure exerted during the respiratory cycle. It does not require instrumentation of the airway and is delivered either by a tight-fitting mask to the face or nose or as a helmet. The simplest CPAP system is a T-piece with a positive-pressure valve attached to the expiratory limb, as with a Mapleson E system. Other methods are also available; some use a balloon reservoir rather than a high-flow oxygen generator (Mapleson A). CPAP helps to improve functional residual capacity (FRC) and compliance.[41] There is no air entrainment, which contributes to the initial rapid improvement. Theoretically the positive pressure aids alveolar recruitment. A potential problem with the T-piece CPAP systems is that the oxygen flow rate has to be adjusted to the patient's PIFR so as to prevent closure of the valve, increasing the inspiratory work of breathing. Other methods of NIV such as bilevel positive airway pressure (BPAP) deliver oxygen at flows that should match the patient's demand.

OTHER METHODS OF OXYGEN DELIVERY

Intravascular oxygenation has been used but not extensively – particularly in the self-ventilating patient population. Extracorporeal membrane oxygenation (ECMO) supporting the lung has recently grown in use, secondary to a landmark study and recent influenza pandemics.[42,43]

MANAGEMENT OF OXYGEN THERAPY

In the correct situations, oxygen is a life-saving drug/therapy. It remains part of the initial resuscitation and ongoing management of the critically unwell. In the United Kingdom at any one time, 15%–17% of all hospital inpatients will be receiving oxygen.[44] However, oxygen can have detrimental effects in certain patient groups and/or situations, and this may result in significant morbidity or mortality.

RESPIRATORY FAILURE

Identifying patients that require oxygen therapy is vital. Supplemental oxygen is required to treat most causes of hypoxia, yet different patient groups may have different resting oxygen concentrations. For example, patients with cyanotic heart disease or chronic neuromuscular disorders may have a Sa_{O_2} of 80%, yet have adapted to tolerate these oxygen tensions. The normal values of Pa_{O_2} and Sa_{O_2} in healthy volunteers are summarised in Table 28.4.[45] In many cases of critical illness, low oxygen tensions are due to hypoxic hypoxia. This may be as a result of reduced environmental oxygen such as that seen at altitude, pulmonary oedema or pneumonia resulting in ventilation–perfusion mismatch and intrapulmonary shunt. This is so-called type I respiratory failure where ventilation is intact, but gas transfer or haemoglobin saturation is impaired. It is defined as a $Pa_{O_2} < 8$ kPa (60 mm Hg) with a normal or low $PaCO_2$.[45] Broadly speaking, hypoxia in any of these situations will be improved by increasing inhaled oxygen concentrations. However, caution must be taken when dealing with ventilatory or type II respiratory failure. The differentiation of the two types of respiratory failure is made using the $PaCO_2$. The normal value is 4.6–6.1 kPa (34–46 mm Hg) and hypoxic patients with $PaCO_2$ concentrations above this range should be considered as being in type II respiratory failure. Many causes of ventilatory failure are not affected by the oxygen tension in the blood (e.g. Guillain–Barré, opioid overdose). However, with commoner causes, such as acute exacerbations of chronic obstructive pulmonary disease and acute severe asthma, the patient's ventilation can be sensitive to oxygen therapy.

TARGETED OXYGEN THERAPY

The need for oxygen to prevent tissue hypoxia and cellular dysfunction is clear. However, it is not possible to define a single level of hypoxaemia that is dangerous to all patients. Some patients with chronic lung disease may be accustomed to living with an Sa_{O_2} of 80%, whereas others with acute organ failure may be harmed by short-term exposure to an Sa_{O_2} of less than 90%. So the level of hypoxaemia has to be given context not just in severity but also in time and evidence of negative physiological effect. There is no evidence that saturations above normal result in benefit. Rather, hyperoxia can have adverse effects. As a rule of thumb, maintaining Sa_{O_2} greater than 90% in critically ill patients is considered best practice and permits a margin of error.[46,47] Those patients at risk of hypercarbic type II respiratory failure should be managed with a little more caution and their Sa_{O_2} target should be set between 88% and 92%.

Table 28.4 Mean (SD) Pa_{O_2} and Sa_{O_2} values (with range) in kPa and mm Hg

AGE (years)	MEAN Pa_{O_2} (kPa and mm Hg)	RANGE ± 2 SD Pa_{O_2} (kPa and mm Hg)	MEAN Sa_{O_2} (%)	Sa_{O_2} ± 2 SD
18–24	13.4 (0.71) 99.9 (5.3)	11.98–14.82 89.3–110.5	96.9 (0.4)	96.1–97.7
25–34	13.4 (0.66) 99.8 (4.9)	12.08–14.72 90–109.6	96.7 (0.7)	95.3–98.1
35–44	13.18 (1.02) 98.3 (7.6)	11.14–15.22 83.1–113.5	96.7 (0.6)	95.5–97.9

MONITORING

All patients demonstrating hypoxia and the need for oxygen therapy should have a full medical history and physical examination. Focus should be placed on pre-existing respiratory or cardiac disease to ensure correct interpretation of the technical data, as well as appropriate oxygen targets being set. Pulse oximetry is extremely valuable as a non-invasive measure of arterial oxygenation. Calibrated on normal subjects, their readings must be treated with caution when less than 80% but are accurate when greater than 88%. They may have decreased accuracy in the critically ill, but the mean difference is within 1.3%.[48] Although pulse oximetry is an excellent tool for assessing Sa_{O_2}, it gives no data regarding pH and/or $PaCO_2$ as a marker of ventilatory function or the haemoglobin concentration. Thus it cannot be used as a monitor of ventilation or an absolute assessment of Ca_{CO_2}. In addition, in scenarios in which hypoxaemia is suspected, an arterial blood gas should be performed and interpreted (Chapters 18 and 94). Arterial blood gas analysis is the gold standard for assessing respiratory failure. Usually assessed from aspirating blood from a systemic artery, ear lobe specimens also have utility in assessing $PaCO_2$ and pH, at less discomfort to the patient. However, they are less accurate and less precise at lower oxygen tensions.[49,50]

PREOXYGENATION AND APNOEIC OXYGENATION

Preoxygenation prior to induction of anaesthesia aims to delay desaturation to provide a safe apnoeic period for endotracheal intubation. In patients with normal lungs and ventilatory drive, preoxygenation with 100% oxygen for 3 minutes of tidal breathing, or eight vital capacity breaths over 60 seconds, maximally denitrogenates the FRC to allow maximal oxygen storage in the lung.[51,52] Many methods of preoxygenation are in common practice. Although the simple method of delivering greater than or equal to 15 L/min O_2 via a tight-fitting semi-rigid face mask with reservoir bag is described, it can achieve only a Fi_{O_2} between 0.6 and 0.7, as described above, which may be inadequate in the critically ill. Methods of preoxygenation with a Fi_{O_2} of 1.0 include: BVM (with or without positive end expiratory pressure [PEEP] valve), HFNC, Mapleson circuit and NIV.[51,53–55] NIV may improve preoxygenation when the other methods are (or are likely to be) ineffective, such as occurs with severe acute and/or chronic hypoxic respiratory failure.[51,53,56] A head up position of 20 degrees or more has been shown to improve the efficacy of preoxygenation, by maximising FRC (and therefore oxygen stores),[51,53,57,58] especially in morbid obesity.[59]

Preoxygenation ends after the patient becomes apnoeic and the oxygen source is removed to allow laryngoscopy and intubation. Continuation of oxygen delivery throughout the apnoeic period (apnoeic oxygenation) has been shown to safely prolong the period of adequate oxygenation, delay the onset of critical desaturation and improve first-pass intubation success.[51,60–62] Apnoeic oxygenation is likely to provide maximal benefit during prolonged or repeated intubation attempts in an adequately preoxygenated patient with a difficult airway (anticipated or unanticipated). Likewise, it may provide a longer safe apnoea period for the inexperienced intubator to either secure the airway or have a more skilled intubator takeover. However, apnoeic oxygenation is unlikely to benefit the maximally preoxygenated patient who is intubated rapidly by an experienced intubator and may unnecessarily complicate the intubation. In ideal conditions, apnoeic oxygenation can achieve a long delay to desaturation by continually replenishing the denitrogenated FRC with oxygen from the nasopharynx reservoir, limited only by the consequential hypercarbia.[63] Ideal conditions (uncommon in the critically ill) include normal lungs, normal pulmonary circulation, normal DO_2 and an open airway (to allow oxygen flow below the vocal cords during apnoea). The most commonly reported technique for apnoeic oxygenation is the delivery of 15 L/min O_2 via nasal cannulae, commenced on induction (or during preoxygenation).[51,60–62] The use of HFNC for both preoxygenation and apnoeic oxygenation may offer some advantages due to the ease of use, patient tolerability, improved maintenance of upper airway patency during apnoea and CO_2 washout delaying hypercarbia.[54,55,64] Despite a rapid uptake of apnoeic oxygenation practice in the emergency department and pre-hospital settings, its role in the ICU setting is yet to be established due to conflicting studies.[64–67] Indeed, the most recent randomised control trial in the emergency department setting was negative, causing further uncertainty as to when, how and in whom to use apnoeic oxygenation.[68] In addition, studies in all settings are limited by a lack of blinding, no control of preoxygenation techniques or patient position, different methods of apnoeic oxygenation (HFNC vs nasal cannulae) and variable experience of the intubator.

Apnoeic oxygenation is also used in clinical brain death testing to demonstrate absence of a brainstem response to severe hypercarbia (see Chapter 53).

HAZARDS OF OXYGEN THERAPY

SUPPLY

Medical oxygen supply is a compressed gas. Pipeline supply to the 'wall' is usually at 4 bars of pressure (3040 mm Hg). The cylinder supply pressure, when full, is 137 bars (104-120 mm Hg). As such, oxygen as explosion is a risk. Direct administration of oxygen at delivery pressures also carries a real risk of barotrauma

to the airway and alveoli, if not governed by an appropriate pressure-limiting valve.

Oxygen also supports combustion. The possibility of sparks in an oxygen-rich environment must be avoided. Patients must not smoke cigarettes when receiving oxygen therapy, even via nasal cannula. Another example is to ensure that oxygen supplies are removed or turned off when defibrillating because a spark can occur in such situations. An ICU fire secondary to an oxygen cylinder explosion has been reported in the literature.[69]

OXYGEN TOXICITY

Despite being a naturally occurring substance, the use of oxygen in a medical environment should be considered pharmacotherapy. As with all drugs, it has side effects in overdose. There has been a great interest in the potential toxic effects of oxygen in recent years. As is evident from the previous management of oxygen therapy, there needs to be a limit to the concentrations of oxygen used. There is no apparent benefit in hyperoxia, except in one or two specific settings. Indeed, in the critical care environment, studies have shown that a high Pa_{O_2} level within the first 24 hours is an independent risk factor for hospital mortality.[70] However, this finding remains contentious, with further studies demonstrating the effect of hypoxia as a predictor of mortality, but no strong effect seen with hyperoxia.[71] Adverse outcomes have also been reported following treatment of postcardiac arrest patients with hyperoxia.[72] These findings also have not been reproduced by further studies, but there is still evidence of a U-shaped mortality curve for Pa_{O_2} in this group of patients.[73] More recently, among critically ill patients with an ICU length of stay of 72 hours or longer, a conservative protocol for oxygen therapy (Pa_{O_2} between 70 and 100 mm Hg or SpO_2 between 94% and 98%) versus conventional therapy (Pa_{O_2} values up to 150 mm Hg or SpO_2 between 97% and 100%) resulted in lower ICU mortality.[74] What is more certain is the effect of resuscitation with 100% oxygen in neonates. This has been shown to lead to an excess mortality, and air is now the recommended gas to be used in the resuscitation of infants.[75]

VASOCONSTRICTION

Oxygen is known to cause constriction of the coronary, cerebral and renal vasculature, which could lead to hypoperfusion of key organ systems – potentially reducing $\dot{D}_{O_2}$ when an increase is desired. This hazard would be played off only against a very moderate increase in Ca_{O_2} assuming all the haemoglobin is saturated. In healthy subjects, hyperoxia reduces cerebral blood flow by 11%–33%.[76,77] This may be associated with a worse outcome following a mild to moderate cerebrovascular accident.[77] Similarly, coronary blood flow is reduced in the presence of hyperoxaemia (8%–29% in healthy subjects).[78] This may promote myocardial ischaemia during acute coronary syndromes, possibly increasing myocardial infarction size.[79] This has led international guidelines for the management of acute coronary syndromes to stipulate that supplementary oxygen should *not* be given to patients with acute chest pain unless there is evidence of hypoxaemia.[80,81] Pulmonary vasculature is a notable exception, whereby alveolar hypoxia induces vasoconstriction of small pulmonary arteries (Euler-Liljestrand mechanism), improving ventilation perfusion matching.[82]

CENTRAL NERVOUS SYSTEM (CNS) TOXICITY (PAUL BERT EFFECT)

Seen in diving, oxygen delivered at high pressure (>3 atmospheres, ≈300 kPa) can lead to acute central nervous system signs and seizures.

LUNG TOXICITY (LORRAINE SMITH EFFECT)

Exposure to a high Fi_{O_2} results in pulmonary injury with a progressive reduction in compliance occurs, and associated interstitial oedema, leading to fibrosis. The mechanism remains unclear but is believed to involve direct cellular damage to the lung tissue by highly reactive oxygen species (ROS). High concentrations of oxygen produce a higher concentration of ROS that overwhelm the normal scavenging mechanism lining the respiratory tract. This is possibly associated with loss of surfactant, increase in sympathetic activity and alveolar collapse due to both the increase in surface tension and the lack of other non-respiratory gases. Evidence for this mechanism is supported by the worsening of lung damage seen in paraquat poisoning. Paraquat produces large amounts of ROS, and the administration of supplemental oxygen worsens its effects. Identifying this as the sole aetiology for pulmonary pathology can be difficult, especially as the usual indications for oxygen therapy usually imply some form of pulmonary pathology. However, the presence of endotoxin has been shown to protect against oxygen-induced lung toxicity.[83,84]

It is reasonable that the risk of oxygen-induced pulmonary toxicity is dependent on concentration and duration of exposure. However, the concentration/duration that 'likely causes toxicity' is not clear. In some subjects, long exposure times and high concentrations do not lead to problems. In general, patients should remain below an Fi_{O_2} of 0.5 where possible, and periods greater than this should be kept to the minimum required.

BRONCHOPULMONARY DYSPLASIA

First described in 1967, this is a form of chronic lung disease associated with neonatal ventilation; its pathophysiology includes the same factors as the adult, but with the additional effect of immaturity.[85] The advent of surfactant in the treatment of respiratory distress of the newborn and the addition of maternal steroid therapy

to promote pulmonary development have lowered the incidence and reduced the severity of the disease.

OTHER PULMONARY EFFECTS

Supplemental oxygen also has other more predictable physiological effects within the lungs that may not been seen as truly toxicological, but cause problems in themselves. The greatest is the effect of oxygen on ventilation, especially in those at risk of type II respiratory failure.

I. *V/Q mismatch:* high concentrations of inspired oxygen will reduce the physiological effects of hypoxic pulmonary vasoconstriction, thus diverting blood through poorly ventilated lung, increasing shunt and reducing Pa_{O_2}. In lungs without chronic disease, this can be compensated for by an increase in ventilation. However, in patients with borderline ventilation, this can lead to increasing $PaCO_2$ and worsening acidaemia.
II. *Ventilatory drive:* hypoxia less than 8 kPa (60 mm Hg) leads to an increase in ventilation. Values greater than this level have little impact on ventilation. It remains contentious whether this mechanism is important when rises in $PaCO_2$ are seen in patients with COPD.[86,87]
III. *Haldane effect:* increasing Fi_{O_2} decreases the CO_2 buffering capacity of haemoglobin, thus potentially leading to an increase in $PaCO_2$ and acidaemia.
IV. *Absorption atelectasis:* in the presence of small-airway obstruction, high alveolar oxygen concentrations result in rapid absorption of gas, causing collapse of the alveoli and reduction in the diffusion surface area. This has been demonstrated even at an Fi_{O_2} of 0.5.[88]
V. *Higher density of oxygen compared with air:* oxygen is more dense than air and thus breathing high concentrations at increased viscosity increases the work of breathing. This effect is probably negligible in patients with normal underlying lungs and neuromuscular function but can be significant in those with chronic disease.

RETINOPATHY OF PREMATURITY

Previously referred to as retrolental fibroplasia, retinopathy of prematurity (ROP) was first described in 1942. It is a vasoproliferative disorder of the eye affecting premature neonates. Similar to the lungs, the completion of development of the retinal vasculature is late in gestation (32–34 weeks).[89] In the 1950s an epidemic of ROP was described and a causal link to uncontrolled oxygen therapy was made.[90] Improved monitoring of oxygen therapy reduced the incidence of ROP but was associated with an increase in perinatal mortality secondary to respiratory failure.[91] Subsequently, and despite good oxygen control, ROP continues to occur. This is now most likely due to the increased survival of increasingly premature low-birth-weight infants[92] rather than high Pa_{O_2} alone. This suggests both oxygen- and non–oxygen-related factors. ROP is a biphasic disease in which the relatively hyperoxic environment following delivery initially leads to a slowing or even cessation of retinal vascular development of the premature infant. Additional oxygen may further contribute to this problem by affecting the expression of vascular growth factors. The second phase of the disease is a hypoxic-induced neovascularisation, similar to that seen in diabetic retinopathy. This leads to fibrous scarring with risk of retinal detachment. How much oxygen is too much remains contentious and further research is required.[93]

HYPEROXIC AND HYPERBARIC OXYGEN THERAPY

As stated previously, there are very few indications for increasing the Pa_{O_2} above 'normal', approximately 13 kPa (100 mm Hg). Indeed, it is likely to be harmful. However, there exist some data to support its use in certain conditions, the majority of which do not involve the critical care physician. These include the treatment of cluster headache, reduction in oxidative stress in colonic surgery and prevention of desaturation during endoscopy.[94–97] The use of hyperoxia to treat postoperative nausea and vomiting and prevent postoperative wound infections lacks high-quality evidence.[95]

ACUTE CARBON MONOXIDE POISONING

Carbon monoxide poisoning as a condition necessitating hyperoxic therapy attracts particular attention. A common consequence of house fires, it binds to haemoglobin with an affinity 210 times that of oxygen. Its half-life in air is 320 minutes, but this can be reduced to 90 minutes by giving the patient 100% oxygen, or 23 minutes with the addition of 3 atmospheres (≈300 kPa) of hyperbaric therapy. Competitive dissociation of carbon monoxide from the haem-binding site and provision of dissolved oxygen to the tissues are believed to combine to reduce the sequelae of carbon monoxide poisoning, but the mechanisms are likely to be more complex.[98] Some studies have suggested both acute and longer-term benefit,[99,100] but others have been unable to conclude significant improvement.[101,102] Investigations have attempted to distinguish those patients more likely to benefit from hyperbaric oxygen therapy. Factors such as increasing age (>35 years), an exposure time of greater than 24 hours, an associated loss of consciousness and carboxyhaemoglobin levels greater than 25% appear to result in an increased incidence of neurological sequelae and probably benefit from hyperbaric oxygen.[103] Geographical distance to an appropriate centre often has a significant influence on hyperbaric use in the acute setting, but mobile units

Box 28.2 Recognised indications for hyperbaric oxygen therapy

Primary therapy	Adjunctive therapy
Carbon monoxide poisoning	Radiation tissue damage
Air or gas embolism	Crush injuries
Decompression sickness (the 'bends')	Compromised skin flaps or grafts
Osteoradionecrosis	Refractory osteomyelitis
Clostridial myositis and myonecrosis	Intracranial abscess
	Chronic wound healing

Bennett M. Randomised controlled trials in diving and hyperbaric medicine. In: Weaver LK, ed. *Hyperbaric Oxygen Indications*. 6th ed. The Hyperbaric Oxygen Therapy Committee Report. Durham, NC: Undersea and Hyperbaric Medicine Society; 2014:259–283.

and some evidence that late therapy may be of benefit should not necessarily preclude its usage.[104,105]

HYPERBARIC OXYGEN

As alluded to in the treatment of carbon monoxide poisoning, oxygen can be delivered to patients at higher than atmospheric pressure (2–3 atmospheres). This serves to increase the amount of oxygen carried in the plasma, rather than bound to haemoglobin. This follows Henry's law, which states: 'At a constant temperature, the amount of a given gas dissolved in a given type and volume of liquid is proportional to the partial pressure of that gas in equilibrium with that liquid.' As the partial pressure of oxygen in the environment rises, so too does the amount of oxygen dissolved in the plasma. Consequently, the contribution of the Pa_{O_2} in the Ca_{O_2} formula (28.3) increases. At rest, the metabolic demands of an average person can be met by dissolved oxygen alone when breathing 100% at 3 atmospheres.

Hyperbaric oxygen therapy can be delivered either in a monoplace chamber designed for one individual, or in multiplace chambers for 2–10 people. The chambers encompass the whole body, and gas is piped from source, heated and humidified. The common indications and complications of hyperbaric oxygen therapy are listed in Boxes 28.2 and 28.3, respectively.[106,107]

Box 28.3 Complications of hyperbaric oxygen therapy

- *barotrauma:* middle ear and sinuses, rupture of the oval or round window, gastrointestinal distension, tooth displacement and pain, gas embolism on decompression
- *oxygen toxicity (as above):* especially a problem in the critically ill who may be on high concentrations for longer periods[78]
- *generalised seizures*: Paul Bert effect
- *visual problems:* acute myopia, cataract formation.

Airway management and acute airway obstruction

Gordon YS Choi, Gavin M Joynt

The primary objective of airway management is to clear or bypass the obstructed airway and protect the lungs from soiling. Acute upper airway obstruction is a life-threatening emergency, resulting from a wide range of pathophysiological processes. Rapid assessment and establishment of a patent airway are vital, often in the absence of a specific diagnosis. As no single airway management modality is universally applicable, the intensive care unit (ICU) physician must be capable of performing a variety of airway management techniques (Fig. 29.1).

AIRWAY MANAGEMENT TECHNIQUES

Airway management techniques can be considered non-invasive or invasive, depending on whether instrumentation occurs above or below the glottis, and is surgical or non-surgical (Table 29.1). Definitive techniques secure the trachea and provide some protection from macroscopic aspiration and soiling. Although most airway management in ICU is still achieved by bag-and-mask ventilation and direct laryngoscopic tracheal intubation, the use of fibreoptic bronchoscopy and video laryngoscopy is increasingly common, especially in special circumstances. Management of failed intubation and ventilation by various alternative techniques (e.g. laryngeal mask airway [LMA] and cricothyroidotomy) is now well described.[1,2]

The technique of choice will depend on each situation and is a consequence of the interaction of patient factors and the clinician's experience (Table 29.2). Other factors include availability of help, levels of training and supervision and accessibility of equipment. A portable storage unit with a wide choice of equipment appropriate for difficult airway management is necessary in the ICU (Box 29.1).

NON-INVASIVE TECHNIQUES

BAG-MASK VENTILATION

As with most airway management techniques, mask ventilation is a basic skill that requires time and experience to master. It should be learned using manikins, simulators and practiced in the controlled environment of the operating theatre so that when used in the emergency setting in the ICU the skill is well established. The bag may be a self-inflating resuscitator or one attached to an anaesthetic circuit. Most resuscitators require a reservoir bag in series with the self-inflating bag that ensures a high oxygen concentration can be delivered. The addition of positive end-expiratory pressure (PEEP) may improve arterial oxygenation and overcome airway obstruction due to laryngospasm.

Some considerations when performing mask ventilation include the following:

- *Inadequate ventilation:* the seal of the mask against the face may be inadequate and good hand positioning is essential. Ventilation of edentulous patients may be aided by improving hand position or special masks. Two operators are recommended if a mask face leak is excessive: one to hold the mask and the other to manipulate the bag-mask resuscitator.
- *Hyperventilation:* unnecessary hyperventilation may occasionally cause dynamic pulmonary hyperinflation and cardiovascular compromise.
- *Gastric insufflation:* this increases the risk of vomiting and aspiration. Carefully applied cricoid pressure may prevent gastric gas insufflation.
- *Pulmonary aspiration:* in the emergency situation with a full stomach, mask ventilation with cricoid pressure may be necessary until the airway can be secured. Passage of a nasogastric tube to aspirate gastric contents may be successful, but emptying cannot be guaranteed and vomiting may be induced.

ORO- AND NASOPHARYNGEAL AIRWAYS

In the unconscious patient, functional obstruction may occur because of loss of muscular tone and inspiratory airway narrowing at the soft palate, epiglottis and tongue base. An oropharyngeal airway device may establish an adequate airway for spontaneous or bag-mask ventilation when proper head positioning is insufficient. It is inserted with the concavity facing the palate and then rotated 180 degrees into the proper position as it is advanced. Complications include mucosal trauma, worsening the obstruction by pressing the epiglottis against the laryngeal outlet if the

ABSTRACT

Obstruction to the airway is a life-threatening emergency. Causes of obstruction are many and varied. Rapid assessment followed by immediate establishment of a patent airway is vital. No single management modality is universally applicable, and therefore the intensivist must be capable of performing a variety of airway management techniques. Non-invasive techniques appear simple, but require manual dexterity and regular practice to guarantee competence. While traditional rigid laryngoscopy remains a gold standard for tracheal intubation, video laryngoscopic techniques are increasingly available and may offer advantages in specific patients and situations. Alternative methods of securing an airway include flexible fibreoptic tracheal intubation, the use of a laryngeal mask, and the execution of a surgical airway, such as cricothyroidotomy or tracheostomy. Upper airway obstruction is uncommon, but immediately life threatening. Participation in airway courses and simulations to improve and maintain diagnostic and interventional skills in this setting is recommended.

tongue displaces posteriorly, and occasionally laryngospasm. The following sizes (length from flange to tip) are recommended: large adult: 100 mm (Guedel size 5), medium adult: 90 mm (Guedel size 4), and small adult: 80 mm (Guedel size 3).

A nasopharyngeal airway is a soft rubber or plastic tube inserted into the nostril and advanced along the floor of the nose (in the direction of the occiput). It is better tolerated by semiconscious patients than the oropharyngeal airway. Complications include epistaxis, aspiration and, rarely, laryngospasm and oesophageal placement.

SUPRAGLOTTIC AIRWAYS

The original LMA is a reusable device that consists of a silicone rubber tube connected to a distal elliptical spoon-shaped mask with an inflatable rim, which is positioned blindly into the pharynx to form a low-pressure seal against the laryngeal inlet.[3] There are a variety of sizes for use in children and adults. LMAs are useful to achieve non-definitive airway patency in many emergency situations (see Fig. 29.1), and can be used to provide limited positive-pressure ventilation.

Once positioned, the LMA can be used to guide the passage of stylets, bougies, the bronchoscope or

even an endotracheal tube into the trachea. The intubating LMA (FasTrach) is a modification of the LMA with several features to facilitate intubation once the LMA is placed. There is a guiding ramp and epiglottic elevating bar at the aperture to direct the endotracheal tube to the glottis. It also has an anatomically curved, rigid shaft and handle to allow easy and firm manipulation during placement and when the endotracheal tube is passed.

iLMA, Intubating laryngeal mask airway; *LMA*, laryngeal mask airway.

The LMA is prepared for insertion by deflating and smoothing out the cuffed rim to be wrinkle-free, and the posterior surface is lubricated with water-soluble jelly. The patient is positioned as for endotracheal intubation, with slight flexion of the neck and extension of the atlanto-occipital joint (sniffing-the-morning-air position). The LMA is inserted with the tip of the cuff continuously applied to the hard palate, and with the right index finger guiding the tube to the back of the tongue until a firm resistance is encountered. The cuff is then inflated with 20–40 mL of air (adult sizes) before attachment of the breathing circuit. The successful use of LMA requires some familiarity with the equipment and technique, and at least simulated exposure is strongly recommended.

Second-generation LMAs are inserted in essentially the same way, although cuff inflation with air may not be required. They have additional advantageous features such as higher seal pressure, facilitate easy passage of a tube for gastric decompression, and allow improved conditions for fibre-optically guided tracheal intubation.[4] Examples include the i-gel (Intersurgical, Wokingham, United Kingdom), the Proseal LMA (PLMA; Teleflex Medical Europe Ltd, Athlone, Ireland), and the LMA Supreme (SLMA; Teleflex Medical Ltd). Differences in clinical performance between the second-generation devices are generally small.[5,6]

Contraindications for using the LMA include inability to open the mouth, pharyngeal pathology, airway obstruction at or below the larynx, low pulmonary compliance or high airway resistance. Complications

Box 29.1 Suggested contents of a portable storage facility for difficult airway management

- Masks
  - Face and nasal masks of differing make and size variety
- Airways
  - Oropharyngeal airways
  - Nasopharyngeal airways
  - Airway intubator guide for oral endoscopic intubation
  - Laryngeal mask airway (LMA) and intubating LMA with appropriate endotracheal tubes
- Rigid laryngoscope with a variety of designs and sizes
  - Short handle or variable angle (Patil–Syracuse) laryngoscope
  - Curved blades: Macintosh, Bizzarri–Giuffrida
  - Straight blades: Miller
  - Bent blades: Belscope
  - Articulating tip blades: McCoy
- Video laryngoscope
  - Disposable
  - Non-disposable
- Endotracheal tubes of assorted size
  - Murphy tubes
  - Microlaryngoscopy tubes
- Endotracheal tube stylets
  - Gum elastic bougie (Eschmann stylet)
  - Malleable stylet
  - Tube changer, hollow tube changer (jet stylet)
  - Lighted stylet (light wand)
- Fibreoptic intubation equipment
  - Patil endoscopic mask for oral endoscopic intubation
  - Fibreoptic endoscopes with light source, adult and paediatric-sized
  - Device for emergency non-surgical airway ventilation
- Combitube
- Emergency surgical airway access
  - Percutaneous cricothyroidotomy set
  - Transtracheal jet ventilation – cannula and high-pressure O_2 source connectors
  - Regulated central wall O_2 pressure (Sanders-type injector)
  - Unregulated central wall O_2 pressure
- Exhaled carbon dioxide monitor
  - Capnometer/capnograph
  - Chemical indicators

include aspiration, gastric insufflation, partial airway obstruction, coughing, laryngospasm, postextubation stridor and kinking of the shaft of the LMA.

COMBITUBE (OESOPHAGEAL–TRACHEAL DOUBLE-LUMEN AIRWAY)

The oesophageal–tracheal Combitube is a double-lumen tube that is blindly inserted into the oropharynx up to the indicated markings.[7] The oesophageal lumen has a stopper at the distal end and side perforations at the pharyngeal level, whereas the tracheal lumen has a hole at the distal end. It has two cuffs, a distal one and a proximal pharyngeal balloon. The patient is ventilated through the oesophageal lumen initially as the Combitube usually enters the oesophagus,[7] with the distal cuff sealing the oesophagus and the proximal balloon sealing the pharynx. Gas exits the perforations and enters the pharynx and larynx. In the event of failure of ventilation, the tracheal lumen is ventilated and the distal cuff seals the trachea.

Although demonstrated to be useful in the prehospital setting, its role in resuscitation and management of the difficult airway in the ICU environment is yet to be established. Barotrauma, especially oesophageal rupture, has been reported.

INVASIVE TECHNIQUES

ENDOTRACHEAL INTUBATION

Endotracheal intubation remains the gold standard airway management technique, allowing for spontaneous and positive-pressure ventilation, with good macroscopic protection from aspiration. Indications include acute airway obstruction, facilitation of tracheal suctioning, protection of the airway in those without protective reflexes and respiratory failure requiring ventilatory support with high inspired concentrations of oxygen and PEEP.

Prior to proceeding with an intubation attempt, regardless of the technique chosen, pre-oxygenation, as well as preparation and checking of all relevant equipment, is essential. Difficult airway management equipment (see Box 29.1) should also be accessible within a few minutes. Food, vomitus, blood or sputum may obstruct the airway and suction should always be available. Suction apparatus should generate at least 300 mm Hg (40 kPa) and 30 L/min. Excessively vigorous suctioning should be avoided, as it can cause laryngospasm, vagal stimulation, mucosal injury and bleeding.

Direct laryngoscopy

Although essential for all intensivists, direct laryngoscopy is a difficult skill to master.[8] If multiple intubation attempts are required, the maximum interruption to ventilation should be about 30 seconds. Adequate ventilation and oxygenation must be provided between attempts. Minimum monitoring should consist of continuous-pulse oximetry, electrocardiogram (ECG) and blood pressure. The BURP (backward, upward, rightward pressure) technique may be helpful to bring the vocal cords into the field of vision. Endotracheal tube size describes the internal diameter and, where possible, 8.0–9.0 mm in adult males and 7.5–8.0 mm in adult females are generally used to facilitate sputum clearance, minimise airway resistance and allow access for fibreoptic bronchoscopy. Special-purpose tubes include double-lumen tubes to facilitate lung isolation, spiral embedded tubes, and laser-resistant tubes.

The route of intubation may be orotracheal or nasotracheal. The orotracheal route is generally recommended because it may be associated with fewer complications.[9] However, nasotracheal intubation allows easier tube fixation and avoids the risk of tube occlusion from biting. It is contraindicated in the presence of fracture of the base of the skull. Other complications include epistaxis, turbinate cartilage and nasal septal damage during insertion.

Stylet guide (introducer)

The 'anterior larynx' can often be more easily intubated if a gum elastic bougie is advanced in the midline and directed anteriorly into the trachea. The endotracheal tube is then advanced over the guide. Clinical signs of correct tracheal placement of the guide include coughing, resistance felt before the guide is fully advanced (usually at 45 cm or less from the lips because of resistance at the carina or bronchus) and a sensation of clicks from the tracheal rings. A number of alternative intubating guides are available, including the hollow endotracheal tube changer, which can be attached to a side-stream capnometer, or to an oxygen source. The lighted stylet is less commonly used and has a light at the distal end that results in a characteristic midline transillumination appearance when the light enters the larynx.

Rigid indirect fibreoptic instruments

The video-laryngoscope (VL) is a relatively new device that generates a view of the glottis from near the laryngoscope tip. When used for difficult airway management, VLs produce similar or better intubation success rates compared with direct laryngoscopy, and reduce cervical spine movement during laryngoscopy.[10] Comparisons between VLs and the traditional laryngoscope for routine use for intubation in ICU have not demonstrated consistent superiority. Glottic visualisation appears better with VL techniques; however, placement of the endotracheal tube may be more challenging. While a recent meta-analysis suggested some superiority for VL, a sensitivity analysis including only randomised controlled trials (RCTs) showed no significant clinical superiority,[11] and a recent RCT showed no improvement in first-pass intubation rate.[12] Limitations do exist for each particular device, and both training and operator experience contribute to successful use. Although increasingly available, there remains insufficient evidence supporting the routine use of video-laryngoscopy as a replacement for traditional direct laryngoscopy.

Fibreoptic bronchoscopic technique

This technique offers advantages of direct visualisation, immediate diagnosis of upper airway lesions and immobility of the neck during the procedure. It also allows reasonably comfortable intubation of a cooperative, awake patient under local anaesthesia, and use of the sitting position. Experience and skill are necessary, especially for dealing with emergent situations, but success rates greater than 96% are expected.[13] Fibreoptic intubation may also be performed in anaesthetised patients, using a modified facemask with diaphragm for oral intubation. Nasal intubation is usually performed through an endotracheal tube placed in the nasopharynx, with the tip just above the glottis. The fibreoptic bronchoscope tip is guided into the trachea and the tube is advanced over the bronchoscope. Correct placement is visually checked before the scope is removed. In ICU, the fibreoptic bronchoscope can be used to improve the safety of airway procedures such as endotracheal tube changes and percutaneous tracheostomy.[14] A number of specially designed oral airways are available to assist oral fibreoptic intubation (e.g. the Ovassapian, Williams or Berman airway). The most common cause of failure is obstructed vision from blood or secretions.

Blind nasal intubation

Blind nasal intubation is sometimes considered in spontaneously breathing patients. Possible indications include inability to open the mouth (e.g. mandibular fracture or temporomandibular joint pathology), and cervical spine and faciomaxillary injury. Contraindications include bleeding disorders, nasal airway obstruction, skull base fracture and pre-existing sinusitis. Operator proficiency is required.

Retrograde intubation technique

A J-tip guidewire (length required in adults approximately 70 cm) is introduced percutaneously through the cricothyroid membrane, and advanced into the retropharynx. The tip is retrieved from the oral cavity, and the wire is used to guide an oral endotracheal tube past the obstruction and into the trachea.[15] The procedure is a relatively simple and safe alternative if other techniques fail or are not possible. Commercial kits are available.

Confirmation of tracheal tube placement

Confirmation of correct intratracheal tube placement is essential. Direct visualisation and measurement of expired CO_2 by capnography are the most reliable methods.[16] Capnography may produce false-positive results with the first few breaths after oesophageal intubation (i.e. detectable PE_{CO_2}), if gastric insufflation from mask ventilation has occurred. A false-negative (decreased PE_{CO_2}, despite correct position) may occur with cardiac arrest and low-cardiac-output states. Position can also be reliably confirmed by the use of self-inflating oesophageal detectors. Other clinical signs, such as auscultation of breath sounds over both sides of the chest and epigastrium, visualisation of condensed water vapour in the tube and chest wall movement are less reliable. The use of capnography is further discussed in Chapter 38.

Complications of endotracheal intubation

These may be classified into those occurring during intubation (e.g. incorrect tube placement, laryngeal trauma, deleterious cardiovascular response to laryngoscopy and intubation, increase in intracranial pressure, hypoxaemia and aspiration), while the tube is in place (e.g. blockage, dislodgement, tube deformation, damage to larynx and complications of mechanical ventilation), and following extubation (e.g. aspiration and postextubation airway obstruction, laryngeal and tracheal stenosis). As few ICU patients can be adequately starved prior to intubation, the use of cricoid pressure, provided it does not obscure the glottic view, is usually required to reduce the risk of aspiration. Hypotension in ICU patients is common immediately following intubation because of drug-induced myocardial depression, decrease in peripheral vascular resistance and sympathetic stimulation, and reduced venous return after positive-pressure ventilation. Fluid administration and the use of vasopressor drugs may be required. Special techniques should be used to minimise side effects such as cardiovascular responses and increases in intracranial pressure when appropriate.

TRANSTRACHEAL JET VENTILATION

Percutaneous transtracheal jet ventilation (TTJV), using a large-bore intravenous (IV) catheter inserted through the cricothyroid membrane, can be used to provide temporary ventilation when other techniques have failed.[17] Ventilation through the cannula with a standard manual resuscitator bag is inadequate, and a jet injector system is necessary. A high-pressure (up to 50 psi or 344 kPa) oxygen source is required for adequate ventilation through a 14 FG IV cannula. Expiratory gases must be able to escape via the glottis. Appropriate chest movements during expiration must be noted. The consequence of expiratory obstruction is severe and potentially fatal barotrauma.

Complications may be caused by insertion of the IV cannula (e.g. bleeding and oesophageal perforation), use of high-pressure gases (e.g. hyperinflation, barotrauma), catheter kinking or displacement (the latter causing potentially catastrophic subcutaneous emphysema) and failure to protect the airway (i.e. aspiration).

CRICOTHYROIDOTOMY

Cricothyroidotomy, by surgery or percutaneously, is a reliable, relatively easy way of providing an emergency airway.[18] It is the method of choice if severe or complete upper airway obstruction exists. The simplest, fastest and most proven method uses a horizontal incision through the cricothyroid membrane (with the space held wide open by the scalpel handle or forceps), followed by insertion of a small tracheostomy or endotracheal tube (Fig. 29.2). Commercial cricothyroidotomy sets, using the Seldinger technique, are available. A tube with internal diameter of 3.0 mm will allow adequate gas flow for self-inflating bag ventilation provided supplemental oxygen is used. Since the diameter of the cricothyroid space is 9 by 30 mm, tubes of 8.5 mm outer diameter or less should avoid laryngeal and vocal cord damage. Complications such as subglottic stenosis (1.6%), thyroid fracture, haemorrhage and pneumothorax are acceptably low. Cricothyroidotomy is generally contraindicated in complete laryngotracheal disruption and age less than 12 years.

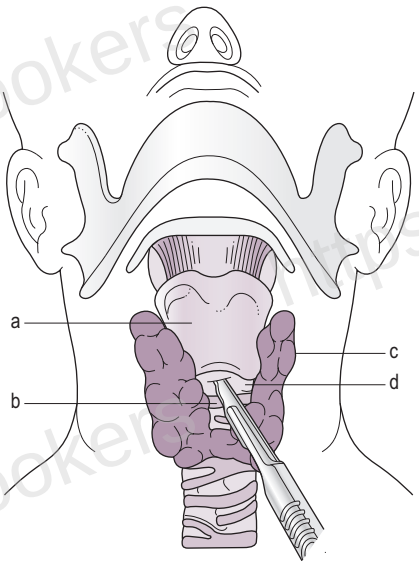

Figure 29.2 Cricothyroidotomy performed with a scalpel: *(a)* thyroid cartilage; *(b)* cricoid cartilage; *(c)* thyroid gland; *(d)* cricoid membrane, usually easily palpable subcutaneously.

TRACHEOSTOMY

There is little agreement on the indications, best technique or optimal timing of tracheostomy in ICU patients. Suggested indications for tracheostomy include[19]:

- bypass of glottic and supraglottic obstruction
- access for tracheal toilet
- provision of a more comfortable airway for prolonged ventilatory support
- protection of the airways from aspiration.

In uncomplicated patients, percutaneous tracheostomy performed by an intensivist at the bedside is at least as safe as surgical tracheostomy performed in the operating room, and is probably associated with a lower incidence of infectious complications.[20,21] Convenience and cost savings have made percutaneous tracheostomy the procedure of choice in many institutions. Ciaglia's percutaneous technique was described in 1985.[22] After making an adequate skin incision and using blunt dissection with forceps, the endotracheal tube is first withdrawn so that its cuff lies just above the vocal cords. The operator confirms tube position

to be above the stoma site by palpation of the trachea. A J-wire is placed in the trachea through a needle inserted through the membrane above or below the second tracheal ring.

Curved dilators can be used to enlarge the stoma. A tracheostomy tube is then inserted into the trachea and the endotracheal tube removed. A modified tapered dilator to avoid the use of multiple dilators is quicker to use, but may cause more tracheal wall injuries and ring fractures. The Griggs technique utilises a Kelly forceps, modified to allow it to be guided by the J-wire, to dilate the tract before insertion of the tracheostomy tube.[23] The speed and safety of the two techniques are similar, although the Griggs technique may cause marginally more bleeding and cannula insertion may be more difficult.[24] Fibreoptic bronchoscopy during percutaneous tracheostomy may help to prevent incorrect guidewire placement and tracheal ring rupture or herniation, but definitive evidence supporting its routine use is lacking.[25]

Minitracheostomy describes the percutaneous insertion of a small 4 mm non-cuffed tracheostomy tube through the cricothyroid membrane or trachea, mainly to facilitate suctioning in patients with poor cough ability. Complications of tracheostomy are listed in Box 29.2.

LOCAL ANAESTHESIA

Instrumentation of the upper airway in awake patients requires good local anaesthesia to increase comfort, improve cooperation, attenuate cardiovascular responses and reduce the risk of laryngospasm. Rapid transcricoid injection, 'spray as you go' with a fibreoptic bronchoscope, or nebulised lidocaine to the nares, posterior pharynx and tongue is effective (Table 29.3).[26] Nerve block techniques may improve analgesia but are not essential. Systemic absorption of topically applied lidocaine (maximum dose 4 mg/kg) is variable, and the clinician should be alert for signs and symptoms of toxicity.

Box 29.2 Complications of tracheostomy

Immediate
- Procedural complications
  - Haemorrhage
  - Surgical emphysema, pneumothorax, air embolism
  - Cricoid cartilage damage
- Misplacement in pretracheal tissues or right main bronchus
- Compression of tube lumen by cuff herniation
- Occlusion of the tip against the carina or tracheal wall

Delayed
- Blockage with secretions
- Infection of the tracheostomy site, tracheobronchial tree, and larynx
- Pressure on tracheal wall from the tracheostomy tube or cuff
  - Mucosal ulceration and perforation
  - Deep erosion into the innominate artery
  - Tracheo-oesophageal fistula

Late
- Granulomata of the trachea
- Tracheal and laryngeal stenosis
- Persistent sinus at tracheostomy site
- Tracheomalacia and tracheal dilatation

Table 29.3 Local anaesthesia of the upper airway in adults

TECHNIQUE	DRUG DOSAGE
NERVE BLOCK	
Internal branch of superior laryngeal nerve	Lidocaine 1%–2% (2 mL/side)
Glossopharyngeal nerve	Lidocaine 1%–2% (3 mL/side)
TOPICAL ANAESTHESIA OF THE TONGUE AND OROPHARYNX	
Gargle	Lidocaine viscous 4% (5 mL)
Commercial lidocaine spray	Lidocaine 10% (5–10 sprays = 50–100 mg)
Nebulised	Lidocaine 4%
Spray as you go	Lidocaine 1%–2%
TOPICAL ANAESTHESIA OF THE NASAL MUCOSA	
Cocaine spray or paste	Cocaine 4%–5% (0.5–2 mL)
Gel	Lidocaine 2% gel (5 mL)
Commercial lidocaine spray	Lidocaine 10% (10 sprays = 100 mg)
Lidocaine laryngeal mask airway + phenylephrine spray	Lidocaine 3% + phenylephrine 0.25% (0.5 mL)
TOPICAL ANAESTHESIA OF GLOTTIS AND TRACHEA	
Spray-as-you-go through bronchoscope	Lidocaine 1%–4% (3 mg/kg)
Cricothyroid membrane puncture	Lidocaine 2% (5 mL)
Nebulised	Lidocaine 4% (4 mL) ± phenylephrine 1% (1 mL)

THE DIFFICULT AIRWAY

The difficult airway has been described as one in which a conventionally trained anaesthesiologist experiences difficulty with mask ventilation, tracheal intubation or both. Difficult intubations may be expected in 1%–3% of patients presenting for general anaesthesia, and the incidence is likely to be considerably higher in ICU patients.

More than 85% of difficult intubations can be managed successfully by experienced clinicians without resorting to a surgical solution. The experience of the operator is probably the most important factor determining success or failure. Experience implies greater manual skills, better anticipation of problems, use of preprepared strategies, and familiarity with multiple techniques. Thus, training of intensivists must specifically include a variety of airway management strategies and skills.

ASSISTANCE AND ENVIRONMENT

The patient's condition may rapidly deteriorate as a consequence of a poorly managed airway emergency. The most senior help available should be immediately summoned. If the situation allows, the patient should be moved to the best location for emergency airway interventions, usually the operating theatre or ICU, and difficult airway equipment requested (see Box 29.1). A senior assistant can help in gaining IV access, administering drugs, setting up equipment and managing the airway. A skilled intensivist or ear, nose and throat surgeon (gowned and standing by) can help to provide a surgical airway or perform rigid bronchoscopy to remove foreign bodies.

ANTICIPATING AND GRADING A DIFFICULT AIRWAY

Intubation difficulty can be anticipated or predicted by the following (although the sensitivity and specificity of individual features and classifications tend to be low):

1. Anatomical or pathological features of difficult intubation in subjects who otherwise appear normal:
   - **a.** short neck, especially if obese or muscular (a thyromental distance <6 cm)
   - **b.** limited neck and jaw movements (e.g. as a result of trismus, osteoarthritis, ankylosing spondylitis, rheumatoid arthritis or perioral scarring)
   - **c.** protruding teeth, small mouth, long high curved palate or receding lower jaw
   - **d.** space-occupying lesions of the oropharynx and larynx
   - **e.** congenital conditions with any of the above features (e.g. Marfan syndrome).
2. Mallampati classification[27] of visualising the oropharyngeal structures (a cooperative sitting patient is required for this assessment, and class >2 predicts possible difficulty):
   - **a.** class 1: visible soft palate, uvula, fauces and pillars
   - **b.** class 2: visible soft palate, uvula and fauces
   - **c.** class 3: visible soft palate and base of uvula
   - **d.** class 4: soft palate is not visible.
3. The degree of difficulty experienced visualising the larynx by direct laryngoscopy should be recorded and is commonly graded by the classification of Cormack and Lehane, and modified by Yentis[28,29]:
   - **a.** grade I: complete glottis is visible
   - **b.** grade IIa: partial view of glottis, and grade IIb: only the posterior part of the cords/arytenoids visible
   - **c.** grade III: epiglottis but not glottis is visible
   - **d.** grade IV: epiglottis is not visible.

FAILED INTUBATION AND VENTILATION ALGORITHMS

A preformulated plan in the event of failed intubation and/or ventilation is essential and a number have been described. The algorithm shown in Fig. 29.1 is an example. Effective implementation depends on the appropriate use of the algorithm and airway techniques described above.

If the initial attempt at intubation fails, call for help immediately. Repeated attempts at direct laryngoscopy should be avoided unless a more experienced operator intervenes, or a potentially helpful manoeuvre has been carried out (e.g. significant repositioning, externally applied laryngeal pressure or change of laryngoscope blade). Hypoxia will quickly result if the patient is inadequately ventilated between attempts. In addition, oedema and bleeding caused by repeated attempts may impair both mask ventilation and the use of alternative techniques such as fibreoptic intubation. When indicated to prevent hypoxia, a surgical airway should not be delayed (see Figs 29.1 and 29.2).

UPPER AIRWAY OBSTRUCTION

ANATOMY AND PATHOPHYSIOLOGY

The upper airway begins at the nose and mouth, and ends at the carina. Obstruction is likely to occur at sites of anatomical narrowing, such as the hypopharynx at the base of the tongue, and the false and true vocal cords at the laryngeal opening. Sites of airway obstruction are classified as supraglottic (above the true cords), glottic (involving the true vocal cords) or infraglottic (below the true cords and above the carina).

The upper airway can also be divided into intrathoracic and extrathoracic portions, which behave differently during inspiration and expiration. The intrathoracic airway dilates during inspiration because it is 'pulled outwards' by negative intrapleural pressure.

Positive intrapleural pressure during expiration causes compression and narrowing. Conversely, the compliant extrathoracic airway, unexposed to intrapleural pressure, collapses during inspiration and expands during expiration. Recalling this phenomenon helps the understanding of typical clinical signs, imaging and flow-volume loops.

AETIOLOGY

Acute upper airway obstruction may result from functional or mechanical causes (Box 29.3). Functional causes include central nervous system and neuromuscular dysfunction. Mechanical causes may occur within the lumen, in the wall or extrinsic to the airway.

Box 29.3 Clinical conditions associated with acute upper airway obstruction

Functional causes
Central nervous system depression
- Head injury, cerebrovascular accident, cardiorespiratory arrest, shock, hypoxia, drug overdose, metabolic encephalopathies

Peripheral nervous system and neuromuscular abnormalities
- Recurrent laryngeal nerve palsy (postoperative, inflammatory or tumour infiltration), obstructive sleep apnoea, laryngospasm, myasthenia gravis, Guillain–Barré polyneuritis, hypocalcaemic vocal cord spasm

Mechanical causes
Foreign-body aspiration
Infections
- Epiglottitis, retropharyngeal cellulitis or abscess, Ludwig angina, diphtheria and tetanus, bacterial tracheitis, laryngotracheobronchitis

Laryngeal oedema
- Allergic laryngeal oedema, angiotensin-converting enzyme inhibitor associated, hereditary angioedema, acquired C1 esterase deficiency

Haemorrhage and haematoma
- Postoperative, anticoagulation therapy, inherited or acquired coagulation factor deficiency

Trauma
Burns
- Inhalational thermal injury, ingestion of toxic chemical and caustic agents

Neoplasm
- Pharyngeal, laryngeal and tracheobronchial carcinoma, vocal cord polyposis

Congenital
- Vascular rings, laryngeal webs, laryngocele

Miscellaneous
- Cricoarytenoid arthritis, achalasia of the oesophagus, hysterical stridor, myxoedema

CLINICAL PRESENTATION

The signs of sudden complete upper airway obstruction are characteristic and progress rapidly. The victim cannot breathe, speak or cough, and may hold the throat between the thumb and index finger – the universal choking sign.[30] Agitation, panic and vigorous breathing efforts are rapidly followed by cyanosis. Respiratory efforts diminish as consciousness is lost, and death results within 2–5 minutes if obstruction is not relieved. Lethargy, diminishing respiratory efforts and loss of consciousness are late signs of hypoxaemia and hypercarbia. Bradycardia and hypotension herald impending cardiac arrest.

Signs of partial airway obstruction include voice changes and coughing, progressing to drooling, gagging, choking, noisy respiration and inspiratory stridor. Paradoxical chest wall movements and intercostal and supraclavicular retractions may be marked in severe obstruction. Powerful respiratory efforts may produce dermal ecchymoses and subcutaneous emphysema. Respiratory decompensation may be of rapid onset, and progress to complete obstruction.

SPECIAL EVALUATION OR INVESTIGATIONS

If the patient remains stable, specific diagnostic evaluation may be undertaken, provided advanced airway management facilities and skilled personnel are immediately available.

LARYNGOSCOPY AND BRONCHOSCOPY

Indirect laryngoscopy in a stable, cooperative patient is useful to diagnose foreign bodies, retropharyngeal or laryngeal masses and other glottic pathology.

Assessment with a flexible fibreoptic bronchoscope or laryngoscope is the evaluation method of choice in ICU patients and enables direct visualisation of upper airway anatomy and function. The procedure can be performed without transporting the patient and risking complete obstruction. It can be applied to an awake, spontaneously breathing patient and, with care, should not worsen the obstruction. Definitive airway control by intubation can usually be achieved. Disadvantages are the need for a skilled operator and a cooperative patient, and a reduced visual field limits effectiveness if blood and secretions are copious.

Direct laryngoscopy enables forceps removal of foreign bodies and high-volume suctioning of blood, vomitus and secretions. Endotracheal intubation can rapidly be achieved under direct vision. A disadvantage is the need for general anaesthesia or good local analgesia (often difficult in the emergency setting). Direct laryngoscopy can be traumatic, and may worsen soft-tissue bleeding and oedema.

RADIOGRAPHIC IMAGING

Patients with potentially unstable airways should not be transported from a ‘safe’ environment like

the emergency room, operating theatre or ICU for radiological investigation until the airway is secure. Anteroposterior and lateral plain neck X-rays may be useful to detect radiopaque foreign bodies. Computed tomography (CT), preferably with three-dimensional postprocessing, may provide detailed diagnostic information and prognostic at initial evaluation in stable patients, or in those in whom the airway has been secured.[31] Although magnetic resonance imaging (MRI) has been used to image the upper airway, its use in acute airway obstruction is unproven.

GAS FLOW MEASUREMENT

Flow-volume loop measurement reveals characteristic patterns corresponding to different types and position of pathological lesions (Fig. 29.3).[32]

MANAGEMENT

Simplified algorithms to assist the management of partial and complete upper airway obstruction are shown in Figs 29.4 and 29.5, respectively. Improvisation may be required for certain difficult problems.

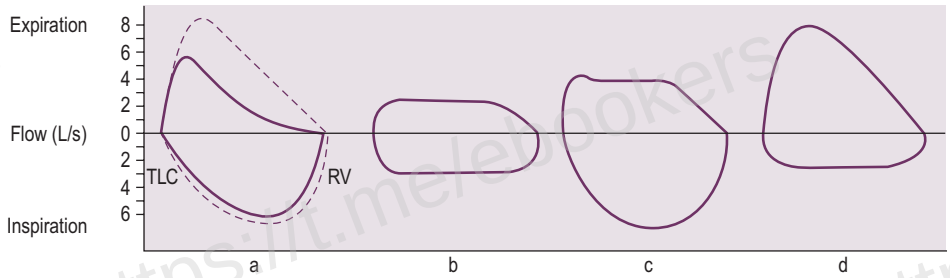

Figure 29.3 Flow-volume loops. Patterns resulting from different pathological lesions: *(a)* lower airway obstruction (e.g. chronic obstructive pulmonary disease or asthma); *(b)* fixed, non-variable upper airway obstruction (e.g. fibrous ring in trachea); *(c)* variable upper airway obstruction, intrathoracic (e.g. tumour in the lower trachea); *(d)* variable upper airway obstruction, extrathoracic (e.g. vocal cord tumour or paralysis). *L/s*, Litres per second; *RV*, residual volume; *TLC*, total lung capacity.

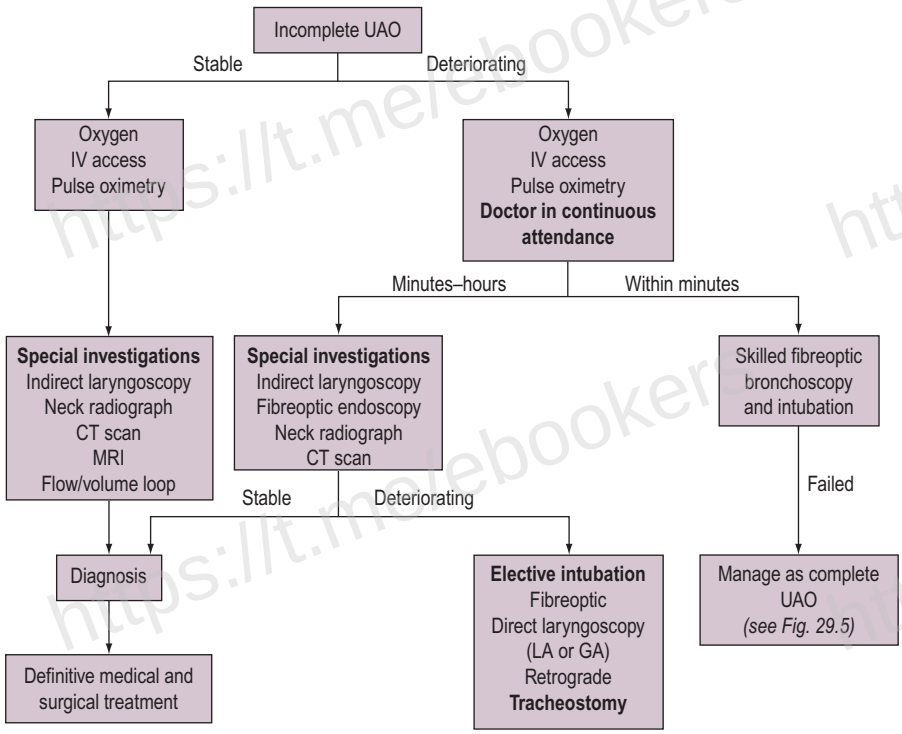

Figure 29.4 Management of partial upper airway obstruction (UAO). *CT*, Computerised tomography; *GA*, general anaesthesia; *IV*, intravenous; *LA*, local anaesthesia; *MRI*, magnetic resonance imaging.

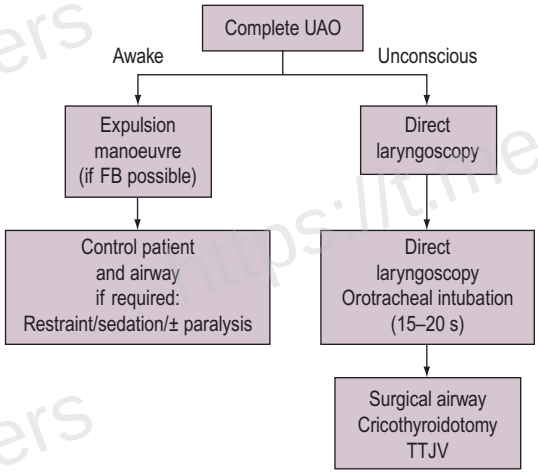

Figure 29.5 Management of complete upper airway obstruction (UAO). Attempts at orotracheal intubation should not take longer than 10–20 seconds. *FB*, Foreign body; *TTJV*, transtracheal jet ventilation.

The chosen technique should be an appropriate one in which the clinician has reasonable skill and experience. Special techniques in patients with suspected cervical spine instability are discussed in Chapter 80.

1. Supplemental oxygen (100%) is immediately administered and adequate help summoned.
2. A choice of equipment for definitive airway control must be available and ready for use (see Box 29.1).
3. In adults IV access should be secured.
4. Initiate continuous monitoring of vital signs and pulse oximetry.
5. The risk and benefit of patient transport before securing the airway must be carefully considered.

AIRWAY MANAGEMENT TECHNIQUES IN AIRWAY OBSTRUCTION

THE UNCONSCIOUS PATIENT

If the upper airway is obstructed by the tongue and retropharyngeal tissues in an unconscious patient, airway patency is initially achieved by using standard airway manoeuvres[33] and oropharyngeal and nasopharyngeal airways. Definitive airway control should follow if consciousness does not immediately return.

ENDOTRACHEAL INTUBATION

1. *Direct laryngoscopic intubation* is the method of choice for the unconscious, apnoeic patient, as it allows rapid evaluation of any supraglottic problem and immediate airway security. *Video laryngoscopy* is an alternative in experienced hands. Both can also be attempted in an awake patient after careful application of local anaesthesia. Although there is some risk of loss of the airway after local anaesthesia, complete loss of the airway under general anaesthesia is common and may be catastrophic.
2. *Awake fibreoptic intubation* in a spontaneously breathing patient is usually safe, but requires a skilled operator. The procedure will take 2–10 minutes or longer,[34] and urgency of the case must be assessed beforehand with this timeframe in mind. Alternatives should be initiated if the obstruction progresses or if intubation fails after a reasonable time. The following points may assist visualisation in acute upper airway obstruction:
   a. The procedure should be clearly explained to the patient.
   b. Good local anaesthesia and mucosal vasoconstrictors are important (see Table 29.3).
   c. If desired, the suction port of the fibrescope can be used to insufflate 100% oxygen or apply local anaesthetic. This also clears the fibrescope tip of secretions. Additional large-bore suction catheters may help. Failure is most commonly due to excessive secretions and bleeding.
3. *Blind nasotracheal intubation* may be considered by experienced operators. Once endotracheal intubation is safely accomplished and confirmed, secure fixation of the endotracheal tube is mandatory. The patient's upper limbs may need to be restrained to avoid self-extubation.

SURGICAL AIRWAYS

A surgical airway is indicated when endotracheal intubation is not possible, or when an unstable cervical spine is threatened by available airway techniques. It is the last line of defence against hypoxia. In airway obstruction, options include the following:

1. *Cricothyroidotomy:* this is the method of choice if severe or complete upper airway obstruction exists.
2. *Percutaneous transtracheal jet ventilation:* the technique must not be used in complete upper airway obstruction because expiratory obstruction can cause severe and potentially fatal barotrauma.
3. *Tracheostomy:* in the emergency setting this is rarely required, although surgical tracheostomy under local anaesthesia may be reasonable under some controlled conditions (see Fig. 29.4).

COMMON CLINICAL CONDITIONS AND THEIR MANAGEMENT

FOREIGN-BODY OBSTRUCTION

Foreign-body obstruction is the most common cause of acute airway obstruction. The elderly, especially those in institutions, are at risk. The use of dentures, alcohol and depressant drugs increases risk. Fatal food asphyxiation or 'café coronary' should be considered in any acute respiratory arrest where the victim cannot be ventilated.[35]

Those still able to cough or speak clearly should be given the opportunity to expel the foreign body spontaneously. Expulsion of the foreign body can be attempted with up to five back blows, followed by the Heimlich manoeuvre.[30,33] Unwanted effects, such as vomiting, aspiration, fractured ribs, barotrauma and ruptured organs, have been reported. If these manoeuvres fail, management immediately proceeds as shown in Figs 29.4 and 29.5.

EXTRINSIC AIRWAY COMPRESSION

Extrinsic space-occupying lesions can cause upper airway obstruction. Compression from haematomas may be associated with trauma, neck surgery, central venous catheterisation, anticoagulants and congenital or acquired coagulopathies. Haematomas following surgery should immediately be evacuated by removing skin and tissue sutures. If this fails, an artificial airway must be secured immediately. In patients with coagulation abnormalities, intubation is preferred over a surgical airway. Most haematomas secondary to coagulopathy do not require surgical intervention, and resolve with conservative therapy (i.e. vitamin K and blood component therapy).

Partial airway obstruction caused by retropharyngeal abscess is best managed by drainage under local anaesthesia. Gentle fibreoptic examination and intubation or direct laryngoscopy and intubation may be considered. Risks are related to inadvertent rupture of the abscess, with subsequent flooding of the airway. Ludwig's angina is a mixed infection of the floor of the mouth resulting in an inflammatory mass in the space between the tongue and the muscles and anterior neck fascia. The supraglottic airway is compressed and becomes narrowed.[36] Direct laryngoscopy is difficult, as the tongue cannot be anteriorly displaced. Awake fibreoptic-guided intubation and a surgical airway, along with antibiotic therapy, are management options.

INTRINSIC AIRWAY COMPRESSION

Burn inhalation and ingestion injury

Patients with large burn area (more than 40%), or with severe facial burns or inhalation injury (soot in the nostrils, burns of the tongue and pharynx, stridor or hoarseness) are at risk of developing progressive supraglottic oedema, usually within 24–48 hours. Such patients may require early prophylactic tracheal intubation. Assessment of injury and need for tracheal intubation can best be decided by frequently repeated awake fibreoptic laryngoscopy, together with close clinical observation.[37] Ingestion of hot fluids or corrosive agents can also cause delayed oedema and airway swelling and should be managed similarly.[38]

Adult epiglottitis

Epiglottitis is an uncommon but increasingly recognised infectious disease in adults.[39] It involves the epiglottis and supraglottic larynx, causing swelling with consequent airway obstruction. *Haemophilus influenzae* and *H. parainfluenzae*, *Streptococcus pneumoniae*, haemolytic streptococci and *Staphylococcus aureus* are common causative organisms. Clinical features are sudden onset of sore throat (pain often greater than suggested by clinical findings), muffled voice, dysphagia, stridor, dyspnoea and respiratory distress. Systemic toxaemia is common. Gentle indirect laryngoscopy, fibreoptic laryngoscopy or lateral neck X-ray confirms the diagnosis. Reported mortality in adults ranges from 0% to 7%.[40]

Airway management is controversial.[40,41] Some experts recommend securing a definitive airway on presentation, whereas others suggest close observation in the ICU. There are, however, reports of sudden obstruction and death with the latter approach.[40] Onset of dyspnoea, dysphonia, stridor, a rapid clinical course and diabetes may predict the need for intubation.[42] Tracheal intubation and tracheostomy are acceptable, but tracheal intubation may result in better long-term outcome.

Prior to securing the airway, patient positioning is important, and changing from a sitting to supine position may induce complete obstruction. In more stable patients, awake fibreoptic intubation is preferable if a skilled operator is available. Endotracheal intubation under general anaesthesia following gaseous induction is often recommended. Obstruction can occur, even when this procedure is undertaken by a skilled anaesthetist in the operating room.[41] A skilled assistant, scrubbed and ready to secure a surgical airway, may prevent disaster. Rapid-sequence induction using muscle relaxants is dangerous and should be avoided. Tracheostomy under local anaesthesia is a safe alternative.

Airway management is followed by antibiotics and supportive care. Cefotaxime 2 g IV 6-hourly or ampicillin 1–2 g IV 6-hourly *plus* chloramphenicol 50 mg/kg per day are empirical regimens. Patient factors, local bacterial sensitivities and cultures of blood and epiglottal swabs may influence the antibiotic choice. Supportive care includes adequate sedation and tracheobronchial toilet. Abscesses should be surgically drained. There is no good evidence supporting the use of steroids.

Angioedema

Allergic responses involving the upper airway may be localised or part of a systemic anaphylactic reaction. Angioedema is characterised by subepithelial swelling. Angioedema of the lips, supraglottis, glottis and infraglottis may result in airway obstruction. The systemic reaction consists of variable combinations of urticaria, bronchospasm, shock, cardiovascular collapse and abdominal pain. Common causative agents are Hymenoptera stings, shellfish ingestion and drugs.

Treatment consists of immediately ensuring an adequate airway (see Figs 29.4 and 29.5), and

administration of oxygen, epinephrine (adrenaline), histamine antagonists and steroids. Close observation in case of relapse for at least 24 hours after severe reactions is necessary. As it is likely to recur, the patient should be followed-up and fully investigated.

Hereditary angioedema is a rare, inherited disorder of the complement system, caused by functionless or low levels of C1 esterase inhibitor.[43] Non-pruritic, usually non-painful angioedema involving skin and subcutaneous tissue occurs in various locations, including the upper airway.[44] Precipitating causes include stress, physical exertion and localised trauma (including dental or maxillofacial surgery and laryngoscopy). Acute attacks do not respond to epinephrine, antihistamines or corticosteroids. Management consists of establishing a secure airway and infusion of C1 esterase inhibitor concentrate (25 U/kg) which has an onset of action of 30–120 minutes.[44,45] If not available, fresh frozen plasma (2–4 units) may be considered.

Stanozolol 2 mg daily or danazol 200 mg/day has been shown to be effective in decreasing frequency and severity of attacks with reduced side effects.[46] Antifibrinolytic agents (e.g. tranexamic acid) are less effective. Guidelines recommend use of C1-inhibitor concentrate for preoperative prophylaxis or, if this is unavailable, the dose of attenuated androgen should be doubled for 5 days before and 2 days after the procedure. Icatibant acetate, a subcutaneous synthetic peptide blocker of the bradykinin-2 receptor, and ecallantide, a subcutaneous recombinant protein kallikrein antagonist, have both recently become available for the symptomatic treatment of hereditary angioedema.[46] Angiotensin-converting enzyme inhibitor-related angioedema is increasingly seen and is possibly the result of reduced bradykinin metabolism.[47] Treatment focuses on airway support.

Postextubation laryngeal oedema

Laryngeal oedema following extubation occurs in about 20% of adults, but is severe enough to precipitate reintubation in only 1%–5%. The risk of postextubation oedema may be increased by excessive airway manipulation, traumatic intubation, high cuff pressures and duration of tracheal intubation greater than 36 hours (however, after 1 week the risk appears to decline again). Prophylactic use of corticosteroids (e.g. methylprednisolone initiated 12 hours before planned extubation at 20 mg IV 4-hourly with the last dose immediately prior to tube removal) has been shown to reduce the incidence of postextubation laryngeal oedema and subsequent reintubation.[48] Treatment in adults is conservative, with close observation and humidified oxygen therapy. Nebulised plain epinephrine (1–2 mL 1:1000 solution diluted with 2 mL saline or undiluted 1:1000 solution 4–5 mL) or racemic epinephrine (0.25–0.5 mL 2.25% solution in 2–4 mL saline) have been used. Nebulisation may need to be repeated every 30–60 minutes.

Postobstruction pulmonary oedema

Postobstruction pulmonary oedema, also known as negative-pressure pulmonary oedema, may occur after general anaesthesia (incidence 0.05%–0.1%) or after relief of acute upper airway obstruction (incidence 11%).[49] This appears to be related to the markedly decreased intrathoracic pressure caused by forced inspiration against a closed upper airway, resulting in transudation of fluid from pulmonary capillaries to the interstitium. In addition, increased venous return may increase pulmonary blood flow and pressure, further worsening oedema. Hypoxia, the hyperadrenergic stress state, and increased ventricular afterload may also affect capillary hydrostatic pressure, although pulmonary capillary occlusion pressure is often normal. The oedema usually occurs within minutes after the relief of the obstruction, but may be delayed several hours.[50] Management includes the application of continuous positive-airways pressure or positive-pressure ventilation with PEEP, maintenance of airway patency, oxygen therapy, diuretics, morphine and fluid restriction.

Acute respiratory failure in chronic obstructive pulmonary disease

Matthew T Naughton, David V Tuxen

The term chronic obstructive pulmonary disease (COPD) is applied to patients with chronic bronchitis and/or emphysema. COPD affects up to 10% of the adult population aged greater than 40 years and is the fourth most common cause of death worldwide.[1] COPD is increasing in prevalence, particularly in women.[2] COPD is commonly associated with cardiovascular disease, depression, gastro-oesophageal reflux, osteoporosis and cancer.[3,4] Severity of COPD can be easily assessed objectively by spirometry[5] (Table 30.1) and functionally based upon dyspnoea and exercise capacity (Table 30.2).[6]

An acute exacerbation of COPD (AECOPD) is defined as 'an event in the natural course of the disease characterised by change in dyspnoea, cough or sputum'.[4] AECOPD is the most common admission diagnosis in UK general hospitals (~16% of admissions).[4] Patients with an AECOPD have an in-hospital mortality of 3%–8%, and a 30-day readmission rate of 23%, and a 30-day mortality of 14%–26% (compared with 8% for myocardial infarction).[4,7–9] Targeted oxygen therapy and non-invasive ventilatory (NIV) support have been the major advances in therapy in the past decade which have resulted in a reduced need for invasive mechanical ventilation (IMV) and improved survival. The need for either IMV or NIV ventilatory support in AECOPD varies considerably across continents; for example, in the United Kingdom, NIV and IMV are used in 11% and 1% of admissions, respectively,[8] whereas in the United States they are used in 5% and 3% of admissions, respectively.[9]

AETIOLOGY

The causes of COPD can be divided into environmental and host factors. Environmental factors include tobacco smoke, air pollution, indoor fumes (e.g. indoor cooking with solid biomass fuel) and poor socioeconomic status. The biggest single factor in over 95% of patients with COPD is tobacco smoking. However, only approximately 15% of smokers develop COPD. Marijuana smoking may cause premature and quite advanced bullous emphysema compared with tobacco smokers due to extremely hot and toxic inhaled smoke held at peak inspiration for prolonged periods of time.[3] Host factors are the balance between circulating proteases and antiproteases (e.g. alpha-1 antitrypsin deficiency) and the intake of antioxidant vitamins (A, C, E) (Fig. 30.1).[10]

PATHOPHYSIOLOGY

Reduced expiratory airflow in COPD is due to both increased airway resistance and reduced lung elastic recoil. Airway resistance is increased by mucosal oedema and hypertrophy, secretions, bronchospasm, airway tortuosity and airflow turbulence and loss of lung parenchymal elastic tissues that normally support the small airways. Loss of lung elastic recoil pressure is due both to loss of lung elastin and loss of alveolar surface tension from alveolar wall destruction.

Reduced lung elastic recoil decreases expiratory airflow by reducing the alveolar pressure driving expiratory airflow and by reducing the intraluminal airway pressure, which normally distends small airways during expiration. Forced expiration increases alveolar driving pressure but also causes dynamic airway compression, resulting in no improvement or sometimes reduction in expiratory airflow. These factors are present in varying proportions, depending on the degree of chronic bronchitis and emphysema and the individual patient.

Airflow limitation results in prolonged expiration, pulmonary hyperinflation, inspiratory muscle disadvantage, increased work of breathing and the sensation of dyspnoea. All these factors are worsened during an exacerbation of COPD.

Pulmonary hyperinflation has both static and dynamic components. The static component remains at the end of an expiratory period long enough for all expiratory airflow to cease (30–120 seconds), enabling the lungs and chest wall to reach their static functional residual capacity (FRC). This component of hyperinflation is due to loss of parenchymal elastic recoil, chest wall adaptation and airway closure that occurs throughout expiration.[12] Dynamic pulmonary hyperinflation is the further increase in hyperinflation due to slow expiratory airflow not allowing completion of

ABSTRACT

Although acute exacerbations of chronic obstructive pulmonary disease (COPD) are most commonly due to bacterial or viral chest infections and underlying cardiac disease (arrhythmias and heart failure), a thorough history and examination should be undertaken to confirm a precise precipitant (e.g. social, nutritional, gastroreflux). Early assessment with blood gases will help identify the third who will develop hypercapnic respiratory failure. In addition to glucocorticoids, bronchodilators and antibiotics (if infective), targeted oxygen therapy to a desired SpO_2 range should be instigated. Note uncontrolled oxygen therapy often causes severe hypercapnic respiratory failure. Attention to underlying cardiac factors (arrhythmia or pump failure) should also be considered. In those with hypercapnic acidosis, non-invasive ventilatory (NIV) support should be considered; if used correctly, it should negate the need for invasive ventilatory support. Nasal high flow (NHF) cannula, which provides a heated humidified air-oxygen mixture with a small amount of positive end-expiratory pressure via comfortable wide-bore nasal pillows, may help those COPD patients with high oxygen needs (>3 lpm), yet normal CO_2 values. Pre-discharge assessment should include confirmation of COPD with spirometry, smoking cessation, vaccination, rehabilitation and need for domiciliary oxygen and/or NIV. The 30-day mortality (14%–26%) and readmission rate (23%) are useful metrics of successful treatment.

expiration before the arrival of the next breath. The extent of dynamic hyperinflation depends on the severity of airflow obstruction, the amount inspired (tidal volume) and the expiratory time.[13] Chest wall hyperinflation leads to suboptimal muscle length-tension relationships and mechanical disadvantage, thereby predisposing patients to respiratory muscle fatigue, as the work of breathing increases, particularly if associated with myopathic situations (steroids, electrolyte disturbances).[14,15] Minor reductions in lung function due to infection, mild cardiac failure or atelectasis increase the work of breathing due to both increases in respiratory impedance and increases in dead space. With acute changes in workload, rapid decompensation with ventilatory failure and acute hypercapnia may occur.

Although chronic hypercapnia, as a consequence of reducing minute ventilation, is a fatigue-sparing mechanism that occurs in some patients, this is usually accompanied by renal compensation with retention of bicarbonate ions to correct the low pH. This has the additional effect of reducing the respiratory distress caused by hypercapnic acidosis. Central respiratory drive may also be impaired, or poorly responsive to physiological triggers – hypoxaemia or hypercapnia – and lead to chronic hypercapnia. This may occur in the setting of sleep (i.e. obstructive sleep apnoea),[12] obesity or drugs (sedatives, antiepileptics, alcohol).

Hypoxia and vascular wall changes lead to pulmonary vasoconstriction, pulmonary hypertension, cor pulmonale, V/Q mismatching, and the development of shunts.

CHRONIC BRONCHITIS OR EMPHYSEMA?

The value of labelling patients as chronic bronchitis or emphysema is uncertain as the two disease processes usually coexist and the principles of management are similar. Five pathophysiological processes may be present to varying degrees in each patient with COPD: (1) inflammatory airway narrowing (bronchiolitis); (2) loss of connective tissues tethering airways; (3) loss of alveoli and capillaries; (4) hyperinflation; and (5) increased pulmonary vascular resistance. Early/mild COPD tends to be dominated by bronchiolitis with a minimal component of emphysema, whereas when COPD becomes severe, the reverse is true. However, recognition that COPD is dominated by one of these patterns is helpful with regard to clinical pattern and prognosis.

PRECIPITANTS OF ACUTE RESPIRATORY FAILURE

In approximately 50% of patients, there is an infective cause, in 25% heart failure and in the remaining 25% retained secretions, air pollution, co-existent medical problems (e.g. aspiration, pulmonary embolus, medication compliance or side effects), social issues or no cause can be identified (Box 30.1).[15,16]

INFECTION

The most common bacterial isolates are *Streptococcus pneumoniae* and *Haemophilus influenzae* in 80% of

Box 30.1 Precipitants of acute respiratory failure in chronic obstructive pulmonary disease

- Uncontrolled oxygen
- Sedation
- Medication – non-compliance or side effects
- Nutritional (K, PO_4, Mg deficiency, CHO excess)
- Sleep apnoea

exacerbations. *Streptococcus viridans*, *Moraxella* (previously *Branhamella*) *catarrhalis*, *Mycoplasma pneumoniae* and *Pseudomonas aeruginosa* may also be found. Viruses can be isolated in 20%–30% of exacerbations and include rhinovirus, influenza and parainfluenza viruses, coronaviruses and occasionally adenovirus, and respiratory syncytial virus. Whether these organisms are pathogens or colonisers is often unclear. Background microbiological agents are identified in 48% of stable COPD compared with 70% during an AECOPD.[17,18] Pneumonia has been estimated to account for 20% of presentations requiring mechanical ventilation.[4]

HEART FAILURE

Left ventricular (LV) systolic failure may result from co-existing ischaemic heart disease, fluid overload, tachyarrhythmias (e.g. atrial fibrillation) or biventricular failure secondary to cor pulmonale. LV diastolic failure occurs commonly and is precipitated by hypoxaemia, tachycardia, pericardial constraint due to intrinsic positive end-expiratory pressure (PEEPi) or right ventricular (RV) dilation.[12,19,20] Increased work of breathing related to COPD will also increase by up to 10-fold the amount of blood flow to the respiratory pump muscles,[21] thereby causing an increased demand upon the overall cardiac output. In patients with borderline cardiac status, this may precipitate heart failure. The components of RV and LV failure can be accurately distinguished by Doppler echocardiography. Pulmonary congestion can be difficult to diagnose because of the abnormal breath sounds and chest X-ray appearance which are commonly present in COPD. In a recent publication, 51% of patients with AECOPD had echocardiographic evidence of left heart failure (systolic 11%, diastolic 32%, systolic and diastolic 7%).[12] A further study of computed tomography (CT) and magnetic resonance (MR) scanning and echocardiography in a large community population (15% of whom had COPD) identified that severity of emphysema on CT scanning indirectly correlated with LV end diastolic volume, stroke volume and cardiac output.[19] These authors concluded that increasing severity of COPD was associated with worsening cardiac function.

UNCONTROLLED OXYGEN

This may precipitate acute hypercapnia in patients with more severe COPD due to: (1) shunting blood to low-V/Q lung units and increasing dead space; (2) loss of hypoxic drive; (3) dissociation of CO_2 from Hb molecule (Haldane effect); and (4) anxiolysis and reduction in tachypnoea.[22] Major randomised controlled trials have indicated significant reductions in need for IMV, hospital length of stay and mortality with targeted oxygen therapy (i.e. a specific SpO_2 range – e.g. 88%–92%) compared with uncontrolled oxygen therapy in ambulance,[22] emergency rooms[23] and hospital wards.[8]

DIAGNOSIS AND ASSESSMENT

The clinical examination findings of COPD should be confirmed and severity quantified by spirometry (see Tables 30.1 and 30.2). In mild stable disease (e.g. forced expiratory volume in 1 second [FEV1] >50% predicted normal), an expiratory wheeze on forced expiration and mild exertional dyspnoea may be the only symptoms.

In moderate-severity COPD (e.g. FEV1 30%–50% predicted normal), modest to severe exertional dyspnoea is associated with clinical signs of hyperinflation (ptosed upper border of liver beyond the fourth intercostal space anteriorly and loss of cardiac percussion) and signs of increased work of breathing (use of accessory muscles and tracheal tug).

In severe stable COPD (e.g. FEV1 <30% predicted normal), marked accessory muscle use is associated with tachypnoea at rest, pursed-lip breathing, hypoxaemia and signs of pulmonary hypertension (RV heave, loud and palpable pulmonary second sound and elevated a-wave in jugular venous pressure [JVP]) and cor pulmonale (elevated JVP, hepatomegaly, ankle swelling).

In severe unstable COPD, there is marked tachypnoea at rest, hypoxaemia and tachycardia, and, in some, signs of hypercapnia (dilated cutaneous veins, blurred vision, headaches, obtunded mentation, confusion).

Clinical examination may also identify associated medical conditions that might have precipitated the exacerbation such as crackles and bronchial breathing due to infection, crackles and cardiomegaly related to heart failure or mediastinal shift related to a pneumothorax. Acute respiratory failure (ARF) in COPD can present with two distinct clinical patterns (Table 30.3),[16] namely, relatively thin and normocapnic or obese and hypercapnic.

Table 30.3 Clinical differences between normocapnic and hypercapnic chronic obstructive pulmonary disease

NORMOCAPNIC ($PaCO_2$ 35–45 mm Hg)	HYPERCAPNIC ($PaCO_2$ >45 mm Hg)
Emphysema > chronic bronchitis	Chronic bronchitis > emphysema
Thin	Obese
Pursed-lip breathing	Central nervous system depression: consider the role of oxygen therapy
Accessory muscle use	Alcohol, sedatives, analgesics
Hyperinflated	Sleep-related hypoventilation
Right heart failure late	Right heart failure early

Basic investigations such as spirometry are very useful in confirming a clinical diagnosis and determining severity of disease. An FEV1/VC ratio less than 70% with an FEV1 of 50%–80% predicted normal without a bronchodilator response usually indicates mild COPD. A significant bronchodilator response, which implies asthma, is regarded as a 12% or greater increase and 200 mL increase in either FEV1 or vital capacity (VC). An FEV1 30%–50% predicted normal indicates moderately severe COPD and FEV1 less than 30% predicted normal indicates severe COPD.[5]

Flow-volume curves usually demonstrate reduced expiratory flow rates at various lung volumes and the characteristic concave expiratory flow pattern. Lung volumes measured by either helium dilution or plethysmography show elevated total lung capacity, FRC and residual volume. Characteristically, the residual volume/total lung capacity ratio is greater than 40% in COPD and represents intrathoracic gas trapping. The total lung carbon monoxide (TLCO) uptake is a measurement of alveolar surface area and its reduction approximates the amount of emphysema present (usually <80% predicted normal).

A chest X-ray will commonly show hyperinflated lung fields, as suggested by 10 ribs visible posteriorly, six ribs visible anteriorly or large airspace anterior to heart (> ⅓ of the length of the sternum), flattened diaphragms (best seen on lateral chest X-ray) and a paucity of lung markings. Pulmonary hypertension is manifest by enlarged proximal and attenuated distal vascular markings and by RV and atrial enlargement. Lung bullae may be evident.

A high-resolution CT scan of the chest (1–2-mm slices) can demonstrate characteristic appearance and regional distribution of emphysema. It can also assess any co-existent bronchiectasis, LV failure and pulmonary fibrosis. Such scans are less sensitive than standard chest CT scans (1-cm slice) for detecting pulmonary lesions (e.g. neoplasms). Nuclear ventilation perfusion scans can also provide a characteristic appearance of COPD.

An electrocardiogram (ECG) is commonly normal but may show features of right atrial or RV hypertrophy and RV strain, including P pulmonale, right-axis deviation, dominant R-waves in V1–2, right bundle-branch block, ST depression and T-wave flattening or inversion in V1–3. These changes may be chronic or may develop acutely if there is significant increase in pulmonary vascular resistance during the illness. The ECG may also show co-existent ischaemic heart disease, tachycardia and atrial fibrillation. Occasionally, continuous ECG monitoring is required to identify transient arrhythmias, which may also precipitate acute deterioration. Plasma brain natriuretic peptide (BNP) levels may also assist in the diagnosis of heart failure (elevated BNP) from pulmonary causes (low BNP) in patients under 70 years free of renal impairment.[24]

DIFFERENTIAL DIAGNOSIS

The history of chronic asthma is one of long-term dyspnoea, wheeze and cough, usually at night or upon exercise, beginning in childhood with clear-cut precipitating agents (e.g. weather, dust, pets, drugs) and a favourable response to either steroids or inhaled β2-agonists. Late-onset asthma (>40 years of age) is not uncommon and is often associated with recurrent gastro-oesophageal reflux. In both forms of asthma, TLCO is normal. There is usually a bronchodilator response in the FEV1 if the patient has unstable asthma. In patients in whom asthma is considered but lung function tests are normal, the FEV1 response to an inhalational challenge (e.g. methacholine or hypertonic saline) may assist in discriminating asthma from other causes of dyspnoea.

Bronchiolitis obliterans is a condition which presents as a fixed airflow obstruction following a viral illness, inhalation of toxic fumes, following bone marrow or heart/lung transplantation, or related to drugs (e.g. penicillamine). It generally begins as a cough some weeks after insult and insidious onset of dyspnoea. There is a broad spectrum of radiological appearances from normal to reticulonodular to diffuse nodular. Lung tissue via bronchoscopy or by thoracoscopy is required for diagnosis. Histologically, there is a characteristic chronic bronchiolar inflammation appearance, and if granulation tissue extends into the alveoli, it is referred to as bronchiolitis obliterans or organising pneumonia. Removal of the offending agent and instigation of steroids are generally associated with a favourable prognosis.

Bronchiectasis is often associated with fixed mild-to-moderate airflow obstruction. A chronic productive cough (daily for 2 consecutive years) is characteristic. Clinical features such as clubbing, localised pulmonary crackles and a characteristic appearance on

high-resolution CT, with dilated or plugged small airways at least twice the size of accompanying blood vessel, assist in the diagnosis.

Congestive heart failure (CHF) may be a differential diagnosis of COPD, or simply co-exist, as both disorders are common in smokers.[12] Orthopnoea and paroxysmal nocturnal dyspnoea are features which correlate with heart failure severity. A past history of myocardial ischaemia or atrial fibrillation should alert one to the possibility of heart failure. An echocardiogram and high-resolution CT (looking for shift in interstitial oedema with changes in posture from supine to prone)[25] are sensitive markers of CHF.

ASSESSMENT OF RESPIRATORY FAILURE

An AECOPD is defined as 'an event in the natural course of the disease characterised by change in dyspnoea, cough or sputum'.[4]

Arterial blood gases are mandatory to assess hypoxia, hypercapnia and acid-base status. Chronic hypercapnia may be recognised by a bicarbonate level greater than 30 mmol/L and a base excess greater than 4 mmol/L indicating renal compensation. However, other causes of a high serum bicarbonate need to be excluded (e.g. diuretic therapy, high-dose steroids or high-volume gastric fluid loss) or chronic hypercapnia may be incorrectly assumed and the severity of COPD overestimated. Renal compensation for chronic hypercapnia will increase the serum bicarbonate by approximately 4 mmol/L for each 10 mm Hg (1.33 kPa) of chronic $PaCO_2$ rise above 40 mm Hg (5.3 kPa), in order to return pH to the low-normal range. Irrespective of the COPD patient's usual $PaCO_2$ level, an acute increase in $PaCO_2$ leads to a decreased arterial pH. This indicates that compensatory mechanisms are exhausted and there is an increased risk of respiratory collapse. The agreement between arterial and peripheral venous blood gases in terms of pH or $PaCO_2$ is extremely poor (±0.1 and ±25 mm Hg, respectively).[26] Thus, the use of peripheral venous blood gases to assess respiratory failure should be used with great caution.

MANAGEMENT OF RESPIRATORY FAILURE

NON-VENTILATORY MANAGEMENT

TARGETED OXYGEN THERAPY

Oxygen given by low-flow intranasal cannulae or 24%–35% Venturi mask should be titrated to achieve a targeted saturation using pulse oximetry (SpO_2) of 88%–92%, as these levels will avoid significant increases in $PaCO_2$ in the majority of COPD patients with ARF. Increases in $PaCO_2$ are most common in patients with initial $PaCO_2$ greater than 50 mm Hg and pH less than 7.35.[27] Excessive oxygen therapy is the cause of increased hypercapnia in a third of acidaemic AECOPD patients.[8] For this reason, ABGs should be repeated 1 hour following initiation of oxygen therapy, as with NIV, to ensure an optimal direction of improvement in the underlying AECOPD. If the rise in $PaCO_2$ is excessive (>10 mm Hg or 1.33 kPa), then FiO_2 should be reduced, titrating SpO_2 to 2%–3% below the previous value, and arterial blood gases should be repeated. If no $PaCO_2$ rise occurs with oxygen therapy, then a higher SpO_2 may be targeted with repeat ABG.

Inadequate reversal of hypoxia (e.g. SpO_2 <85%) is suggestive of an additional problem such as pneumonia, pulmonary oedema or embolus, or a pneumothorax. Investigation of this should commence and a higher O_2 delivery system [e.g. nasal high flow (NHF)] should be used (see Chapter 28). Although high levels of O_2 should be avoided, reversal of hypoxia is important and O_2 should not be withheld in the presence of hypercapnia, or withdrawn if it worsens.

BRONCHODILATORS

Bronchodilators are routinely given in all acute exacerbations of COPD because a small reversible component of airflow obstruction is common, and bronchodilators improve mucociliary clearance of secretions. A large meta-analysis of 22 large randomised controlled long-term trials of ambulatory COPD patients involving either anticholinergics and/or β2 agonists (short- and long-acting) over 3–60 months indicated that anticholinergics are more favourable than placebo in terms of acute exacerbations and hospitalisations.[3,28] There were no favourable advantages with β2-agonists compared with placebo for acute exacerbations or hospitalisations, and placebo was better than β2-agonists in terms of respiratory death.[28] There is a cardiovascular risk if given in excessive doses.[29]

Anticholinergic agents, such as ipratropium bromide, have been shown to have a similar or greater bronchodilator action than β-agonists in COPD, and also to have fewer side effects and no tachyphylaxis. Anticholinergic agents should be used routinely in AECOPD. An ipratropium bromide nebule of 0.5 mg in 2 mL should be nebulised initially 2-hourly, then every 4–6 hours. Long-term use of ipratropium bromide has been shown to reduce the incidence of exacerbations[30] and is therefore recommended for chronic use in ambulatory COPD. Long-acting anticholinergics (e.g. tiotropium) offer potential of once-daily dosing.

Nebulised β-agonists are also effective bronchodilators in COPD, although they may cause tachycardia, tremor, mild reductions in potassium and $PaCO_2$ (due to pulmonary vasodilatation) and tachyphylaxis. As in asthma, lactic acidosis may also occur with excessive β-agonists, either nebulised or intravenous. Nebulised β-agonists (e.g. salbutamol, terbutaline or fenoterol) given 2–4-hourly should be used routinely in combination with ipratropium. This combination has been shown to be more effective than either agent alone.

Parenteral sympathomimetic agents are not recommended for routine use. In stable patients, long-term use of β-agonists may improve symptoms of dyspnoea, particularly in the subgroup of COPD with an objective bronchodilator response.

STEROIDS

In acute exacerbations of COPD, short-term steroids have been shown to improve airflow obstruction including those patients requiring mechanical ventilation for COPD.[31] Doses similar to those for acute asthma should be used. Methylprednisolone 0.5 mg/kg, given 6-hourly for 72 hours, was used in the study by Albert et al., demonstrating benefit in patients with an exacerbation of COPD.[32] Current guidelines recommend the equivalent to oral prednisolone at 0.5 mg/kg body weight for 5 days,[33] then ceasing; however, this will depend upon the response to treatment, and their premorbid use. Steroids should be avoided if the deterioration is clearly due to bacterial pneumonia without bronchospasm.

Longer-term oral steroids in COPD are associated with a substantial increased risk of side effects (osteoporosis, diabetes, peptic ulcer, myopathy, systemic hypertension, fluid retention, weight gain), and are therefore not recommended.[5] A small group of patients (15%) may demonstrate a significant bronchodilator response; co-existent asthma is likely in these patients and longer-term high-dose (oral or inhaled) steroids may be necessary. In the majority of patients, long-term inhaled steroids do not improve lung function or survival and may contribute to recurrent pulmonary infections; however, they may improve quality of life and reduce admissions in a small select population.[5]

ANTIBIOTICS

Antibiotics have an accepted role in the treatment of infection-induced exacerbations of COPD. Amoxicillin is a suitable first-line agent against *H. influenzae* and *Streptococcus pneumoniae* for outpatient exacerbations.[4] Serious exacerbations requiring hospital admission require newer agents such as ciprofloxacin or a third-generation cephalosporin. Antibiotics for pneumonia are discussed in Chapter 36.

AMINOPHYLLINE

Aminophylline is a weak bronchodilator in COPD. It improves diaphragm contractility, stimulates respiratory drive, improves mucociliary transport and right heart function, is anti-inflammatory and is a weak diuretic.[34,35] Some studies have shown no benefit and significant side effects, whereas others have shown small benefit[36] in stable COPD. For an exacerbation, a trial of aminophylline can be considered (loading dose 5–6 mg/kg IV over 30 min, followed by an infusion of 0.5 mg/kg per hour). Serum theophylline levels must be monitored regularly to reduce risk of toxicity.

ANTICOAGULANTS

Subcutaneous heparin (e.g. 5000 units b.d.) is recommended as a prophylactic measure against venous thromboembolism. There is no evidence for warfarinisation in COPD patients with pulmonary hypertension.

ELECTROLYTE CORRECTION

Electrolyte correction is important. Hypophosphataemia,[14] hypomagnesaemia,[37] hypocalcaemia[15] and hypokalaemia may impair respiratory muscle function. Hyponatraemia may occur with inappropriate antidiuretic hormone release or with excess use of diuretics and inappropriate intravenous fluids.

NUTRITION

Nutrition is important, as patients with severe COPD are often undernourished – a subnormal body mass index (BMI) is a risk factor for mortality in COPD.[6] Excessive carbohydrate calories should be avoided, as this increases CO_2 production (by >15%) and may worsen respiratory failure. Low-carbohydrate/high-fat combinations are preferred in ARF during spontaneous ventilation.

CHEST PHYSIOTHERAPY

Chest physiotherapy should be initiated and regularly repeated as both a curative and preventive measure. Encouragement of coughing and deep breathing are the two most important factors. 'Bubble positive expiratory pressure (PEP)' is an inexpensive method of assisting sputum clearance in patients with retained secretions or those having difficulty expectorating.

NEBULISED MUCOLYTIC AGENTS

Nebulised mucolytic agents, such as N acetylcysteine, continue to be proposed, although their benefit has never been established in acute exacerbations of COPD. Oral mucolytics have been shown to reduce cough frequency and severity in stable COPD.[38]

NON-INVASIVE VENTILATION

NIV, a technique in which ventilatory support is provided via a nasal or facial mask without endotracheal intubation, is now a routine standard of care for AECOPD. When applied well, NIV has the same physiological effect as IMV.[39] Two landmark randomised controlled trials in intensive care wards in 1995[40] and in general medical wards in 2001[41] clearly indicated a role for NIV in hypercapnic AECOPD. Since then, there have been several randomised controlled trials and meta-analyses of NIV in hypercapnic AECOPD which have demonstrated improved respiratory physiology, reduced mortality (up to 12 months), reduced iatrogenic complications, reduced need for intubation and mechanical ventilation and reduced length of stay in hospital.[8,9,42,43] All studies have shown good tolerance of the technique (>80% of patients),

with few side effects, and improvements in both oxygenation and $PaCO_2$ compared with medically treated control patients.

Two important reviews of acute NIV use in AECOPD from the United States and the United Kingdom have been recently been published. In the United States between 1998 and 2008, the use of NIV increased (from 1.0 to 4.5% of all admissions) and IMV decreased (from 6.0 to 3.5%), with NIV eclipsing IMV in 2008.[9] Associated with this significant change in pattern of ventilatory support was an overall reduction in mortality in those started on NIV or IMV early.[9] In the United Kingdom, during a 3-month snapshot of 232 hospitals during 2008, 11% of all admissions with AECOPD received NIV.[8] Oxygen toxicity was found to occur in a third of hypercapnic AECOPD.[8] In both US and UK studies, NIV failure with transfer to IMV was associated with greatest mortality (estimated to be ~30% [US]–40% [UK]) compared with successfully used NIV (6% [US]–11% [UK]) and non-hypercapnic COPD (~3% [US], 5% [UK]).

The goal of NIV is: (1) to unload respiratory muscles and augment ventilation and oxygenation, reduce CO_2 and correct acidosis until the underlying problem can be reversed; (2) when applied intermittently, to offset the adverse effects of sleep or position-induced adverse changes to ventilation, increased upper airway resistance and lung volume.

Indications for NIV are a deterioration of COPD with: (1) acute dyspnoea; (2) respiratory rate greater than 28 breaths/min; (3) $PaCO_2$ greater than 45 mm Hg with a pH less than 7.35, despite optimal medical treatment and not related to excessive supplemental oxygen.[8,42,43] Although these indications are for mild exacerbations, most randomised studies have used these as entry guidelines. Initial guidelines recommended NIV use to be limited to patients with pH in the range 7.25–7.35; however, recent evidence suggests that NIV is useful even in those patients with lower pH values (to as low as 7.0) and associated more severe hypercapnia (as high as 140 mm Hg).[44]

Included in the indications are recently extubated patients in whom NIV has been shown to reduce reintubation rates significantly.[45,46] Recently, NIV has been advocated for use in patients with hypoxic respiratory failure,[47] but success is significantly less in the setting of hypoxaemia and either normocapnia or hypocapnia. NIV may also have a role in some patients where mechanical ventilation is considered inappropriate.

Side effects of NIV include discomfort, intolerance, skin necrosis, gastric distension and aspiration. Pressure support has been reported as better tolerated than assist/control.[48] End-of-life plans should be considered in all patients with AECOPD, particularly those undergoing NIV, as ~20% of patients will fail to respond or deteriorate. This period of time on NIV can be used to assess resuscitation status.

INVASIVE MECHANICAL VENTILATION

When respiratory failure progresses despite aggressive conservative management, including NIV, IMV support may be necessary. The decision to ventilate requires careful consideration in some patients who may have near-end-stage lung disease and whose quality of life may not justify aggressive treatment. This decision requires consideration of the outcome of ARF.

An episode of ARF further decreases survival (Fig. 30.2). ARF precipitated only by bronchitis has a better outcome, whereas ARF due to more serious causes, such as pneumonia, LV failure and pulmonary embolus, has a worse outcome and studies including all such outcomes have lower survival rates.

If ARF requires IMV, survival decreases further still (see Fig. 30.2). Although only 1%[8]–3.5%[9] of patients with AECOPD require IMV, and 4.5%[9]–11%[8] need NIV, the short-term survival in this more severe subset is still good, with a hospital survival rate in some series as high as 90%, but 2- and 3-year survival is significantly lower. The severity of ARF and the severity of underlying COPD based on FEV1, lifestyle score and dyspnoea score are also predictors of outcome. Lifestyle and dyspnoea categories may be the most useful factors in the decision to withhold IMV. Lifestyle categories 3 (house-bound and at least partly dependent) and 4 (bed- or chair-bound) indicate both a poor outcome[49] and quality of life that may not justify aggressive treatment.

Thus IMV may be withheld in end-stage lung disease when low survival, poor quality of life or permanent ventilator dependence are likely. If end-stage lung disease is suspected but there is insufficient information, then a brief trial of aggressive therapy, including IMV, should be undertaken and subsequently withdrawn if unsuccessful. Despite this, most patients with COPD who present with ARF do not have end-stage disease and, although their immediate problems may be life threatening, their short-term outcome is sufficiently good to justify full active treatment.

Many studies have indicated that hospitals with high NIV use have a very low need for IMV to treat AECOPD. In the largest study to date, NIV use for AECOPD varied from 9% to 94% in the United States, and was independent of severity of COPD.[50] Moreover, the greater the NIV use, the less IMV was needed, with downstream benefits in terms of hospital length of stay, reduced costs and reduced mortality. Thus, familiarity with NIV is hugely important to the successful caring of patients with AECOPD.

INVASIVE MECHANICAL VENTILATION TECHNIQUE

The goals of IMV in COPD are to support ventilation while reversible components improve, to allow respiratory muscle to rest and recover whilst preventing

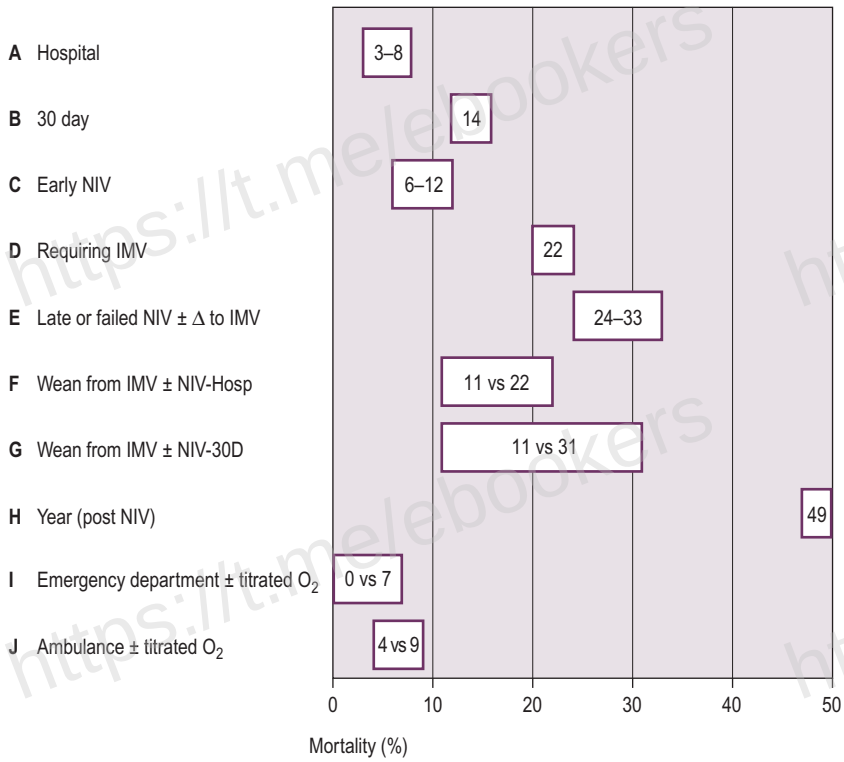

Figure 30.2 Estimated mortality for groups of patients with acute exacerbations of chronic obstructive pulmonary disease (AECOPD). A and B groups: refer to in-hospital and 30-day mortality[8,9]; C group: refers to early institution of non-invasive ventilatory (NIV)[8,9]; D group: refers to patients requiring invasive mechanical ventilation (IMV)[9]; E group: refers to hypercapnic AECOPD patients either failing NIV and needing IMV, or those identified late as requiring NIV[8,9]; F and G groups: weaned from IMV and randomised to either immediate NIV or not (i.e. randomised controlled trial) with in-hospital and 30-day mortality[45]; H group: 1-year mortality post NIV[7]; I and J groups: effect of titrated versus untitrated oxygen at emergency department[23] and ambulance.[22]

wasting from total inactivity and to minimise dynamic hyperinflation. This is usually best accomplished with low-level ventilatory support. Patients requiring low-level support may be commenced on 8–15 cm H_2O pressure support, with 3–8 cm H_2O PEEP. Patients who are completely exhausted, post-arrest, comatose or not tolerating pressure support alone, should be commenced or transferred to synchronised intermittent mandatory ventilation mode.

Excessive dynamic hyperinflation must be avoided by using a low-minute ventilation – 115/mL per kg is a guideline and allowing adequate time for expiration. This should be achieved by the use of a small tidal volume (8 mL/kg) and a ventilator rate less than 14 breaths/min. Dynamic hyperinflation can be assessed clinically by visualising the expiratory flow-curve, and by measuring plateau airway pressure (Pplat) or PEEPi. Pplat should be measured by applying an end-inspiratory pause of 0.5 seconds. This should only be applied following a single breath as it shortens expiratory time and, if it is applied to a series of breaths, it increases dynamic hyperinflation, resulting in an increased Pplat level and increased risk to the patient. If Pplat is greater than 25 cm H_2O, there is likely to be excessive dynamic hyperinflation, and the ventilator rate should be reduced. However, Pplat may be high without dynamic hyperinflation if chest wall compliance is low. Intrinsic PEEP measured as a prolonged end-expiratory pause more directly assesses dynamic hyperinflation. Provided PEEPi is accurately measured, it is a useful tool to follow dynamic hyperinflation. In severe airflow limitation it may be necessary to accept low levels of PEEPi, but as PEEPi rises above 8–10 cm H_2O, further prolongation of expiratory time must be considered. Although still controversial, the use of a high inspiratory flow rate is recommended as it results in a shorter inspiratory time and hence a longer expiratory time for a given ventilatory rate.[12,51] It has been shown to reduce dynamic hyperinflation and alveolar pressure[13] further and to improve gas exchange.[51]

If dynamic hyperinflation is excessive and causing circulatory compromise or risk of barotrauma, then minute ventilation should be decreased, hypercapnic acidosis accepted and spontaneous ventilation, which will only increase dynamic hyperinflation, should be

discouraged by sedation. Muscle relaxants should be avoided unless essential. When dynamic hyperinflation is critical during controlled mechanical ventilation, PEEPi increases pulmonary hyperinflation and should not be applied.[52]

If dynamic hyperinflation is not excessive, then spontaneous ventilation should be encouraged to promote ongoing respiratory muscle activity and to minimise wasting. Flow-by, pressure support and low-level continuous positive airway pressure (CPAP) may all reduce the work of spontaneous breathing and promote a better ventilatory pattern. CPAP approximately equal to the level of PEEPi is most commonly recommended.[53] Care must be taken with all of these supports, as each can increase dynamic hyperinflation by a different mechanism, leading to circulatory compromise or risk of barotrauma. Flow-by increases resistance through the expiratory valve, pressure support increases tidal volume and may increase inspiratory time and CPAP reduces threshold load and makes ventilator triggering easier in patients with PEEPi.

WEANING FROM INVASIVE MECHANICAL VENTILATION

Approximately 6%–20% of patients on IMV support fail weaning and place themselves in a high mortality and morbidity group (see Chapter 31).[45,46] Numerous criteria have been proposed to assess the capacity of the patient to wean[54]; however, the predictive value of any of these individual criteria is limited. The simple criterion of patient respiration rate/tidal volume less than 100 breaths/min per litre had the best predictive value for weaning success, but the advantage of this overly simple clinical assessment during weaning is uncertain. Other indications to safely extubate COPD patients include FiO_2 less than 40%; PaO_2/FiO_2 greater than 200, PEEP 5 cm H_2O, cardiovascular stability, afebrile, pH greater than 7.35, $PaCO_2$ less than 50 mm Hg, Glascow Coma Score greater than 10 and if available to be measured static compliance greater than 25 mL/cm H_2O.[45] Some patients unable to achieve these criteria may require weaning with $PaCO_2$ 50–65 mm Hg with a bicarbonate level of greater than 30 mmol/L allowed or encouraged to reduce the work of breathing and achieve a less abnormal pH. Following extubation, weaning can be continued with immediate placement upon NIV or NHF which is associated with reduced reintubation rates, lower intensive care unit and hospital length of stay and mortality and morbidity.[45,46] Synchronisation of NIV, especially during sleep, is crucial and may require polysomnography.[55]

TRACHEOSTOMY

Tracheostomy may be beneficial in a small group of patients who have failed extubation despite NIV, or who have successfully weaned but are unable to adequately clear secretions, or who have required long-term ventilatory support. After 10 days of endotracheal intubation, the risk of laryngeal trauma and sepsis increases.

A tracheostomy allows long-term ventilatory support, sputum clearance, protection of the upper airway from oral secretions and, off mechanical ventilation, reduced dead space and upper-airway resistance. Compared with naso/orotracheal intubation, tracheostomy is much less intrusive and therefore less sedation is required. Also, it allows direct access to the large airways for the purpose of suctioning and bronchoscopy. However, patients are unable to generate sufficient upper-airway seal to cough, and as such may have ongoing atelectasis until tracheostomy removal and the development of an effective cough. Usually a nasoenteric feeding tube is required. Consider percutaneous endoscopic gastrostomy (PEG) tube feeding if long-term tracheostomy is being considered to avoid nasal trauma and infection and to reduce oesophagitis. Minimal occlusion tracheostomy cuff pressures (usually <20 cm H_2O) should be checked 8-hourly. Temporary tracheostomies require specific attention to adequate humidification. In addition, tracheostomies should have an inner and outer cannula; the inner cannula needs to be changed 1–3 times per day.

Consider removing the tracheostomy when:

1. the oxygenation requirement is low (e.g. FiO_2 <40%)
2. the patient does not require ventilatory support or requires only intermittent low-level ventilatory support and NIV support is available.
3. the patient is cooperative and has a good capacity to cough and can, for example, clear secretions via the tracheostomy tube
4. the patient has a low suction frequency requirement (<2–4-hourly)

Before tracheostomy removal, always ensure the patient is able to protect the upper airway from aspiration and can swallow safely and there is an absence of upper-airway obstruction (e.g. no granulation tissue or tracheal stenosis).

NASAL HIGH FLOW CANNULA

Nasal high flow cannula has emerged to be a novel therapy in patients with acute hypoxic respiratory failure[56] or when weaning from IMV in patients with a high risk of reintubation.[57] This therapy is characterised by the delivery of heated and humidified room air with entrained oxygen via large-bore cannula to the nares. The nasal high flow devices are electrically driven CPAP flow generators with built-in humidifiers and supplemental oxygen inlets plus oxygen and temperature analysers which are displayed within the device. Nasal high flow has distinct physiological advantages over standard oxygen prongs and NIV. It provides warm humidified room air-oxygen blend,

at an accurate FiO_2 (determined by the inflow rate of oxygen) and temperature (31–37°C) and overall flow rate of 30–60 L/min. The 'high flow' has been shown to provide low-level positive airway pressure (about 35 lpm flow equates to 3 cm H_2O PEEP)[58] and greater patient comfort due to the warm air-oxygen mix. The PEEP has two actions: first, to reduce work of breathing, estimated in stable COPD patients by about 40% during sleep[59] and improve lung mechanics[60]; second, to reduce physiological airway dead space by flushing out CO_2.[61]

Clinically, nasal high flow is useful in ARF without hypercapnia[56] and post extubation from IMV.[57]

POST INTENSIVE UNIT CARE

CARE BUNDLES

A systematic approach to the management of acute exacerbations of COPD, summarised in so-called 'care bundles', used at the time of admission and discharge, are associated with improved survival, greater NIV use, shorter length of stay and reduced readmission rates.[62] Care bundles are a method of ensuring optimal care is provided uniformly across large organisations. Using 'care bundles' during the time of admission, attention is given to (1) obtaining a correct diagnosis, (2) targeted oxygen therapy, (3) recognition and management of respiratory acidosis (i.e. NIV), (4) correct treatment and (5) respiratory specialist review within 24 hours. At the time of discharge, 'care bundles' are directed towards ensuring (1) inhaler technique, (2) self-care management plans, (3) smoking, (4) pulmonary rehabilitation and (5) telephone contact within 72 hours post discharge.

REASSESSMENT OF POTENTIAL PRECIPITATING CAUSES

COPD is commonly associated with cardiovascular disease, depression (and social isolation) and occult malignancy, all of which may need further management following an admission. Lung function assessment is crucial post admission and during regular follow-up.

Assessment for long-term oxygen therapy should be undertaken (PaO_2 <55 mm Hg or <60 mm Hg with cor pulmonale), as there are two trials indicating a survival benefit. Current smoking is a contraindication to domiciliary oxygen therapy due to the risk of fire. This can be checked by assessing carboxyhaemoglobin values on ABG (>2% suggests smoking) or urinary cotinine levels.

Assessment of underlying obstructive sleep apnoea (COPD & OSA = overlap syndrome) should be considered. Treatment of this combination with CPAP is associated with an improved survival and exacerbation-free survival over a 9.5 year period according to a large, although uncontrolled, Spanish trial.[63] Habitual snoring, witnessed apnoeas, obesity (BMI >30), large neck size (>45 cm) and crowded oropharynx (Mallampati grade 3–4) provide clues of the possibility of underlying obstructive sleep apnoea.

DOMICILIARY NOCTURNAL NON-INVASIVE VENTILATORY SUPPORT

In COPD patients with chronic hypercapnia, avoidance of excessive domiciliary oxygen therapy is advised. Whether long-term domiciliary nocturnal NIV is required in this group is less clear. Four large and long-term studies have been conducted in which most,[64–66] but not all,[67] have indicated improved physiology (sleep quality and ABG) with an improvement in survival and readmission rate without changes in FEV1. Long-term NIV has also been associated with improved ventilation perfusion matching.[29] Patients may benefit from domiciliary NIV if they have the following: (1) confirmed COPD diagnosis with optimal medical treatment and reversal of co-existent medical problems, (2) chronic hypercapnia extending at least 2 weeks following an acute hypercapnic admission with COPD, (3) at least two admissions with acute acidotic hypercapnia which responded to NIV, (4) demonstration of sleep-related hypoventilation (e.g. total sleep time hypoxic [SpO_2 <90%] >30% plus a rise in $PaCO_2$ of >5 mm Hg) and (5) one-month trial of domiciliary NIV with objective adherence and improved quality of life and (6) an improvement in physiological markers (e.g. awake $PaCO_2$ or 6-minute walk distance).

REHABILITATION

Rehabilitation should be considered for all patients with COPD, particularly those following ARF. There are numerous randomised controlled trials showing improvements in exercise physiology, lung function, quality of life and reduced hospitalisation rates.[68] The change in 6-minute walk distance with rehabilitation is a powerful predictor of improved survival and significant patient motivator.[69]

VACCINATION AND ANTIBIOTICS

Two large trials have recently advocated the use of macrolide antibiotics (Erythromycin[16] or Azithromycin[17]) for stable COPD. Both studies, conducted over a 12-month period, indicated a significant reduction in exacerbations, probably via anti-inflammatory and antibacterial effects. However, this benefit needed to be offset against potential for greater long-term microbiological resistance and side effects such as hearing loss. Vaccination should be considered in all patients with COPD when stable. Annual influenza and 5-yearly pneumococcal vaccination is recommended.[4]

DOMICILIARY OXYGEN

Based upon two studies[70,71] conducted in the 1970s–1980s indicating a mortality benefit, supplemental oxygen should be provided to patients with advanced COPD who (1) are optimally controlled medically, (2) do not smoke, (3) and have PaO_2 less than 55 mm Hg or PaO_2 less than 60 mm Hg with cor pulmonale. Great caution should be undertaken to avoid excessive oxygen at home when stable (aim for overnight oximetry of 88%–92%) and during acute exacerbations.[8,22,23]

LUNG TRANSPLANTATION

Lung transplantation is another palliative surgical procedure for patients with advanced disabling COPD who are aged less than 65 years, are not ventilator-dependent, are on less than 10 mg prednisolone/day and are free of significant coexistent disease.[72] The current 1-, 2- and 5-year international survival figures are 75%, 66% and 50%, respectively. Common complications are systemic hypertension, bronchiolitis obliterans, acute rejection, viral infection with cytomegalovirus and neoplasms.

PROGNOSIS

Patients with sufficiently severe COPD to warrant hospital admission incur an inpatient mortality of 8%, and 90-day mortality of 15% in the United Kindom.[8,9] Predictors of mortality were performance status, age and admission urea, albumin, pH, $PaCO_2$ and SpO_2 plus the presence of respiratory physicians involved in the care.[73] Although in-hospital mortality for hypercapnic COPD patients may reach 62%,[74] in an Australian report, in-hospital mortality for hypercapnic COPD patients treated with NIV was 11% and all deaths were with palliative intent, which followed time to allow for patient and family discussions.[44] In Hong Kong, acute hypercapnic COPD patients have a 12-month readmission rate of 80% and a 49% 1-year mortality.[7] The BMI, airflow obstruction, dyspnoea and exercise capacity (BODE) index is a 10-point scale made up from the following four variables: (1) BMI; (2) airflow obstruction; (3) severity of dyspnoea; and (4) exercise capacity, and has been found to be very useful in predicting survival in ambulatory patients with COPD (see Table 30.2).[6]

Mechanical ventilator support

Andrew D Bersten

Mechanical ventilation for acute respiratory failure (ARF) is now routine in the intensive care unit (ICU). The 1952 Copenhagen polio epidemic introduced the notion of organised areas (ICU) for the provision of positive-pressure ventilation,[1] which was usually applied through a tracheostomy that had been inserted to allow suction of secretions. However, methods of ventilatory assistance without intubation had proliferated prior to the polio epidemic (both negative-pressure chest wall devices and positive-pressure face-mask devices), and current trends are to an increased use of non-invasive ventilation (NIV) in patients with respiratory failure.[2]

Almost all of the ventilatory modes that are conventionally applied during *intubated* ventilation (IV) can be applied *non-invasively*; however, IV remains the primary mode of respiratory assistance in critically ill patients. There is also an increasing number of patients receiving chronic ventilatory assistance, but, since the majority of these use chronic NIV, this chapter is primarily directed at intubated mechanical ventilation for both ARF and acute-on-chronic respiratory failure.

A PHYSIOLOGICAL APPROACH

During normal spontaneous breathing, contraction of the respiratory muscles overcomes both the elastic recoil and resistance of the respiratory system (lung and chest wall). A fall in regional pleural pressure results in alveolar inflation due to the resultant pressure gradient. Expiration is usually passive, but the expiratory muscles may assist the elastic recoil of the respiratory system.

The work (W) performed by the respiratory muscles (W_{mus}) can be measured from the relationship between pressure (P) and volume (V), and partitioned into elastic (W_{el}) and resistive (W_{res}) work:

$$W_{mus} = W_{el} + W_{res} \quad (31.1)$$

Inertial work is negligible, and usually ignored; furthermore, Eq. 31.1 does not explicitly describe the elastic work required to initiate inspiration when intrinsic PEEP ($PEEP_i$) is present.

Because volume is constant in Eq. 31.1, it can be simplified to:

$$P_{mus} = P_{el} + P_{res} \quad (31.2)$$

It follows that during positive-pressure ventilatory assistance, where P_{ao} is the ventilatory pressure applied at the airway:

$$P_{ao} + P_{mus} = P_{el} + P_{res} \quad (31.3)$$

and that when the work is solely applied by the ventilator with no respiratory muscle contraction (controlled mechanical ventilation [CMV]):

$$P_{ao} = P_{el} + P_{res} \quad (31.4)$$

This nomenclature allows physiological discussion of the different ventilatory modes from controlled ventilation to spontaneous, unassisted ventilation, and introduces the equation of motion that is used in the estimation of respiratory mechanics (see Chapter 38):

$$P_{ao} = E_{rs} \bullet V + R_{rs} \bullet \dot{V} + P_o \quad (31.5)$$

where E_{rs} is the respiratory system (lung and chest wall) elastance (the inverse of compliance), R_{rs} is the respiratory system resistance, $\dot{V}$ is the gas flow rate, and P_o is the total PEEP (the sum of extrinsic PEEP [$PEEP_e$] and $PEEP_i$). $PEEP_i$ imposes a threshold load – additional elastic work, as inspiratory muscle contraction must occur without $\dot{V}$ until P_{ao} falls below atmospheric pressure (see below, patient-ventilator interaction).

MODES OF VENTILATION

CONTROLLED MECHANICAL VENTILATION

The simplest form of positive-pressure breath occurs in a relaxed subject, and the ventilator provides a constant gas flow during inspiration.

$$P_{ao} = E_{rs} \bullet V + R_{rs} \bullet \dot{V} + P_o$$

The volume delivered will depend upon the inspiratory time (T_i), and P_{ao} during inspiration will reflect E_{rs} and R_{rs} (Fig. 31.1). Expiration is a passive, and usually exponential, decline in volume to the relaxation volume

ABSTRACT

Mechanical ventilator assistance is routine in the intensive care unit; while the most basic form is controlled mechanical ventilation where the ventilator performs all the work of the respiratory muscles, a variety of modes of partial-ventilatory assistance are available and commonly used. The benefits of mechanical ventilation include improved oxygenation through recruitment of poorly aerated lung, control of alveolar ventilation and $PaCO_2$, reduced work of breathing, and airway access and security when the patient is intubated or has a tracheostomy. Protective ventilation aims to minimise lung injury from excessive lung stretch and repeated recruitment-derecruitment of air sacs; while this has been termed ventilator-induced lung injury, similar processes may occur during partial-ventilatory support, non-invasive ventilator support and spontaneous breathing. Consequently, the concept of protective ventilation may have broader application than initially thought.

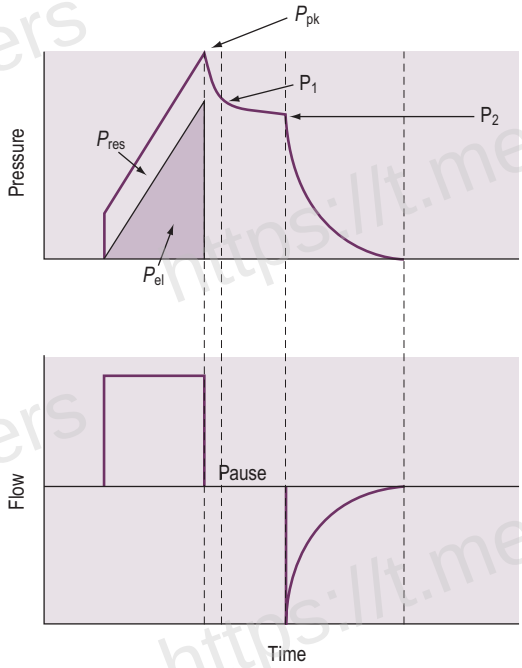

Figure 31.1 Schematic diagram of a volume-controlled breath with constant inspiratory flow. A period of no inspiratory gas flow has been interposed before expiration (pause) to illustrate dissipation of lung resistance as airways resistance (fall from P_{pk} to P_1) and tissue resistance (fall from P_1 to P_2). The inspiratory pressure due to the elastic properties of the respiratory system is illustrated in the top panel as the filled area (P_{el}), and the lung resistive pressure is labelled as P_{res}. (See text for more detail.)

of the respiratory system, also termed the functional residual capacity (FRC).

CMV is the most basic form of mechanical ventilation; however, it is extremely useful, and still commonly used. Preset minute ventilation is made up from a fixed respiratory rate (f) and tidal volume (V_T). Provided that there are not large variations in alveolar dead space, this maintains a preset alveolar ventilation (V_A) and CO_2 clearance. Consequently, CMV is useful in conditions where there is alveolar hypoventilation (e.g. respiratory muscle weakness), when $PaCO_2$ needs to be maintained in a fixed range (e.g. raised intracranial pressure) or when the work of breathing must be minimised (e.g. severe cardiorespiratory failure). Because CMV may not match respiratory drive, and spontaneous, supported or assisted breaths are not possible during CMV, sedation and sometimes muscle paralysis may be needed. CMV is usually combined with $PEEP_e$, which can recruit collapsed lung and reduce intrapulmonary shunt. The components are discussed below.

TIDAL VOLUME

Larger V_T, typically 12–15 mL/kg, or intermittent recruitment manoeuvres (sighs) prevent progressive atelectasis and intrapulmonary shunt during general anaesthesia.[3] However, this may result in excessive lung stretch, leading to ventilator-induced lung injury (VILI). For example, in acute respiratory distress syndrome (ARDS), V_T of 6 mL/kg versus 12 mL/kg predicted body weight (i.e. often 4–5 mL/kg vs. 9–10 mL/kg true weight) reduced mortality from 40% to 31%.[4] Consequently, lower V_T should be strongly considered during CMV, and other forms of ventilatory assistance, in patients with ARDS; however, greater levels of PEEP are usually required. Whereas the reduction in V_T is particularly applicable to ARDS where a smaller proportion of the lung is ventilated (see Chapter 33) clinical outcomes are improved with protective lung ventilation in both critically ill patients without ARDS, and following general anaesthesia.[5,6] Intermediate V_T offers more efficient V_A when ventilator support is required for obstructive lung disease, as the anatomical dead space fraction is lower.

RESPIRATORY RATE (f)

The desired minute ventilation is determined by the product of V_T and f. Common CMV rates are 10–20 breaths/min in adults. Sufficient expiratory time (T_e) must be allowed to minimise dynamic hyperinflation and $PEEP_i$. Although high f (up to 35 breaths per minute) was allowed in the ARDS Network protocol, and the low V_T, low mortality group had a mean f of ~30 breaths per minute,[4] laboratory data suggest a possible additive role of high f in VILI.[7]

INSPIRATORY FLOW PATTERN

The simplest form of CMV uses a constant inspiratory $\dot{V}$ ($\dot{V}_I$) and, in combination with T_i, a preset volume is delivered. This is also called volume-controlled ventilation (VCV); some ventilators use V_T and T_i to set $\dot{V}_I$. Alternative $\dot{V}_I$ patterns that are commonly available with VCV include a ramped descending flow pattern and a sine pattern. When a time preset inspiratory pressure is delivered, this is termed pressure-controlled ventilation (PCV).

Although there are no convincing physiological or outcome data differentiating these different modes of CMV,[8] PCV is increasingly used when the peak airway pressure (P_{pk}) is high with VCV. However, the alveolar distending pressure, which is usually inferred from the plateau pressure (P_{plat}), is no different provided that T_i and V_T are the same.[9] During PCV, P_{res} is dissipated during inspiration so P_{pk} and P_{plat} are equal, and during VCV P_{res} accounts for the difference between P_{pk} and P_{plat} (Fig. 31.2). Similarly, different CMV $\dot{V}_I$ patterns will alter P_{pk} without changing P_{plat} or mean airway pressure (P_{mean}) when T_i and V_T are constant. In ARDS patients, comparing VCV and PCV there was no difference in haemodynamics, oxygenation, recruited lung volume or distribution of regional ventilation.[10] Although PCV may dissipate viscoelastic strain earlier,[10] high $\dot{V}_I$ may cause or exacerbate VILI,[11]

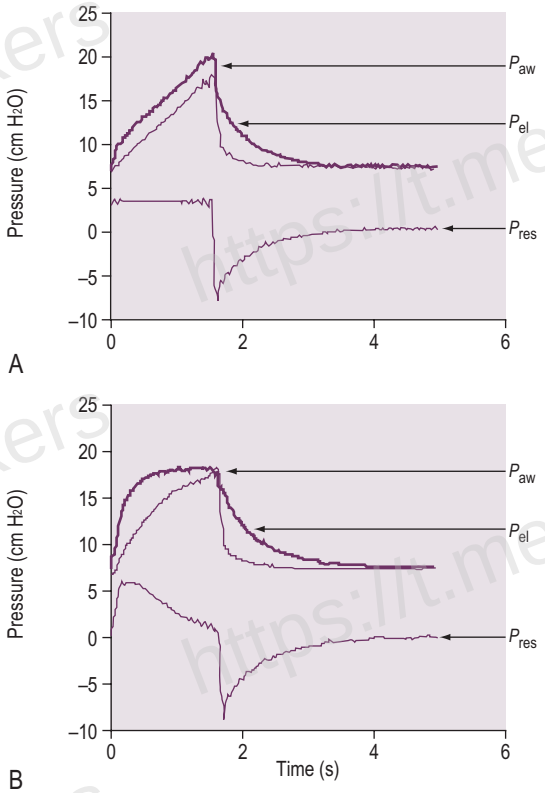

Figure 31.2 Actual pressure-time data from a patient with acute respiratory distress syndrome ventilated with volume-controlled ventilation *(panel a)*, and then with pressure-controlled ventilation *(panel b)*; tidal volume, I:E ratio and respiratory rate are constant. The airway pressure (P_{aw}, *bold line*) has been broken down to its components, P_{el} and P_{res} (see Fig. 31.1). Although there is no inspiratory pause, there is marked similarity between *panel a* and Fig. 31.1, with the inspiratory difference between P_{aw} and P_{el} due to a constant P_{res}. In *panel b*, the decelerating inspiratory flow pattern seen with pressure-controlled ventilation results in dissipation of P_{res} by end inspiration. Consequently, during pressure-controlled ventilation $P_{aw} \approx P_{plat}$ obtained during volume-controlled ventilation. In other words, for the same ventilator settings there is no difference in the elastic distending pressure.

which may explain why some animal models have found PCV, which inherently has a high early $\dot{V}_I$, to be injurious compared with VCV.

Pressure-regulated volume control (PRVC) is a form of CMV where the V_T is preset, and achieved at a minimum pressure using a decelerating flow pattern.

INSPIRATORY PAUSE

An end-inspiratory pause allows examination of the decay in P_{pk}, and measurement of P_{plat} (see Chapter 38), and may alter the distribution of ventilation. If T_i and V_T are maintained constant, there is no improvement in oxygenation, and a more rapid $\dot{V}_I$ will be needed. Theoretically, during an end-inspiratory pause, 32% of the total energy loss within the respiratory system will be dissipated,[12] which may significantly reduce the forces driving expiration, potentially exacerbating gas trapping in patients with severe air-flow limitation.

INSPIRATORY TIME, EXPIRATORY TIME, I:E RATIO

The combination of V_T and inspiratory $\dot{V}$ will determine T_i, which in combination with f sets T_e. A typical T_i is 0.8–1.2 seconds; with a V_T of 500 mL and inspiratory $\dot{V}$ of 0.5 L/s, the T_i is 1.0 second. During spontaneous ventilation, the distribution of ventilation at low $\dot{V}$ is determined by regional E, and at high inspiratory $\dot{V}$ by regional R, leading to greater ventilation of non-dependent lung. In patients with severe air-flow limitation, high inspiratory flow rates may be used in order to prolong T_e and minimise dynamic hyperinflation.[13]

The I:E ratio is usually set at or below 1:2 to allow an adequate T_e for passive expiration. During inverse ratio ventilation (IRV), the I:E ratio is greater than 1:1. The putative benefits of a prolonged T_i include higher expiratory $\dot{V}$ and improved mucus clearance,[14] and recruitment of long time-constant alveoli, and a short T_e results in gas trapping and $PEEP_i$. Early reports of clinical benefit did not control for $PEEP_i$, and, when total PEEP, f and V_T are constant,[9,10] pressure controlled inverse ratio ventilation (PCIRV) tends to reduce $PaCO_2$ but does not improve oxygenation, and may have deleterious haemodynamic effects and exaggerate regional overinflation.[10]

POSITIVE END-EXPIRATORY PRESSURE

Positive end-expiratory pressure (PEEP) is an elevation in the end-expiratory pressure upon which all forms of mechanical ventilation are to be imposed. When PEEP is maintained throughout the respiratory cycle in a spontaneously breathing subject, the term constant positive airway pressure (CPAP) is used. The primary role of PEEP is to maintain recruitment of collapsed lung, increase FRC and minimise intrapulmonary shunt. PEEP may also improve oxygenation by redistributing lung water from the alveolus to the interstitium and, although there is no direct effect of PEEP to reduce extravascular lung water, this may occur in patients with left ventricular failure due to a reduction in venous return and left ventricular afterload. Furthermore, inadequate PEEP may contribute to VILI by promoting tidal opening and closing of alveoli. PEEP levels of 5–15 cm H_2O are commonly used, and levels up to 25 cm H_2O may be required in patients with severe ARDS. Although meta-analysis of three large multicentre trials[15] found no benefit of higher PEEP levels in ARDS, mortality was lower in more hypoxaemic patients and there were fewer rescue therapies required, suggesting individual titration may need to be considered.

PEEP titration in ARDS is complex (see Chapter 33), and should aim to improve oxygenation and minimise VILI. Since PEEP reduces venous return, cardiac output and O_2 delivery may fall despite an improvement in Pa_{O_2}; indeed, this concept has been used to optimise PEEP in ARF.[16] However, in addition to recruitment, increasing PEEP may lead to overinflation of non-dependent alveoli that are already aerated at end expiration.[17,18] Patients with focal ARDS are a particular risk group as recruitment is limited; VILI can be minimised when PEEP is reduced below standard levels.[19] In general, overinflation and VILI are less likely if alveolar distending pressure is kept less than 30–35 cm H_2O, or the change in driving pressure is less than 2 cm H_2O when V_T is constant.[20]

$PEEP_e$ is applied by placing a resistance in the expiratory circuit (Fig. 31.3), with most ventilators using a solenoid valve. Independent of the technique, a threshold resistor is preferred since it offers minimal resistance to flow once its opening P is reached. This will minimise expiratory work, and avoid barotrauma during coughing or straining.

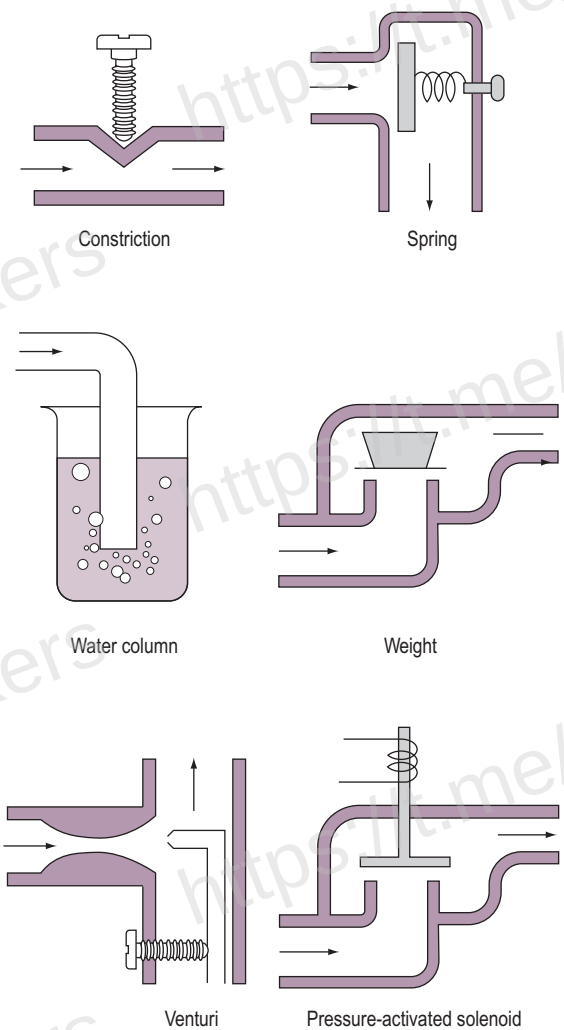

Figure 31.3 Positive end-expiratory pressure values.

$PEEP_i$ is an elevation in the static recoil pressure of the respiratory system above $PEEP_e$ at end expiration. $PEEP_i$ arises due to an inadequate T_e, usually in the setting of severe air-flow obstruction. However, it may be a desired end-point during IRV. The sum of $PEEP_e$ and $PEEP_i$ is the total PEEP ($PEEP_{tot}$). The distribution of $PEEP_i$ is likely to be less uniform than an equivalent $PEEP_e$; this may not have the same physiological effects. When patients with severe air-flow obstruction are triggering ventilation, $PEEP_e$ less than $PEEP_i$ may be applied to reduce elastic work (see later in the chapter, Patient-Ventilator Interaction).

FRACTIONAL INSPIRED OXYGEN CONCENTRATION (Fi_{O_2})

Adequate arterial oxygen saturation is achieved through a combination of minute ventilation, PEEP and Fi_{O_2} adjustment. Even patients with normal respiratory systems usually need an $Fi_{O_2} > 0.21$ due to ventilation-perfusion mismatch secondary to positive-pressure ventilation. In patients with ARF, it is common to start with an Fi_{O_2} of 1 and titrate down as PEEP and minute ventilation are adjusted. Because high Fi_{O_2}s are damaging to the lung, and nitrogen washout may exacerbate atelectasis, it is reasonable to aim at an $Fi_{O_2} \leq 0.6$. The target PaO_2 or SpO_2 remains controversial; as both hypoxaemia and hyperoxia increase the risk of adverse clinical outcomes,[21] normoxia should be targeted until further evidence is available.

SIGH

Many ventilators have the ability to intermittently deliver a breath at least twice V_T. Sighs may reduce atelectasis, in part, through release of pulmonary surfactant,[22] resulting in recruitment and improved oxygenation in ARDS.[23] However, if sighs or recruitment manoeuvres are used, care must be taken to avoid recurrent excessive lung stretch.

ASSIST-CONTROL VENTILATION

During assist-control ventilation (ACV), in addition to the set f, patient effort can trigger a standard CMV breath (Fig. 31.4). This allows greater patient comfort, and V_T is controlled at a safe level; however, there may be little reduction in respiratory work compared to an unassisted breath at low $\dot{V}_I$ because the respiratory muscles continue to contract through much of the breath.[24] The equivalent PCV breath is termed pressure assist-control ventilation (PACV). Differences between triggering modes will be discussed later in the chapter (Patient-Ventilator Interaction).

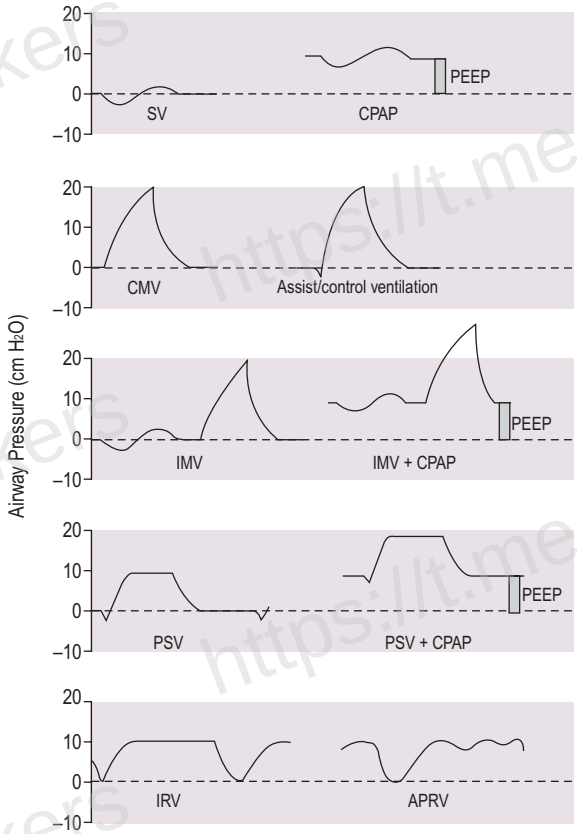

Figure 31.4 Schematic representation of airway pressure versus time for a variety of forms of ventilatory assistance. *APRV*, Airway pressure release ventilation; *CMV*, controlled mechanical ventilation; *CPAP*, continuous positive airway pressure; *IMV*, intermittent mandatory ventilation; *IRV*, inverse-ratio ventilation; *PEEP*, positive end-expiratory pressure; *PSV*, pressure support ventilation; *SV*, spontaneous ventilation.

INTERMITTENT MANDATORY VENTILATION, SYNCHRONISED INTERMITTENT MANDATORY VENTILATION

Intermittent mandatory ventilation (IMV) was introduced over 20 years ago to aid weaning from CMV by allowing the patient to take 'unimpeded' breaths while still receiving a background of controlled breaths. Proposed advantages include a reduction in sedation, lower mean intrathoracic pressure with less barotrauma and adverse haemodynamic consequences, improved intrapulmonary gas distribution, continued use of respiratory muscles and faster weaning. During synchronised intermittent mandatory ventilation (SIMV) T_i is partitioned into patient-initiated and true spontaneous breaths to avoid breath stacking. However, during spontaneous breaths the work of breathing imposed by the endotracheal tube, circuit and ventilator must be overcome.[25] In weaning studies comparing SIMV with T-piece trials and pressure support ventilation (PSV), SIMV is the slowest.[26] Many clinicians add PSV during gradual reduction in respiratory rate with SIMV to overcome the added respiratory work imposed by the circuit and endotracheal tube; however, this approach has not been formally compared with other weaning techniques, and upper airway oedema following extubation increases extubated W_{res} similar to that imposed by the endotracheal tube prior to extubation.[27]

PRESSURE SUPPORT VENTILATION

During PSV, each patient-triggered breath is supported by gas flow to achieve a preset pressure, usually designated to be above the $PEEP_e$. This can be explained by referring to the equation of motion where:

$$P_{mus} + P_{ao} = E_{rs} \bullet V + R_{rs} \bullet \dot{V} + P_o \quad (31.6)$$

During PSV, P_{ao} is the targeted variable by the ventilator, which leads to a significant and important reduction in P_{mus} and work of breathing.[28] The detection of neural expiration varies between ventilators, but commonly relies upon a fall in the inspiratory $\dot{V}$ to either 25% of the initial flow rate or to less than 5 L/min; some ventilators allow titration of the percentage reduction in initial flow to allow improved patient-ventilator synchrony. PSV may also be titrated to offset the work imposed by the circuit and endotracheal tube. The absolute level required to offset this will vary with endotracheal tube size and inspiratory $\dot{V}$,[29] but is commonly 5–10 cm H_2O.[30] PSV can be used during weaning, or as a form of variable ventilatory support with pressures of 15–20 cm H_2O commonly used. Disadvantages include variable V_T, and hence minute ventilation, the potential to deliver an excessive V_T (common in patients recovering from ARDS) and patient-ventilator asynchrony, which is common with high levels of PSV (see later).

Volume-assured pressure support (VAPS) is a mode of adaptive PSV where breath-to-breath logic achieves a preset V_T.

PROPORTIONAL ASSIST VENTILATION

Proportional assist ventilation (PAV) is a form of partial ventilatory support where inspiratory P is applied in proportion to patient effort. Because this allows the breathing pattern and minute ventilation to be matched to patient effort, it is only suitable if respiratory drive is normal or elevated. In concept, this should optimise the patient-ventilator interaction; however, the prescription of PAV requires a greater level of physiological understanding than similar forms of partial ventilatory support such as PSV, since there is no target P, V or $\dot{V}$. PAV is usually prescribed using volume assist (VA) and flow assist (FA), with V

and $\dot{V}$ measured continuously. VA generates greater P as V increases, leading to elastic unloading, and FA generates greater P as $\dot{V}$ increases, leading to resistive unloading. Not surprisingly, the units of VA are cm H_2O/L (i.e. an elastance term) and those for FA are cm H_2O/L/s (i.e. a resistance term). This can be illustrated by referring to Eq. 31.6:

$$P_{mus} + P_{ao} = E_{rs} \bullet V + R_{rs} \bullet \dot{V} + P_o$$

where P_{ao} is determined by PAV, where PAV = VA +FA, so:

$$P_{mus} + VA \bullet V + FA \bullet \dot{V} = E_{rs} \bullet V + R_{rs} \bullet \dot{V} + P_o \quad (31.7)$$

$$\text{consequently } P_{mus} = (E_{rs} - VA) \bullet V + (R_{rs} - FA) \bullet \dot{V} + P_o \quad (31.8)$$

If E_{rs} and R_{rs} are known, PAV can, at least in principle, be targeted to reduce a specified proportion of either, or both, elastic and resistive respiratory work. For example, when VA and FA are adjusted to counterbalance E_{rs} and R_{rs} so as to achieve normal values, minute ventilation increases, and respiratory drive and work decrease; if $PEEP_i$ is present, work can be further reduced by applying $PEEP_e$.[31] Respiratory mechanics are relatively hard to estimate in spontaneously breathing patients, and although they are now offered on some ventilators, their accuracy has been questioned,[32] which may reduce the validity of adjusting PAV according to estimated load (PAV+). Consequently, PAV is often titrated to patient comfort. Despite a growing body of data demonstrating reduced work of breathing, and improved patient-ventilator synchrony with PAV, it is a more difficult technique to use, and definitive studies showing a clinically important outcome difference are awaited.

NEURALLY ADJUSTED VENTILATORY ASSISTANCE

During neurally adjusted ventilatory assistance (NAVA), a modified nasogastric tube is used to record diaphragmatic electrical activity, which is used to control the assisting level of inspiratory pressure. This short-circuits trigger and feedback functions with improved patient-ventilator interaction, less asynchrony and less overassistance compared with PSV[33] in small physiological trials. However, in a multicentre trial[34] of 128 patients, although NAVA was well tolerated and reduced asynchrony overall, autocycling and double triggering were more common, there was no clinically significant benefit compared to PSV, and a pneumothorax resulted from misplacement of the NAVA catheter. NAVA may also improve oxygenation, perhaps by allowing more variable V_T consistent with the concept of biological variability. Although NAVA is available on some commercial ventilators, its use is limited, and there are no data showing a clinically important benefit.

BILEVEL VENTILATION

Also described as biphasic positive airway pressure (BIPAP), this is a ventilatory mode where two levels of airway pressure are provided. Cycling between these two levels of airway pressure may be time cycled or triggered by ventilatory effort, in which case inspiratory positive airway pressure (IPAP) and expiratory positive airway pressure (EPAP) are set; however, this is no different to equivalent support with PSV and PEEP. Patient-triggered bilevel ventilation is most commonly used during NIV.

AIRWAY PRESSURE RELEASE VENTILATION

During airway pressure release ventilation (APRV), spontaneous breathing is possible in addition to time-triggered and time-cycled biphasic pressure levels (high and low CPAP). Usually the time cycling provides a prolonged T_i aimed at recruiting slow time-constant air spaces. Minute ventilation and CO_2 excretion are augmented by brief (1–1.5 seconds) periodic cycling to the lower level of CPAP. A 'personalised' form of APRV has been described where the expiratory time is set using the end-expiratory flow as a fraction of the peak expiratory flow, typically a ratio of 75% with a Te of 0.3–0.6 seconds.[35] As the augmented V_T is dependent upon elastance of the respiratory system, it will be smaller in patients with 'stiff' respiratory systems. APRV without spontaneous breathing has a similar pressure profile to PCIRV.

APRV offers a number of benefits and is usually applied during IV. The prolonged T_i is usually associated with improved oxygenation at a similar or lower P_{aw} to conventional ventilation. Spontaneous respiratory efforts may: (1) improve matching of ventilation and perfusion due to increased dependent aeration, (2) increase venous return and hence cardiac output or pulmonary blood flow in infants following cardiac surgery[36] and (3) promote reduced sedation. However, while there are encouraging case series and physiological studies,[36,37] randomised clinical trials have not shown improved outcomes,[38,39] unsupported spontaneous breaths may increase left ventricular afterload and promote ventilator-patient asynchrony and, as slow time-constant air spaces are also slow to empty, APRV is contraindicated in COPD and asthma.

HIGH-FREQUENCY VENTILATION

High-frequency ventilation (HFV) encompasses techniques where small V_T (1–3 mL/kg) are delivered at high f (100–600/min). This offers reduced tidal lung stretch and reduced VILI. Hazards include inadequate humidification and gas trapping in patients with severe air-flow limitation. High-frequency jet ventilation (HFJV) utilises dry gas from a high-pressure source delivered into an intratracheal catheter or specifically

manufactured endotracheal tube. Although HFJV has been used with improvement in gas exchange in adults with ARDS,[40] high-frequency oscillation (HFO) has received more interest including neonatal, paediatric and adult use.

HFO uses oscillatory flow within the airway to provide active inspiration and expiration at rates of 3–10 Hz. There are a number of putative mechanisms of gas exchange in addition to the more usual bulk flow seen during CMV and SV.[41] Ventilation and V_T are determined by the driving pressure, which controls the reciprocating flow, and by $1/f$. Oxygenation is determined by the mean P_{aw} sometimes in combination with recruitment manoeuvres which influence the volume of recruited lung. Typically, the mean P_{aw} is set 5 cm H_2O above the CMV value.[42] Although the mean P_{aw} during HFO is theoretically dissipated with lower alveolar pressures, and this appears to be the case in homogeneous lung injury, damaged regions of the lung with low compliance, and hence short time constants, may be exposed to alveolar pressures approaching mean P_{aw},[43] resulting in regional VILI.

Although oxygenation is improved in both infants and patients with ARDS, definitive outcome data are lacking. HFO appears to be equivalent to CMV in preterm infants with similar mortality and chronic lung disease.[44] In ARDS, two large randomised trials have reported either no improvement (OSCAR trial),[45] or an increase (OSCILLATE trial)[46] in mortality (47% vs. 35% at hospital discharge). Contributing factors include greater vasopressor use, and greater use of sedation and neuromuscular blockade, with a tendency to greater positive balance, consistent with higher mean airway pressure leading to reduced venous return and greater right ventricular strain.[47] These data refute a meta-analysis that suggested reduced mortality with HFO[48]; however, the largest trial included in this analysis administered a V_T of around 10.6 mL/kg predicted body weight in the control CMV group[37] as compared with protective ventilation in the OSCAR and OSCILLATE studies. Unless new clinical trial data become available, HFO cannot be recommended for routine care in ARDS.

LIQUID VENTILATION

Perfluorocarbons have a high solubility for both O_2 and CO_2, and reduce surface tension, somewhat analogous to pulmonary surfactant. Partial liquid ventilation is now the most common method of administration, with perfluorocarbon equal to the FRC administered via the endotracheal tube. The non-dependent lung is still ventilated, and may have increased blood flow due to compression of the pulmonary circulation in the dependent lung by the perfluorocarbon. Together with the perfluorocarbon-mediated reduction in surface tension, alveoli are recruited and oxygenation improved. However, when PEEP is applied, the perfluorocarbon may be pushed distally and overdistend dependent alveoli.

Small clinical studies have reported improved gas exchange and respiratory mechanics after administration of perfluorocarbons[49]; however, a moderately large clinical study (n = 311) found that patients receiving conventional ventilation compared with both low- and high-dose perflourocarbons had more ventilator-free days and tended to reduced mortality.[50] Consequently, liquid ventilation cannot be recommended.

INDICATIONS AND OBJECTIVES OF MECHANICAL VENTILATION[51]

Institution of mechanical ventilation is a clinical decision; it can only be supported by parameters such as blood gases or measures of respiratory muscle function. Even then, the decision to choose IV over NIV will be influenced by numerous factors including the indication and its likely course. Often there will be an indication for intubation (Box 31.1) and mechanical ventilation; however, if intubation is required to overcome upper airway obstruction, no ventilatory assistance may be needed despite the increase in respiratory work imposed by the endotracheal or tracheostomy tube.[25] Once the decision has been made to proceed to ventilatory support, the choice of mode should be based on a physiological approach, local expertise and simplicity.

Patients who are likely to need ventilatory assistance (e.g. acute severe asthma) should be considered for early ICU admission, since this will allow faster responses and avoid cardiorespiratory arrest. Specific issues and methods of ventilatory assistance are

Box 31.1 Indications and objectives of intubated mechanical ventilation

Endotracheal intubation or tracheostomy
- For airway protection (e.g. coma)
- For suction of secretions
- To assist sedation and neuromuscular paralysis (e.g. to $\downarrow\dot{V}_{O_2}$ $\downarrow$ *respiratory distress*)
- To overcome upper-airway obstruction

Mechanical ventilation
- To manipulate alveolar ventilation (V_A) and $PaCO_2$ (e.g. reverse respiratory acidosis, $\downarrow$ cerebral blood flow and intracranial pressure)
- To $\uparrow Sa_{O_2}$ and Pa_{O_2} (by $\uparrow$ FRC, $\uparrow$end-inspiratory lung volume, $\uparrow V_A$, $\uparrow Fi_{CO_2}$)
- To $\downarrow$ work of breathing (e.g. to overcome respiratory muscle fatigue)
- To $\uparrow$ FRC (e.g. $\uparrow Pa_{O_2}$, $\downarrow$ ventilator-induced injury)
- To control lung stretch during spontaneous breathing, non-invasive ventilation or partially assisted ventilation
- To stabilise the chest wall in severe chest injury

dealt with in the chapters on ARDS, asthma, COPD and NIV. In patients with traumatic brain injury, IV is commonly required to protect the airway and to assist control of ICP; similarly, patients with severe pancreatitis or serious abdominal infection may need prolonged IV to maintain an adequate FRC, reduce work of breathing, protect their airway and allow suctioning of secretions.

MINIMISATION OF LUNG INJURY

Protective ventilation aims to minimise excessive regional lung stretch and cyclic recruitment and collapse, and reduce VILI. Typical protective ventilation combines V_T of 6 mL/kg pbw[4] combined with moderate PEEP[15] and plateau pressures less than 30 cm H_2O (see Chapter 33, ARDS for further discussion). Although the focus has been on protective ventilation during CMV, these processes can occur during spontaneous breathing without ventilator assistance, and during both NIV and partial ventilator support. High respiratory drive due to lung injury or metabolic acidosis may result in relatively large V_T; despite reducing ventilator support, regional differences in aeration can lead to pendelluft and lung injury compared to a controlled breath at the same V_T and transpulmonary pressure, and falls in alveolar pressure may result in greater transmural vascular pressure and pulmonary oedema.[52] The corollaries of this include great care when providing partial ventilator support, and VILI prophylaxis as a possible indication for mechanical ventilation (see Box 31.1).

INITIATION OF INTUBATED MECHANICAL VENTILATION

A manual resuscitation circuit, mechanical ventilator and equipment for safe endotracheal intubation (see Chapter 29) should be available. Initial ventilator settings are commonly set to achieve adequate oxygenation and V_A; however, this will depend upon the patient's condition. Common settings are: V_T 6–8 mL/kg, f 10–20 breaths/min, PEEP 5 cm H_2O, and Fi_{O_2} 1.0, and these will need to be adjusted according to the specific pathophysiology and response.

MANUAL RESUSCITATION CIRCUITS

Manual resuscitation circuits are primarily used to provide emergency ventilation when spontaneous effort is absent or inadequate. They may be used with a face or laryngeal mask, or an endotracheal tube. Occasionally they are used to provide a high inspired O_2 concentration during spontaneous breathing; however, this may impose significant additional respiratory work.[53] In the ICU they are commonly used for preoxygenation and manual lung inflation.

Their basic design includes a fresh gas flow of O_2, a reservoir bag and valves to allow spontaneous or positive-pressure breathing. Most manual resuscitation circuits use a self-inflating reservoir bag since this allows the circuit to be used by unskilled personnel and does not require a fresh gas flow. However, circuits using reservoir bags that are not self-inflating are still used in some institutions since they allow a better manual assessment of the respiratory mechanics, the 'educated hand', and it is clear when there is an inadequate seal with a mask. Oxygen-powered manually triggered devices have been used for many years; however, their use has declined markedly since high $\dot{V}$ and P may lead to barotrauma or gastric inflation.

Self-inflating reservoir bags use a series of one-way valves to allow fresh gas flow oxygen and entrained air to fill the bag. Inspired oxygen fractions as high as 0.8 may be achieved with neonatal or paediatric bags when an additional reservoir bag is used to allow fresh gas flow filling during expiration, after the bag has refilled.[54] However, lower Fi_{O_2}s (~0.6) will be obtained with both conventional O_2 flow rates of 8–15 L/min, and usual V_T and f, with an adult bag. Generally, the valves are simple flap or duckbill in nature, and both positive pressure and spontaneous ventilation are possible. The reservoir bag volume in adults is typically 1600 mL, and V_T can be judged from chest wall movement. It is essential these devices use standard 15/22 mm connectors to allow rapid connection to standard endotracheal tubes and ventilator circuits.

COMPLICATIONS OF MECHANICAL VENTILATION

Although mechanical ventilation may be vital, it also introduces numerous potential complications (Box 31.2).[51] Monitoring includes a high nurse:patient ratio (usually 1:1), ventilator alarms, and pulse oximetry. Capnography is required to confirm endotracheal tube placement, both at the time of intubation and during ventilatory support, and may be used to monitor the adequacy of V_A; however, expired CO_2 is strongly influenced by factors that alter alveolar dead space such as cardiac output. Intermittent blood gases, $PEEP_i$, airway pressures in volume-preset modes and V_T in pressure-preset modes should be recorded. Individual patients may benefit from more extensive monitoring of their respiratory mechanics or tissue oxygenation.

The patient's airway (i.e. patency, presence of leaks and nature and amount of secretions), breathing (i.e. rate, volume, oxygenation), and circulation (i.e. pulse, blood pressure and urine output) must be monitored. Ventilatory and circuit alarms should be adjusted to monitor an appropriate range of V, P and temperature. This should alert adjacent staff to changes in P and/or V that may be caused by an occluded endotracheal tube, tension pneumothorax or circuit disconnection. These alarms may be temporarily disabled while the cause is detected, but never permanently disabled.

Box 31.2 Complications of intubation and mechanical ventilation[51]

Equipment
- Malfunction or disconnection
- Incorrectly set or prescribed
- Contamination

Pulmonary
- Airway intubation (e.g. damage to teeth, vocal cords, trachea; see Chapter 29)
- Ventilator-associated pneumonia (reduced lung defence; see Chapter 36)
- Ventilator-associated lung injury (e.g. diffuse lung injury due to regional overdistension or tidal recruitment of alveoli)
- Overt barotrauma (e.g. pneumothorax)
- O_2 toxicity
- Patient-ventilator asynchrony

Circulation
- ↓ Right ventricular preload →↓ cardiac output
- ↑ Right ventricular afterload (if the lung is overdistended)
- ↓ Splanchnic blood flow with high levels of positive end-expiratory pressure (PEEP) or mean P_{aw}
- ↑ Intracranial pressure with high levels of PEEP or mean P_{aw}
- Fluid retention due to ↓ cardiac output →↓ renal blood flow

Other
- Gut distension (air swallowing, hypomotility)
- Mucosal ulceration and bleeding
- Peripheral and respiratory muscle weakness (see Chapter 57)
- Sleep disturbance, agitation and fear (which may be prolonged after recovery)
- Neurocognitive complications

Sudden difficulties with either high P during volume-preset ventilation or oxygenation must initiate an immediate search for the cause. This should start with the patency of the airway, followed by a structured approach both to the circuit and ventilator, and to factors altering the E and R of the lung and chest wall such as bronchospasm, secretions, pneumothorax and asynchronous breathing. In addition to careful clinical examination, an urgent chest radiograph and bronchoscopy may be required.

Mechanical ventilation is also associated with a marked increase in the incidence of nosocomial pneumonia due to a reduction in the natural defences of the respiratory tract, and this represents an important advantage offered by NIV. In patients successfully managed with NIV, Girou and colleagues reported a reduction in the incidence of nosocomial pneumonia, associated with improved survival, compared to IV.[55] Erect versus semirecumbent posture[56] also reduces the incidence of ventilator-associated pneumonia.

Whereas lung overdistension may result in alveolar rupture leading to pulmonary interstitial air, pneumomediastinum or pneumothorax, it may also lead to diffuse alveolar damage similar to that found in ARDS. Both are termed VILI, and V_T reduction leads to a marked decrease in ARDS mortality due to a reduction in multiple organ dysfunction (see Chapter 33).[4] Laboratory data suggest that inadequate PEEP with tidal recruitment and derecruitment of alveoli also leads to VILI; however, this has not been proven in a clinical trial. Finally, patient-ventilator asynchrony may result in wasted respiratory work, impaired gas exchange and respiratory distress.

Positive-pressure ventilation elevates intrathoracic pressure, which reduces venous return, right ventricular preload and cardiac output. The impact is reduced by hypervolaemia, and partial ventilatory support where patient effort and a reduction in pleural pressure augments venous return. Secondary effects include a reduction in regional organ blood flow leading to fluid retention by the kidney, and possibly impaired hepatic function. This latter effect is seen only at high levels of PEEP where an increase in resistance to venous return and a reduction in cardiac output may combine to reduce hepatic blood flow.

Sleep disturbance, delirium and discomfort are common in mechanically ventilated patients. These effects may be reduced with analgesia and sedation until weaning is planned; however, it is also important not to prolong mechanical ventilation due to excessive use of sedatives, which may also depress blood pressure and spontaneous respiratory effort. A recent large clinical trial found no advantage of daily interruption of sedation over continuous infusion of sedation targeted to the lowest effective dose.[57] Both methods offer early mobilisation in ventilated subjects, shorter duration of ventilation, reduced delirium, ICU and hospital length of stay, and improved mortality and functional outcomes.[58,59] However, this direction must be balanced with strategies such as use of neuromuscular blockers in the first 48 hours of mechanical ventilation in ARDS, which reduced mortality,[60] which prevent or reduce asynchronous ventilatory effort.

Although pulmonary function has generally recovered by 12 months, complex neurocognitive and physical sequelae persist to at least 5 years in surviving ARDS patients.[61] Cognitive impairment has been associated with hypotension, hypoxaemia and hyperglycaemia. In addition, anxiety, depression and post-traumatic stress disorder are common and appear to be associated with the severity of illness, duration of mechanical ventilation and premorbid factors including depression. All of these issues are increasingly important as improvements in care and greater numbers of patients treated result in more survivors from critical illness. Of particular note, it appears that early interventions can be effective, but that late interventions fail to improve outcomes. For example,

physical therapy commenced a median of 7 days after initiation of mechanically ventilation for ARF failed to improve long-term physical function,[62] while much earlier intervention in post-surgical patients resulted in improved functional outcomes and reduced length of ICU and hospital stay.[63]

WITHDRAWAL (WEANING) FROM MECHANICAL VENTILATION

Once the underlying process necessitating mechanical ventilation has started to resolve, withdrawal of ventilatory support should be considered; increased duration of ventilation leads to a progressive rise in complications such as ventilator-associated pneumonia. However, other important parameters that must be considered include the neuromuscular state of the patient (ability to initiate a spontaneous breath), adequacy of oxygenation (typically low requirements for PEEP [5–8 cm H_2O] and Fi_{O_2} [<0.4–0.5]), and cardiovascular stability.[64] Once a patient is considered suitable to wean, a secondary question is whether an artificial airway is still required for airway protection or suction of secretions. Many patients can rapidly make the transition from mechanical ventilation to extubation, but ~20% of patients fail weaning despite meeting clinical criteria.[26] Advanced age, prolonged mechanical ventilation and chronic obstructive pulmonary disease all increase the likelihood that weaning will be difficult.[26]

Weaning failure is usually associated with an increase in respiratory drive, and respiratory rate and a fall in V_T, which contributes to hypercapnea[65]; about 10% of patients fail due to central respiratory depression. Various indices such as maximal inspiratory pressure (MIP), minute ventilation (V_E), f, V_T, f/V_T ratio and the dynamic compliance, respiratory rate, oxygenation, maximum inspiratory pressure (CROP) index have been investigated as predictors of weaning failure (Table 31.1). They are rarely used alone and careful clinical assessment is often adequate, yielding a re-intubation rate as low as 3%,[66] and none of these indices assess airway function following extubation. Although the typical threshold value for the rapid shallow breathing index (f/V_T ratio) is greater than 105, a large multicentre study reported progressive increase in risk as this increased with a threshold of 57; in addition, a positive fluid balance immediately prior to extubation was a significant risk factor for re-intubation.[67] Consequently, weaning indices should not necessarily delay extubation or a weaning trial. However, they may quantitate important issues in the general clinical assessment, and may be directly relevant for a given patient. For example, frequent small V_T, an inadequate vital capacity (less than 8–12 mL/kg), large minute ventilation (≥15 L/min), depressed respiratory drive, and reduced respiratory muscle strength (MIP ≤ –15 cm H_2O) or drive should be strongly factored into deciding whether a patient is ready to safely undergo a trial of weaning.

Table 31.1 Sample of measurements that have been used to predict successful outcome from weaning in critically ill patients

PARAMETER	TYPICAL THRESHOLD VALUE*	COMMENT
V_E	≤15 L/min	Moderate to high sensitivity, low specificity
MIP	≤–15 cm H_2O	High sensitivity, low specificity
CROP index†	≥13	Moderate to high sensitivity, modest specificity
DURING A SPONTANEOUS BREATHING TRIAL		
f	≤38 breaths/min	High sensitivity, low specificity
V_T	≥325 mL (4 mL/kg)	High sensitivity, low specificity
f/V_T	≤105	High sensitivity, moderate specificity

*Although threshold values are often used, the data are not dichotomous. For example, as the f/V_T ratio increases, so does the rate of re-intubation.[53]

†CROP index = $(C_{dyn} \times \text{MIP} \times [Pa_{O_2}/PA_{O_2}]/f)$.[22]

See reference 64 for further detail.

CROP, Compliance, respiratory rate, oxygenation, maximal inspiratory pressure; *MIP*, maximal inspiratory pressure.

Direct comparisons between T-piece trials, PSV and SIMV as weaning techniques have been performed in patients previously failing a 2-hour trial of spontaneous breathing. In the study by Brochard and colleagues,[68] PSV led to fewer failures and a shorter weaning period. In contrast, Esteban and coworkers[69] found that a once-daily trial of spontaneous breathing resulted in the shortest duration of mechanical ventilation; however, a relatively high proportion of patients required re-intubation (22.6%). Viewed together, these studies suggest that weaning was slower with SIMV,[26] although SIMV with PSV was not studied, and that either PSV or a T-piece trial are the preferred methods for weaning. Since low levels of PSV can help compensate for the additional work of breathing attributable to the endotracheal tube and circuit, some clinicians use low levels of PSV (5–7 cm H_2O) during weaning or during a spontaneous breathing trial. However, the work of breathing following extubation is usually higher than expected, probably due to upper airway oedema and dysfunction, so that work is similar to that during a T-piece trial.[26]

Re-intubation is relatively common, with reported rates of 15%, and is associated with a 7–11-fold increased risk of hospital death.[26] Although this may reflect extubation of sicker patients, there does appear to be a specific effect of extubation failure on outcome, perhaps due to the risks of re-intubation itself along with its haemodynamic consequences, and an increased risk of infection. Thille and co-workers[70] reported that 27% of patients developed pneumonia, and that 50% of patients died following re-intubation. They identified age greater than 65 years and underlying cardiorespiratory disease as risk factors for extubation failure. Unplanned extubations were associated with higher endotracheal tube position on chest radiograph. Hence, an important goal during mechanical ventilation will be to proceed to early and expeditious extubation with a low re-intubation rate.

PATIENT-VENTILATOR INTERACTION

During partial ventilatory support or spontaneous breathing, the ventilator should match neural drive; however, suboptimal patient-ventilator interaction, also termed asynchrony, is common, frequently not diagnosed and is associated with prolonged mechanical ventilation, increased length of stay both in hospital and in the ICU, and with increased mortality when more than 30% of breaths are asynchronous.[71] Clinical signs of asynchrony include agitation, diaphoresis, tachycardia, hypertension and failure of weaning or NIV. Once this pattern is identified, it is crucial that airway complications (partial obstruction, displacement) or a major change in the clinical state (e.g. pneumothorax, acute pulmonary oedema) are excluded before considering problems with patient-ventilator interaction.

Although both PAV and NAVA reduce asynchrony, they are complex and less commonly used. Recognition and management of asynchrony are assisted by a physiological approach to the respiratory cycle: (1) triggering of inspiration, (2) inspiration and (3) cessation of inspiration. Difficulties at each of these phases will lead to changes in respiratory drive and effort that may be expressed throughout the respiratory cycle. Careful bedside observation of the patient-ventilator interaction is essential, as isolated observation of P, V and $\dot{V}$ waveforms displayed by the ventilator leads to under-recognition of asynchrony. In one series[72] ineffective triggering accounted for most of the asynchronous episodes with autocycling the next most common cause. Prevalence of asynchrony increased with PSV ≥12 cm H_2O, large V_T and low respiratory rates in part reflecting dynamic hyperinflation and $PEEP_i$.

TRIGGERING OF INSPIRATION

1. $PEEP_i$ is an important hindrance to the triggering of inspiration in patients with severe air-flow limitation, since their inspiratory muscles must first reduce P_{ao} below ambient pressure.[73] Consequently, P_{mus} must exceed $PEEP_i$ prior to triggering an assisted breath, usually by either reducing airway pressure (pressure trigger) or reducing circuit flow (flow trigger). This inspiratory threshold load may be up to 40% of the total inspiratory work in ARF when dynamic hyperinflation is present, and commonly results in ineffective triggering. Triggering can be markedly improved and respiratory work reduced by low levels of $PEEP_e$,[73,74] commonly 80%–90% of dynamic $PEEP_i$[75] if this is measured.
2. Patient effort may be sensed, and the ventilator cycled (triggered) to inspiratory assistance, by changes in any of P_{ao}, flow, volume, shape-signal and detection of neural drive (NAVA). During pressure triggering a fall in P_{ao} is usually sensed at the expiratory block of the ventilator. Sensing at the Y-piece may not be superior since there can be a similar delay in sensing, as the transducer is usually sited in the ventilator (the usual position) and this demands a similar or greater length of gas tubing. Flow triggering senses a fall in continuous circuit flow, and was introduced as a method of reducing inspiratory work. However, there has been a marked improvement of both pressure and flow triggering in modern ventilators with the trigger time delay falling from ~400 ms to <60 ms in most modern ventilators,[76] and a similar improvement in the maximum fall in airway pressure[77]; consequently, ventilator triggering contributes about 5% of respiratory effort. Attempts to improve the trigger function by oversetting the pressure sensitivity (<–0.5 cm H_2O) may lead to autocycling, which may also occur with overset flow triggering. This is due to the P and $\dot{V}$ effects of cardiac oscillations, hiccups, circuit rainout or mask leak with NIV, and has been reported as a cause of apparent respiratory effort in brain-dead patients.[78] Flow triggering reduces the risk of autocycling at a given trigger sensitivity, and reduces respiratory effort a small amount compared with pressure triggering; however, it does not alter the frequency of ineffective efforts, or patient effort following triggering.[76] A combination of shape-signal and volume triggering is used on the Vision (Philips Respironics) ventilator; the increased sensitivity of shape-signal triggering reduces effort but increases autocycling.[76]

INSPIRATION

Once inspiration is triggered or sensed by the ventilator, $\dot{V}$ is determined by P, Ti or $\dot{V}$. For example, during PSV ventilation a target P is held until expiration is sensed, and during ACV $\dot{V}$ is held for a set T_i. During ACV there may be continued inspiratory effort, and since inspiratory $\dot{V}$ is fixed, this will be reflected by a scalloping of the P_{ao}–T graph if $\dot{V}$ is inadequate. Again this may be illustrated using the equation of motion:

$$P_{mus} + P_{ao} = E_{rs} \bullet V + R_{rs} \bullet \dot{V} + P_o \quad (31.9)$$

P_{mus} will reflect the difference between P_{ao} due to E, R and P_o and the observed P_{ao}. In contrast, during P-cycled ventilation (PACV) greater patient effort is rewarded and inspiratory work is lower than during equivalent ACV.[79]

Modern ventilators allow adjustment of inspiratory $\dot{V}$ and $\dot{V}$ pattern, and the rate of rise of P_{ao}. Low inspiratory $\dot{V}$ rates during ACV results in significant inspiratory work, but this may be markedly reduced by increasing inspiratory $\dot{V}$ to 65 L/min.[80] However, these issues are quite complex, and f increases (probably due to a lower respiratory tract reflex) as $\dot{V}_I$ increases,[81] reducing Te, which may contribute to dynamic hyperinflation in patients with severe air-flow obstruction. During PSV and PACV, many ventilators allow adjustment of the rate of rise of P to its target. Although an excessively steep P ramp leads to earlier attainment of the P target and greater early $\dot{V}$ rates, this is associated with increased dyspnoea and effort, as is too flat a P ramp.[76]

CESSATION OF INSPIRATION

During PSV, an increase in airway resistance will result in a longer expiratory time constant and a delayed fall in $\dot{V}_I$. Since this is the usual trigger for cycling to expiration, the ventilator may continue to provide $\dot{V}_I$ while the patient desires to exhale. This commonly leads to recruitment of expiratory muscles, detected both clinically and as a transient rise in the end-inspiratory P_{aO}.[82] Some modern ventilators allow control of the fall in $\dot{V}_I$ that is sensed as end inspiration; the default is usually a reduction of $\dot{V}_I$ to 25% of the peak $\dot{V}_I$ rate. When airway resistance is high, a higher cycling threshold (e.g. 45%) can reduce T_i, V_T and $PEEP_i$ with reduced trigger effort. However, this may result in premature termination of inspiration in ARDS where the time constant is short. High levels of PSV (≥20 cm H_2O), weak respiratory muscles and mask leak with NIV are other common causes of asynchrony at the termination of inspiration. In this last group, PACV, which is time cycled, allows improved patient-ventilator synchrony at end-inspiration compared with PSV.[83]

High V_T, commonly associated with high levels of PSV, often precedes wasted efforts due to shortened T_e and $PEEP_i$. As asynchrony is reduced with less PSV, the optimum level of PSV will occur when there is minimal increase in f and P_{mus}. This typically occurs at a PSV of 13 cm H_2O with V_T 6 mL/kg and T_i 0.8 seconds.[84]

Humidifiers and inhalation therapy

Steven T Galluccio, Andrew D Bersten

The upper airway normally warms, moistens and filters inspired gas. When these functions are impaired by disease or when the nasopharynx is bypassed by endotracheal intubation, artificial humidification of inspired gases must be provided.

PHYSICAL PRINCIPLES

Humidity, the amount of water vapour in a gas, may be expressed as:

- *absolute humidity (AH):* the total mass of water vapour in a given volume of gas at a given temperature (g/m^3)
- *relative humidity (RH):* the actual mass of water vapour (per volume of gas) as a percentage of the mass of saturated water vapour, at a given temperature. Saturated water vapour exerts a saturated vapour pressure (SVP). Because the SVP has an exponential relation with temperature (Table 32.1), addition of further water vapour to the gas can occur only with a rise in temperature
- *partial pressure.*

PHYSIOLOGY

Clearance of surface liquids and particles from the lung depends on beating cilia, airway mucus and transepithelial water flux. Airway mucus is derived from secretions from goblet cells, submucosal glands and Clara cells and from capillary transudate. Conducting airways are lined with pseudostratified, ciliated columnar epithelium and numerous fluid-secreting glands. As the airway descends, the epithelium becomes stratified, and then cuboidal and partially ciliated, with very few secretory glands at the terminal airways. The cilia beat in a watery layer (sol) over which is a viscous mucus layer (gel), and move a superficial layer of mucus from deep within the lung towards the glottis (at a rate of 10 mm/min at 37°C and 100% RH). Both cilia function and mucus composition are influenced by temperature and adequate humidification.

The nasal mucosa has a large surface area with an extensive vascular network that humidifies and warms inhaled gas more effectively than during mouth breathing. Heating and humidification of dry gas are progressive down the airway, with an isothermic saturation boundary (i.e. 100% RH at 37°C or AH of 43 g/m^3) just below the carina.[1] Under resting conditions, approximately 250 mL of water and 1.5 kJ (350 kcal) of energy are lost from the respiratory tract in a day. A proportion (10%–25%) is returned to the mucosa during expiration due to condensation.

The minimal moisture level to maintain ciliary function and mucus clearance is uncertain. Although reproducing an isothermic saturation boundary at the carina may be ideal, it does not seem essential in all situations. Mucus flow is markedly reduced when RH at 37°C falls to less than 75% (AH of 32 g/m^3), and ceases when RH is 50% (AH of 22 g/m^3).[2] This suggests that an AH exceeding 33 g/m^3 is needed to maintain normal function. Mucociliary function is also impaired by upper respiratory tract infection, chronic bronchitis, cystic fibrosis, bronchiectasis, immotile cilia syndrome, dehydration, hyperventilation, general anaesthetics, opioids, atropine and exposure to noxious gases. High fractional inspired oxygen concentrations (Fi_{O_2}) may lead to acute tracheobronchitis, with depressed tracheal mucus velocity within 3 hours.[3] Inhaled β_2-adrenergic agonists increase mucociliary clearance by augmenting ciliary beat frequency, and mucus and water secretion.[4]

CLINICAL APPLICATIONS OF HUMIDIFICATION

TRACHEAL INTUBATION

The need for humidification during endotracheal intubation and tracheostomy is unquestioned. As the upper airway is bypassed, RH of inspired gas falls to less than 50% with adverse effects, including[5]:

- increased mucus viscosity
- depressed ciliary function
- cytological damage to the tracheobronchial epithelium, including mucosal ulceration, tracheal inflammation and necrotising tracheobronchitis[6]
- microatelectasis from obstruction of small airways, and reduced surfactant leading to reduced lung compliance

ABSTRACT

The adequate conditioning of inhaled gases and the effective delivery of therapeutic aerosols are both routine but vitally important aspects of managing critically ill patients. These issues can be tackled from a variety of approaches, with different types of humidifiers and aerosol generators and differing indications and modes of implementation. Surprisingly, there is often a lack of high-quality data to guide practice. Furthermore, despite being core business, knowledge of these facets amongst critical care physicians appears to be lacking, and guidelines when available and supported by evidence are not commonly implemented. Ongoing research is needed to further clarify how to best to apply these components of critical care medicine.

37	47.1	6.3	43.4
40	55.3	7.4	51.7
46	78.0	10.4	68.7

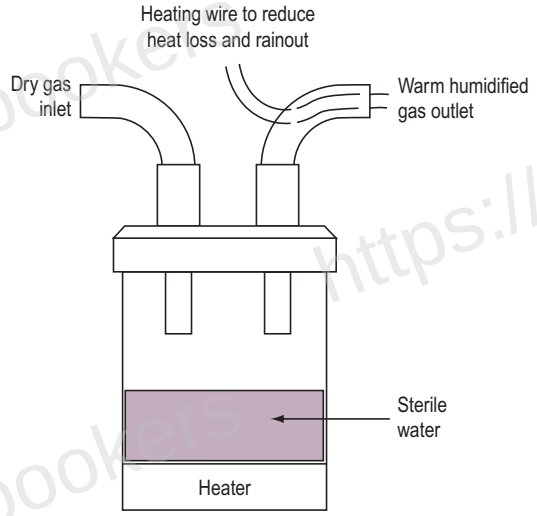

Figure 32.1 Hot-water 'blow-by' humidifier.

- airway obstruction due to tenacious or inspissated sputum with increased airway resistance.

Metaplasia of the tracheal epithelium occurs over weeks to months in patients with a permanent tracheostomy. These patients do not usually require humidified gas, suggesting that humidification occurs lower down the respiratory tree. Nevertheless, humidification of inspired gas may be needed during an acute respiratory tract infection.

HEAT EXCHANGE

The respiratory tract is an important avenue to adjust body temperature by heat exchange. Humidification of gases reduces the fall in body temperature associated with anaesthesia and surgery.[5] Excessive heat from humidification may produce mucosal damage, hyperthermia and overhumidification.[7] However, if water content is not excessive, mucociliary clearance is unaffected up to temperatures of 42°C. Overhumidification may increase secretions and impair mucociliary clearance and surfactant activity, resulting in atelectasis.[6]

IDEAL HUMIDIFICATION

The basic requirements of a humidifier should include the following features[8]:

- the inspired gas is delivered into the trachea at 32°C–36°C with a water content of 30–43 g/m^3
- the set temperature remains constant and does not fluctuate
- humidification and temperature remain unaffected by a large range of fresh gas flows, especially high flows
- the device is simple to use and to service
- humidification can be provided for air, oxygen or any mixture of inspired gas, including anaesthetic agents
- the humidifier can be used with spontaneous or controlled ventilation
- there are safety mechanisms, with alarms, against overheating, overhydration and electrocution
- the resistance, compliance and dead space characteristics do not adversely affect spontaneous breathing modes
- the sterility of the inspired gas is not compromised.

METHODS AND DEVICES

WATER-BATH HUMIDIFIERS

Inspired gas is passed over or through a water reservoir to achieve humidification. Their efficiency is dependent on ambient temperature and the surface area available for gas vaporisation.

Cold-water humidifiers

These units are simple and inexpensive but are inefficient, with a water content of approximately 9 g/m^3 (i.e. approximately 50% RH at ambient temperatures). They are also a potential source of microbiological contamination. Routine use of cold-water humidifiers to deliver oxygen with simple face masks is both unnecessary and at risk of suggesting the gas is adequately humidified.

Hot-water humidifiers (Figs 32.1 and 32.2)

Inspired gas is passed over (blow-by humidifier) or through (bubble or cascade humidifier) a heated-water reservoir. Gas leaving the reservoir theoretically contains high water content. The water-bath temperature is thermostatically controlled (e.g. at 45°C–60°C) to

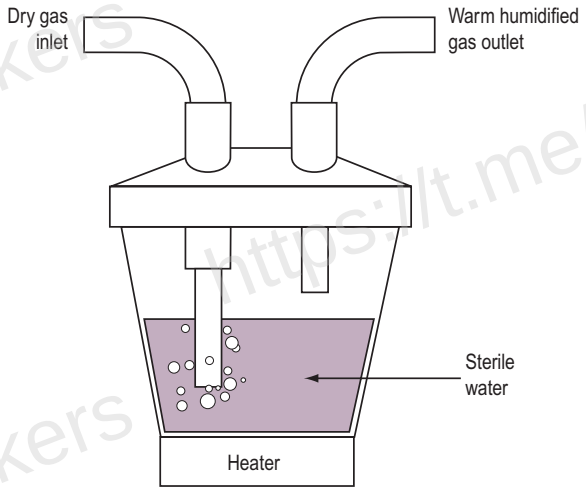

Figure 32.2 Hot-water 'cascade' or 'bubble' humidifier.

compensate for cooling along the inspiratory tubing targeting an inspired RH of 100% at 37°C. A heated wire may be sited in the inspiratory tubing to maintain preset gas temperature and humidity. It is commonly believed that hot-water humidifiers do not produce aerosols, but microdroplets (mostly less than 5 µm diameter) have been reported with bubble humidifiers,[9] and this may be a potential source of infection.

Fisher–Paykel humidifier This is a commonly used blow-by humidifier. The delivery hose is heated by an insulated heating wire to achieve a manual preset inspired temperature. Audible alarms indicate disconnection and variations greater than 2°C from the set delivery temperature. The heater base is protected from overheating by a thermostat set at 47°C. If this fails, another safety thermostat operates at 70°C. A disposable humidification chamber is filled manually with water or by a gravity-feed set. To minimise rainout, the chamber outlet can be set at a temperature less than the delivery hose outlet temperature; 2°C–3°C is usually adequate and does not compromise RH. Temperature alarms are fixed at 41°C and 29.5°C, with a back-up safety set at 66°C for the delivery chamber.

Although these humidifiers are often regarded as providing optimal humidification in ventilated patients, their performance is lower than expected both in practice and under optimal conditions in bench studies.[10] Under conditions of high ambient and/or high ventilator output temperature, the inlet temperature to the humidification chamber can be high enough that the heater base operates at a low enough temperature that humidification is impaired, with reduction in inspired water content.[10] The automatic compensation now available on this humidifier helps to compensate for poor performance, which can also be prevented by setting the chamber outlet and hose to 40°C. High minute ventilation is well tolerated, but a small decrease in water content output has also been found with higher respiratory rates.[11]

HEAT AND MOISTURE EXCHANGERS

Heat and moisture exchangers (HMEs) are popular intensive care unit (ICU) humidifiers due to their simplicity and increased efficiency. Modern HMEs are light with a small dead space (30–95 mL) but show great heterogeneity in humidity output, often not matching manufacturer-claimed performance.[12]

Hygroscopic HMEs adsorb moisture on to a foam or paperlike material that is chemically coated (often calcium chloride or lithium chloride), and this tends to increase their efficiency (i.e. AH approximately 30 g/m^3) compared with hydrophobic HMEs (i.e. AH 20–25 g/m^3).[13-18] Such hydrophobic HMEs possess antimicrobial properties and may act as a microbial filter (HME filter or 'HMEF'). These filters can have efficiencies greater than 99.9977%[19] (i.e. less than 23 out of 1 million bacteria will pass through; filters that can exclude all virus particles are not currently available). Modern HMEs include both hydroscopic and hydrophobic properties (Fig. 32.3). However, because nosocomial pneumonia is primarily due to aspiration of oropharyngeal secretions followed by secondary ventilator tubing colonisation, HMEs have not been shown to reduce the frequency of nosocomial pneumonia more than hot-water humidifiers when compared during prolonged ventilation.[19-21]

The efficiency of older HMEs decreases with time[11]; however, modern HMEs may retain their ability to humidify for prolonged periods with minimal change in resistance (a measure of tube patency and thus adequacy of humidification).[22,23] In patients undergoing invasive ventilation for a mean duration greater than 1 week, there was no difference in endotracheal tube resistance between HME and active humidification.[23] However, allocation of humidification device was not randomised but based on perceived clinical need. Consequently, HMEs that achieve relatively high AH may be suitable for long-term mechanical ventilation in selected patients, particularly because the majority of reported HME complications (e.g. thick secretions and endotracheal tube occlusion) occur with units of lower humidification levels.[24-26] Nevertheless, HMEs increase dead space and imposed work of breathing and cannot match the humidification offered by hot-water humidifiers, which remain the gold standard, particularly if secretions are thick or bloody or minute ventilation is high[16,19,27] or in children and neonates.

COMPLICATIONS OF HUMIDIFICATION

INADEQUATE HUMIDIFICATION

An AH exceeding 30 g/m^3 is recommended in respiratory care.[27] Inadequate humidification is usually a problem only with HMEs. However, with hot-water

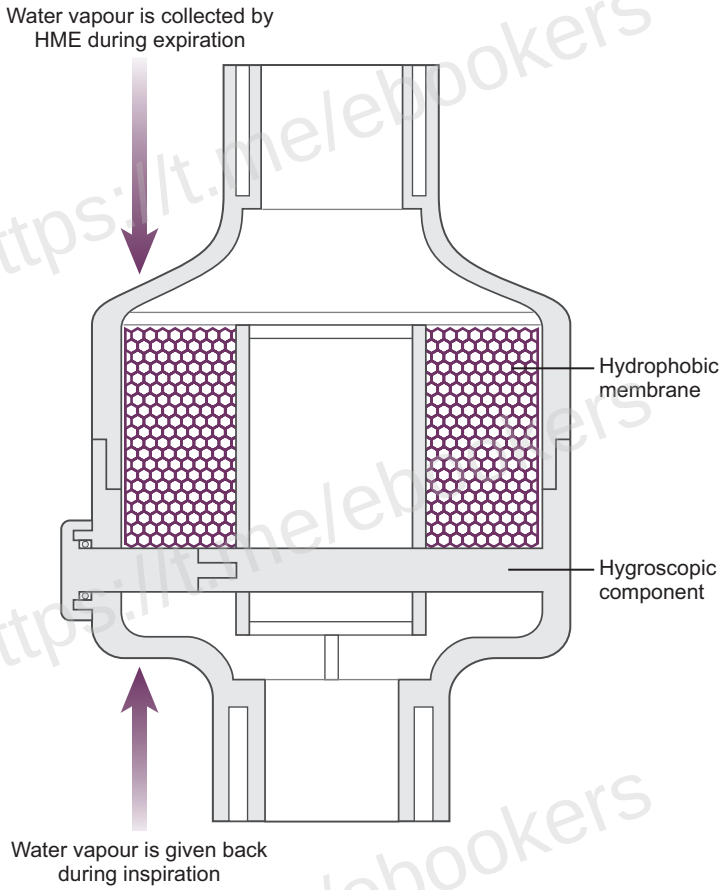

Figure 32.3 Schematic representation of a heat and moisture exchanger (HME). *Adapted from Al Ashry HS, Modrykamien AM. Humidification during mechanical ventilation in the adult patient.* Biomed Res Int. *2014;2014:715434.*

humidifiers, efficiency is reduced by increasing gas flow rates and rainout. A decrease of approximately 1°C occurs for each 10 cm of tubing beyond the end of the delivery hose (i.e. the Y-connector and right-angled connector) and should be catered for. Inadequate humidification in high-frequency ventilation can be overcome by using superheated humidification of the entrained gas with a temperature thermistor built into the endotracheal tube.[24,28]

OVERHUMIDIFICATION

Overheating malfunction of hot-water humidifiers may cause a rise in core temperature, water intoxication, impaired mucociliary clearance and airway burns.[7]

IMPOSED WORK OF BREATHING

The work of breathing imposed by a humidifier is primarily resistive work and increases with inspiratory flow rate; the progressive increase in water content of HMEs is also associated with increased resistance.[29] The Fisher–Paykel humidifier imposes relatively low work compared with a bubble humidifier,[30] and HMEs typically have a resistance of 2.5 cm H_2O/L per second.[16]

INFECTION

Humidifiers do not appear to be an important factor in nosocomial respiratory tract infection. Although water reservoirs represent a good culture medium for bacteria such as *Pseudomonas* species, it is rare to culture bacteria from humidifiers and is usually preceded by colonisation of the circuit by the patient's own flora within the first 24 hours of use.[31,32] Indeed the incidence of nosocomial pneumonia is reported to be higher (due to outside contamination) if the circuit is changed frequently (every 24 or 48 hours).[32,33]

HUMIDIFICATION DURING NON-INVASIVE VENTILATION

The hygrometric effects of non-invasive ventilation (NIV) depend upon several factors, including the type

of ventilator (conventional versus turbine), patient–ventilator interface, V_T, peak inspiratory flow rates, Fi_{O_2}, degree of mask leak and even ambient room temperature.[34-36] NIV applied without artificial humidification has been associated with accumulation of dried secretions in the oropharynx with subsequent aspiration, difficult intubation or frank airway obstruction.[37] In healthy volunteers a delivered AH of at least 15 mg H_2O/L was necessary to ensure comfort during NIV.[38] This level is achievable with either passive or active humidification, but in patients with acute respiratory failure, a higher humidity output may be required. Furthermore, the increased dead space and work of breathing associated with HMEs may be undesirable in these situations.[36] Acknowledging the lack of robust data, current guidelines suggest the use of heated humidification over HMEs.[27]

HUMIDIFICATION FOR OXYGEN THERAPY DURING SPONTANEOUS BREATHING

Despite the ubiquity of oxygen therapy, there is no evidence to guide the addition of humidification for spontaneously breathing patients. No discrete oxygen flow rate or duration of exposure mandates artificial humidification. However, even with flow rates of ≤15 L/min, patient discomfort during oxygen therapy is ameliorated with the use of heated humidification compared with bubble humidifiers or no artificial humidification at all.[39,40] Yet, it is unknown to what extent patient discomfort signals inadequate humidification and the potential for complications such as deranged mucociliary transport or increased airway resistance. An emerging relevant trend is the use of 'high-flow nasal cannula (HFNC) therapy', whereby significantly higher rates of gas flow, typically at 30–60 L/min, are delivered via nasal cannulae.[41,42] In this context, heated humidification is always recommended.

INHALATION THERAPY

Therapeutic aerosols are particles suspended in gas that are inhaled and deposited within the respiratory tract. Numerous factors, including particle size, inertia and physical nature, gravity, volume and pattern of ventilation, temperature and humidity, airway geometry, lung disease and the delivery system, alter aerosol deposition. In general, particles of diameter 40 µm deposit in the upper airway, those of 8–15 µm deposit in bronchi and bronchioles, those of 3–5 µm deposit in peripheral conducting airways and those of 0.8–3.0 µm settle in lung parenchyma. Optimal particle size will depend on the clinical indication and agent used. Obviously, if an HME with filtration characteristics is being used, the aerosol needs to be delivered proximal to the filter. Clinical efficacy of newer HME designs incorporating the facility for aerosol delivery remains to be quantified.[43]

AEROSOL DELIVERY

Therapeutic aerosols may be delivered by nebuliser (jet, ultrasonic or vibrating mesh), pressurised metered-dose inhaler (pMDI) or dry-powdered inhaler (DPI). Although each of these methods tends to be less efficient in ventilated patients, provided that care is taken to optimise their performance, each can provide equivalent clinical effect. Despite being commonly used in the ICU, literacy around aerosol therapy appears low amongst intensive care physicians.

NEBULISERS

The most common jet nebulisers are sidestream nebulisers. These use an extrinsic gas flow through a narrow orifice, to create a pressure gradient that draws the drug mixture from a liquid reservoir (i.e. Bernoulli principle; Fig. 32.4). The gas is then directed at a baffle to reduce the mean particle size. This extrinsic gas flow (usually 3–10 L/min) adds to the inspiratory flow and may increase patient tidal volume unless the ventilator automatically compensates or the preset tidal volume is adjusted. Furthermore, this additional gas flow may impair ventilator triggering because it may prevent the development of a negative pressure or necessary reduction in continuous flow needed. Mainstream nebulisers use inspiratory gas flow to actuate nebulisation. These are commonly large-volume water nebulisers that entrain air to achieve fresh gas flow rates of 20–30 L/min.

Ultrasonic nebulisers use high-frequency sound waves (typically 1 MHz) to create an aerosol above a liquid reservoir, to produce small uniform droplets (<5 µm) and a high mist density (i.e. 100–200 g/m^3). Tidal volume is not altered; however, ultrasonic nebulisers may cause overhydration and increased airway resistance. Further drawbacks in the critical care setting include size, poor battery life and the potential for drug inactivation by ultrasonic waves and heating.[44,45]

More recent nebuliser designs have used a vibrating mesh or plate. Medication in solution or suspension is forced through multiple apertures in the mesh or plate to produce an aerosol. A variety of vibrating mesh nebulisers are commercially available; common features include aerosol generation with high fine-particle fraction and overall higher drug output with minimal residual volume compared with jet nebulisers; additional benefits over ultrasonic types are the lack of heating effect or potential for drug degradation.[44] A comparison of the features of aerosol generators is shown in Table 32.2.

Nebuliser aerosol deposition is highly variable, with significant rainout in the ventilatory circuit, endotracheal tube and large conducting airways. In a bench study, delivery ranged from 6% of nebuliser charge to 37% depending upon humidification and breath activation; parallel in vivo data were similar but found a 20-fold difference in drug delivery.[47] Numerous factors

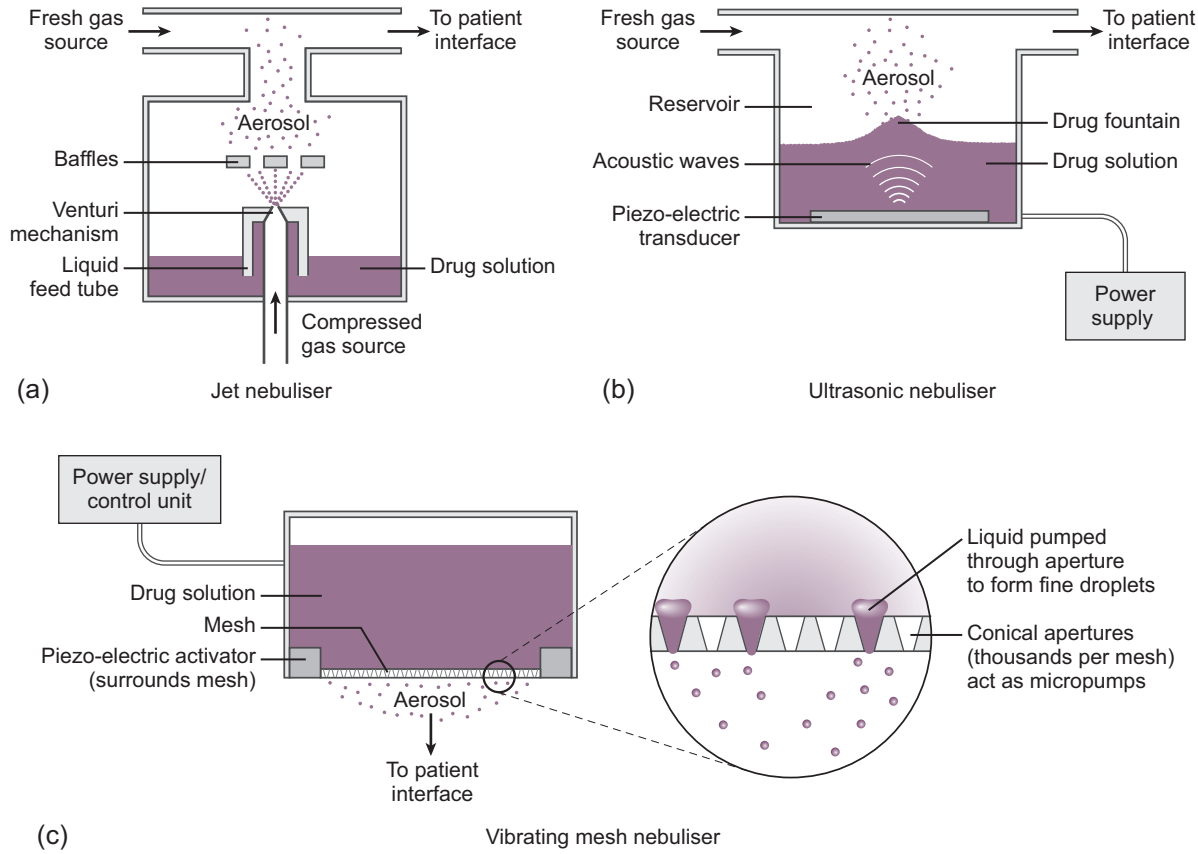

Figure 32.4 Schematic representation of nebuliser design (a) jet nebuliser, (b) ultrasonic nebuliser and (c) vibrating mesh nebuliser. *Yeo LY, Friend JR, McIntosh MP, et al. Ultrasonic nebulization platforms for pulmonary drug delivery.* Expert Opin Drug Deliv. *2010;7(6):663–679.*

have been shown to improve aerosol deposition, but only some of these are commonly practiced (Table 32.3). For example, although heating and humidification reduce aerosol deposition approximately 50% due to increase in both droplet size and rainout, regular circuit disconnection and exclusion of humidification prior to nebulisation are not practical. The position of the aerosol generator within the ventilator circuit also effects aerosol delivery. Vibrating mesh and ultrasonic nebulisers, as well as pMDIs, are most efficient when placed in the inspiratory limb of the circuit approximately 15 cm from the Y-piece.[50] Jet nebulisers function more efficiently when placed closer to the inspiratory port of the ventilator (further from the Y-connector), allowing the tubing to act as a spacer or aerosol-holding chamber. Inspiratory activation of the nebuliser increases deposition by twofold and threefold under dry and humidified conditions, respectively[45]; use of a large chamber fill, tidal volume of 500 mL or more and minimisation of turbulent inspiratory flow (low flow rate, prolonged inspiratory time) also augment aerosol delivery.[40]

METERED-DOSE INHALERS

pMDIs contain drug in ethanolic solution with a hydrofluoroalkane (HFA) propellant, allowing a relatively fixed volume (i.e. dose) to be delivered with each actuation (e.g. 100 µg for salbutamol and 20 µg for ipratropium).[44,51] Aerosol delivery is approximately 4%–6% in ventilated adults but increases to 11% when a spacer chamber is used, which is similar to optimal no-spacer values reported in the ambulant population.[52] Similar to nebulisers, absence of humidification, inspiratory limb position, inspiratory activation and minimisation of turbulence by lowering inspiratory flow rate and prolonging inspiratory time will increase aerosol delivery. It is important to avoid use of an elbow adapter because this has been associated with dramatic reductions in aerosol delivery and efficacy.

DRY-POWDERED INHALERS

DPIs are commonly used in ambulant practice. Their use is not recommended in patients undergoing mechanical ventilation because they are breath actuated (requiring inspiratory flow rates close to 60 L/

Table 32.2 Aerosol generator characteristics

min) and, moreover, circuit humidification can cause powder clumping with impeded aerosol formation.[53]

CLINICAL APPLICATIONS OF INHALATION THERAPY

HUMIDIFICATION

Humidifiers produce gas with a water content dictated by temperature and water vapour pressure, whereas nebulisers produce gas with a water content determined by the aerosol content. The latter can provide water to the respiratory tract, particularly if the water reservoir is heated to increase mist density. However, the risk of infection is increased because droplets can carry bacteria to the alveoli. Consequently, only sterile water should be used to fill the reservoir, and all units should be regularly changed and sterilised.

MUCOLYTICS

N-acetylcysteine and other thiol derivatives such as carbocysteine and erdosteine have the ability to liquefy mucus by directly severing disulfide bridges in mucoproteins and DNA. In outpatients with chronic obstructive pulmonary disease (COPD), particularly in those not receiving inhaled corticosteroids, these mucolytic agents result in a very modest reduction in COPD exacerbations and improved quality of life.[54,55] Notably, these clinical trials have used oral formulations of these agents because inhalational administration can induce bronchospasm. Underway currently is a multicentre trial of nebulised *N*-acetylcysteine (in conjunction with salbutamol) in invasively ventilated ICU patients.[56] Case reports of recombinant human DNase (dornase alfa) appear promising when standard regimens fail to clear thick secretions,[52] but the main evidence base for DNase utility is limited to bronchiectasis specifically due to cystic fibrosis.[57,58]

BRONCHODILATOR THERAPY

Optimal aerosol delivery and bronchodilator response are extremely important in critically ill patients with severe airflow limitation; this can be achieved using either a nebuliser or pMDI technique, provided that care is taken to optimise performance. For mechanically ventilated patients, there is currently no evidence to recommend one device type over another.[59] Efficacy of pMDI administration is improved by use of a spacer with actuation synchronised with the onset of inspiration.[44] The response can be judged clinically, and in ventilated patients monitored by changes in peak-to-plateau airway pressure gradient, calculated airways resistance and intrinsic positive end-expiratory pressure (PEEP). Numerous studies show effective bronchodilatation with β_2-agonists and anticholinergic

Table 32.3 Factors favouring effective aerosol delivery

Ventilator settings	Lower flow rate (30–50 L/min ideal) Long inspiratory time Higher PEEP Larger tidal volume (≥500 mL) Lower bias-flow Breath-actuated mechanism
Circuit factors	Larger endotracheal or tracheostomy tube better Delivery *without* humidification better (i.e. remove HME; turn off heated humidification 10 min prior to therapy) Preferred positioning of aerosol generator (during invasive mechanical ventilation): VMN, USN, pMDI: inspiratory limb, 15 cm from Y-piece Jet nebuliser: inspiratory limb, 15 cm from ventilator outlet Preferred positioning of aerosol generator (during NIV): Close to patient interface Driving gas: potentially increased peripheral deposition with heliox
Drug factors	Particle size 2–5 μm more likely to deposit further in respiratory tract
Patient factors	Ensure clear and patent airway
Type of aerosol generator	See Table 32.2 Nebulisers allow for continuous and potentially greater cumulative aerosol delivery For pMDIs, shake and warm to hand temperature prior to use

agents such as ipratropium in ventilated patients, and their combination is more effective than a single agent alone.[52] For non-obstructive pulmonary conditions, including acute respiratory distress syndrome (ARDS), routine use of inhaled bronchodilators is not beneficial and has been associated with increased harm.[60,61]

Bronchodilator dosing

Standard doses of salbutamol for acute asthma are 2.5–5 mg administered by a nebuliser or 4–6 puffs of a pMDI (400–600 μg), but the bronchodilator response can be shorter lasting than in ambulatory subjects. Consequently, dosing should be 3–4 hourly. Ipatropium is usually administered as 0.5 mg by a nebuliser or four puffs (80 μg) of a pMDI. Higher or more frequent drug dosing is often effective when there is severe, reversible airflow obstruction, and continuous nebulisation of a β_2-agonist may be used in acute severe asthma until there has been a clinical response. If the patient is moribund with minimal ventilation or is unable to tolerate nebulisation, parenteral administration should be considered; however, under most circumstances, there is no particular benefit with this route.[62]

NON-INVASIVE VENTILATION

There is no requirement to interrupt NIV to administer inhaled bronchodilator therapy. Both nebulisers and pMDIs appear effective during NIV, although in this context, ultrasonic nebulisers are associated with greatest drug loss.[52,63-65] In contradistinction to invasive mechanical ventilation, optimal positioning of the aerosol generating device in a single-limb NIV circuit appears to be closer to the patient interface and distanced from the ventilator (i.e. between the mask and the leak port).[64]

HIGH-FLOW NASAL CANNULAE

There is very little evidence to guide aerosol delivery during HFNC. It is likely that at high gas flows, significant amounts of drug are lost both through impaction in the circuit and directly to the atmosphere,[64] but a successful approach has been described in a bench study.[66]

INHALED CORTICOSTEROIDS

Inhaled corticosteroids are recommended in moderate persistent asthma[67] and in COPD when associated with frequent exacerbations or persistent symptoms despite use of long-acting inhaled bronchodilators.[68] However, in acute episodes of these conditions, inhalational delivery does not preclude the need for systemic corticosteroid therapy.[69] Small-particle inhaled corticosteroids offer the theoretical benefit of improved total and peripheral lung distribution.[70] HFA-propelled ciclesonide, flunisolide and beclomethasone dipropionate all have mass median aerodynamic diameters (particle size) of less than 2 μm.[70,71] Emerging data would suggest that clinical efficacy is at least equivalent to larger-particle formulations with potential benefits of lower dosing and less adverse effects. Data in mechanically ventilated patients remain to be demonstrated.

DELIVERY OF ANTIBIOTICS AND ANTIVIRAL AGENTS

With clinical experience spanning many decades, aerosolised antibiotics have entered a renaissance. International surveys suggest that inhaled antibiotic use is common in ICU patients undergoing mechanical ventilation,[72] and several reviews of the topic have recently been published.[73-79] The main driver of this renewed interest has been the emergence of multidrug-resistant (MDR) pathogens. Albeit contentious, pulmonary delivery of antibiotics has theoretical benefits of achieving high tissue concentration at the site of infection while minimising systemic adverse effects. A further consideration is that in patients with

purulent secretions, antibiotic concentrations may need to exceed 10–25 times the minimum inhibitory concentration to be effective.[80]

The argument for inhaled antibiotics is most appealing for aminoglycosides and polymixins. These antibiotic classes exhibit concentration-dependent bactericidal effect and have significant systemic toxicities and are perhaps the best studied agents in this context. In humans, gentamicin by conventional intravenous dosing has been shown to reach only subinhibitory concentrations in the alveolar lining fluid.[81] In animal models of bronchopneumonia, inhaled amikacin achieved 3- to 30-time increases in lung tissue concentrations and better sterilisation of lung compared with intravenous administration.[82]

Inhaled tobramycin is strongly recommended in patients with cystic fibrosis and chronic *Pseudomonas aeruginosa* infection, due to its association with improvement in several clinically relevant end points, such as improved lung function per spirometry, improved quality of life and decreased exacerbation frequency and hospitalisation rates.[83-85] Similar benefit has been demonstrated with aztreonam, with lesser evidence for colistin.[76]

For the intensivist, a broader question goes to the role of inhaled antibiotics in treating ventilator-associated pneumonia (VAP) and ventilator-associated tracheitis (VAT). Improved clinical cure rates have been found with nebulised gentamicin[86] and colistin.[78,87] The presumption of emerging bacterial resistance with increased aerosolised antibiotic use, akin to the known risk with systemic delivery, is not confirmed by the available data. Paradoxically, emergence of resistance may be reduced via higher pathogen eradication rates, earlier intervention in treating VAT and reduced exposure to systemic therapy.[88]

However, overall the data suffer from methodological heterogeneity and small patient numbers. The described dosing in VAP (total daily amount) varies widely amongst studies: gentamcin (240–320 mg), colistin (75–300 mg) and amikacin (200–1200 mg). Moreover, there is little consistency in factors known to affect aerosol delivery, such as aerosol generator type or set ventilator parameters. Two systematic reviews of inhaled antibiotics in VAP (with or without combined parenteral antibiotics) have not shown definitive benefit.[75,77] A pragmatic approach is taken by the Infectious Diseases Society of America and American Thoracic Society Guidelines, which state that for patients with VAP due to MDR Gram-negative bacilli (susceptible only to aminoglycosides or polymyxins) both inhaled and systemic antibiotics are recommended, rather than systemic antibiotics alone.[89] It is also considered reasonable to add inhaled antibiotics for patients deteriorating despite appropriate parenteral therapy, even if the organism in not identified as MDR.[89] This rationale places preferential weighting of the potential benefits in these high-risk patient populations against any potential adverse effects. The same guidelines do not extend this recommendation to the treatment of VAT.[89] It should be noted that rarely, and ironically, even systemic adverse effects may result from inhaled administration.[79]

Other antimicrobials that have been safely nebulised include vancomycin, ceftazdime, fluoroquinolones and pentamidine. Inhaled amphotericin B may have a role in treating and preventing invasive fungal disease in select immunosuppressed patients (such as those with haematological malignancy or lung transplantation) but may result in bronchospasm. Aerosolised ribavirin has limited evidence of benefit for respiratory syncytial virus infection[90,91] but may have a significant role specifically in adult hematopoietic stem cell transplant recipients.[92] Ribavirin deposition in the circuit may cause valve malfunction, and concerns of teratogenicity in health care personnel have dictated its use with care.[91] Inhaled zanamivir is associated with reduced duration of illness with influenza infections but can also cause bronchospasm.[93] However, the inhalational powder is not recommended for nebulisation or use in mechanically ventilated patients due to potential for obstruction of the ventilator expiratory filter.[94]

SPUTUM INDUCTION

Hypertonic nebulised saline (typically as 3% solution) is effective in sputum induction for diagnosing *Pneumocystis jiroveci* pneumonia in patients with the acquired immunodeficiency syndrome. The need for bronchoscopy can be obviated,[95] with specificity of sputum induction approaching 100% and sensitivity of at least 55%.[96] Similar benefits are noted for diagnosis of pulmonary tuberculosis.[97] Sputum induction has been used to diagnose a number of other infections and appears to be safe in patients with severe airflow limitation.[98] In any case the procedure should be performed by trained personnel with appropriate personal and environmental protection.

SURFACTANT THERAPY

Surfactant preparations have been delivered by instillation and as an aerosol in neonates with respiratory distress syndrome and in adults with ARDS. Aerosolised surfactant can theoretically achieve more uniform distribution and avoid problems of instilling liquid into injured lungs. However, large amounts are needed for lung deposition, and preferential distribution occurs to less-damaged lung areas that receive better ventilation.[99] Unfortunately, clinical studies of exogenous surfactant in adult ARDS have not shown any mortality benefit and may be associated with excess harm.[100]

INHALED NITRIC OXIDE

The therapeutic potential of inhaled nitric oxide (iNO) lies as a selective pulmonary vasodilator with minimal systemic side effects. iNO improves outcomes in newborns with persistent pulmonary hypertension and

severe hypoxaemia, reducing the need for extracorporeal membrane oxygenation.[101] In adult patients with ARDS, iNO results in an improvement in oxygenation in approximately 60%–80% of patients, with a 10% reduction in pulmonary arterial pressure.[102] However, these physiological gains have not translated into benefits on mortality or duration of mechanical ventilation.[103] iNO is effective in assessment of pulmonary vasoreactivity, but practical difficulties and a lack of long-term safety data limit its application in the ongoing treatment of pulmonary arterial hypertension. Despite a lack of high-level evidence, iNO can be effective in salvaging a failing right ventricle in the setting of pulmonary hypertension. Potential adverse effects, in high doses, include methemoglobinemia, renal injury, direct pulmonary toxicity and, if stopped abruptly, rebound pulmonary hypertension.[103] Rapid deterioration following initiation of iNO might imply venoocclusive disease as the aetiology for the underlying pulmonary hypertension.

PROSTANOIDS

Inhaled prostanoids follow a similar pharmacological rationale to iNO. By selective pulmonary vasodilatation to well-aerated areas, similar improvements in oxygenation as iNO are achieved in patients with the ARDS.[104,105] Iloprost (a synthetic epoprostenol/prostacyclin analogue) has a longer half-life (approximately 20–30 minutes compared with 3 minutes for prostacyclin) and is approved for use in chronic pulmonary hypertension (2.5–5 mg 6–9 times/day).[106] Treprostinil has a longer half-life still, allowing 4 times daily dosing. With an established role in chronic pulmonary arterial hypertension, particular caution is required when delivering these agents systemically in critically ill patients with acute right ventricular failure because any benefit of reducing pulmonary vascular resistance can be offset by the potential for worsening oxygenation and inducing systemic hypotension due to non-selective pulmonary and systemic vasodilatation, respectively.

INHALED HELIUM MIXTURES

Helium is 7.2 and 8 times less dense than air and oxygen, respectively. This property is useful in the setting of increased airways resistance because less turbulent and more efficient laminar flow is encouraged. Therefore, albeit an inert gas without any direct anatomical effect, helium can improve dynamic respiratory mechanics and reduce work of breathing. Effect size relates to the relative helium concentration; in practice at least 60%–70% helium is required, limiting applicability to patients able to tolerate Fi_{O_2} of 30%–40%. Helium–oxygen mixtures (heliox) potentially have a role in managing obstructive disease of both the upper and lower airways.[102] However, clinical use of heliox remains controversial and without evidence-based guidelines. In patients with COPD exacerbations requiring NIV, heliox has not been proven to reduce the NIV failure or the duration of NIV.[107,108] Similarly, there is no definitive evidence that heliox improves outcomes in asthma exacerbations, but its use can be considered in mechanically ventilated patients with severe asthma.[42] It should be noted that heliox, as a driving gas, will influence delivery of other inhaled agents in a ventilator circuit and also aerosols via nebulisers. Heliox may improve particle distribution to the peripheral small airways, perhaps as a function of reduced turbulence.[109] There is some evidence that bronchodilators driven by heliox (vs oxygen) result in improved clinical outcomes.[110]
